The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic serum calcium levels are required, since changes may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Despite optimal therapy, patients with hypoparathyroidism have been reported to have an overall reduced quality of life. Affected patients have a high risk of mood and psychiatric disorders and a reduced overall sense of well being.

HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- ▶ Frequently detected incidentally by routine blood testing.
- ▶ Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- ▶ Bone pain; rarely, cystic lesions and pathologic fractures.
- ▶ Elevated PTH, serum and urine calcium, and urine phosphate; serum phosphate low to normal; alkaline phosphatase normal to elevated.

▶ General Considerations

Primary hyperparathyroidism is the most common cause of hypercalcemia, with a prevalence of 1–4 cases per 1000 persons. It occurs at all ages but most commonly in the seventh decade and in women (74%). Before age 45, the prevalence is similar in men and women. It is more prevalent in blacks, followed by whites, then other races.

Parathyroid glands vary in number and location and ectopic parathyroid glands have been found within the thyroid gland, high in the neck or carotid sheath, in the retroesophageal space, and within the thymus or mediastinum. Hyperparathyroidism is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia by two or more parathyroid glands (20%), or carcinoma (1% or less). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and parathyroid carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases. However, hyperparathyroidism presenting before age 45 has a higher chance of being familial. Parathyroid hyperplasia may arise in MEN types 1, 2 (2A), and 4. (See Table 26–14.) In MEN 1, multiglandular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2 (2A) is less frequent than in MEN 1 and is usually milder. Familial hyperparathyroidism can also occur in the hyperparathyroidism-jaw tumor syndrome, a rare autosomal dominant familial condition in which parathyroid cystic adenomas or carcinomas are associated with ossifying fibromas of the mandible and maxilla as well as renal lesions (cysts, hamartomas, Wilms tumors). Affected individuals usually present with severe hypercalcemia as teenagers or young adults; the pathology is usually a single parathyroid adenoma.

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least

Fong J et al. Hypocalcemia: updates in diagnosis and management for primary care. *Can Fam Physician.* 2012 Feb;58(2):158–62. [PMID: 22439169]

5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Excessive PTH can cause cortical demineralization that is particularly evident at the wrist and hip; trabecular bone is usually spared as evidenced by relatively higher spinal bone density compared to the wrist. Severe, chronic hyperparathyroidism can cause diffuse demineralization, pathologic fractures, and cystic bone lesions throughout the skeleton, a condition known as **osteitis fibrosa cystica**.

Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for less than 1% of hyperparathyroidism. However, it occurs in about 15% of patients with hyperparathyroidism jaw-tumor syndrome and is also more common in patients with familial hyperparathyroidism or MEN. There is typically a palpable neck mass (75%). About 90% of parathyroid carcinomas are functional and present with serum calcium levels greater than or equal to 14.0 mcg/dL (3.5 mmol/L) or serum PTH levels greater than 5 times normal. However, some cases present with smaller tumors, less severe hypercalcemia, and benign-appearing histologic features. Local recurrence is the rule if surgical margins are positive. Distant metastases arise most commonly in the lungs but also in bones, liver, brain, and mediastinum. Although parathyroid carcinoma is typically indolent, an increasing tumor burden is associated with critically severe hypercalcemia and death.

Secondary and tertiary hyperparathyroidism usually occurs in patients with chronic kidney disease, in which hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol ($1,25[\text{OH}]_2\text{D}_3$) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as **renal osteodystrophy**. See Disorders of Mineral Metabolism, Chapter 22. Hypercalcemia often occurs after kidney transplant. Secondary hyperparathyroidism predictably develops in patients with a deficiency in vitamin D. Serum calcium levels are typically in the normal range, but may rise to become borderline elevated with time, with tertiary hyperparathyroidism due to parathyroid glandular hyperplasia.

Clinical Findings

A. Symptoms and Signs

In the developed world, hypercalcemia is typically discovered incidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with “bones, stones, abdominal groans, psychic moans, with fatigue overtones.”

1. Skeletal manifestations—Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Low bone density is typically most prominent at the

wrist. Postmenopausal women are prone to asymptomatic vertebral fractures. Although significant bone demineralization is uncommon in mild hyperparathyroidism, osteitis fibrosa cystica may present as pathologic fractures or as “brown tumors” or cysts of the jaw. More commonly, patients experience arthralgias and bone pain, particularly involving the legs.

2. Hypercalcemia manifestations—Mild hypercalcemia may be asymptomatic. However, hypercalcemia of hyperparathyroidism usually causes a variety of manifestations whose severity is not entirely predictable by the level of serum calcium or PTH. In fact, patients with only mild hypercalcemia can have significant symptoms, particularly depression, constipation, and bone and joint pain. **Neuromuscular** manifestations include paresthesias, muscle cramps and weakness, and diminished deep tendon reflexes. **Central nervous system** manifestations include malaise, headache, fatigue, intellectual weariness, insomnia, irritability, and depression. Patients may have cognitive impairment that can vary from intellectual weariness to more severe disorientation, psychosis, or stupor. **Cardiovascular** symptoms include hypertension, palpitations, prolonged P-R interval, shortened Q-T interval, bradyarrhythmias, heart block, asystole, and sensitivity to digitalis. **Renal** manifestations include polyuria and polydipsia, caused by hypercalcemia-induced nephrogenic diabetes insipidus. Among all patients with newly discovered hyperparathyroidism, calcium-containing renal calculi have occurred or are detectable in about 18%. Patients with asymptomatic hyperparathyroidism have a 7% incidence of asymptomatic calcium nephrolithiasis, compared to 1.6% incidence in age-matched controls. **Gastrointestinal** symptoms include anorexia, nausea, heartburn, vomiting, abdominal pain, weight loss, constipation, and obstipation. Pancreatitis occurs in 3%. **Pruritus** may be present. Calcium may precipitate in the corneas (“band keratopathy”), in extravascular tissues (calcinosis) and in small arteries, causing small vessel thrombosis and skin necrosis (calciophylaxis).

3. Normocalcemic primary hyperparathyroidism—Patients with normocalcemic primary hyperparathyroidism generally have few symptoms. However, on average, such patients have higher blood pressures (systolic blood pressure 10 mm Hg higher and diastolic blood pressure 7 mm Hg higher) than controls. Also, affected patients can have very subtle symptoms, such as mild fatigue, that may not be appreciated as abnormal.

4. Hyperparathyroidism during pregnancy—Pregnant women having mild hyperparathyroidism with a serum calcium below 11.0 mg/dL (less than 2.75 mmol/L) generally tolerate pregnancy well with normal outcomes. However, the majority of women with more severe hypercalcemia during pregnancy experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, and cognitive changes. Hypercalcemic crisis may occur, especially postpartum. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, and low birth weight. Newborns have hypoparathyroidism that can be permanent.

Hypocalcemia in the infant can present with tetany even 2–3 months after delivery.

5. Parathyroid carcinoma—Parathyroid carcinoma must always be suspected in patients with a serum calcium greater than or equal to 14.0 mcg/dL (3.5 mmol/L), a serum PTH greater than or equal to 5 times normal, or hyperparathyroidism with a large neck mass. FNA biopsy is not recommended because it may seed the biopsy tract with tumor and cytologic distinction between benign and malignant tumors is problematic.

B. Laboratory Findings

The hallmark of primary hyperparathyroidism is hypercalcemia, with the serum adjusted total calcium greater than 10.5 mg/dL (10.6 mmol/L) (Figure 26–1). The adjusted total calcium = measured serum calcium in mg/dL + $[0.8 \times (4.0 - \text{patient's serum albumin in g/dL})]$. Serum ionized calcium levels should be in the 4.6–5.3 mg/dL (1.15–1.32 mmol/L) range.

The urine calcium excretion may be high or normal (averaging 250 mg/g creatinine) but it is usually low for the degree of hypercalcemia. The serum phosphate is often less than 2.5 mg/dL (0.8 mmol/L). There is an excessive loss of phosphate in the urine in the presence of hypophosphatemia (25% of cases), whereas the serum phosphate may be high in kidney disease, which causes secondary hyperparathyroidism. The alkaline phosphatase is elevated only if

bone disease is present. The plasma chloride and uric acid levels may be elevated. Vitamin D deficiency is common in patients with hyperparathyroidism, and it is prudent to screen for vitamin D deficiency with a serum 25-OH vitamin D determination. Serum 25-OH vitamin D levels below 20 mcg/L (50 nmol/L) can aggravate hyperparathyroidism and its bone manifestations; vitamin D replacement may be helpful in treating such patients with hyperparathyroidism.

Elevated serum levels of intact PTH (immunoradiometric assay) confirm the diagnosis of hyperparathyroidism. Patients with apparent hyperparathyroidism should be screened for familial benign hypocalciuric hypercalcemia with a 24-hour urine for calcium and creatinine. Patients should discontinue thiazide diuretics prior to this test. Calcium excretion of less than 50 mg/24 hours (12.5 mmol/24 hours) or less than 5 mg/dL (1.25 mmol/L) on a random urine is not typical for primary hyperparathyroidism and indicates possible familial benign hypocalciuric hypercalcemia.

Patients with low bone density who have an elevated serum PTH but a normal serum calcium must be evaluated for causes of secondary hyperparathyroidism (eg, vitamin D or calcium deficiency, hyperphosphatemia, renal failure). In the absence of secondary hyperparathyroidism, patients with an elevated serum PTH but normal serum calcium are determined to have normocalcemic hyperparathyroidism. Such individuals require monitoring, since hypercalcemia develops in about 19% of patients over 3 years of follow-up.

▲ **Figure 26–1.** Parathyroid hormone and calcium nomogram. Relationship between serum intact parathyroid hormone (PTH) and serum calcium levels in patients with hypoparathyroidism, pseudohypoparathyroidism, nonparathyroid hypercalcemia, primary hyperparathyroidism (HPT), and secondary hyperparathyroidism. (Used with permission from GJ Strewler, MD.) Note: A multivariate model that adds clinical and demographic information may perform better than the nomogram alone. (See O’Neill SS et al. Multivariate analysis of clinical, demographic, and laboratory data for classification of disorders of calcium homeostasis. *Am J Clin Pathol.* 2011 Jan;135(1):100–7. [PMID: 21173131])

C. Imaging

Parathyroid imaging is not necessary for the diagnosis of hyperparathyroidism, which depends on serum parathyroid and calcium levels. Imaging is performed for most patients prior to parathyroid surgery and is particularly important for patients who have had prior neck surgery. The visualization of an apparent parathyroid adenoma helps secure the diagnosis when there is occasional diagnostic difficulty and often allows for minimally invasive surgery.

Ultrasound of the neck should be performed with a high-resolution transducer (5–15 MHz) and should scan the neck from the mandible to the superior mediastinum in an effort to locate ectopic parathyroid adenomas. Ultrasound has a sensitivity of 79% for single adenomas but only 35% for multiglandular disease.

Sestamibi scintigraphy with ^{99m}Tc -sestamibi and single-photon emission computed tomography (SPECT) is most useful for localizing parathyroid adenomas. However, false-positive scans are common, caused by thyroid nodules, thyroiditis, or cervical lymphadenopathy. Sestamibi-SPECT imaging improves sensitivity for single parathyroid adenomas. Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

Conventional CT and MRI imaging are not usually required prior to a first neck surgery for hyperparathyroidism, since they are generally inferior to ultrasound and sestamibi imaging. However, a four-dimensional CT (4D-CT), with the fourth dimension referring to time, captures the rapid uptake and washout of contrast from parathyroid adenomas; it is particularly useful for preoperative imaging when ultrasonography and sestamibi scans are negative. It can also be helpful for patients who have had prior neck surgery and for those with ectopic glands. In such patients, 4D-CT has a sensitivity of 88%, versus 54% for sestamibi SPECT and 21% for ultrasound. However, 4D-CT delivers more radiation to the thyroid and so is used mostly for older patients. MRI may also be useful for repeat neck operations and when ectopic parathyroid glands are suspected. MRI has the advantages of delivering no radiation and showing better soft tissue contrast than CT.

Patients with hyperparathyroidism have a high risk of calcium nephrolithiasis. Therefore, it has been suggested that all patients with hyperparathyroidism have noncontrast-enhanced CT scanning of the kidneys to determine whether calcium-containing stones are present. For patients with apparently asymptomatic hyperparathyroidism, the presence or absence of calcium nephrolithiasis can be a deciding factor about whether to have parathyroidectomy surgery.

Bone density measurements by dual energy x-ray absorptiometry (DXA) are helpful in determining the amount of bone loss in patients with hyperparathyroidism. Bone loss occurs mostly in long bones, and DXA should ideally include three areas: lumbar spine, hip, and distal radius.

Bone radiographs are usually normal and are not required to make the diagnosis of hyperparathyroidism. There may be demineralization, subperiosteal resorption

of bone (especially in the radial aspects of the fingers), or loss of the lamina dura of the teeth. There may be cysts throughout the skeleton, mottling of the skull (“salt-and-pepper appearance”), or pathologic fractures. Articular cartilage calcification (chondrocalcinosis) is sometimes found.

Patients with renal osteodystrophy may have ectopic calcifications around joints or in soft tissue. Such patients may exhibit radiographic changes of osteopenia, osteitis fibrosa cystica, or osteosclerosis, alone or in combination. Osteosclerosis of the vertebral bodies is known as “rugger jersey spine.”

► Complications

Pathologic long bone fractures are more common in patients with hyperparathyroidism than in the general population. Urinary tract infection due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (MEN type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In tertiary hyperparathyroidism due to chronic kidney disease, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciphylaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciphylaxis, but a calcium (mg/dL) \times phosphate (mg/dL) product over 70 is usually present.

► Differential Diagnosis

Artifactual hypercalcemia is common, so a report of hypercalcemia should always prompt a confirmatory serum calcium level that is drawn after an overnight fast along with a serum protein, albumin, and triglyceride while ensuring that the patient is well-hydrated. Hypercalcemia may be due to high serum protein concentrations; in the presence of very high or low serum albumin concentrations, an adjusted serum calcium or a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration. Spurious elevations in serum calcium have also been reported with severe hypertriglyceridemia, when the calcium assay uses spectrophotometry.

Hypercalcemia of malignancy occurs most frequently with breast, lung, pancreatic, uterine, and renal cell carcinoma, and paraganglioma. Most of these tumors secrete PTH-related protein (PTHrP), which has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those caused by PTH. Serum phosphate is often low. Other tumors can secrete excessive $1,25(\text{OH})_2$ vitamin D_3 , particularly lymphoproliferative and ovarian malignancies. The clinical features of

malignant hypercalcemia can closely simulate hyperparathyroidism. However, serum PTH levels are usually low. Serum PTHrP or $1,25(\text{OH})_2$ vitamin D_3 may be elevated.

Multiple myeloma causes hypercalcemia in older individuals. Many other hematologic cancers, such as monocytic leukemia, T cell leukemia and lymphoma, and Burkitt lymphoma, have also been associated with hypercalcemia.

Sarcoidosis and other granulomatous disorders, such as tuberculosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and foreign-body granuloma, can cause hypercalcemia. Macrophages and perhaps other cells present in granulomatous tissue have the ability to synthesize $1,25(\text{OH})_2\text{D}_3$. Increased intestinal calcium absorption and hypercalciuria are more common than hypercalcemia. Serum levels of $1,25(\text{OH})_2\text{D}_3$ are elevated. Sarcoid granuloma can also secrete PTHrP.

Excessive calcium or vitamin D ingestion can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. If hypercalcemia persists, the possibility of associated hyperparathyroidism should be considered. In vitamin D intoxication, hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol ($25[\text{OH}]\text{D}_3$) are helpful to confirm the diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

Familial benign hypocalciuric hypercalcemia can be easily mistaken for mild hyperparathyroidism. It is a common autosomal dominant inherited disorder (prevalence: 1 in 16,000) caused by a loss-of-function mutation in the gene encoding the calcium sensing receptor. Calcium sensing receptors are found on the surface of the parathyroid glands and allow the parathyroid glands to vary PTH secretion according to serum calcium levels. Reduced function of the calcium sensing receptor causes the parathyroid glands to falsely “sense” hypocalcemia and inappropriately release slightly excessive amounts of PTH. The renal tubule calcium sensing receptors are also affected, causing hypocalciuria. Familial benign hypocalciuric hypercalcemia is characterized by hypercalcemia, hypocalciuria (usually less than 50 mg/24 h), variable hypermagnesemia, and normal or minimally elevated serum levels of PTH. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. The condition has an excellent prognosis and is easily diagnosed with a family history and urinary calcium determination.

Prolonged immobilization at bed rest commonly causes hypercalcemia, particularly in adolescents, critically ill patients, and patients with extensive Paget disease of bone. Hypercalcemia develops in about one-third of acutely ill patients being treated in intensive care units, particularly patients with acute kidney injury. Serum calcium elevations are typically mild but may reach 15 mg/dL (3.75 mmol/L). Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism but may be suppressed or normal.

Rare causes of hypercalcemia include untreated adrenal insufficiency. Modest hypercalcemia is occasionally

seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level with hypercalcemia. Hyperthyroidism causes increased turnover of bone and occasional hypercalcemia. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism. Hypercalcemia may also occur following liver transplantation. Other causes of hypercalcemia are shown in Table 21–8.

▶ Treatment

A. “Asymptomatic” Primary Hyperparathyroidism

Patients with mild hyperparathyroidism should only be considered “asymptomatic” after very close questioning. Many patients may not realize they have manifestations, such as cognitive slowing, having become accustomed to such symptoms over years. It is important to assess blood pressure, kidney function with a serum BUN and creatinine, and to determine the presence of nephrolithiasis or nephrocalcinosis by radiography, ultrasonography, or CT scan of the kidneys. Truly asymptomatic patients may be closely monitored and advised to keep active, avoid immobilization, and drink adequate fluids. For postmenopausal women with hyperparathyroidism, estrogen replacement therapy reduces serum calcium by an average of 0.75 mg/dL (0.19 mmol/L) and slightly improves bone density.

Affected patients should avoid thiazide diuretics, large doses of vitamin A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked at least twice yearly, kidney function and urine calcium once yearly, and three-site bone density (distal radius, hip, and spine) every 2 years. Rising serum calcium should prompt further evaluation and determination of serum PTH levels.

If it is not clear whether a patient with primary hyperparathyroid is symptomatic, it is reasonable to consider a trial of medical therapy with cinacalcet.

B. Medical Measures

1. Fluids—Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline.

2. Cinacalcet—Cinacalcet hydrochloride is a calcimimetic agent that binds to sites of the parathyroid glands’ extracellular calcium sensing receptors to increase the glands’ affinity for extracellular calcium, thereby decreasing PTH secretion. Cinacalcet may be used as the initial therapy for patients with hyperparathyroidism or for failed surgical parathyroidectomy. For mild hypercalcemia, an initial dose of 15 mg (one-half of a 30 mg tablet) is advisable with weekly monitoring of serum calcium and an increased dose every 2 weeks if hypercalcemia persists until the patient becomes normocalcemic, which is successful in 73% of patients. Patients with parathyroid carcinoma and severe hypercalcemia are treated with cinacalcet in addition to zoledronate. For parathyroid cancer, cinacalcet is administered in doses of 30 mg orally twice daily, increased

progressively to 60 mg twice daily, then 90 mg twice daily to a maximum of 90 mg every 6–8 hours. Cinacalcet is usually well tolerated but may cause nausea and vomiting, which are usually transient. Hypocalcemia has occurred, even at 30 mg/day.

About 50% of azotemic patients with secondary or tertiary hyperparathyroidism are resistant to vitamin D analogs. Cinacalcet is given orally in starting doses of 30 mg daily to a maximum of 250 mg daily, with dosage adjustments to keep the serum PTH in the range of 150–300 pg/mL (15–30 pmol/L).

3. Bisphosphonates—Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism. Pamidronate in doses of 30–90 mg (in 0.9% saline) is administered intravenously over 2–4 hours. Zoledronate 5 mg is administered intravenously over 15–20 minutes. These drugs cause a gradual decline in serum calcium over several days that may last for weeks to months. Such intravenous bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve bone mineral density in the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low bone mineral density. It may also be combined with cinacalcet for the medical treatment of osteoporosis in patients with persistent hyperparathyroidism.

4. Denosumab—For patients with severe hypercalcemia due to parathyroid carcinoma, denosumab 120 mcg subcutaneously monthly may be effective.

5. Vitamin D and vitamin D analogs—

A. PRIMARY HYPERPARATHYROIDISM—For patients with vitamin D deficiency, vitamin D replacement may be beneficial to patients with hyperparathyroidism. Aggravation of hypercalcemia does not ordinarily occur. Serum PTH levels may fall with vitamin D replacement in doses of 800–2000 international units daily or more to achieve serum 25-OH vitamin D levels 30 ng/mL or more (50 nmol/L or more).

B. SECONDARY AND TERTIARY HYPERPARATHYROIDISM ASSOCIATED WITH AZOTEMIA—**Calcitriol**, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of kidney disease. For patients with normal serum calcium levels, it is given orally in starting doses of 0.25 mcg on alternate days or daily. Calcitriol often causes hypercalcemia, so that serum levels of calcium and phosphate must be monitored to ensure that the serum $\text{Ca}^{2+} \times \text{PO}_4^{3-}$ product remains no greater than 70. If the product exceeds 70, the dose of calcitriol is decreased or the patient is switched to therapy with vitamin D analogs or cinacalcet.

The vitamin D analogs **paricalcitol** and **doxercalciferol** suppress PTH secretion and cause less hypercalcemia than calcitriol. The doses are adjusted to keep serum PTH levels

in the range of 150–300 pg/mL (15–30 pmol/L). **Paricalcitol** is administered intravenously during dialysis three times weekly in starting doses of 0.04–0.1 mcg/kg to a maximum dose of 0.24 mcg/kg three times weekly. Alternatively, paricalcitol may be administered orally at doses of 1–2 mcg daily for serum PTH levels 100–500 pg/mL (10–50 pmol/L) or 2–4 mcg daily for serum PTH levels greater than 500 pg/mL (50 pmol/L). Dialysis patients receiving paricalcitol have improved survival compared with patients receiving calcitriol. **Doxercalciferol** is administered intravenously three times weekly during hemodialysis to patients with azotemic secondary hyperparathyroidism in starting doses of 4 mcg three times weekly to a maximum dose of 18 mcg three times weekly. Alternatively, doxercalciferol may be administered orally three times weekly at dialysis, starting with 10 mcg three times weekly at dialysis to a maximum of 60 mcg/wk.

6. Other measures—Estrogen replacement reduces hypercalcemia slightly in postmenopausal women with hyperparathyroidism. Similarly, oral raloxifene (60 mg/day) may be given to postmenopausal women with hyperparathyroidism; it reduces serum calcium an average of 0.4 mg/dL (0.1 mmol/L), while having an anti-estrogenic effect on breast tissue. Beta-blockers, such as propranolol, may also be useful for preventing the adverse cardiac effects of hypercalcemia. Parathyroid carcinoma metastases may be treated with radiofrequency ablation or arterial embolization.

C. Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with hyperparathyroidism who are symptomatic or who have nephrolithiasis or bone disease. During pregnancy, parathyroidectomy is performed in the second trimester for women who are symptomatic or have a serum calcium above 11 mg/dL (2.75 mmol/L).

Some patients with seemingly **asymptomatic hyperparathyroidism** may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL (0.25 mmol/L) above the upper limit of normal with urine calcium excretion greater than 50 mg/24 h (off thiazide diuretics), (2) urine calcium excretion greater than 400 mg/day (10 mmol/day), (3) creatinine clearance less than 60 mL/min, (4) nephrolithiasis or nephrocalcinosis, (5) cortical bone density (wrist, hip) indicating osteoporosis (T score below –2.5) or previous fragility bone fracture, (6) relative youth (under age 50 years), (7) difficulty ensuring medical follow-up, or (8) pregnancy.

Surgery for patients with “asymptomatic” hyperparathyroidism may improve bone mineral density and confer modest benefits in social and emotional well being and overall quality of life in comparison to similar patients being monitored without surgery. Cognitive function may benefit with improvements in nonverbal abstraction and memory.

Preoperative parathyroid imaging has been used in an attempt to allow unilateral minimally invasive neck surgery (see Imaging, above). The reported success rates vary considerably. Even in patients with concordant sestamibi and

ultrasound scans, and an intraoperative PTH drop of more than 50%, hyperparathyroidism may persist postoperatively in up to 15% of patients.

Without preoperative localization studies, bilateral neck exploration is usually advisable for the following: (1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Patients undergoing unilateral neck exploration can have the incision widened for bilateral neck exploration if two abnormal glands are found or if the serum quick PTH falls by less than 63% within 10 minutes of the parathyroid resection. Parathyroid glands are not uncommonly supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum). The optimal surgical management for patients with MEN type 1 is subtotal parathyroidectomy that usually results in a cure, although recurrent hyperparathyroidism develops in 18% and the rate of postoperative hypoparathyroidism is high.

Intraoperative near-infrared autofluorescence spectroscopy imaging may improve intraoperative localization of parathyroid glands in primary hyperparathyroidism. The parathyroid glands have intrinsic near-infrared fluorescence that can be detected with a specialized camera. Near-infrared imaging may improve localization of parathyroid adenomas, particularly when preoperative localization studies have been negative or discrepant. However, operating lights must be turned off during image capture.

Parathyroid hyperplasia is commonly seen with secondary or tertiary hyperparathyroidism associated with uremia. Cinacalcet is an alternative to surgery. When surgery is performed, a subtotal parathyroidectomy is optimal; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

Parathyroid carcinoma surgery consists of en bloc resection of the tumor and ipsilateral thyroid lobe with care to avoid rupturing the tumor capsule. If the surgical margins are not clear of tumor, postoperative neck radiation therapy may be given. Local and distant metastases may be debulked or irradiated. Preoperative MRI scanning is required to delineate the tumor. Zoledronate is given preoperatively. Severe hypercalcemia requires multiple medical measures, including hydration, furosemide, cinacalcet, and zoledronate.

Complications—Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to “hungry bones” and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long-term by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. In symptomatic patients, short-term treatment with propranolol may be required for several days.

► Prognosis

Patients with symptomatic hyperparathyroidism usually experience worsening disease (eg, nephrolithiasis) unless they have treatment. Conversely, the majority of completely asymptomatic patients with a serum calcium below 11.0 mg/dL (2.75 mmol/L) remain stable with follow-up. However, worsening hypercalcemia, hypercalciuria, and reductions in cortical bone mineral density develop in about one-third of asymptomatic patients. Therefore, asymptomatic patients must be monitored carefully and treated with oral hydration and mobilization.

Surgical removal of apparently single sporadic parathyroid adenomas is successful in 94%. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism frequently recurs. Despite treatment for hyperparathyroidism, patients remain at increased risk for all-cause mortality, cardiovascular disease, renal calculi, and renal failure. These increased risks are likely the residuals of pretreatment hypertension and nephrolithiasis.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if hyperparathyroidism is successfully treated. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant renal damage may progress even after removal of a parathyroid adenoma.

Parathyroid carcinoma is associated with a 5-year survival of about 80% if surgical margins are clear and there are no detectable metastases postoperatively. Conversely, positive surgical margins or metastases predict a very poor 5-year survival. Repeat surgical debulking procedures may improve survival. Aggressive medical management can also prolong life. Metastases are relatively radiation-resistant, but additional therapies such as radiofrequency ablation or arterial embolization may be palliative.

► When to Refer

Refer to parathyroid surgeon for parathyroidectomy.

► When to Admit

Patients with severe hypercalcemia for intravenous hydration.

METABOLIC BONE DISEASE

The term “metabolic bone disease” denotes those conditions producing diffusely decreased bone density and diminished bone strength. It is categorized by histologic appearance: osteoporosis (bone matrix and mineral both decreased) and osteomalacia (bone matrix intact, mineral decreased). Osteoporosis and osteomalacia often coexist in the same patient.

OSTEOPOROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fracture propensity of spine, hip, pelvis, and wrist from demineralization.
- ▶ Serum PTH, calcium, phosphorus, and alkaline phosphatase usually normal.
- ▶ Serum 25-hydroxyvitamin D levels often low as a comorbid condition.

General Considerations

Osteoporosis is a skeletal disorder characterized by a loss of bone osteoid that reduces bone integrity and bone strength, predisposing to an increased risk of fracture. In the United States, osteoporosis causes over 1.5 million fractures annually, most commonly vertebral fractures, followed by hip fractures (300,000 annually) and pelvic fractures. Vertebral fractures are associated with increased mortality, pain, and spinal kyphosis. Hip fractures are also associated with

---	---

¹See Table 26–11 for causes of osteomalacia.

increased mortality, pain, reduced independence, and diminished quality of life.

The frequency of fragility fractures varies with ethnicity, sex, and age. The lifetime risk of hip fracture in the United States is 15.8% in white women and 6.0% in white men, 2.4% in Chinese women and 1.9% in Chinese men, 8.5% in Hispanic women and 3.8% in Hispanic men. Blacks also have a much lower risk for fracture due to higher bone mineral density and hip morphology that is less fracture-prone. There is much less ethnic variability for vertebral fractures. The prevalence of vertebral fractures in women older than 65 years is 70% for white women, 68% for Japanese women, 55% for Mexican women, and 50% in African American women.

Osteoporosis can be caused by a variety of factors, which are listed in Table 26–10. The most common causes include aging, sex hormone deficiency, alcoholism, smoking, and high-dose glucocorticoid administration. Hypogonadal men frequently develop osteoporosis. Anti-androgen therapy for prostate cancer can cause osteoporosis and such men should be monitored with bone densitometry.

Clinical Findings

A. Symptoms and Signs

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a carefully directed history and physical examination must be performed to determine its cause (Table 26–10).

B. Laboratory Findings

Serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. Vitamin D deficiency is very common and serum determination of 25-hydroxyvitamin D should be obtained for every individual with low bone density. Serum 25-hydroxyvitamin D levels below 20 ng/mL (50 nmol/L) are considered frank vitamin D deficiency. Lesser degrees of vitamin D deficiency (serum 25-hydroxyvitamin D levels in the range of 20–30 ng/mL (50–75 nmol/L) may also increase the risk for hip fracture. Testing for thyrotoxicosis and hypogonadism may be required. Celiac disease may be screened for with serum tissue transglutaminase antibody determinations.

C. Bone Densitometry

Dual-energy x-ray absorptiometry (DXA) is used to determine the bone density of the lumbar spine, hip, and distal radius. Bone densitometry should be performed on all patients who are at risk for osteoporosis or osteomalacia, including all postmenopausal women age 65 years and older and all men age 70 years and older. DXA screening should also be considered for younger postmenopausal women with elevated risk, especially women with early menopause and those with a family history of osteoporosis. It should also be performed in younger patients who have had pathologic fractures or radiographic evidence of diminished bone density. DXA delivers negligible radiation, and the measurements are quite accurate. However, DXA cannot distinguish osteoporosis from osteomalacia; in fact, both are often present. Also, the bone mineral density does not directly measure bone quality and is only fairly successful at predicting fractures. Vertebral bone mineral density may be misleadingly high in compressed vertebrae and in patients with extensive arthritis. DXA also overestimates the bone mineral density of taller persons and underestimates the bone mineral density of smaller persons.

Bone mineral density is typically expressed in g/cm², for which there are different normal ranges for each bone and for each type of DXA-measuring machine. The “T score” is a simplified way of reporting bone density in which the patient’s bone mineral density is compared to the young normal mean and expressed as a standard deviation score. The World Health Organization has established criteria for defining osteoporosis based upon the T score:

T score \geq -1.0: Normal.

T score -1.0 to -2.5: Osteopenia (“low bone density”).

T score $<$ -2.5: Osteoporosis.

T score $<$ -2.5 with a fracture: Severe osteoporosis.

It is prudent to obtain DXA bone density measurements at two or three sites, including total lumbar spine and total hip. DXA bone density of the non-dominant distal radius is helpful for patients with hyperparathyroidism, for men receiving androgen deprivation therapy, and for patients with conditions causing other DXA measurement artifacts. Such artifacts can be caused by hip arthroplasties, spinal orthopedic hardware, severe spinal arthritis,

or lumbar vertebral compression fractures; in such patients, only noncompressed vertebrae are relevant. Any bone density classification is somewhat arbitrary and there really is no bone mineral density fracture threshold; instead, the fracture risk increases about twofold for each standard deviation drop in bone mineral density. Surveillance DXA bone densitometry is recommended for postmenopausal women and elderly men with a frequency according to their T scores: obtain DXA every 5 years for T scores -1.0 to -1.5, every 3–5 years for scores -1.5 to -2.0, and every 1–2 years for scores under -2.0.

The “Z score” is used to express bone density in premenopausal women and young adult men. The Z score is a statistical term expressing an individual’s bone density as standard deviation from age-matched, race-matched, and sex-matched means.

Fracture Risk Assessment Tool (FRAX) was developed by the World Health Organization to better predict an individual’s 10-year risk of hip or other major osteoporotic fracture. It takes into consideration age, sex, ethnicity, bone mineral density, and other risk factors. It is available for use online at www.shef.ac.uk/frax/.

► Differential Diagnosis

Osteopenia and fractures can be caused by osteomalacia and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients and cannot be distinguished with bone densitometry.

► Prevention & Treatment

A. Nonpharmacologic Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic corticosteroid (oral, parenteral, or inhaled) should be reduced or discontinued if possible. Cigarette smoking cessation is strongly urged. Excessive alcohol intake must be avoided. Exercise is strongly recommended to increase both bone density and strength, thereby reducing the risk of fractures due to frailty falls. Walking increases the bone density at both the spine and hip. Resistance exercise increases spine density. The patient must choose an enjoyable exercise regimen to facilitate long-term compliance. Other fall prevention measures include adequate home lighting, handrails on stairs, handholds in bathrooms, and physical therapy training in fall prevention and balance exercises. Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Medications that cause orthostasis, dizziness, or confusion should also be avoided.

B. Pharmacologic Measures

Many treatment options are available, so a regimen is tailored to each patient. Generally, treatment is indicated for all patients with osteoporosis (DXA T scores below -2.5), women with previous fragility fractures of the hip or vertebra, or a DXA T score between -2.5 and -1.5 with FRAX-determined (see above) 10-year hip fracture risk greater than 3% or major osteoporotic fracture risk greater than 20%.

1. Vitamin D and calcium—Deficiency of vitamin D or calcium causes osteomalacia, rather than osteoporosis, but they often coexist and cannot be distinguished by DXA bone densitometry; it is crucial to ensure sufficient vitamin D and calcium intake. Recommended daily vitamin D intake of 600–800 units/day is difficult to achieve by diet (unless high in fish) and sun exposure, particularly during winter months and for patients with intestinal malabsorption or during prolonged hospitalization or nursing home care. Oral vitamin D₃ (cholecalciferol) is given either as a universal supplement of 800–2000 units/day or in doses titrated to achieve 25-hydroxyvitamin D (25-OHD) serum levels greater than or equal to 20 ng/mL (50 nmol/L) for most of the population. However, the 25-OHD serum levels should be maintained at 30 ng/mL (75 nmol/L) or higher for those “at risk”: pregnant women, older adults, and those with osteoporosis or fragility fractures. There is early observational data of adverse outcomes (increased heart disease and all-cause mortality) at 25-OHD serum levels greater than 50 ng/mL (125 nmol/L), so the optimal therapeutic range for 25-OHD serum levels appears to about 30–50 ng/mL (75–125 nmol/L).

A total elemental calcium intake at least 1000 mg/day is recommended for all adults and 1200 mg/day for postmenopausal women and men older than 70 years. Most healthy individuals do not require calcium supplementation, and 74% of cohort studies showed no association between dietary calcium intake and fracture risk. Other studies have reported that associated calcium supplementation (1 g/day or more) showed no reduced risk for hip or forearm fractures and a mere 14% reduction in vertebral fractures. Calcium supplements are generally reserved for patients with intestinal malabsorption or calcium-deficient diets that do not include dairy products, dark leafy greens, sardines, tofu, or fortified foods. Calcium citrate does not require acid for absorption and is preferred for patients receiving acid blockers. Calcium carbonate should be taken with food to enhance calcium absorption. Calcium supplements are usually taken along with vitamin D₃, and many commercial supplements contain the combination.

Some reports have indicated that calcium supplements increase the risk of myocardial infarction. However, the Women's Health Initiative found that 7 years of vitamin D and calcium supplementation did not increase cardiovascular disease but did increase the risk of nephrolithiasis by 13%. Taking calcium supplements with meals can reduce the risk of nephrolithiasis. Although calcium supplements are usually tolerated, some patients experience intestinal bloating and constipation.

2. Sex hormones—Sex hormone replacement can prevent osteoporosis in hypogonadal women and men but is not an effective therapy for established osteoporosis. Low-dose transdermal systemic estrogen prevents osteoporosis in women with hypogonadism; however, it is not covered by medical insurance for women over age 64 in the United States (see Estrogen Replacement Therapy). Testosterone replacement therapy prevents osteoporosis in hypogonadal men (see Male Hypogonadism).

3. Bisphosphonates—Bisphosphonate therapy is indicated for patients with a pathologic spine fracture or a low-impact

hip fracture, and for patients with osteoporosis, defined as a DXA T score of -2.5 or less in the spine, total hip, or femoral neck. They are also indicated for patients with osteopenia (DXA T score between -2.5 and -1.5) and a FRAX-determined (see above) 10-year hip fracture risk greater than 3% or major osteoporotic fracture risk greater than 20%. Bisphosphonates all work similarly, inhibiting osteoclast-induced bone resorption. They increase bone density significantly and all reduce the incidence of vertebral fractures; all but ibandronate have been demonstrated to also reduce the risk of nonvertebral fractures. Bisphosphonates have also been effective in preventing corticosteroid-induced osteoporosis. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 40 minutes before consumption of anything else. The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. These medications are excreted in the urine. However, no dosage adjustments are required for patients with creatinine clearances above 35 mL/min. There has been little experience giving bisphosphonates to patients with severe kidney disease; if given, the dose would need to be greatly reduced and serum phosphate levels monitored. Bone density falls in 18% of patients during their first year of treatment with bisphosphonates, but 80% of such patients gain bone density with continued bisphosphonate treatment. The half-life of bisphosphonates in bone is about 10 years. Therefore, after 3 years, a DXA bone densitometry may be obtained. If the patient's T score has risen above -2.5 and the patient has a relatively low fracture risk, the bisphosphonate may be discontinued. However, for patients with continued osteoporosis and a high fracture risk, the bisphosphonate may be continued another 2 years.

Alendronate is administered orally once weekly as either a 70-mg standard tablet (Fosamax) or a 70-mg effervescent tablet (Binosto). The effervescent tablet must be dissolved in 4 oz plain water over at least 5 minutes and stirred 10 seconds before drinking; it is easier to swallow for some patients and may reduce esophageal injury, but there have been no studies comparing it to standard alendronate tablets. **Risedronate** (Actonel) may be given once monthly as a 150 mg tablet. Both medications reduce the risk of vertebral and nonvertebral fractures, but alendronate appears to be superior to risedronate in preventing nonvertebral fractures. **Ibandronate sodium** (Boniva) is taken once monthly in a dose of 150 mg orally. It reduces the risk of vertebral fractures but not nonvertebral fractures; its effectiveness has not been directly compared with other bisphosphonates. Oral bisphosphonates can cause nausea, chest pain, and hoarseness. Erosive esophagus can occur, particularly in patients with hiatal hernia and gastroesophageal reflux. Although no increased risk of esophageal cancer has been conclusively demonstrated, the FDA recommends that bisphosphonates not be used by patients with Barrett esophagus.

For patients who cannot tolerate oral bisphosphonates or for whom oral bisphosphonates are contraindicated, intravenous bisphosphonates are available. Zoledronate (Zometa, Reclast) is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 12 months in doses of 2–5 mg intravenously over at least

15–30 minutes. **Pamidronate** (Aredia) can be given in doses of 30–60 mg by slow intravenous infusion in normal saline solution every 3–6 months.

Bisphosphonate therapy can cause several side effects that are collectively known as the acute-phase response. Such a response occurs in 42% of patients following the first infusion of zoledronate and usually starts within the first few days following the infusion. Among patients receiving their first infusion of zoledronate, these adverse side effects have included fever, chills, or flushing (20%); musculoskeletal pain (20%); nausea, vomiting, or diarrhea (8%); nonspecific symptoms, such as fatigue, dyspnea, edema, headache, or dizziness (22%); and ocular inflammation (0.6%). Loratadine may reduce musculoskeletal pain. Intravenous zoledronate has caused seizures that may be idiosyncratic or due to hypocalcemia. The acute-phase response tends to diminish with time. Symptoms are transient, lasting several days and usually resolving spontaneously but typically recurring with subsequent doses. For patients experiencing a severe acute-phase response with zoledronate, intravenous pamidronate can be substituted for subsequent treatment. Symptoms may be treated with acetaminophen or NSAIDs. In addition, patients who experience an especially severe acute-phase response can be given prophylactic corticosteroids and ondansetron prior to subsequent bisphosphonate infusions.

Osteonecrosis of the jaw is a rare complication of bisphosphonate therapy for osteoporosis. A painful, necrotic, nonhealing lesion of the jaw occurs, particularly after tooth extraction. About 95% of jaw osteonecrosis cases have occurred with high-dose therapy with zoledronate or pamidronate for patients with myeloma or solid tumor osteolytic metastases. Only about 5% of cases have occurred in patients receiving oral (or, less frequently, intravenous) bisphosphonates for osteoporosis. The incidence of osteonecrosis is estimated to be about 1:100,000 patients treated for osteoporosis and 1:100 patients being treated for cancer. In a prospective 3-year trial of 7714 women who received intravenous zoledronate 5 mg/year, there were no cases of osteonecrosis. For patients with painful osteonecrotic exposed bone, treatment is 90% effective (without resolution of the exposed bone) using antibiotics along with 0.12% chlorhexidine antiseptic mouthwash. Patients receiving bisphosphonates must receive regular dental care and try to avoid dental extraction.

Atypical low-impact “chalkstick” fractures of the femoral shaft are a rare complication of bisphosphonate therapy. Atypical fractures are subtrochanteric or diaphyseal, occur with little trauma, and are usually transverse as opposed to the more typical comminuted or spiral femoral shaft fractures. In more than 52,000 postmenopausal women taking bisphosphonates for 5 years or longer, a subtrochanteric fracture occurred in 0.22% during the subsequent 2 years; 27% of such fractures were bilateral. About 70% of affected patients have had prodromal thigh pain prior to the fracture. The risk for atypical femoral fractures is particularly increased among Asian women and among patients taking high-dose corticosteroids and those receiving bisphosphonate treatment for more than 5 years. Teriparatide may be helpful to promote healing of such fractures. Despite this

rare complication, the overall risk of hip fracture is reduced among patients taking bisphosphonates for up to 5 years.

In patients taking bisphosphonates, hypercalcemia is seen in 20% and serum PTH levels increase above normal in 10%, mimicking primary hyperparathyroidism. Hypocalcemia occurs frequently, resulting in secondary hyperparathyroidism; such patients may be treated with oral calcium supplements (500–1000 mg/day) and with oral vitamin D₃ (starting at 1000 units/day).

4. Denosumab—Denosumab (Prolia, Xgeva) is a monoclonal antibody that inhibits the proliferation and maturation of preosteoclasts into mature osteoclast bone-resorbing cells. It does this by binding to the osteoclast receptor activator of nuclear factor-kappa B ligand (RANKL). It is indicated for treatment of osteoporosis, major fragility fractures, or osteopenia with a high FRAX score in both men and women. It is also used for patients with high fracture risk who are receiving sex hormone suppression therapy for breast cancer or prostate cancer. Treatment reduces vertebral fractures by 68% and reduces hip fractures by 40%. Denosumab is administered in doses of 60 mg subcutaneously every 6 months. It increases bone mineral density more than oral alendronate. Unlike bisphosphonates, denosumab can be given to patients with severe kidney disease. It has been relatively well tolerated, with an 8% incidence of flu-like symptoms. It can decrease serum calcium and should not be administered to patients with hypocalcemia. Other side effects include hypercholesterolemia, eczema and dermatitis, serious infections, new malignancies, and pancreatitis. Its efficacy is comparable to bisphosphonates. With prolonged use, it predisposes to atypical femoral fractures and osteonecrosis of the jaw and is additive to bisphosphonates in that regard. As with bisphosphonates, denosumab is usually administered for a 3–5 year course.

5. Teriparatide—Teriparatide (Forteo, Parathar) is an analog of PTH. Teriparatide stimulates the production of new collagenous bone matrix that must be mineralized. Patients receiving teriparatide must have sufficient intake of vitamin D and calcium. When administered to patients with osteoporosis in doses of 20 mcg/day subcutaneously for 2 years, teriparatide dramatically improves bone density in most bones except the distal radius. Teriparatide may also be used to promote healing of atypical femoral chalkstick fractures associated with bisphosphonate therapy. The recommended dose should not be exceeded, since teriparatide has caused osteosarcoma in rats when administered in very high doses. Due to the potential risk for osteosarcoma, patients are excluded from receiving teriparatide if they have an increased risk of osteosarcoma due to the following: Paget disease of bone, unexplained elevations in serum alkaline phosphatase, prior radiation therapy to bones, open epiphyses, or a past history of osteosarcoma or chondrosarcoma. Side effects may include injection site reactions, orthostatic hypotension, arthralgia, muscle cramps, depression, or pneumonia. Hypercalcemia can occur and manifest as nausea, constipation, asthenia, or muscle weakness. Teriparatide is approved for only a 2-year course of treatment.

Teriparatide should not be used for patients with hypercalcemia. Similarly, teriparatide should be used with caution

in patients if they are also taking corticosteroids and thiazide diuretics along with oral calcium supplementation because hypercalcemia may develop.

Following a course of teriparatide, bisphosphonates should be considered in order to retain the improved bone density. Alternatively, for severe osteoporosis, teriparatide may be administered along with denosumab; combined treatment for 2 years is more effective than any other single therapy.

6. Selective estrogen receptor modulators (SERMs)—

SERMs can prevent osteoporosis but are not effective therapy for established osteoporosis. **Raloxifene** 60 mg/day orally may be taken by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. It reduces the risk of vertebral fractures by about 40% but does not appear to reduce the risk of nonvertebral fractures. Raloxifene produces a reduction in LDL cholesterol but not the rise in high-density lipoprotein (HDL) cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flashes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, however, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is relatively contraindicated in women capable of pregnancy. Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur. **Tamoxifen** is another SERM that is commonly administered to women for up to 5 years after resection of breast cancer that is estrogen receptor positive.

Bazedoxifene is a SERM that is available as a fixed-dose combination medication with conjugated estrogens (Dua-vee). It is FDA-approved for the prevention of osteoporosis in postmenopausal women with an intact uterus. However, unlike raloxifene, it has not been shown to reduce the risk of breast cancer. It is expected that women taking this combination medication long-term will experience an increased risk of thromboembolic disease.

7. Calcitonin—Calcitonin therapy is much less effective than other treatments for osteoporosis. Long-term calcitonin therapy increases the risk of liver cancer but reduces the risk of breast cancer. Calcitonin is used primarily for its analgesic effect for the pain of acute osteoporotic vertebral compression fractures. It is ineffective for chronic pain. Its analgesic effect may be seen within 2–4 weeks. If it appears to be effective for analgesia, it is continued for up to 3 months. A nasal spray of calcitonin-salmon (Miacalcin) is available that contains 2200 units/mL in 2-mL metered-dose bottles. The usual dose is one puff (0.09 mL, 200 international units) once daily, alternating nostrils. Nasal symptoms such as rhinitis and epistaxis occur commonly; other less common adverse reactions include flu-like symptoms, allergy, arthralgias, back pain, and headache. Calcitonin reduces the incidence of vertebral fractures, but its effect upon non-vertebral fractures has not been established. If calcitonin is

administered, other more effective treatments for osteoporosis should be given simultaneously.

8. Orthopedic surgery—Percutaneous vertebroplasty or kyphoplasty may be considered for patients with vertebral compression fractures who fail conservative pain management. However, no prospective randomized study has adequately compared the effectiveness of these orthopedic procedures compared to conservative therapy.

► Prognosis

Bone mineral density densitometries can detect whether progressive osteopenia or frank osteoporosis is developing. Osteoporosis should ideally be prevented, since it can be only partially reversed. Measures noted above are reasonably effective in preventing and treating osteoporosis and reducing fracture risk.

OSTEOMALACIA

ESSENTIALS OF DIAGNOSIS

- ▶ Painful proximal muscle weakness (especially pelvic girdle); bone pain and tenderness.
- ▶ Decreased bone density from defective mineralization.
- ▶ Increased alkaline phosphatase, decreased 25-hydroxy-vitamin D, hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- ▶ Classic radiologic features may be present.

General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia. It is caused by any condition that results in inadequate calcium or phosphate mineralization of bone osteoid.

Etiology (Table 26–11)

A. Vitamin D Deficiency and Resistance

Vitamin D deficiency is the most common cause of osteomalacia and its incidence is increasing throughout the world as a result of diminished exposure to sunlight caused by urbanization, automobile and public transportation, modest clothing, and sunscreen use. Significant vitamin D deficiency, with serum 25OHD less than 20 ng/mL (50 nmol/L), was found in 24.3% of postmenopausal women from 25 countries. The incidence varied: less than 1% in Southeast Asia, 29% in the United States, and 36% in Italy. Patients in whom clinically severe osteomalacia develops typically have had chronic severe vitamin D deficiency (serum 25OHD under 25 nmol/L or under 10 ng/mL). The prevalence of severe vitamin D deficiency is 3.5% in the

United States and 12.5% in Italy. Among US men over age 65 years, 25% have serum 25OHD levels below 20 ng/mL; men over age 75 with such low vitamin D levels have particularly accelerated bone loss. Vitamin D deficiency is particularly common in the institutionalized elderly, with the incidence exceeding 60% in some groups not receiving vitamin D supplementation. Deficiency of vitamin D may arise from insufficient sun exposure, malnutrition, or malabsorption (due to pancreatic insufficiency, cholestatic liver disease, celiac disease, inflammatory bowel disease, jejunoileal bypass, Billroth type II gastrectomy). Orlistat is a weight-loss medication that causes fat malabsorption and reduced serum 25OHD levels. Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D-binding protein in the urine.

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25OHD and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization.

Vitamin D-dependent rickets type I is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1- α -hydroxylase leading to defective synthesis of 1,25(OH)₂D. It presents in childhood with rickets and alopecia; osteomalacia develops in adults with this condition unless treated with oral calcitriol in doses of 0.5–1 mcg daily.

Vitamin D-dependent rickets type II (better known as hereditary 1,25[OH]₂D-resistant rickets) is caused by a genetic defect in the 1,25(OH)₂D receptor. Patients have hypocalcemia with childhood rickets and adult osteomalacia. Alopecia is common. These patients respond variably to oral calcitriol in very large doses (2–6 mcg daily).

Table 26–11. Causes of osteomalacia.¹

Vitamin disorders
Decreased availability of vitamin D
Insufficient sunlight exposure
Nutritional deficiency of vitamin D
Malabsorption: aging, excess wheat bran, bariatric surgery, pancreatic enzyme deficiency
Nephrotic syndrome
Vitamin D–dependent rickets type I
Liver disease
Chronic kidney disease
Kidney transplantation
Phenytoin, carbamazepine, valproate, or barbiturate therapy (chronic)
Dietary calcium deficiency
Phosphate deficiency
Intestinal malabsorption
Nutritional deficiency of phosphorus
Phosphate-binding antacid therapy
Increased renal loss
Adefovir therapy
X-linked hypophosphatemic rickets
Tumoral hypophosphatemic osteomalacia
Association with other disorders, including paraproteinemias, glycogen storage diseases, neurofibromatosis, Wilson disease, Fanconi syndrome, renal tubular acidosis, and alcoholism
Inhibitors of mineralization
Aluminum
Bisphosphonates
Disorders of bone matrix
Hypophosphatasia
Fibrogenesis imperfecta
Axial osteomalacia

¹See Table 26–10 for causes of osteoporosis.

B. Deficient Calcium Intake

The total daily consumption of calcium should be at least 1000 mg daily. Patients who have deficient calcium intake develop rickets (childhood) or osteomalacia (adulthood) despite sufficient vitamin D. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in the elderly, since intestinal calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

C. Phosphate Deficiency

Hypophosphatemia can cause severe major muscle weakness, dysphagia, diplopia, cardiomyopathy, and respiratory muscle weakness. Patients may have impaired cognition. Chronic hypophosphatemia can cause bone pain and affect bone integrity. Phosphate deficiency in childhood causes classic rickets, whereas phosphate deficiency in adulthood causes osteomalacia.

1. Genetic disorders—Fibroblast growth factor-23 (FGF23) is a phosphaturic factor (phosphatonin) that is secreted by bone osteoblasts in response to elevated serum phosphate levels. Families with autosomal dominant hypophosphatemic rickets have a gain-of-function mutation in the gene encoding FGF23 that makes it resistant

to proteolytic cleavage, thereby increasing serum FGF23 levels. In X-linked hypophosphatemic rickets, there is a mutation in the gene encoding PHEX endopeptidase, which fails to cleave FGF23, resulting in elevated serum FGF23 levels. An autosomal recessive form of hypophosphatemic rickets is caused by mutations in DMP1, a transcription factor that regulates FGF23 production in bone. All three conditions have high serum FGF23 levels causing hypophosphatemia and bone mineral depletion.

2. Tumor-induced osteomalacia—A variety of mesenchymal tumors (87% benign) secrete fibroblast growth factor-23 (FGF23) and cause marked hypophosphatemia due to renal phosphate wasting. Such tumors are usually small and are often difficult to locate. The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced or normal serum $1,25(\text{OH})_2\text{D}$ concentrations, and osteomalacia. Serum levels of FGF23 are elevated. Such tumors are often small and difficult to find, frequently lying in extremities. Imaging with ^{111}In -octreotide or ^{18}F FDG-PET should include the entire body and may help localize the tumor.

3. Other causes of hypophosphatemia—Osteomalacia from hypophosphatemia can be caused by severe intestinal malabsorption or poor nutrition. Severe hypophosphatemia can occur with refeeding after starvation (eg, concentration camp victims, malnourished alcoholics). Other causes of hypophosphatemia include respiratory alkalosis, glucose infusions, salicylate intoxication, mannitol, and bisphosphonate therapy. Additional causes include chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel). Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi syndrome.

D. Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels. Osteomalacia may develop in patients being maintained on long-term total parenteral nutrition if the casein hydrolysate used for amino acids contains high levels of aluminum.

E. Hypophosphatasia

Hypophosphatasia must not be confused with hypophosphatemia. Hypophosphatasia refers to a severe deficiency of bone alkaline phosphatase. It is a rare genetic cause of osteomalacia that is commonly misdiagnosed as osteoporosis. The incidence in the United States is about 1 in 100,000 live births; about 1 in 300 adults is a carrier. The phenotypic presentation of hypophosphatasia is extremely variable. At its mildest, hypophosphatasia can present in middle age with premature loss of teeth, foot pain (due to metatarsal stress fractures), thigh pain (due to femoral pseudofractures), or arthritis (due to chondrocalcinosis). Serum alkaline phosphatase is low. To confirm the diagnosis, a 24-hour urine should be assayed for phosphoethanolamine, a

substrate for tissue-nonspecific alkaline phosphatase, whose excretion is always elevated in patients with hypophosphatasia. Prenatal genetic testing is available for the infantile form of hypophosphatasia. There is no proven therapy for hypophosphatasia, except for supportive care. Teriparatide has been ineffective for treatment.

F. Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense “fishnet” appearance on radiographs. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

► Clinical Findings

The clinical manifestations of defective bone mineralization depend on the age at onset and the severity. In adults, osteomalacia is typically asymptomatic at first. Eventually, bone and joint pain occurs, along with reduced muscle strength and endurance. Pathologic fractures may occur with little or no trauma. These manifestations can occur with either hypocalcemia or hypophosphatemia.

► Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and $25[\text{OH}]_2\text{D}_3$ determinations. Bone densitometry helps document the degree of osteopenia. Radiographs may show diagnostic features.

In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94% of patients; the calcium or phosphorus was low in 47% of patients; $25(\text{OH})_2\text{D}_3$ was low in 29% of patients; pseudofractures were seen in 18% of patients; and urinary calcium was low in 18% of patients. $1,25(\text{OH})_2\text{D}_3$ may be low even when $25(\text{OH})_2\text{D}_2$ levels are normal.

Genetic testing can confirm the diagnosis of autosomal dominant hypophosphatemic rickets (FGF23), X-linked hypophosphatemic rickets (PHEX), and autosomal recessive hypophosphatemic rickets (DMP1).

► Differential Diagnosis

Osteomalacia is often seen together with osteoporosis. The relative contribution of the two entities to diminished bone density may not be apparent until treatment, since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

► Prevention & Treatment

To obtain adequate sunshine vitamin D, the face, arms, hands, or back must have sun exposure without sunscreen for 15 minutes at least twice weekly. The main natural food

source of vitamin D is fish, particularly salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow's milk is fortified with vitamin D at about 400 international units per quart; however, skim milk and other dairy products contain much less vitamin D.

Many vitamin supplements contain plant-derived vitamin D₂, which has less biologic availability than once believed. Over-the-counter multivitamin/mineral supplements contain variable amounts of vitamin D, and vitamin D toxicity has occurred from two different multivitamins sold in the United States. Therefore, it is prudent to recommend that patients take a dedicated vitamin D supplement from a reliable manufacturer.

In sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), the recommended daily allowance should be vitamin D₃ 1000 international units daily. In such individuals, vitamin D₃ supplements should be given prophylactically. Patients receiving long-term phenytoin therapy should also receive vitamin D₃ supplementation.

Frank vitamin D deficiency is treated with ergocalciferol (D₂), 50,000 international units orally once weekly for 8 weeks. Following that, vitamin D₃ (cholecalciferol) supplementation is used at a dose of 2000 international units daily. Vitamin D₃ is more effective than vitamin D₂ in raising serum levels of 25(OH)D. Some patients require long-term supplementation with ergocalciferol of up to 50,000 international units weekly. In patients with intestinal malabsorption, oral doses of 25,000–100,000 international units of vitamin D₃ daily may be required. Some patients with steatorrhea respond better to oral 25(OH)D₃ (calcifediol), 50–100 mcg/day. Serum levels of 25(OH)D should be monitored and the dosage of vitamin D adjusted to maintain serum 25(OH)D levels above 30 ng/mL. During treatment with high-dose vitamin D, serum calcium should also be monitored to avoid hypercalcemia.

Beyond increasing the intestinal absorption of calcium, vitamin D supplementation may have additional effects. Vitamin D supplementation has been associated with improved muscle strength and a reduced fall risk, factors that reduce the risk of bone fracture.

The addition of calcium supplements to vitamin D is probably not necessary for the prevention of osteomalacia in the majority of otherwise well-nourished patients. However, patients with malabsorption or poor nutrition should receive calcium supplementation. Recommended doses of calcium are as follows: calcium citrate (eg, Citracal), 0.4–0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1–1.5 g elemental calcium per day. Calcium supplements are best administered with meals.

In hypophosphatemic rickets or osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum 1,25(OH)₂D levels, a search is conducted for occult tumors that may be resected; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements

must be given long-term. Calcitriol, 0.25–0.5 mcg/day, is given also to improve the impaired calcium absorption caused by the oral phosphate. If necessary, rhGH may be added to the above regimen to reduce phosphaturia. The hypophosphatemia of autosomal dominant hypophosphatemic rickets has been reported to resolve with high-dose dietary iron supplementation.

Patients with hypophosphatasia have been treated with teriparatide with improvement in bone pain and fracture healing.

PAGET DISEASE OF BONE (Osteitis Deformans)

ESSENTIALS OF DIAGNOSIS

- ▶ Often asymptomatic.
- ▶ Bone pain may be the first symptom.
- ▶ Kyphosis, bowed tibias, large head, deafness, and frequent fractures.
- ▶ Serum calcium and phosphate normal; alkaline phosphatase elevated; urinary hydroxyproline elevated.
- ▶ Dense, expanded bones on radiographs.

▶ General Considerations

Paget disease is manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. The involved bone first has increased osteoclast activity, causing lytic lesions in bone that may progress at about 1 cm/year. Increased osteoblastic activity follows, producing a high rate of disorganized bone formation. Involved bones become vascular, weak, and deformed. Eventually, there appears to be a final burned-out phase with markedly reduced bone cell activity and abnormal bones that may be enlarged with skeletal deformity.

The prevalence of Paget disease has declined by about 36% over the past 20 years. However, it remains a common disease in certain countries, with striking geographic variation in prevalence. It is most common in the United Kingdom and in areas of European migration, particularly New Zealand, Australia, the United States, South Africa, Quebec, and Brazil. Interestingly, the disease appears equally common among different races in these countries. In the United States, Paget disease occurs in 2–3% of all individuals over age 55 years, with its prevalence increasing with age. It is uncommon in Africa, Asia, and Scandinavia. Usually diagnosed in patients over age 40 years, its

prevalence doubles with each decade thereafter, reaching an incidence of about 10% after age 80. It is most often discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase.

The cause of Paget disease is unknown. However, there is believed to be a genetic component with autosomal dominant transmission; about 20% of affected patients have a first-degree relative with the disease. Mutations in the *SQSTM1* gene have been discovered in 25–50% of cases with familial Paget disease and in 5–10% of patients with apparently sporadic Paget disease.

▶ Clinical Findings

A. Symptoms and Signs

Paget disease is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. Paget disease involves multiple bones (polyostotic) in 72% and only a single bone (monostotic) in 28%. It occurs most commonly in the pelvis, vertebrae, femur, humerus, and skull. The affected bones are typically involved right away and the disease tends not to involve additional bones during its course. Pain is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. The pain is usually described as aching and deep and often worse at night. Paget disease typically first affects long bones proximally and then advances distally, with bone pain at the osteolytic front being aggravated by weight bearing. Joint surfaces (such as the knee) can be involved and cause arthritic pain. The bones can become soft, leading to bowed tibias, kyphosis, and frequent “chalkstick” fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Involvement of the petrous temporal bone frequently damages the cochlea and causes hearing loss (mixed sensorineural and conductive) and occasionally tinnitus or vertigo. Increased vascularity over the involved bones causes increased warmth and can cause vascular “steal” syndromes.

B. Laboratory Findings

Serum alkaline phosphatase is usually markedly elevated. However, some patients with limited monostotic involvement may have normal serum alkaline phosphatase levels. A serum bone-specific alkaline phosphatase is usually high and is useful for patients with a normal serum alkaline phosphatase and to distinguish the source of an elevated alkaline phosphatase as being from bone (rather than liver). Other useful measures for bone turnover are serum N-terminal propeptide of type 1 collagen (NTx) and serum betaC-terminal propeptide of type 1 collagen (betaCTx). However, such bone turnover markers may overestimate or underestimate the response to treatment. Serum calcium may be elevated, particularly if the patient is at bed rest. A serum 25-OH vitamin D determination should be obtained to screen for vitamin D deficiency, which can also present with an increased serum alkaline phosphatase and bone pain. Also, any vitamin D deficiency should be corrected before prescribing a bisphosphonate.

C. Imaging

On radiographs, the initial lesions are typically osteolytic, with focal radiolucencies (“osteoporosis circumscripta”) in the skull or advancing flame-shaped lytic lesions in long bones. Bone lesions may subsequently become sclerotic and have a mixed lytic and sclerotic appearance. The affected bones eventually become thickened and deformed. Technetium pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent.

▶ Differential Diagnosis

Certain rare familial types of sclerosing bone dysplasias share phenotypic homologies with Paget disease of bone. Familial expansile osteolysis, familial early-onset Paget disease, and familial skeletal hyperphosphatasia are autosomal dominant disorders caused by different tandem duplications of the gene encoding RANK, resulting in its constitutive activation. The differential diagnosis also includes myelofibrosis, intramedullary osteosclerosis, Erdheim-Chester disease, Langerhans cell histiocytosis, and sickle cell disease.

Paget disease must be differentiated from primary bone lesions such as osteogenic sarcoma, multiple myeloma, and fibrous dysplasia and from secondary bone lesions such as osteitis fibrosa cystica and metastatic carcinoma to bone. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget disease; serum alkaline phosphatase is likewise elevated. This condition may be associated with paraproteinemias.

▶ Complications

If immobilization occurs, hypercalcemia and renal calculi may develop. With severe polyostotic disease, the increased vascularity may give rise to high-output heart failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. **Skull involvement** can also cause a vascular steal syndrome with somnolence or ischemic neurologic events; the optic nerve may be affected, resulting in loss of vision. Jaw involvement can cause the teeth to spread intraorally and become misaligned. Vertebral collapse can cause compression of spinal cord or spinal nerves, resulting in radiculopathy or paralysis. **Vertebral involvement** can also cause a vascular steal syndrome with paralysis. Surgery for fractured long bones is often complicated by excessive blood loss from these vascular lytic lesions.

A sarcoma or giant cell tumor may develop in longstanding lesions but is rare (less than 1%). Sarcomatous change is suggested by a marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion.

▶ Treatment

Asymptomatic patients may require only clinical surveillance and no treatment. However, treatment should be

considered for asymptomatic patients who have significant involvement of the skull, long bones, or vertebrae. Patients must be monitored carefully before, during, and after treatment with clinical examinations and serial serum alkaline phosphatase determinations.

Bisphosphonates are used to treat patients with Paget disease. Intravenous zoledronate is the treatment of choice. Administered intravenously as a single 5 mg dose, it normalizes the serum alkaline phosphatase in 89% of patients by 6 months and in 98% by 2 years. Oral bisphosphonate regimens are frankly inferior to intravenous zoledronate.

In order to reduce the risk of intraoperative hemorrhaging and loosening of the prosthesis postoperatively, intravenous zoledronate should be administered prior to total arthroplasty for a Paget-involved joint. Similarly, intravenous zoledronate should be administered before osteotomy for severe bowing of a lower extremity caused by Paget disease. For patients with paraplegia due to vertebral involvement, intravenous zoledronate should be given while neurosurgical consultation is obtained.

Patients frequently experience a paradoxical increase in pain at sites of disease soon after commencing bisphosphonate therapy; this is the “first dose effect” and the pain usually subsides with further treatment. Flu-like symptoms occur fairly frequently. Following intravenous zoledronate, patients frequently experience fever, fatigue, myalgia, bone pain, and ocular problems. Serious side effects are rare but include seizures, uveitis, and acute kidney disease. Hypocalcemia is common and may be severe, especially if intravenous bisphosphonates are given along with loop diuretics. Therefore, it is advisable to administer calcium and vitamin D supplements, especially during the first 2 weeks following treatment. Asthma may occur in aspirin-sensitive patients. To prevent esophageal complications, oral bisphosphonates should be taken with 8 oz of plain water only; they are relatively contraindicated in patients with a history of esophagitis, esophageal stricture, dysphagia, hiatal hernia, or achalasia.

► Prognosis

The prognosis in general is good, but relapse can occur after an initial successful treatment with bisphosphonate. By 6.5 years after initial therapy, the recurrence rate is 12.5% after treatment with zoledronate and 62% after risendronate. Therefore, patients must be monitored long-term, measuring serum alkaline phosphatase at least yearly. In general, the prognosis is worse the earlier in life the disease starts. Fractures usually heal well. In the severe forms, marked deformity, intractable pain, and heart failure occur. These complications should become rare with prompt bisphosphonate treatment. Osteosarcoma that arises at sites of Paget disease results in a 2-year survival of only 25%.

DISEASES OF THE ADRENAL CORTEX

PRIMARY ADRENAL INSUFFICIENCY (Addison Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, fatigue, anorexia, weight loss; nausea, vomiting, diarrhea; abdominal pain, muscle and joint pains; amenorrhea.
- ▶ Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
- ▶ Hypotension, small heart.
- ▶ Serum sodium low; potassium, calcium, and BUN elevated; mild anemia and relative neutropenia, lymphocytosis, and eosinophilia.
- ▶ Plasma ACTH level elevated; cosyntropin (ACTH_{1–24}) unable to stimulate an increase in serum cortisol to 20 mcg/dL or more.
- ▶ Acute adrenal crisis: above manifestations become critical, along with fever, shock, confusion, coma, death.

► General Considerations

Primary adrenal insufficiency (Addison disease) is caused by dysfunction or absence of the adrenal cortices. It is distinct from secondary adrenal insufficiency caused by deficient secretion of ACTH.

Addison disease is an uncommon disorder with a prevalence of about 140 per million and an annual incidence of about 4 per million in the United States. Addison disease is characterized by a chronic deficiency of cortisol. Serum ACTH and alpha-MSH levels are consequently elevated, causing pigmentation that ranges from none to strikingly dark. Patients with destruction of the adrenal cortices or with classic 21-hydroxylase deficiency also have mineralocorticoid deficiency, typically with hyponatremia, volume depletion, and hyperkalemia. In contrast, mineralocorticoid deficiency is not present in patients with familial glucocorticoid deficiency and Allgrove syndrome.

Acute adrenal (addisonian) crisis is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic adrenal insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency than in secondary adrenal insufficiency.

Adrenal crisis may occur in the following situations: (1) during stress, (eg, infection, trauma, surgery, hyperthyroidism, or prolonged fasting) in a patient with latent or treated adrenal insufficiency; (2) following sudden

withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol; (3) following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal gland; (4) following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with adrenal insufficiency; (5) following injury to both adrenals (by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma); and (6) following administration of intravenous etomidate (used for rapid anesthesia induction or intubation).

▶ Etiology

Autoimmunity is the most common cause of Addison disease in the United States (accounting for about 80% of spontaneous cases). With such autoimmunity, adrenal function decreases over several years as it progresses to overt adrenal insufficiency. It may occur alone or as part of a **polyglandular autoimmune (PGA) syndrome**. **Type 1 PGA**, also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome, is caused by a defect in T cell-mediated immunity inherited as an autosomal recessive trait. Type 1 PGA usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjögren syndrome.

Type 2 PGA usually presents in young adults aged 20–40 years, usually women (female:male ratio is 3:1). The following conditions occur in type 2 PGA: autoimmune adrenal insufficiency, type 1 diabetes mellitus, and autoimmune thyroid disease (usually hypothyroidism, sometimes hyperthyroidism). The combination of Addison disease and hypothyroidism is known as Schmidt syndrome. Patients may also have vitiligo, alopecia areata, Sjögren syndrome, or celiac disease. Type 2 PGA is also associated with autoimmune primary ovarian failure; testicular failure (5%); pernicious anemia (4%); and, rarely, autoimmune hypophysitis, encephalitis, or hypoparathyroidism (late-onset).

Infection is a relatively rare cause of Addison disease in the United States but is common in much of the world. Tuberculosis is the most common infection of the adrenals, and parallels its prevalence worldwide. Coccidioidomycosis and other infections are rare causes, particularly in immunocompetent patients.

Bilateral adrenal hemorrhage may occur with sepsis, heparin-associated thrombocytopenia, anticoagulation, or the antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously and present with flank pain; MRI may show adrenal enlargement with increased T2-weighted imaging. Meningococemia may be associated with purpura and

adrenal insufficiency secondary to adrenal infarction (Waterhouse-Friderichsen syndrome).

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common. Psychiatric symptoms often include mania, psychosis, or cognitive impairment. Neurologic deterioration may be severe or mild (particularly in heterozygote women), mimics symptoms of multiple sclerosis, and can occur years after the onset of adrenal insufficiency.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, coccidioidomycosis, histoplasmosis, cytomegalovirus infection (more frequent in patients with AIDS), syphilitic gummata, scleroderma, amyloidosis, and hemochromatosis.

Congenital adrenal insufficiency occurs in several conditions. **Familial glucocorticoid deficiency** is an autosomal recessive disease that is caused by mutations in the adrenal ACTH receptor (melanocortin 2 receptor, MC2R). It is characterized by isolated cortisol deficiency and ACTH resistance and may present with neonatal hypoglycemia, frequent infections, and dark skin pigmentation. **Triple A (Allgrove) syndrome** is caused by a mutation in the AAAS gene that encodes a protein known as ALADIN (*alacrima, achalasia, adrenal insufficiency, neurologic disorder*). It is characterized by variable expression of the following: adrenal ACTH resistance with cortisol deficiency, achalasia, alacrima, nasal voice, autonomic dysfunction, and neuromuscular disease of varying severity (hyperreflexia to spastic paraplegia). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life. **Congenital adrenal hypoplasia** causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss.

Congenital adrenal hyperplasia is caused by various genetic defects in the enzymes responsible for steroid synthesis. Due to defective cortisol synthesis, patients have variable degrees of adrenal insufficiency and increased levels of ACTH that causes hyperplasia of the adrenal cortex. The most common enzyme defect is *P450c21 (21-hydroxylase deficiency)*. Patients with severely defective *P450c21* (classic congenital adrenal hyperplasia) manifest a deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Hypertension commonly develops in older adult patients with classic congenital adrenal hyperplasia. Testicular adrenal rests can be found in 44% of men with the condition. Women with milder enzyme defects have adequate cortisol but develop hirsutism in adolescence or adulthood and are said to have “late-onset” congenital adrenal hyperplasia.

Patients with deficient *P450c17 (17-hydroxylase deficiency)* have varying degrees of cortisol deficiency with associated hypertension, hypokalemia, and primary hypogonadism. Severely affected genetic 46 XY males may present with female genitalia at birth (pseudohermaphroditism). The diagnosis is confirmed with high serum levels of

11-deoxycorticosterone and corticosterone. The absence of sex hormones results in primary amenorrhea.

Patients with deficient *P450c11* (*11-hydroxylase deficiency*) present at birth with partial virilization and ambiguous genitalia in genetically female infants, childhood virilization in both sexes, and virilization and reduced fertility in adult women. Most patients have hypertension and variable degrees of cortisol deficiency. The diagnosis is established with elevated serum levels of 11-deoxycorticosterone and 11-deoxycortisol.

Drugs that cause primary adrenal insufficiency include mitotane (for adrenocortical carcinoma) and abiraterone acetate (a *P450c17* inhibitor used for prostate cancer).

Clinical Findings

A. Symptoms and Signs

The onset of symptoms can present suddenly but usually develops gradually over months or years. The diagnosis is often delayed, since many early symptoms are nonspecific. Nearly all patients complain of fatigue, reduced stamina, weakness, anorexia, and weight loss. Abdominal pain, nausea, and vomiting eventually develop in most patients; diarrhea can occur. Fevers and lymphoid tissue hyperplasia may also occur. Patients often have significant pain: arthralgias, myalgias, chest pain, abdominal pain, back pain, leg pain, or headache. Psychiatric symptoms include anxiety, irritability and depression. Cerebral edema can cause headache, vomiting, gait disturbance, and intellectual dysfunction that may progress to coma. Hypoglycemia can occur and worsen the patient's weakness and mental functioning. Patients often have salt craving and complain of orthostatic light-headedness. Blood pressure is usually low and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Hypotension is aggravated by dehydration caused by nausea or vomiting.

Skin hyperpigmentation eventually occurs in most patients due to increased pituitary secretion of alpha-MSH (melanocyte-stimulating hormone). Skin hyperpigmentation varies among affected patients (eg, from none to increased freckling to diffuse darkening that resembles a suntan or a bronze appearance). Sun-exposed areas darken the most, but nonexposed areas darken as well. Hyperpigmentation is often especially prominent over the knuckles, elbows, knees, posterior neck, palmar creases, gingival mucosa, and vermilion border of the lips. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin also darkens in pressure areas, such as the belt or brassiere lines and the buttocks. Skin folds and new scars may also become pigmented. Conversely, patches of autoimmune vitiligo can be found in about 10% of patients. Scant axillary and pubic hair typically develops in women.

In pregnancy, undiagnosed adrenal insufficiency is rare, since the condition tends to cause anovulation and reduced fertility. In the first trimester, symptoms such as fatigue, nausea, vomiting, abdominal pain, and orthostasis are typically attributed to the pregnancy, thus delaying the diagnosis. Worse, the increased skin pigmentation of

adrenal insufficiency may be mistaken for chloasma (melasma). Undiagnosed adrenal insufficiency can cause intrauterine growth retardation and fetal loss. Pregnant women with undiagnosed adrenal insufficiency can experience shock from adrenal crisis, particularly during the first trimester, concurrent illness, labor, or postpartum.

Patients with preexistent type 1 diabetes experience more frequent hypoglycemia with the onset of adrenal insufficiency, such that their insulin dosage must be reduced.

Acute adrenal crisis is an immediate threat to life. Nausea, vomiting, fever, dehydration, and profound hypotension progresses to life-threatening shock that does not fully respond to intravenous fluids and vasopressors.

B. Laboratory Findings

The WBC count typically shows moderate neutropenia, lymphocytosis, and eosinophilia (total eosinophil count over 300/mcL). Among patients with chronic adrenal insufficiency, the serum sodium is usually low (88%) and the potassium usually elevated (64%). (Patients with vomiting or diarrhea may not be hyperkalemic.) Fasting hypoglycemia is common. Hypercalcemia may be present.

A plasma cortisol less than 3 mcg/dL (83 nmol/L) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level greater than 200 pg/mL (44 pmol/L). The diagnosis is confirmed by a simplified cosyntropin stimulation test: (1) Synthetic ACTH₁₋₂₄ (cosyntropin), 0.25 mg, is given intramuscularly. (2) Serum cortisol is obtained 45 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL (550 pmol/L), whereas patients with adrenal insufficiency have stimulated serum cortisol levels less than 20 mcg (550 pmol/L). For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol. Cortrosyn is a pregnancy class C drug and may be used during pregnancy. However, the test may lack sensitivity, since adrenal ACTH-responsiveness increases during pregnancy.

Serum DHEA levels are less than 1000 ng/mL (350 nmol/L) in 100% of patients with adrenal insufficiency but also in about 15% of the population, so the test is very sensitive but not specific.

Anti-adrenal antibodies are found in the serum in about 50% of cases of autoimmune Addison disease. The presence of serum antibodies to 21-hydroxylase helps secure the diagnosis of autoimmune adrenal insufficiency. Antibodies to thyroid (45%) and other tissues may be present.

Salt-wasting congenital adrenal hyperplasia due to 21-hydroxylase deficiency is usually diagnosed at birth in females due to ambiguous genitalia. Males and patients with milder enzyme defects may present later. The diagnosis of adrenal insufficiency is made as above. The specific diagnosis requires elevated serum levels of 17-OH progesterone.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for fludrocortisone administration. Serum epinephrine levels are

low in patients with adrenal insufficiency, since these patients do not have the high local concentrations of cortisol that are required to induce the enzyme PNMT in adrenal medulla for the synthesis of epinephrine from norepinephrine.

Young men with idiopathic Addison disease are screened for X-linked adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

In acute adrenal crisis, blood, sputum, or urine cultures may be positive if bacterial infection is the precipitating cause.

C. Imaging

When adrenal insufficiency is not clearly autoimmune, a CT scan of the adrenal glands should be obtained. Small, noncalcified adrenals are seen in autoimmune Addison disease. The adrenals are enlarged in about 85% of cases related to metastatic or granulomatous disease. Adrenal calcifications occur in about 50% of cases of tuberculous Addison disease but are also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

Differential Diagnosis

Patients with secondary adrenal insufficiency (see Hypopituitarism) lack ACTH and have normal to decreased skin pigmentation that has been described as “alabaster skin.” This contrasts with the increased skin pigmentation in patients with Addison disease. The hyperpigmentation may be confused with that due to ethnic or racial factors. Patients with ACTH deficiency have normal mineralocorticoid production and do not develop hyperkalemia. Addison disease should be considered in any patient with unexplained hypotension, but acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic).

Unexplained weight loss, weakness, and anorexia may be mistaken for occult cancer. Nausea, vomiting, diarrhea, and abdominal pain may be misdiagnosed as intrinsic gastrointestinal disease. Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas in adrenal insufficiency there is lymphocytosis and eosinophilia. Weight loss may simulate anorexia nervosa or emotional stress. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hemochromatosis also causes bronze skin hyperpigmentation, but hemochromatosis may in fact be the cause of Addison disease. About 17% of patients with AIDS have symptoms of cortisol resistance. AIDS can also cause frank adrenal insufficiency.

Hyperkalemia can be caused by hyporeninemic hypoaldosteronism related to type IV renal tubular acidosis. Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and certain drugs (eg, angiotensin-converting enzyme [ACE] inhibitors, spironolactone, and drospirenone).

Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery). Nearly

40% of critically ill patients have low serum cortisol levels due to low serum albumin levels, such that their total serum cortisol levels may be low but their serum free cortisol levels are normal.

Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur in adrenal insufficiency, and intercurrent infections may precipitate an acute adrenal crisis. Associated autoimmune diseases are common (see above).

Treatment

A. General Measures

Patients with Addison disease must be thoroughly informed about their condition. Patients are advised to wear a medical alert bracelet or medal reading, “Adrenal insufficiency—takes hydrocortisone.” All infections should be treated immediately and vigorously, with hydrocortisone administered at appropriately increased doses.

B. Specific Therapy

Replacement therapy should include a combination of glucocorticoids and mineralocorticoids. In mild cases, glucocorticoids alone may be adequate.

1. Glucocorticoid replacement therapy—Maintenance therapy for most patients with Addison disease involves 15–30 mg of hydrocortisone orally daily in two divided doses, two-thirds in the morning and one-third in the late afternoon or early evening. Some patients respond better to prednisone (available in 1 mg tablets) or methylprednisolone (4 mg tablets) in doses of about 2–4 mg orally in the morning and 1–2 mg in the evening. Adjustments in dosage are made according to the clinical response. Plenadren (5 or 20 mg modified-release tablets) is a once-daily dual-release preparation of hydrocortisone that may be administered once daily in the morning (usual dose range is 20–30 mg); it is not available in the United States.

A proper glucocorticoid dose usually results in clinical improvement, a normal WBC count differential, and no manifestations of Cushing syndrome. Serum ACTH levels vary substantially and should not be used to determine dosing. The dose of glucocorticoid should be raised in case of infection, trauma, surgery, stressful diagnostic procedures, or other forms of stress. With infection, note that rifampin increases the clearance of hydrocortisone and necessitates increased dosing of hydrocortisone by up to 50%. During the third trimester of pregnancy, glucocorticoid requirements are higher, so usual glucocorticoid doses are increased by 50%. For severe stress of major illness, surgery, or delivery, a maximum stress dose of hydrocortisone is given as 50–100 mg intravenously or intramuscularly, followed by 50 mg every 6 hours. Lower doses, oral or parenteral, are used for less severe stress. The dose is reduced back to normal as the stress subsides.

2. Mineralocorticoid replacement therapy—Fludrocortisone acetate has a potent sodium-retaining effect. The

dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, an elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased. During treatment with hydrocortisone with maximum doses appropriate for stress, fludrocortisone replacement is not required. Some patients cannot tolerate fludrocortisone and must substitute NaCl tablets to replace renal sodium loss.

DHEA is given to some women with adrenal insufficiency. In a double-blind clinical trial, women taking DHEA 50 mg orally each morning experienced an improved sense of well-being, increased muscle mass, and a reversal in bone loss at the femoral neck. DHEA replacement did not improve fatigue, cognitive problems, or sexual dysfunction; however, its placebo effect may be significant in that regard. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

3. Acute adrenal crisis therapy—If acute adrenal crisis is suspected but the diagnosis of adrenal insufficiency is not yet established, blood is drawn for routine emergency laboratory tests and blood cultures, as well as serum cortisol and ACTH levels. Without waiting for the results, treatment is initiated *immediately* with hydrocortisone phosphate or hydrocortisone sodium succinate 100–300 mg intravenously along with saline solution. Thereafter, hydrocortisone is continued as intravenous infusions of 50–100 mg every 6 hours for the first day. The dosage may then be reduced according to the clinical picture and laboratory test results.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures. The patient must also be treated for electrolyte abnormalities, hypoglycemia, and dehydration, as indicated.

When the patient is able to take food by mouth, hydrocortisone is administered orally in doses of 10–20 mg every 6 hours, and the dosage is reduced to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (10–20 mg in am; 5–10 mg in pm). Mineralocorticoid replacement is not needed when large amounts of hydrocortisone are being given, but as its dose is reduced it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg orally daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause, if possible.

▶ Prognosis

The life expectancy of patients with Addison disease is reasonably normal, as long as they are compliant with their medications and knowledgeable about their condition.

However, one retrospective Swedish study of 1675 patients with Addison disease found an unexpected increase in all-cause mortality, mostly from cardiovascular disease, malignancy, and infection. Associated conditions can pose additional health risks. For example, patients with adrenoleukodystrophy or Allgrove syndrome may suffer from neurologic disease. Patients with adrenal tuberculosis have a serious systemic infection that requires treatment. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Patients who take excessive doses of corticosteroid replacement can develop Cushing syndrome, which imposes its own risks.

Most patients with Addison disease are able to live fully active lives. However, some patients feel residual fatigue, despite glucocorticoid and mineralocorticoid replacement. This may be due, in part, to the inadequacy of oral replacement to duplicate cortisol's normal circadian rhythm. Also, patients with Addison disease are deficient in epinephrine, but replacement epinephrine is not available. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent hypothyroidism or diabetes mellitus.

For patients with acute adrenal crisis, rapid treatment is usually lifesaving. However, if adrenal crisis is unrecognized and untreated, shock that is unresponsive to fluid replacement and vasopressors can result in death.

CUSHING SYNDROME (Hypercortisolism)

ESSENTIALS OF DIAGNOSIS

- ▶ Central obesity, muscle wasting, thin skin, hirsutism, purple striae.
- ▶ Psychological changes.
- ▶ Osteoporosis, hypertension, poor wound healing.
- ▶ Hyperglycemia, glycosuria, leukocytosis, lymphocytopenia, hypokalemia.
- ▶ Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

▶ General Considerations

The term Cushing “syndrome” refers to the manifestations of excessive corticosteroids, commonly due to supraphysiologic doses of corticosteroid drugs and rarely due to spontaneous production of excessive corticosteroids by the adrenal cortex. Cases of spontaneous Cushing syndrome are rare (2.6 new cases yearly per million population in the United States) and have several possible causes.

About 40% of cases are due to Cushing “disease,” by which is meant the manifestations of hypercortisolism due to ACTH hypersecretion by the pituitary. Cushing disease is caused by a benign pituitary adenoma that is typically smaller than 5 mm and usually located in the anterior pituitary (98%) or in the posterior pituitary (2%). It is at least three times more frequent in women than men. Excessive ingestion of gamma-hydroxybutyric acid (GHB, sodium oxybate) can also induce ACTH-dependent Cushing syndrome that resolves after the drug is stopped.

About 10% of cases are due to nonpituitary ACTH-secreting neuroendocrine neoplasms that produce excessive amounts of ectopic ACTH. Hypokalemia and hyperpigmentation are commonly found in this group. Ectopic locations include the lungs (55%), pancreas (9%), mediastinum-thymus (8%), adrenal (6%), gastrointestinal tract (5%), thyroid (4%), and other sites (13%). About 15% of cases are due to ACTH from a source that cannot be initially located.

About 30% of cases are due to excessive autonomous secretion of cortisol by the adrenals—independently of ACTH, serum levels of which are usually low. Most such cases are due to a unilateral adrenal tumor. Benign adrenal adenomas are generally small and produce mostly cortisol; adrenocortical carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens but may be nonsecretory. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells’ abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food dependent and serum ACTH may not be completely suppressed. Bilateral primary pigmented adrenal macronodular adrenocortical disease is a rare cause of Cushing syndrome in children and young adults. Bilateral primary pigmented adrenal macronodular adrenocortical disease may be an isolated condition or part of the **Carney complex**, an autosomal dominant condition with additional features consisting of myxomas of the heart and skin with spotty skin pigmentation and facial freckles.

▶ Clinical Findings

A. Symptoms and Signs

The manifestations of Cushing syndrome vary considerably. Early in the course of the disease, patients frequently complain of fatigue or reduced endurance but may have few, if any, of the physical stigmata described below. Central obesity with a plethoric “moon face,” “buffalo hump,” supraclavicular fat pads, protuberant abdomen, and thin

extremities eventually develop in most patients with Cushing syndrome. Muscle atrophy causes weakness, with difficulty standing up from a seated position or climbing stairs. Patients may also experience backache, headache, hypertension, osteoporosis, avascular necrosis of bone, acne, superficial skin infections, and oligomenorrhea or amenorrhea in women or erectile dysfunction in men. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen), and easy bruisability. Unusual bacterial or fungal infections are common. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections.

Adrenocortical carcinomas can usually be distinguished from benign adrenal adenomas since they are usually larger (average 11 cm diameter) and many have metastases that are visible on preoperative scans. However, some adrenal carcinomas are smaller and the histopathologic diagnosis can be difficult. Some adrenal carcinomas have microscopic metastases that can only be inferred from the presence of detectable cortisol levels following removal of the primary adrenal tumor. The ENSAT staging system is used: stage 1 is a localized tumor 5 cm or smaller; stage 2 is a localized tumor larger than 5 cm; stage 3, tumor with local metastases; stage 4, tumor with distant metastases.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

▶ Tests for Hypercortisolism

The biochemical evaluation for Cushing syndrome can be difficult, since test results are often misleading or conflicting. The **dexamethasone suppression test** is the easiest screening test for Cushing syndrome. Dexamethasone 1 mg is given orally at 11 PM and serum is collected for cortisol determination at 8 AM the next morning; a cortisol level less than 5 mcg/dL (135 nmol/L, fluorometric assay) or less than 1.8 mcg/dL (49 nmol/L, high-performance liquid chromatography [HPLC] assay) excludes Cushing syndrome with some certainty. However, 8% of established patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels less than 2 mcg/dL (55 nmol/L). Therefore, when other clinical criteria suggest hypercortisolism, further evaluation is warranted even in the face of normal dexamethasone-suppressed serum cortisol. Antiseizure drugs (eg, phenytoin, phenobarbital, primidone) and rifampin accelerate the metabolism of dexamethasone, causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or HRT—may also cause lack of dexamethasone suppressibility.

A **24-hour urinary free cortisol and creatinine** is the usual confirmatory test for patients with an abnormal dexamethasone suppression test. An abnormally high 24-hour urine free cortisol (or free cortisol to creatinine ratio of greater than 95 mcg cortisol/g creatinine helps confirm hypercortisolism. A misleadingly high urine free cortisol excretion occurs with high fluid intake. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal. Carbamazepine and fenofibrate cause false elevations of urine free cortisol when determined by HPLC. **Late-night salivary cortisol** assays are useful due to the inconvenience of obtaining a midnight blood specimen for serum cortisol. Late-night salivary cortisol levels are normally less than 150 ng/dL (4.0 nmol/L). Late-night salivary cortisol levels that are consistently greater than 250 ng/dL (7.0 nmol/L) are considered very abnormal. The late-night salivary cortisol test has a relatively high sensitivity and specificity for Cushing syndrome, but false-positive and false-negative tests occur.

Midnight serum cortisol levels greater than 7.5 mcg/dL (200 nmol/L) are indicative of Cushing syndrome and distinguish it from other conditions associated with a high urine free cortisol (pseudo-Cushing states). Requirements for this test include being in the same time zone for at least 3 days, being without food for at least 3 hours, and having an indwelling intravenous line established in advance for the blood draw.

▶ Finding the Cause of Hypercortisolism

Once hypercortisolism is confirmed, a plasma or serum ACTH is obtained. It must be collected properly in a plastic tube on ice and processed quickly by a laboratory with a reliable, sensitive assay. A level of ACTH below 20 pg/mL (4.4 pmol/L) indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors.

▶ Localizing Techniques

In ACTH-independent Cushing syndrome, CT of the adrenals usually detects a mass lesion. Most such lesions are benign adrenal adenomas, but an adrenal carcinoma is suspected in the following circumstances: (1) diameter of 4 cm or more; (2) nodule growth; or (3) atypical imaging: density on noncontrast CT greater than 10 Hounsfield units (HU) or CT contrast washout 60% or more or relative contrast washout 40% or more at 15 minutes after intravenous administration.

In ACTH-dependent Cushing syndrome, MRI of the pituitary demonstrates a pituitary lesion in about 50% of cases. Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny (less than 5 mm diameter) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease. Inferior petrosal sinus sampling is also done during ovine CRH (oCRH or Acthrel) administration, which

ordinarily causes the ACTH levels in the inferior petrosal sinus to be over three times the peripheral ACTH level when the pituitary is the source of ACTH.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of ACTH commences with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. In patients with ACTH-dependent Cushing syndrome, chest masses should not be assumed to be the source of ACTH, since opportunistic infections are common, so it is prudent to biopsy a chest mass to confirm the pathologic diagnosis prior to resection.

For Cushing syndrome due to ectopic ACTH, CT scanning fails to detect the source of ACTH in about 34% of cases. In such cases, the most sensitive (82%) scanning technique is whole-body imaging with ^{68}Ga -somatostatin receptor-PET/CT (either ^{68}Ga -DOTATATE-PET/CT or ^{68}Ga -DOTATOC-PET/CT). The next most sensitive (58%) scanning technique is whole-body imaging with ^{18}F -DOPA-PET/CT.

In non-ACTH-dependent Cushing syndrome, a CT scan of the adrenals can localize the adrenal tumor in most cases.

▶ Differential Diagnosis

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Pregnant women have elevated serum ACTH levels, increased urine free cortisol, and high serum cortisol levels due to high serum levels of cortisol-binding globulin. Critically ill patients frequently have hypercortisolism, usually with suppression of serum ACTH. Regular use of gamma hydroxybutyrate (GHB, sodium oxybate) has been reported to cause reversible ACTH-dependent Cushing syndrome. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Cushing syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome.

Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as “striae distensae” and are not indicative of Cushing syndrome. Patients with familial partial lipodystrophy type I develop central obesity and moon facies, along with thin extremities due to atrophy of subcutaneous fat. However, these patients’ muscles are strong and may be hypertrophic, distinguishing this condition from Cushing syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad (“buffalo hump”) causing pseudo-Cushing syndrome.

Adrenal nodules are discovered incidentally on up to 4% of abdominal CT or MRI scans obtained for other reasons; they have been dubbed “**adrenal incidentalomas.**” It is always necessary to determine whether such masses are malignant or secretory. Although the overwhelming majority of adrenal incidentalomas are benign adrenal adenomas, the differential diagnosis includes adrenal carcinoma, pheochromocytoma, metastases, lymphoma, myelolipoma, infection, and cysts. When an adrenal incidentaloma larger than 4 cm in diameter is detected in a patient without a history of malignancy, it should be resected, unless it is an unmistakably benign myelolipoma, hemorrhage, or adrenal cyst. Masses 3–4 cm in diameter may be resected if they have suspicious features (heterogeneity or irregularity). Smaller adrenal incidentalomas are usually observed. A noncontrast CT scan can determine the density of the mass; adrenal incidentalomas with a density less than 10 HU on CT are unlikely to be a pheochromocytoma or metastasis. An adrenal intravenous contrast “washout” CT scan is obtained; the density of the adrenal incidentaloma in HU is calculated 60 seconds after contrast and again 15 minutes after contrast; a reduction (washout) of 40% or more is consistent with a benign adrenal adenoma. However, such testing is never absolutely accurate; so if the adrenal incidentaloma is not resected, a follow-up CT of the adrenals in 6–12 months is recommended to look for growth.

All patients with an adrenal nodule require a clinical assessment for Cushing syndrome and hyperaldosteronism. In particular, patients with hypertension or any possible manifestations of Cushing syndrome require an appropriate biochemical evaluation. All (even normotensive) patients with an adrenal incidentaloma require testing for pheochromocytoma with plasma fractionated free metanephrines.

▶ Treatment

Patients with Cushing syndrome of any etiology face a high complication rate after treatment and all patients require intensive clinical care and close follow-up. All patients and their families must receive thorough education about the effects of Cushing syndrome and its treatment. Patients must receive treatment for cortisol-dependent comorbidities, including osteoporosis, psychiatric disorders, diabetes mellitus, hypertension, hypokalemia, muscle weakness, and infections. Affected patients should also receive vaccinations against influenza, pneumococcus, and herpes zoster. All patients undergoing surgery should have prophylaxis against venous thromboembolism.

A. Surgical Therapy

Pituitary Cushing disease is best treated with transsphenoidal selective resection of the pituitary adenoma. With an experienced pituitary neurosurgeon, reported remission rates range from 65% to 90%. Postoperative hyponatremia occurs frequently, so serum sodium should be monitored frequently for the first 2 weeks postoperatively. The patient should be screened for secondary hypothyroidism with a serum free T_4 within 1–2 weeks after surgery. After

successful pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticosteroids remain suppressed and require 6–36 months to recover normal function. Therefore, patients receive empiric replacement-dose hydrocortisone postoperatively. Postoperative secondary adrenal insufficiency is a mark of successful pituitary surgery; screening may include a morning serum cortisol 6–8 hours following the prior evening dose of hydrocortisone. The cosyntropin test becomes abnormal by 2 weeks following successful pituitary surgery. Patients with secondary adrenal insufficiency require patient education about the condition and must continue glucocorticoid replacement until a cosyntropin stimulation test is normal. A pituitary MRI should be obtained within 2–3 months postoperatively and repeated as indicated for clinical evidence of recurrent Cushing disease or Nelson syndrome.

Cushing disease may persist after pituitary surgery, particularly when there has been cavernous sinus involvement. After apparent successful pituitary surgery, Cushing disease recurs in 16% after a mean of 38 months. Patients must have repeated evaluations for recurrent Cushing disease for years postoperatively. For patients with persistent or recurrent Cushing disease, repeat transsphenoidal pituitary surgery may be warranted if the recurrent tumor is visible and deemed resectable. Otherwise, bilateral laparoscopic adrenalectomy is usually the best treatment option, particularly for patients with very severe disease, since it renders an immediate remission in a condition with significant morbidity and mortality. Residual or recurrent ACTH-secreting pituitary tumors may also be treated with stereotactic radiosurgery, which normalizes urine free cortisol in 70% of patients within a mean of 17 months, compared with a 23% remission rate with conventional radiation therapy. Pituitary radiosurgery can also be used to treat Nelson syndrome, the progressive enlargement of ACTH-secreting pituitary tumors following bilateral adrenalectomy.

Benign adrenal adenomas may be resected laparoscopically if they are smaller than 6 cm in diameter; cure is achieved in most patients. However, most patients experience prolonged secondary adrenal insufficiency. Patients with bilateral adrenal macronodular hyperplasia usually require bilateral adrenalectomies and an evaluation for Carney complex that can be confirmed with a genetic evaluation for activating mutations in the gene *PRKARIA* or genetic changes at chromosome 2p16. Such patients require regular screening for testicular and thyroid tumors and frequent echocardiogram screening for atrial myxomas.

Adrenal carcinomas are resected surgically. Postoperative secondary adrenal insufficiency is a good prognostic sign, with an increased chance that the tumor was completely resected without metastases. However, the postoperative presence of detectable cortisol indicates metastases or residual tumor. Most patients are treated postoperatively with mitotane for 2–5 years, since it improves survival. Mitotane is given orally with meals, beginning with 0.5 g twice daily, increasing to 1 g twice daily within 2 weeks, with subsequent increased doses every 2–3 weeks to reach

serum levels of 14–20 mcg/mL. Unfortunately, only half the patients are able to reach these levels due to side effects. Mitotane can cause hypogonadism and can suppress TSH and cause hypothyroidism. Mitotane often causes primary adrenal insufficiency. Replacement hydrocortisone or prednisone should be started when mitotane doses reach 2 g daily. The replacement dose of hydrocortisone starts at 15 mg in the morning and 10 mg in the afternoon, but must often be doubled or tripled because mitotane increases cortisol metabolism and cortisol binding globulin levels; the latter can artifactually raise serum cortisol levels. Other chemotherapy regimens have been used, usually adding etoposide to mitotane. When this regimen fails, chemotherapy with cisplatin (alone or with other agents) is usually used.

Ectopic ACTH-secreting tumors should be located, when possible, and surgically resected. If that cannot be done, laparoscopic bilateral adrenalectomy is usually recommended. Medical treatment with a combination of mitotane (3–5 g/24 h), ketoconazole (0.4–1.2 g/24 h), and metyrapone (3–4.5 g/24 h) often suppresses the hypercortisolism. Octreotide LAR, 20–40 mg injected intramuscularly every 28 days, suppresses ACTH secretion in about one-third of such cases. Pasireotide may prove more effective. Potassium-sparing diuretics are often helpful.

Patients who are successfully surgically treated for Cushing syndrome typically develop “cortisol withdrawal syndrome,” even when given replacement corticosteroids for adrenal insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg orally twice daily can improve these symptoms; the dosage is then reduced slowly as tolerated. Patients with Cushing syndrome are prone to develop osteoporosis. Bone densitometry is recommended for all patients and treatment is commenced for patients with osteoporosis.

B. Medical Therapy

1. Cushing syndrome—For patients with Cushing syndrome who decline surgery or for whom surgery has been unsuccessful, medical therapy is available. Mineralocorticoid hypertension can be treated with spironolactone, eplerenone, and dihydropyridine calcium channel blockers. Women with hyperandrogenism may be treated with flutamide. Cabergoline, 0.5–3.5 mg orally twice weekly, was successful in 40% of patients with Cushing disease in one small study. Pasireotide, a multireceptor-targeting somatostatin analog, is another potential treatment for refractory ACTH-secreting pituitary tumors causing Cushing disease or Nelson syndrome. Ketoconazole inhibits adrenal steroidogenesis and is another treatment option when given in doses of about 200 mg orally every 6 hours; however, it is marginally effective and can cause liver toxicity.

2. Hypercortisolism—Metyrapone can also suppress hypercortisolism; required median daily doses were 1250–1500 mg/d in divided doses. It may be combined with ketoconazole. Metyrapone also may be used for patients

with secretory adrenocortical carcinoma whose hypercortisolism is not fully controlled with mitotane.

► Prognosis

The manifestations of Cushing syndrome regress with time, but patients are often left with residual cognitive or psychiatric impairment, muscle weakness, osteoporosis, and sequelae from vertebral fractures. Continued impaired quality of life is more common in women compared to men. Younger patients have a better chance for full recovery.

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful, which can be predicted if the postoperative nonsuppressed serum cortisol is less than 2 mcg/dL (55 nmol/L). Following successful treatment, overall mortality remains particularly higher for patients with older age at diagnosis, higher preoperative ACTH concentrations, and longer duration of hypercortisolism.

Transsphenoidal surgery incurs a failure rate of about 10–20%, often due to the adenoma’s ectopic position or invasion of the cavernous sinus. Those patients who have a complete remission after transsphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Laparoscopic bilateral adrenalectomy may be required. Recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%.

In patients with adrenocortical carcinoma, 5-year survival rates of treated patients have correlated with the ENSAT stage. For stage 1, the 5-year survival was 81%; for stage 2, 61%; for stage 3, 50%; and for stage 4, 13%. In patients with stage 1 or 2 disease, long-term survival does occur. However, despite apparent complete resection in stage 1, 2 or 3 tumors, visible metastases develop in about 40% of patients within 2 years. Adjuvant therapy with mitotane appears to improve the prognosis. Patients with stage 4 disease at the time of surgery have a poorer prognosis, but debulking surgery and therapy with mitotane may be beneficial.

► Complications

Cushing syndrome, if untreated, produces serious morbidity and even death. The patient may suffer from the complications of hypertension or diabetes mellitus. Susceptibility to infections is increased. Compression fractures of the osteoporotic spine and aseptic necrosis of the femoral head may cause marked disability. Nephrolithiasis and psychosis may occur. Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively (Nelson syndrome), causing local destruction (eg, visual field impairment, cranial nerve palsy) and

hyperpigmentation. Following successful therapy for Cushing syndrome, secondary adrenal insufficiency occurs and requires long-term glucocorticoid replacement. Five years after successful surgery, secondary hypoadrenalism resolves in about 58% of patients with pituitary Cushing disease, 82% of those with ectopic ACTH, and only 38% of those who had an adrenal tumor.

▶ When to Refer

Dexamethasone suppression test is abnormal.

▶ When to Admit

- Transsphenoidal hypophysectomy.
- Adrenalectomy.
- Resection of ectopic ACTH-secreting tumor.

PRIMARY ALDOSTERONISM

ESSENTIALS OF DIAGNOSIS

- ▶ Hypertension that may be severe or drug-resistant.
- ▶ Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- ▶ Low plasma renin; elevated plasma and urine aldosterone levels.

▶ General Considerations

Primary aldosteronism (hyperaldosteronism) refers to an inappropriately high aldosterone secretion that does not suppress adequately with sodium loading. Most affected patients have hypertension, although some may be

normotensive. Primary aldosteronism is believed to account for 8–10% of all cases of hypertension and 20% of cases of resistant hypertension. It should be suspected with early-onset hypertension or stroke before age 50 years (or both). It may be difficult to distinguish primary aldosteronism from cases of low renin essential hypertension, with which it may overlap. Patients of all ages may be affected, but the peak incidence is between 30 years and 60 years. Excessive aldosterone production increases sodium retention and suppresses plasma renin. It increases renal potassium excretion, which can lead to hypokalemia. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%). Primary aldosteronism may be caused by a unilateral aldosterone-producing adrenal adenoma (Conn syndrome), 40% of which have been found to have somatic mutations in a gene involved with the potassium channel. Primary aldosteronism is most commonly caused by unilateral or bilateral adrenal hyperplasia. Bilateral aldosteronism may be corticosteroid suppressible, due to an autosomal-dominant genetic defect allowing ACTH stimulation of aldosterone production. Malignant ovarian tumors are a rare cause of hyperaldosteronism.

▶ Clinical Findings

A. Symptoms and Signs

Primary aldosteronism is the most common cause of refractory hypertension in youths and middle-aged adults. Patients have hypertension that is typically moderate but may be severe. Some patients have only diastolic hypertension, without other symptoms and signs. Edema is rarely seen in primary aldosteronism. About 37% of patients have hypokalemia that may be spontaneous or triggered by diuretic therapy. Hypokalemia can produce muscle weakness (at times with paralysis simulating periodic paralysis), paresthesias with frank tetany, headache, polyuria, and polydipsia.

B. Laboratory Findings

Plasma potassium should be determined in hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an adrenal adenoma and 17% of those with adrenal hyperplasia. Besides hypokalemia, many patients with primary aldosteronism have metabolic alkalosis with an elevated serum bicarbonate (HCO_3^-) concentration.

Testing for primary aldosteronism should be done for all hypertensive patients with (1) hypokalemia, whether spontaneous or diuretic induced; (2) treatment-resistant hypertension (despite three drugs); (3) severe hypertension: greater than 160 mm Hg systolic or greater than 100 mm Hg diastolic; (4) early-onset hypertension; (5) low-renin hypertension; (6) hypertension with an adrenal mass; (7) hypertension with a family history of early-onset hypertension or cerebrovascular accident before age 40 years; and (8) a first-degree relative who has aldosteronism.

For at least 2 weeks prior to testing, patients should consume a diet high in NaCl (more than 6 g/day)

and ideally hold certain medications: all diuretics, ACE inhibitors, ARBs (stimulate PRA); beta-blockers, clonidine, NSAIDs (suppress PRA); oral estrogens and oral contraceptives should also ideally be held. Medications that are allowed include slow-release verapamil, hydralazine, terazosin, and doxazosin.

For blood testing, the patient should be out of bed for at least 2 hours and seated for 15–60 minutes before the blood draw, which should preferably be obtained between 8 AM and 10 AM. Proper phlebotomy technique is important to avoid spurious increases in potassium. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist clenching. Plasma potassium, rather than the routine serum potassium, should be measured in cases of unexpected hyperkalemia, with the separation of plasma from cells within 30 minutes of collection. (Serum potassium levels must be normal, since hypokalemia suppresses aldosterone.) For practical purposes, the same blood draw can be used for simultaneous assays for plasma potassium, PRA, and direct renin assay (DRA). Patients with primary aldosteronism have a suppressed PRA less than 0.65 ng/mL/h or DRA less than 0.36 ng/mL. **PRA of 1 ng/mL/h (12.8 pmol/L/min) is equivalent to a DRA of 5.2 ng/mL (8.2 milli-units/L).** Blood specimens for PRA must be transported to the laboratory at room temperature for prompt separation and freezing of plasma. Serum aldosterone should ideally be measured with tandem mass spectrometry. Suppressed PRA or DRA with a serum aldosterone concentration greater than 15 ng/dL (416 pmol/L) indicates hyperaldosteronism. Serum aldosterone (ng/dL): PRA (ng/mL/h) ratios less than 24 exclude primary aldosteronism, whereas ratios between 24 and 67 are suspicious and ratios greater than 67 are very suggestive of primary aldosteronism. Such elevated ratios are not diagnostic; rather, they indicate the need to document increased aldosterone secretion with a 24-hour urine collection. To confirm the diagnosis, a 24-hour urine is collected in an acidified container for aldosterone, cortisol, and creatinine; urine aldosterone greater than 20 mcg/24 h (55 nmol/24 h) confirms primary aldosteronism.

C. Imaging

Some patients with undiagnosed primary aldosteronism are incidentally found to have an adrenal nodule (incidentaloma) during abdominal or chest imaging. All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma. In the absence of a large adrenal carcinoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having a sensitivity of 78% and a specificity of 78% for unilateral aldosteronism. Therefore, the decision to perform a unilateral adrenalectomy should not be based solely on the adrenal CT scan. Adrenal vein sampling is often required.

E. Adrenal Vein Sampling

Unfortunately, bilateral selective adrenal vein sampling is invasive, expensive, not widely available, and often unsuccessful. The procedure (and surgery) may not be required for patients whose blood pressure is well controlled with

spironolactone or eplerenone and for those with familial hyperaldosteronism. It is indicated only if surgery is contemplated in order to direct the surgeon to the correct adrenal gland. Adrenal vein sampling is probably not required in patients who have a classic adrenal adenoma (Conn syndrome), which is characterized by hypokalemia and a unilateral adrenal adenoma 10 mm or larger in diameter on CT.

Before this procedure, the patient must be properly prepared (see Laboratory Findings). However, patients with a persistently suppressed PRA may continue mineralocorticoid blockade. To ensure proper catheterization of both adrenal veins, the blood samples are assayed for both aldosterone and cortisol following cosyntropin administration. Aldosterone hypersecretion on one side usually indicates that adrenal has a unilateral aldosteronoma or hyperplasia, particularly when aldosterone secretion from the contralateral adrenal is suppressed, in which case unilateral surgery improves hypertension in 96%. The procedure has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. This procedure entails a 0.57% risk of major complications.

► Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia in patients with essential hypertension, especially diuretic therapy; chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism.

Real (black) licorice (derived from anise) or anise-flavored drinks (sambuca, pastis) contain glycyrrhizic acid, which has a metabolite that inhibits the enzyme that normally inactivates cortisol in the renal tubule. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia but PRA is high. Excessive adrenal secretion of other corticosteroids (besides aldosterone), certain congenital adrenal enzyme disorders, and primary cortisol resistance may also cause hypertension with hypokalemia. The differential diagnosis also includes Liddle syndrome, an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low.

► Complications

Cardiovascular complications occur more frequently in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

► Treatment

The unilateral adrenal adenoma of Conn syndrome is usually treated by laparoscopic adrenalectomy. During pregnancy, such surgery is best performed during the second trimester. However, long-term medical therapy is an option for unilateral hyperaldosteronism, if adequate blood pressure control can be maintained. Bilateral adrenal hyperplasia is best treated with medical therapy. Medical treatment must

include a potassium-sparing diuretic, particularly spironolactone, eplerenone, or amiloride. Spironolactone is the most effective drug but also has antiandrogen activity and men frequently experience breast tenderness, gynecomastia, or reduced libido; it is given at initial doses of 12.5–25 mg orally once daily; the dose may be titrated upward to 200 mg daily. Spironolactone might lead to undervirilization of male infants and is contraindicated in pregnancy; reproductive-age women are cautioned to use contraception during therapy. Eplerenone is favored during pregnancy and for men, since it does not have antiandrogen effects; it must be taken orally twice daily in doses of 25–50 mg. Blood pressure must be monitored daily when beginning these anti-mineralocorticoid medications; significant drops in blood pressure have occurred when these drugs are added to other antihypertensives. Other antihypertensive drugs may be required, particularly amlodipine, and ACE inhibitors or ARBs. Glucocorticoid-remediable aldosteronism is very rare but may respond well to suppression with low-dose dexamethasone.

▶ Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns despite surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

PHEOCHROMOCYTOMA & PARANGLIOMA

ESSENTIALS OF DIAGNOSIS

- ▶ “Attacks” of headache, perspiration, palpitations, anxiety. Multisystem crisis.
- ▶ Hypertension, frequently sustained but often paroxysmal, especially during surgery or delivery.
- ▶ Elevated urinary plasma free metanephrines. Normal serum T₄ and TSH.
- ▶ Frequent germline mutations.

▶ General Considerations

Both pheochromocytomas and non-head-neck paragangliomas are tumors of the sympathetic nervous system. Pheochromocytomas arise from the adrenal medulla and usually secrete both epinephrine and norepinephrine. Paragangliomas (“extra-adrenal pheochromocytomas”) arise from sympathetic paraganglia, often metastasize, and secrete norepinephrine or are nonsecretory. Excessive levels of norepinephrine or neuropeptide Y cause hypertension, while epinephrine causes tachyarrhythmias. These tumors may be located in either or both adrenals or anywhere along the sympathetic nervous chain, and sometimes in the mediastinum, heart, or bladder.

These tumors are particularly dangerous and deceptive, although they account for less than 0.4% of hypertension cases. The incidence is higher in patients with moderate to severe hypertension, particularly in the presence of suspicious symptoms of headache, significant palpitations, or diaphoretic episodes. They account for about 4% of adrenal incidentalomas. The yearly incidence is 2 to 4 new cases per million population. However, many cases are undiagnosed during life, since the prevalence of pheochromocytomas and paragangliomas in autopsy series is 1 in 2000.

Nonsecretory paragangliomas arise in the head or neck, particularly in the carotid body, jugular-tympanic region, or vagal body; only about 4% secrete catecholamines. They often arise in patients who harbor *SDHD*, *SDHC*, or *SDHB* germline mutations.

Over 30% of patients with pheochromocytomas or paragangliomas harbor a germline mutation in 1 of at least 14 genes that makes them prone to develop the tumor, usually in an autosomal dominant manner with incomplete penetrance. For a patient with a pheochromocytoma or paraganglioma, the chance of harboring a germline mutation is nearly 100% with a family history of pheochromocytoma or paraganglioma or with multiple sites of primary tumor, compared to 17% in patients without such family history.

Pheochromocytomas develop in about 20% of patients with **von Hippel-Lindau (VHL) disease type 2** (hemangiomas of the retina, cerebellum, brainstem, and spinal cord; hyperparathyroidism; pancreatic cysts; endolymphatic sac tumors; cystadenomas of the adnexa or epididymis; pancreatic neuroendocrine tumors; renal cysts, adenomas, and carcinomas); inheritance is autosomal dominant. Patients with VHL develop pheochromocytomas that are less likely to be extra-adrenal, less likely to be malignant (3.5%), more likely to be bilateral, and more likely to present at an early age. Pheochromocytomas that arise in patients with VHL secrete exclusively norepinephrine and its metabolite normetanephrine. Therefore, individuals who carry type 2 VHL mutations should be screened for pheochromocytoma with plasma normetanephrine levels.

MEN 2 is associated with pheochromocytomas, hyperparathyroidism, cutaneous lichen amyloidosis, and medullary thyroid carcinoma. **MEN 3** may be familial but usually arises from a *de novo ret* mutation; **MEN 3** is associated with pheochromocytoma (50%), aggressive medullary thyroid carcinoma, mucosal neuromas, and marfanoid habitus.

von Recklinghausen neurofibromatosis type 1 (NF-1) is associated with an increased risk of pheochromocytomas/

paragangliomas as well as cutaneous neurofibromas, optic and brainstem gliomas, astrocytomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots. **Familial paraganglioma** can be caused by mutations in the genes encoding succinate dehydrogenase (SDH) subunits B, C, or D. Patients with such germline mutations are more apt to have bilateral pheochromocytomas or multicentric paragangliomas. Patients with *SDHB* germline mutations are particularly prone to develop paragangliomas that metastasize aggressively; they are also prone to develop renal cell carcinomas and neuroblastomas.

Some kindreds are prone to develop pheochromocytomas and paragangliomas due to less common germline mutations in other tumor susceptibility genes: *SDHA*, *SDHAF2*, *TMEM127*, *MAX*, *KIF1B*, *HIF2A*, and *PHD2*. Pheochromocytomas are also more common in patients with Carney triad, Sturge-Weber syndrome, and tuberous sclerosis.

Clinical Findings

A. Symptoms and Signs (Table 26–12)

Pheochromocytomas can be lethal unless they are diagnosed and treated appropriately. Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur

spontaneously or may be triggered by needle biopsy or manipulation of the mass, intravenous contrast dye or glucagon injection, vaginal delivery, trauma, anesthesia, or surgery (both unrelated to the tumor or for its removal). Exercise, bending, lifting, or emotional stress can trigger paroxysms. Certain drugs can precipitate attacks: fluoxetine and other selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase (MAO) inhibitors, caffeine, nicotine, decongestants, amphetamines, cocaine, ionic intravenous contrast, and epinephrine. Bladder paragangliomas may present with paroxysms during micturition.

Paroxysms typically produce hypertension (90%), severe headache (80%), perspiration (70%), and palpitations (60%); other symptoms may include anxiety (50%), a sense of impending doom, or tremor (40%). Vasomotor changes during an attack cause mottled cyanosis and facial pallor. As the attack subsides, facial flushing may occur as a result of reflex vasodilation. Epinephrine secretion by an adrenal pheochromocytoma may cause episodic tachyarrhythmias, hypotension, or even syncope. Acute coronary syndrome can be caused by coronary vasoconstriction. Confusion, psychosis, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Aortic aneurysms may dissect and

Table 26–12. Clinical manifestations of pheochromocytoma and paraganglioma.

Blood pressure	Hypertension: severe or mild, paroxysmal or sustained; orthostasis; hypotension/shock; normotension
Vasospasm	Cyanosis, Raynaud syndrome, gangrene; severe radial artery vasospasm with thready pulse; falsely low blood pressure by radial artery transducer
Multisystem crisis	ARDS, severe hypertension/hypotension, acute heart failure, fever, renal failure, hepatic failure, encephalopathy, death
Cardiovascular	Palpitations, dysrhythmias, chest pain, acute coronary syndrome, cardiomyopathy, heart failure, cardiac paragangliomas
Gastrointestinal	Abdominal pain, nausea, vomiting, weight loss, intestinal ischemia; pancreatitis, cholecystitis, jaundice; rupture of abdominal aneurysm; constipation, toxic megacolon
Metabolic	Hyperglycemia/diabetes, lactic acidosis, fevers
Neurologic	Headache, paresthesias, numbness, dizziness, CVA, TIA, hemiplegia, hemianopsia, seizures, hemorrhagic stroke; skull metastases may impinge on brain structures, optic nerve, or other cranial nerves; spinal metastases may impinge on cord or nerve roots
Pulmonary	Dyspnea; hypoxia from ARDS
Psychiatric	Anxiety attacks or constant anxiety; depression; chronic fatigue; psychosis
Renal	Renal insufficiency, nephrotic syndrome, malignant nephrosclerosis; large tumors often involve the kidneys and renal vessels
Skin	Apocrine sweating during paroxysms, drenching sweats as attack subsides; eczema; mottled cyanosis during paroxysm
Thyroid	Paroxysmal thyroid swelling
Ectopic hormones	ACTH (Cushing syndrome); VIP (Verner-Morrison syndrome); PTHrP (hypercalcemia); erythropoietin (erythrocytosis)
Children	More commonly have sustained hypertension, diaphoresis, visual changes, polyuria/polydipsia, seizures, edematous or cyanotic hands; more commonly harbor germline mutations, multiple tumors, and paragangliomas
Women	More symptomatic than men: more frequent headache, weight loss, numbness, dizziness, tremor, anxiety, and fatigue
Pregnancy	Hypertension mimicking eclampsia; hypertensive multisystem crisis during vaginal delivery; postpartum shock or fever; high mortality
General laboratory	Leukocytosis, erythrocytosis, eosinophilia

ACTH, adrenocorticotropic hormone; ARDS, acute respiratory distress syndrome; CVA, cerebrovascular accident; PTHrP, parathyroid hormone-related protein; TIA, transient ischemic attack; VIP, vasoactive intestinal peptide.

Used, with permission, from Gardner D, Shoback D (editors). *Greenspan's Basic and Clinical Endocrinology*. 9th edition, McGraw-Hill, 2011.

rupture. Abdominal pain, nausea, vomiting, and even ischemic bowel can be due to splanchnic vasoconstriction. Large or hemorrhagic abdominal tumors can also cause abdominal pain. Peripheral vasoconstriction can cause Raynaud phenomenon or even gangrene. Patients may experience nervousness and irritability, increased appetite, and loss of weight. Other patients have pulmonary edema and heart failure due to cardiomyopathy. Although most patients are symptomatic, some patients are normotensive and asymptomatic, particularly when the tumor is nonsecretory or discovered at an early stage.

Cytokine release from pheochromocytomas or paragangliomas can cause proteinuria and nephrotic syndrome. Such patients have an increased risk of **multisystem crisis**: acute respiratory distress syndrome (ARDS), acute heart failure, severe hypotension, kidney failure, liver failure, and death. Multisystem crisis can occur spontaneously, or it may be provoked by surgery, vaginal delivery, or treatment of metastatic disease.

B. Laboratory Findings

Plasma fractionated free metanephrines is the single most sensitive test for secretory pheochromocytomas and paragangliomas. The blood specimen may be obtained after sitting quietly in the laboratory for at least 15 minutes. Normal levels rule out pheochromocytoma and paraganglioma with some certainty and the work-up can usually end there. However, misleading elevations in plasma metanephrines or normetanephrines occur at a rate of about 10–20% and can be caused by drawing blood in a sitting position. Therefore, patients with elevated levels drawn in the sitting position should have the test repeated while lying supine in a quiet room for 30 minutes before the blood is drawn. Other causes for misleading elevations with all assay methods include physical or emotional stress, sleep apnea, and certain drugs: sympathomimetics, cocaine, MAO inhibitors, tricyclic antidepressants, and phenoxybenzamine. Patients with confirmed elevations in plasma metanephrines or normetanephrines require further evaluation.

Assay of urinary fractionated metanephrines and creatinine effectively confirms most pheochromocytomas that were detected by elevated plasma fractionated metanephrines. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more than 2.2 mcg of total metanephrine per milligram of creatinine, and more than 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas.

Some drugs, foods, and stresses can cause misleading elevations in catecholamine excretion (Table 26–13). About 10% of hypertensive patients have a misleadingly elevated level of one or more tests.

Serum chromogranin A (CgA) is elevated in 90% of patients with pheochromocytoma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum CgA must be assayed in the fasting state, since levels rise after meals. Misleading CgA levels also

¹Note that assays for metanephrine using tandem mass spectrometry (MS/MS) are not prone to interference from drugs or foods, except those that increase catecholamine excretion.

²May cause confounding peaks for catecholamines or metanephrines with an HPLC-ECD chromatogram.

³Increases measured catecholamine excretion.

⁴Decreases measured catecholamine excretion.

⁵May decrease urine metanephrine excretion.

⁶Increases plasma and urinary normetanephrine and metanephrine.

occur in patients with azotemia or hypergastrinemia, and in those treated with corticosteroids or proton pump inhibitors.

Initial testing results are frequently inconclusive. When metanephrines are elevated but less than three times the upper limit of normal, there is a significant chance of the test result being falsely positive. False-positive test results

should be particularly suspected when the ratio of normetanephrine to norepinephrine is less than 0.52 or the ratio of metanephrine to epinephrine is less than 4.2. In such cases, it is best to repeat biochemical testing under optimal conditions, eg, after eliminating potentially interfering drugs. Pharmacologic provocative and suppressive tests that evaluate the rise or fall in blood pressure are usually not required or recommended.

Hyperglycemia is present in about 35% of patients but is usually mild. Proteinuria is present in about 10–20% of patients. Leukocytosis is common. Eosinophilia occurs rarely. The ESR is sometimes elevated. PRA may be increased by catecholamines. Genetic testing should ideally be performed on all patients with pheochromocytoma or paraganglioma. Testing for VHL, *ret* protooncogene, and *SDHB/SDHC/SDHD* mutations is advisable. Family members may then be screened for the specific gene mutation.

C. Imaging

1. CT and MRI scanning—Imaging should only be performed in patients with suggestive laboratory findings, since adrenal pheochromocytomas can appear similar to benign adrenal adenomas that are very common (2–4% of all scans). When a pheochromocytoma is suspected because of biochemical testing or a genetic condition predisposing to pheochromocytoma, a noncontrast CT scan of the abdomen is performed, with thin sections through the adrenals. The CT usually shows an adrenal mass with a density greater than 10 HU. If an adrenal mass is present, another CT is immediately performed, infusing nonionic contrast (to reduce the risk of stimulating catecholamine release from a pheochromocytoma) with a “washout” protocol. Pheochromocytomas are usually avid for contrast and 84% of tumors retain greater than 40% of contrast after 15 minutes. Glucagon should not be used during scanning, since it can provoke hypertensive crisis.

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood and for serial imaging. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

2. Nuclear imaging—A whole-body ^{123}I -meta-iodobenzylguanidine (^{123}I -MIBG) scan can localize tumors with a sensitivity of 94% and a specificity of 92%. However, it is less sensitive for MEN 2- or MEN 3-related pheochromocytomas and for metastases. Preoperative ^{123}I -MIBG scanning may help confirm that a mass is a pheochromocytoma or paraganglioma. Whole-body ^{123}I -MIBG scanning can also be useful to search for a nonadrenal paraganglioma when the adrenals and abdomen appear normal on CT scan in patients in whom a secretory paraganglioma is suspected. It is also prudent to perform a whole-body

^{123}I -MIBG scan about 3 months postoperatively to determine if metastatic or recurrent tumor is present. Drugs that reduce ^{123}I -MIBG uptake should be avoided, including tricyclic antidepressants and cyclobenzapriline (6 weeks). Other drugs, such as amphetamines, diet pills, decongestants, cocaine, phenothiazines, haloperidol, labetalol, and serotonin and norepinephrine reuptake inhibitors (venlafaxine, desvenlafaxine, duloxetine), can potentially reduce ^{123}I -MIBG uptake for up to 2 weeks. Drug interference is suspected in negative ^{123}I -MIBG scans that do not show normal uptake in salivary glands.

Somatostatin receptor imaging using ^{111}In -labeled octreotide is only 25% sensitive for detecting an adrenal pheochromocytoma. However, ^{111}In -labeled octreotide scanning is quite sensitive for detecting extra-adrenal pheochromocytomas (paragangliomas) and metastatic pheochromocytomas, sometimes locating tumors that were missed by ^{123}I -MIBG scanning.

PET/CT scanning usually detects tumors and metastases using ^{18}F -labeled deoxyglucose (^{18}F FDG-PET) or ^{18}F -labeled dopamine (^{18}F DA-PET), and may demonstrate tumors that are not visible on ^{123}I -MIBG scanning.

► Differential Diagnosis

Certain conditions mimic pheochromocytoma: thyrotoxicosis, essential hypertension, myocarditis, glomerulonephritis or other renal lesions, eclampsia, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), anxiety attacks, and cocaine or amphetamine use, and clonidine withdrawal.

Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine. Patients with erythromelalgia can have hypertensive crises. Pheochromocytomas can cause chest pain and ECG changes that mimic acute cardiac ischemia. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma.

False-positive testing for catecholamines and metabolites occurs in about 10–20% of hypertensive patients, but levels are usually less than 50% above normal and typically normalize with repeat testing.

► Complications

All of the complications of severe hypertension may be encountered. In addition, a catecholamine-induced cardiomyopathy may develop. Severe heart failure and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. Multisystem crisis and ARDS can occur acutely and thus the initial manifestation of pheochromocytoma may be hypotension or even shock. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of acute kidney injury or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

Malignant pheochromocytomas may metastasize. Cells can also be seeded within the peritoneum, either spontaneously or as a complication during surgical resection. Such seeding of the abdomen can result in multifocal recurrent intra-abdominal tumors, a condition known as pheochromocytomatosis.

▶ Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/paraganglioma. Patients are advised to measure their blood pressures daily and immediately during paroxysms. Some patients with pheochromocytoma or paraganglioma are not hypertensive and do not require preoperative antihypertensive management. Alpha-blockers or calcium channel blockers can be used, either alone or in combination. Blood pressure should be controlled before cardioselective beta-blockers are added for control of tachyarrhythmias. Normotensive patients with pheochromocytoma or sympathetic paraganglioma do not require preoperative alpha blockade, which increases their requirement for vasopressors and colloid after the tumor resection.

Alpha-blockers are typically administered preparatory to surgery. Phenoxybenzamine is a long-acting nonselective alpha-blocker with a half-life of 24 hours; it is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually by about 10 mg/day about every 3 days until hypertension is controlled. Maintenance doses range from 10 mg/day to 120 mg/day. Doxazosin (half-life 22 hours), a selective alpha-1-blocker, may also be used in doses of 2–32 mg daily. Preoperative preparation with phenoxybenzamine reduces intraoperative hypertension but may increase the risk post-resection compared to patients given a preoperative selective alpha-1-blocker. Optimal alpha-blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial pressure above 80/45 mm Hg.

Calcium channel blockers (nifedipine ER or nicardipine ER) are very effective and are usually added to alpha-blockers, but may be used alone. Nifedipine ER is initially given orally at a dose of 30 mg/day, increasing the dose gradually to a maximum of 60 mg twice daily. Calcium channel blockers are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. However, they should not be used for patients with severe heart failure. For acute hypertensive crisis (systolic blood pressure higher than 170 mm Hg) a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite successful for treating acute hypertension in patients with pheochromocytoma/paraganglioma, even at home; it is reasonably safe as long as the blood pressure is carefully monitored.

Beta-blockers (eg, metoprolol XL) are often required after institution of alpha-blockade or calcium channel blockade. The use of a beta-blocker as initial antihypertensive therapy has resulted in an “unopposed alpha” status that causes paradoxical worsening of hypertension. Labetalol has combined alpha- and beta-blocking activity and is an effective agent but can cause paradoxical hypertension

if used as the initial antihypertensive agent. Labetalol can also interfere with catecholamine determinations in some laboratories and reduces the tumor’s uptake of radioisotopes, such that it must be discontinued for at least 4–7 days before ^{123}I -MIBG or ^{18}F FDG-PET scanning or therapy with high-dose ^{131}I -MIBG.

▶ Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. The ECG should be monitored until it becomes stable. (It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2–6 mcg/kg/min, or nitroprusside, 0.5–10 mcg/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1–2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension and shock caused by desensitization of the vascular alpha-1-receptors. Shock is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

▶ Detecting & Managing Metastatic Pheochromocytoma & Paraganglioma

Surgical histopathology for pheochromocytoma and paraganglioma cannot reliably determine whether a tumor is malignant. Therefore, all pheochromocytomas and paragangliomas must be approached as possibly malignant. Even if no metastases are visible at the time of surgery, they may become apparent years later. So all patients require lifetime follow-up. Therefore, it is essential to recheck blood pressure and plasma fractionated metanephrine levels about 4–6 weeks postoperatively, at least every 6 months for 5 years, then once yearly for life and immediately if hypertension, suspicious symptoms, or metastases become evident. With familial pheochromocytoma, carriers of germline mutations also require close

lifetime surveillance. Patients with nonsecretory tumors frequently have elevated serum levels of chromogranin A that can also be used as a tumor marker. It is also prudent to perform a whole-body ^{123}I -MIBG scan about 3 months postoperatively, since previously undetected metastases may become visible.

Since some metastases are indolent, it is important to tailor treatment to each individual according to their tumor's aggressiveness. Most surgeons resect the main tumor and larger metastases (debulking). Asymptomatic, indolent metastases may be kept under close surveillance without treatment.

A. Chemotherapy

Various chemotherapy regimens have been used, but there have been no controlled clinical trials to prove the effectiveness of one regimen over another or whether any regimen actually improves overall survival. The most common chemotherapy regimen combines intravenous cyclophosphamide, vincristine, and dacarbazine over 2 days in cycles that are repeated every 3 weeks (Table 39–11). About one-third of patients experience some degree of temporary remission. Sunitinib, a tyrosine kinase inhibitor, can also produce remissions, given orally in doses of 50 mg/day for 4 weeks on and then 2 weeks off; alternatively, a dose of 37.5 mg/day can be given continuously. Another chemotherapy regimen uses temozolomide, 250 mg/day orally for 5 days, repeating the cycle every 28 days; this is usually the best-tolerated chemotherapy and is particularly effective for metastatic pheochromocytoma or paraganglioma in patients with *SDHB* germline mutations. Each chemotherapy regimen has toxicities.

Metyrosine reduces catecholamine synthesis but does not impede the progressive growth of metastases; the initial metyrosine dosage is 250 mg four times daily, increased daily by increments of 250–500 mg to a maximum of 4 g/day. Metyrosine causes CNS side effects and crystalluria; hydration must be ensured.

B. ^{131}I -MIBG Therapy

About 60% of patients with metastatic pheochromocytoma or paraganglioma have tumors with sufficient uptake of ^{123}I -MIBG on diagnostic scanning to allow for therapy with high-activity ^{131}I -MIBG. Medications that reduce MIBG uptake must be avoided, particularly labetalol, phenothiazines, tricyclics, and sympathomimetics. Activities of 125–500 mCi are infused, with many centers administering repeated infusions of 2 mCi/kg to cumulative activities of at least 500–800 mCi. Radioisotope therapy can suppress the bone marrow temporarily. Myelodysplastic syndrome and leukemia can develop several years after ^{131}I -MIBG therapy, with the risk proportional to the cumulative amount of isotope. ARDS and multisystem failure occur rarely after ^{131}I -MIBG therapy, particularly in patients with pretreatment proteinuria.

C. Treatment for Bone Metastases

Patients with significant osteolytic bone metastases may be treated with external beam radiation therapy, which is

often helpful in relieving pain and stabilizing local osseous disease. Patients with vertebral metastases and spinal cord compression require surgical decompression and kyphoplasty. Intravenous zoledronate or subcutaneous denosumab may also be administered to patients with osteolytic bone metastases.

► Prognosis

A pheochromocytoma or sympathetic paraganglioma is considered malignant if metastases are present, but metastases may take many years to become clinically evident. Therefore, lifetime surveillance is required (see above). Malignancy is more likely for larger tumors and for sympathetic paragangliomas. The prognosis is good for patients with pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery but may persist or return in 25% of patients despite successful surgery. Although this may be essential hypertension, biochemical reevaluation is nonetheless required, looking for a second or metastatic pheochromocytoma.

The surgical mortality is under 3% with the use of laparoscopic surgical techniques, intraoperative monitoring, and preoperative blood pressure control with alpha-blockers or calcium channel blockers.

Patients with metastatic pheochromocytoma and paraganglioma have an extremely variable prognosis. Patients with a heavy and progressive tumor burden and distant metastases have a worse prognosis. Patients harboring *SDHB* germline mutations tend to have more aggressive tumors as do patients with pulmonary metastases. Patients with metastases limited to bones or the abdomen tend to have a better prognosis. Patients with intraperitoneal seeding (pheochromocytomatosis) rather than true metastases seem to have a better prognosis.

Patients who receive surgery and chemotherapy have a median 5-year survival of about 44%. Patients receiving surgery followed by high-activity ^{131}I -mIBG therapy have been reported to have a 5-year survival rate of 75%. Some patients have an indolent malignancy; prolonged survivals of up to 30 years have been reported with no treatment.

GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS (GEP-NETS) & CARCINOID TUMORS

ESSENTIALS OF DIAGNOSIS

- ▶ GEP-NETs are a subset of neuroendocrine tumors (NETs) that arise from the stomach, intestines, and endocrine pancreas. They may release monogenic amines or polypeptide hormones.
- ▶ Secretory GEP-NETs present with different manifestations depending on the hormones secreted.
- ▶ Half of GEP-NETs are nonsecretory or secretory without clinical manifestations; they may be detected incidentally on scans or may present with weight loss, abdominal pain, or jaundice.
- ▶ Carcinoid tumors arise from either the intestines or lung, secrete serotonin, and may metastasize.

General Considerations

GEP-NETs are a subset of neuroendocrine tumors that arise from the stomach, intestines, or endocrine pancreas. Pancreatic neuroendocrine tumors (pNETs) arise from different islet cells, each with distinct chemical and microscopic features: the A cells (20%) secrete glucagon, the B cells (70%) secrete insulin,¹ the D cells (5%) secrete somatostatin or gastrin, and the F cells secrete pancreatic polypeptide. Gastrin-producing cells also found in the duodenum. Serotonin-producing cells are found throughout the gut, particularly near the terminal ileum.

The reported incidence of GEP-NETs has increased to about 37 per million yearly in the United States due to the incidental detection of small tumors on abdominal scans. About 40% are functional, producing hormones that also serve as tumor markers, important for diagnosis and follow-up. Up to 25% of GEP-NETs are associated with one of four different inherited disorders: MEN 1, von Hippel-Lindau disease (VHL), neurofibromatosis 1 (NF-1), and tuberous sclerosis complex (TSC). At presentation, 65% of GEP-NETs are unresectable or metastatic. In MEN 1, GEP-NETs are usually gastrinomas, carcinoids, or nonfunctioning tumors and are a common cause of death. In VHL, GEP-NETs are usually benign and multiple.

Insulinomas are the most common functional type of GEP-NET and are usually small, intrapancreatic, and benign (90%) and secrete excessive amounts of insulin. Insulinomas also produce proinsulin and C-peptide. Insulinomas are solitary in 95% of sporadic cases but are multiple in about 90% of cases arising in MEN 1. (See Chapter 27.)

Gastrinomas secrete excessive quantities of the hormone gastrin (as well as “big” gastrin). About 50% of gastrinomas are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%),

pancreas (24%), or lymph nodes (11%). Sporadic gastrinoma is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of gastrinomas arise in patients with MEN 1, who usually present at a younger age, often with multiple tumors; hyperparathyroidism can occur many years before or after the discovery of a gastrinoma.

Glucagonomas are rare and usually malignant, despite their benign histologic appearance. They usually arise as a large intrapancreatic tumor with 60% having liver metastases apparent by the time of diagnosis. Besides glucagon, they usually secrete additional hormones, including gastrin.

Somatostatinomas are very rare and usually single. They arise in the pancreas (50%) or small intestine. They secrete somatostatin.

VIPomas are very rare and usually single intrapancreatic tumors with metastases usually evident (80%) at diagnosis. They produce vasoactive intestinal polypeptide (VIP).

CCKomas are rare tumors of the endocrine pancreas that secrete cholecystokinin.

Carcinoid tumors can arise from the small bowel (53%, particularly terminal ileum), colon (12%), esophagus through duodenum (6%), or lung (bronchial carcinoid [5%]). About 20% of cases present with metastases without a known primary location. Carcinoids are multiple in about 28% of cases. Although tumors are usually indolent, metastases are common, particularly to liver, lymph nodes, and peritoneum.

Nonfunctional pancreatic neuroendocrine tumors produce no significant hormones and usually grow to large size prior to detection. They may secrete chromogranin A (CgA) or pancreatic polypeptide, which can be used as tumor markers.

Clinical Findings

A. Symptoms and Signs

Nonfunctioning tumors typically present with mass effect and metastases, such as pancreatitis, jaundice, abdominal pain, or weight loss.

Insulinomas secrete insulin and present with the symptoms of fasting hypoglycemia. (See Chapter 27.)

Gastrinomas usually present with peptic ulcer disease—abdominal pain (75%), heartburn (44%), bleeding (25%)—or weight loss (17%) (Zollinger-Ellison syndrome). Endoscopy usually shows hyperplastic gastric rugae (94%).

Glucagonomas usually present with weight loss caused by glucagon-stimulated protein hepatic gluconeogenesis and related protein catabolism. Other common manifestations include diarrhea, nausea, peptic ulcer, hypomagnesemia, or necrolytic migratory erythema, known as “glucagonoma syndrome”. Diabetes mellitus develops in about 35% of patients. The median survival is 34 months after diagnosis.

Somatostatinomas can present with a classic triad of symptoms: diabetes mellitus due to its inhibition of insulin and glucagon secretion; cholelithiasis due to its inhibition of gallbladder motility; and steatorrhea due to its inhibition

¹ Insulinomas and hypoglycemia are discussed in Chapter 27.

of pancreatic exocrine function. Diarrhea, hypochlorhydria, and anemia can also occur.

VIPomas present with profuse watery diarrhea, (unrelenting) hypokalemia, and *achlorhydria* (“WDHA”), the so-called Verner-Morrison syndrome.

CCKomas may present with liver metastases and symptoms of diarrhea, peptic ulcer disease, and weight loss. Patients have elevated serum levels of cholecystokinin and chromogranin A.

Carcinoid tumors can produce “carcinoid syndrome”: episodes of abdominal pain, diarrhea, bronchospasm, and weight loss. Skin flushing typically affects the upper body, neck, and face and lasts from 30 seconds to 30 minutes, although flushing with bronchial carcinoids can persist for days. Flushing can be unprovoked or precipitated by exercise, anesthesia, emotional stimuli, or foods (bananas, tomatoes, cheese, kiwi, eggplant, and alcohol). However, the full-blown carcinoid syndrome occurs with only about 10% of tumors. Other manifestations include carcinoid heart disease caused by endocardial fibrotic plaques. Tumor-induced fibrosis can also occur in the retroperitoneum causing ureteral obstruction or in the penis causing Peyronie disease. Pellagra (glossitis, confusion, dry skin), which results from the conversion of tryptophan (a precursor to niacin) to serotonin by tumor cells, may develop in affected patients with widespread metastases. Affected patients have high serum levels of chromogranin A and serotonin as well as elevated urinary excretion of 5-HIAA, a renally-excreted product of serotonin metabolism.

Bronchial carcinoids secrete serotonin and can produce carcinoid syndrome even without hepatic metastases. Foregut carcinoids secrete serotonin that is metabolized by the liver and only produce carcinoid syndrome when they have metastasized to the liver. Hindgut carcinoids rarely produce serotonin and do not cause carcinoid syndrome.

Ectopic hormones can be secreted by GEP-NETs. Ectopic ACTH secretion from bronchial carcinoids or pNETs can produce Cushing syndrome.

B. Imaging

Localization of noninsulinoma GEP-NETs and their metastases is best done with somatostatin receptor scintigraphy (SRS) with ^{111}In -DTPA-octreotide (Octreoscan), which detects about 75% of noninsulinomas. PET scanning with ^{68}Ga -DOTA-TATE, a radiolabeled somatostatin analog, is more sensitive. ^{18}F -DOPA PET/CT may be helpful in detecting occult carcinoid tumors. CT and MRI are also useful.

For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, and arteriography 45%. Nearly all insulinomas can be successfully located at surgery by the combination of intraoperative palpation (sensitivity 55%) and ultrasound (sensitivity 75%). An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%). MRI is used to screen members

of kindreds with genetic syndromes that predispose them to GEP-NETs.

▶ Treatment

Surgery is the primary initial treatment for all types of GEP-NETs and is a reasonable option even for patients with stage IV disease. The aggressiveness of the surgery may vary from conservative debulking to radical resection and even liver transplantation.

With gastrinomas, the gastric hyperacidity of Zollinger-Ellison syndrome is treated with a proton pump inhibitor at quadruple the usual doses. Proton pump inhibitors increase serum gastrin, which would otherwise be useful as a tumor marker for gastrinoma recurrence after surgical resection.

Tumor visualization on octreotide scanning indicates that they may respond to long-acting preparations of somatostatin analogs, including lanreotide (Somatuline Depot) and octreotide (Sandostatin LAR Depot). Subcutaneous injections of Octreotide LAR 20–30 mg are required every 4 weeks. Treatment improves symptoms in patients with functioning tumors and also appears to improve progression-free survival in patients with either functioning or nonfunctioning GEP-NETs. Enlarging hepatic metastases may be embolized with ^{90}Y -labeled resin or glass microspheres. For patients with progressive metastatic disease, chemotherapy with everolimus or sunitinib improves progression-free survival when added to somatostatin analog therapy. Other chemotherapeutic agents such as dasatinib may also prove effective. Chemotherapy with combined streptozocin, 5-fluorouracil and doxorubicin or combined capecitabine with streptozocin can also produce remissions.

▶ Prognosis

The prognosis for patients with GEP-NETs is variable, depending on the tumor grade and stage. Patients with well or moderately-well differentiated GEP-NETs (Ki-67 less than 20%) have a much better survival than those with poorly differentiated tumors. Smaller tumors without detectable metastases have a much lower chance of recurrence after surgery. However, most patients with GEP-NETs are stage IV with hepatic metastases by the time of diagnosis. Nevertheless, low-grade metastases may be indolent or slow-growing and may respond to octreotide or lanreotide. The overall prognosis for patients with GEP-NETs is much better than that for adenocarcinomas that arise from the same organs.

The surgical complication rate for GEP-NETs is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%). For patients with gastrinomas, the 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for patients with sporadic gastrinomas are 62%, 50%, and 31%, respectively.

MULTIPLE ENDOCRINE NEOPLASIA (MEN)

MEN TYPES 1–4

ESSENTIALS OF DIAGNOSIS

- ▶ **MEN 1:** tumors of the parathyroid glands, endocrine pancreas and duodenum, anterior pituitary, adrenal, thyroid; carcinoid tumors; lipomas and facial angiofibromas.
- ▶ **MEN 2 (MEN 2A):** medullary thyroid cancers, pheochromocytomas, Hirschsprung disease.
- ▶ **MEN 3 (MEN 2B):** medullary thyroid cancers, pheochromocytomas, Marfan-like habitus, mucosal neuromas, intestinal ganglioneuroma, delayed puberty.
- ▶ **MEN 4:** tumors of the parathyroid glands, anterior pituitary gland, adrenal gland, ovary, testicle, kidney.

Syndromes of MEN are inherited as autosomal dominant traits that cause a predisposition to the development of tumors of two or more different endocrine glands (Table 26–14). MEN syndromes are caused by different germline mutations and tumors arising when certain additional somatic mutations occur in predisposed

organs. Patients with MEN should have genetic testing so that their first-degree relatives may then be tested for the specific mutation.

1. MEN 1

Multiple endocrine neoplasia type 1 (MEN 1, Wermer syndrome) is a tumor syndrome with a prevalence of 2–10 per 100,000 persons in the United States. About 90% of affected patients harbor a detectable germline mutation in the *menin* gene. Genetic testing is able to detect the specific mutation in 60–95% of cases.

The presentation of MEN 1 is quite variable, even in the same kindred. Affected patients are prone to many different tumors, particularly involving the parathyroids, endocrine pancreas and duodenum, and anterior pituitary. With close endocrine surveillance of affected individuals, the initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations usually present in the third or fourth decade.

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life. The hyperparathyroidism of MEN 1 is notoriously difficult to treat surgically, due to multiple gland involvement and the frequency of supernumerary glands and ectopic parathyroid tissue. Typically, three and one-half glands are resected, leaving one-half of the most normal-appearing gland intact. Also, during neck surgery, a thymectomy is performed to resect any intrathymic parathyroid glands or occult thymic carcinoid tumors. Nevertheless, the surgical failure rate is about 38%, and there is a recurrence rate of about 16%, with hypercalcemia often recurring many years after neck surgery. Aggressive parathyroid resection can cause permanent hypoparathyroidism. Patients with persistent or recurrent hyperparathyroidism should avoid oral calcium supplements and thiazide diuretics; oral therapy with a calcimimetic drug, such as cinacalcet, may be effective.

Table 26–14. Multiple endocrine neoplasia (MEN) syndromes: Incidence of tumor types.

Tumor Type	MEN 1	MEN 2 (MEN 2A)	MEN 3 (MEN 2B)	MEN 4
Parathyroid	95%	20–50%	Rare	Common
Pancreatic	54%			Common
Pituitary	42%			Common
Medullary thyroid carcinoma		> 90%	80%	
Pheochromocytoma	Rare	20–35%	60%	
Mucosal and gastrointestinal ganglioneuromas		Rare	> 90%	
Subcutaneous lipoma	30%			
Adrenocortical adenoma	30%			Common
Thoracic carcinoid	15%			
Thyroid adenoma	55%			Common
Facial angiofibromas and collagenomas	85%			

GEP-NETs and carcinoids occur in up to 70% of patients with MEN 1. The GEP-NETs may secrete only pancreatic polypeptide or be nonsecretory altogether (20–55%). **Gastrinomas** occur in about 40% of patients with MEN 1. Concurrent hypercalcemia, due to hyperparathyroidism in MEN 1, stimulates gastrin and worsens gastric acid secretion; control of the hypercalcemia often reduces serum gastrin levels and gastric acid secretion. Gastrinomas of MEN 1 tend to be small, multiple, and ectopic; they are frequently found outside the pancreas, usually in the duodenum. They can metastasize to the liver; but in patients with MEN 1 (depending on the kindred), hepatic metastases tend to be less aggressive than those from sporadic gastrinomas. Treatment of gastrinomas of MEN 1 is usually conservative, using long-term high-dose proton pump inhibitor therapy and control of hypercalcemia; surgery is palliative and usually reserved for aggressive gastrinomas and those tumors arising in the duodenum. Carcinoid tumors can arise in the lung or abdomen and can metastasize, especially to liver.

Insulinomas occur in about 10% of patients with MEN 1. Surgery is usually attempted, but the tumors can be small, multiple, and difficult to detect. **Glucagonomas** occur in 1.6% of patients with MEN 1, **VIPomas** in 1%, and **somatostatinomas** in 0.7%. **Extrapancreatic NETs** are common in MEN 1, are frequently malignant, and include carcinoid tumors usually in foregut locations (69%), such as the lung, thymus, duodenum, or stomach.

Pituitary adenomas are the presenting tumor in 29% of patients with MEN 1 and eventually are found in about 42% of patients with MEN 1. About 78% of these pituitary adenomas occur in women. In MEN 1 patients with a pituitary adenoma, hyperparathyroidism is more common (92%). The majority of pituitary adenomas are found on routine screening of patients with known MEN 1. About 42% of the pituitary adenomas secrete prolactin, while others secrete GH (6%), ACTH (3%), gonadotrophins (2%), or multiple hormones (5%). The prolactinomas usually respond to medical therapy with cabergoline. In MEN 1, about 42% of pituitary adenomas are nonsecretory. While nonsecretory pituitary microadenomas (less than 1 cm diameter and detected on routine MRI screening) are usually indolent, about 25% of nonsecretory pituitary adenomas are macroadenomas (1 cm or more in diameter) and more aggressive.

Adrenal adenomas or **hyperplasia** occurs in about 40% of patients with MEN 1 and 50% are bilateral. They are generally benign and nonfunctional. These adrenal lesions are ACTH-independent.

Thymic NETs occur in 3.4% of affected patients, mostly in males, with a 10-year survival of 25%. **Lung NETs** occur in 13%, with a 10-year survival of 71%.

Benign thyroid adenomas or multinodular goiter occurs in about 55% of MEN 1 patients. Patients may undergo a thyroidectomy at the time of parathyroidectomy.

Nonendocrine tumors occur commonly in MEN 1, particularly small head-neck angiofibromas (85%) and lipomas (30%). Collagenomas are common (70%), presenting as firm dermal nodules. Affected patients may

also be more prone to meningiomas, breast cancer, colorectal cancers, prostate cancer, and malignant melanomas.

Variants of MEN 1 also occur. Kindreds with MEN 1 Burin variant have a high prevalence of prolactinomas, late-onset hyperparathyroidism, and carcinoid tumors, but rarely enteropancreatic tumors. Overall, patients with MEN 1 have an increased mortality rate with a mean life expectancy of only 55 years.

2. MEN 2 (MEN 2A)

Multiple endocrine neoplasia type 2 (MEN 2A, Sipple syndrome) is a rare autosomal-dominant tumor syndrome that arises in patients with a germline *ret* protooncogene mutation. Genetic testing identifies about 95% of affected individuals. Each kindred has a certain *ret* codon mutation that correlates with a particular variation in the MEN 2 (2A) syndrome. However, there is incomplete penetrance, and about 30% of those with germline *ret* protooncogene mutations never manifest any of the following endocrine tumors.

Medullary thyroid carcinoma (greater than 90%); **hyperparathyroidism** (20–50%), with hyperplasia or adenomas of multiple parathyroid glands developing in over 70% of cases; **pheochromocytomas** (20–35%), which are often bilateral; or **Hirschsprung disease** may develop in patients with MEN 2 (2A). The medullary thyroid carcinoma is of mild to moderate aggressiveness. Children harboring an MEN 2A *ret* mutation are advised to have a prophylactic total thyroidectomy by age 6 years. No patients with MEN 2 should receive therapy for diabetes with glucagon-like peptide 1 (GLP 1) agonists that may increase the risk for medullary thyroid carcinoma. Before any surgical procedure, MEN 2 (2A) carriers should be screened for pheochromocytoma (see above) and for medullary thyroid carcinoma. The latter screening involves a thyroid ultrasound and a serum calcitonin drawn after 3 days of omeprazole, 20 mg orally twice daily; in medullary thyroid carcinoma, calcitonin levels usually rise to greater than 80 pg/mL (23 pmol/L) in women or greater than 190 pg/mL (56 pmol/L) in men.

3. MEN 3 (MEN 2B)

Multiple endocrine neoplasia type 3 (MEN 2B) is a familial, autosomal dominant multiglandular syndrome that is also caused by a mutation of the *ret* protooncogene. MEN 3 (2B) is characterized by mucosal neuromas (in more than 90% of affected patients) with bumpy and enlarged lips and tongue, Marfan-like habitus (75% of cases), adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral, and medullary thyroid carcinoma (80%). Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%). Medullary thyroid carcinoma is aggressive and presents early in life. Therefore, infants having a parent with MEN 3 (2B) must receive early genetic screening, with those carrying the *ret* protooncogene mutation undergoing a prophylactic total thyroidectomy by age 6 months.

4. MEN 4

Multiple endocrine neoplasia type 4 (MEN 4) is a rare autosomal-dominant familial tumor syndrome caused by germline mutations in the gene *CDKN1B*. Affected patients are particularly prone to adenomas of the pituitary, parathyroid glands, and NETs of the pancreas. Unlike patients with MEN 1, those with MEN 4 are also appear to be prone to adrenal tumors, renal tumors, testicular cancer, and neuroendocrine cervical carcinoma.

OTHER SYNDROMES OF MULTIPLE ENDOCRINE NEOPLASIA

Tumors in the adrenal cortex, pituitary, thyroid, and gonads as well as cardiac myxomas and hyperpigmentation are seen in patients with **Carney complex**. In patients with **Cowden disease** thyroid abnormalities (66%) such as benign adenomas and follicular adenocarcinomas, along with breast cancer (20–36% in women), and multiple hamartomas that affect the skin and multiple other organs develop. Precocious puberty (particularly girls) due to gonadal hypersecretion, Cushing syndrome caused by multiple adrenal nodules, hyperthyroidism from autonomously functioning thyroid nodules, and acromegaly caused by GH-secreting pituitary tumors are seen in patients with **McCune-Albright syndrome**. Patients have fibrous dysplasia of bones and hypophosphatemia, and bone fractures are common. Sudden death has been reported.

Thakker RV. Multiple endocrine neoplasia type 1 (MEN 1) and type 4 (MEN 4). *Mol Cell Endocrinol.* 2014 Apr 5;386(1–2): 2–15. [PMID: 23933118]

DISEASES OF THE TESTES & MALE BREAST

MALE HYPOGONADISM

ESSENTIALS OF DIAGNOSIS

- ▶ Diminished libido and erections.
- ▶ Fatigue, depression, reduced exercise endurance.
- ▶ Decreased growth of body hair.
- ▶ Testes small or normal in size.
- ▶ Serum total testosterone or free testosterone level is decreased.
- ▶ Serum gonadotropin (LH and FSH) levels are decreased or normal in hypogonadotropic hypogonadism; they are increased in testicular failure (hypergonadotropic hypogonadism).

Table 26–15. Causes of male hypogonadism.

Hypogonadotropic (Low or Normal LH)	Hypergonadotropic (High LH)
Aging	Aging
Alcohol	Antitumor chemotherapy
Chronic illness	Bilateral anorchia
Congenital syndromes	Idiopathic
Constitutional delay	Klinefelter syndrome
Cushing syndrome	Leprosy
Drugs	Lymphoma
Estrogen	Male climacteric
GnRH agonist (leuprolide)	Mumps
Ketoconazole	Myotonic dystrophy
Marijuana	Noonan syndrome
Prior androgens	Orchitis
Spironolactone	Radiation therapy
Hemochromatosis	Sertoli cell-only syndrome
Hypopituitarism	Testicular trauma
Hypothyroidism	Tuberculosis
Idiopathic	Uremia
Kallmann syndrome	
17-Ketosteroid reductase deficiency	
Major medical or surgical illnesses	
Malnourishment	
Obesity (BMI > 30)	
Prader-Willi syndrome	

BMI, body mass index; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic); (2) pathology in the testes themselves (hypergonadotropic); or (3) both (Table 26–15). Partial male hypogonadism may be difficult to distinguish from the physiologic reduction in serum testosterone seen in normal aging, obesity, and illness.

Etiology

A. Hypogonadotropic Hypogonadism (Low Testosterone with Normal or Low LH)

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See Hypopituitarism.) Hypogonadotropic hypogonadism can be **primary**, defined as failure to enter puberty by age 14, with causes including isolated hypogonadotropic hypogonadism, hypopituitarism, or simple constitutional delay of growth and puberty; or it can be **acquired**, with causes including pituitary or hypothalamic tumors, granulomatous diseases, lymphocytic hypophysitis, or hemochromatosis; Cushing syndrome; adrenal insufficiency; and thyroid hormone excess or deficiency. Genetic conditions (eg, Kallmann syndrome or *PROKR2* mutations) account for about 40% of cases of isolated, and apparently

idiopathic, acquired hypogonadotropic hypogonadism with a serum testosterone level less than 150 ng/dL (5.2 nmol/L).

Partial male hypogonadotropic hypogonadism is defined as a serum testosterone in the range of 150–300 ng/dL (5.2–10.4 nmol/L). The main causes of acquired partial male hypogonadotropic hypogonadism include obesity, poor health, or normal aging, such that it is termed **age-related hypogonadism**. Spermatogenesis is usually preserved. After age 40, serum total testosterone declines variably by an average of 1–2% annually; serum free testosterone levels decline even faster, since sex hormone binding globulin increases with age. Serum levels of free testosterone are lower in men aged 40–70 compared with younger men, without any increase in serum LH. A problem with the diagnosis of age-related hypogonadism is that many laboratories provide reference ranges for testosterone that are derived from young men and may not provide age-adjusted reference ranges for serum testosterone and free testosterone. Consequently, among men ages 60–79 years, 20% have low serum total testosterone levels less than 317 ng/dL (11 nmol/L) and 25% have low serum free testosterone levels less than 65 pg/mL (225 pmol/L). Among men over age 80 years, 25% have low serum total testosterone levels and 45% have low serum free testosterone levels. Increasing obesity is the main reversible condition that contributes to the general decline in serum free testosterone with aging. After age 70, LH levels tend to rise, indicating a contribution of primary gonadal dysfunction with advancing age.

B. Hypergonadotropic Hypogonadism (Testicular Failure with High LH)

A failure of the testicular Leydig cells to secrete adequate testosterone causes a rise in LH. If testicular Sertoli cell function is deficient, FSH will also be elevated. Conditions that can cause testicular failure include viral infection (eg, mumps), irradiation, cancer chemotherapy or radioisotope therapy, autoimmunity, myotonic dystrophy, uremia, XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, Klinefelter syndrome, and male climacteric. In men who have had a unilateral orchiectomy for cancer, the remaining testicle frequently fails, even in the absence of radiation or chemotherapy. Male hypergonadotropic hypogonadism can also be caused by a congenital partial deficiency in the steroidogenic enzyme CYP17 (17-hydroxylase). CYP17 may be deliberately inhibited by abiraterone acetate, a drug for prostate cancer.

Klinefelter syndrome (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500. It is caused by the expression of an abnormal karyotype, classically 47,XXY. Other karyotypes occur, eg, 46,XY/47,XXY mosaicism, 48,XXYY, 48,XXXYY, or 46,XX males. The manifestations of Klinefelter syndrome are variable and diagnosed in less than 25% of patients. Testes feel normal during childhood, but during adolescence they usually become firm, fibrotic, small, and nontender to palpation. Affected children have an increased risk of cryptorchidism, decreased penile size,

delayed speech, learning disabilities, psychiatric disturbances, and mediastinal malignancies. Up to 75% of affected boys experience some gynecomastia at puberty. Although puberty occurs at the normal time, the degree of virilization is variable. Serum testosterone is usually low and gonadotropins are elevated. Adult men usually have somewhat reduced facial and pubic hair. Over 95% have azoospermia or severe oligospermia, although some sperm production is often present in their early teens. Men with 46,XY/47,XXY mosaicism may have spontaneous fertility. Also, testicular biopsy reveals sperm in up to 50% of affected patients, allowing some men to be fertile with the use of in vitro fertilization using intracytoplasmic sperm injection (ICSI). Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (eg, height more than 3 cm greater than arm span). Patients with multiple X or Y chromosomes are more apt to have mental deficiency and other abnormalities such as clinodactyly or synostosis. They may also exhibit problems with coordination and social skills. Other problems include a higher incidence of breast cancer, chronic pulmonary disease, varicosities of the legs, osteoporosis, and diabetes mellitus (8% of patients) and impaired glucose tolerance (in another 19%).

The diagnosis of Klinefelter syndrome is confirmed by karyotyping or by determining the presence of RNA for X-inactive-specific transcriptase (XIST) in peripheral blood leukocytes by polymerase chain reaction. On semen analysis, most men (about 95%) with classic Klinefelter syndrome have azoospermia. **XY gonadal dysgenesis** describes several conditions that result in the failure of the testes to develop normally. *SRY* is a gene on the Y chromosome that initiates male sexual development. Mutations in *SRY* result in testicular dysgenesis. Affected individuals lack testosterone, which results in sex reversal: female external genitalia with a blind vaginal pouch, no uterus, and intra-abdominal dysgenetic gonads. Affected individuals are raised as girls and appear normal until their lack of pubertal development and amenorrhea leads to the diagnosis. Intra-abdominal rudimentary testes have an increased risk of developing a malignancy and are usually resected. Patients are considered women and receive estrogen replacement therapy.

C. Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

► Clinical Findings

A. Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations, known as “testosterone deficiency syndrome.” Most men experience decreased libido. Others complain of erectile dysfunction, poor morning erection, or hot sweats. Men often have

depression, fatigue, or decreased ability to perform vigorous physical activity. The presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient's history often gives a clue to the cause (Table 26–15).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair, but only after years of severe hypogonadism. Men with hypogonadism lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or infection (eg, leprosy, tuberculosis).

B. Laboratory Findings

The evaluation for hypogonadism begins with a morning serum testosterone or free testosterone measurement (or both). Serum testosterone levels are considered low if they are confirmed to be less than 320 ng/dL (11 nmol/L). Serum free testosterone levels are considered low if they are confirmed to be less than 64 pg/mL (220 pmol/L).

Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25–50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the “normal range.” Serum testosterone levels in men are highest at age 20–30 years and slightly lower at age 30–40 years; testosterone falls gradually but progressively after age 40 years. Testing for serum free testosterone is especially important for detecting hypogonadism in elderly men, who generally have high levels of sex hormone binding globulin. A low serum testosterone should be verified with a repeat assay and further evaluated with serum LH and FSH levels. LH and FSH are high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism or normal aging. High serum estradiol levels are seen in men with obesity-related hypogonadotropic hypogonadism; sufficient weight loss causes a decrease in serum estradiol in such men.

Testosterone stimulates erythropoiesis in men, causing the normal red blood count range to be higher in men than in women; mild anemia is common in men with hypogonadism. For men with long-standing male hypogonadism, bone densitometry is recommended. Men with severe osteoporosis may require treatment with bisphosphonates and vitamin D, in addition to testosterone replacement therapy.

1. Hypogonadotropic hypogonadism—A serum PRL determination is obtained but may be elevated for many reasons (see Table 26–2). Men with gynecomastia may be screened for partial 17-ketosteroid reductase deficiency with serum determinations for androstenedione and estrone, which are elevated in this condition. Hypogonadotropic hypogonadism can also be seen with X-linked congenital adrenal hypoplasia, which causes hypogonadotropic hypogonadism and arrested puberty, azoospermia, and primary adrenal insufficiency; adrenal insufficiency usually presents in childhood but may remain undiagnosed into adulthood. The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis and have an MRI of the pituitary and hypothalamic region to look for a tumor or other lesion.

2. Hypergonadotropic hypogonadism—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST. Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

▶ Treatment

Testosterone replacement is reasonable for boys who have not entered puberty by age 14 years. It is also beneficial for most men with primary testicular failure (hypergonadotropic hypogonadism). Testosterone replacement is also warranted for men with severe hypogonadotropic hypogonadism of any etiology with serum testosterone levels less than 150 ng/mL (5.2 nmol/L). Many men have partial hypogonadotropic hypogonadism (“age-related hypogonadism”) with serum testosterone levels low but greater than 150 ng/mL (5.2 nmol/L) or serum free testosterone level low but greater than 40 pg/mL (140 pmol/L). Testosterone therapy should be considered for men with age-related hypogonadism if they have at least three of the following six symptoms: erectile dysfunction, poor morning erection, low libido, depression, fatigue, and inability to perform vigorous activity; testosterone replacement should be continued only if they clearly derive clinical benefit from therapy.

Testosterone therapy carries certain risks. The FDA has registered concern over the use of testosterone therapy for age-related hypogonadism, since there have been no controlled trials to determine the effects of testosterone therapy on cardiovascular outcomes. Due to such potential risks, testosterone therapy should not be given to men unless they have had a documented low serum total or free testosterone. Testosterone therapy should not be given to men with active breast cancer or prostate cancer. In men over age 50 years, a digital prostate examination and serum prostate-specific antigen (PSA) level should be done before beginning testosterone therapy. Men with symptoms of prostatic hypertrophy, a palpable prostate nodule, or a PSA greater than 4 ng/mL (greater than 3 ng/mL in men of

African ancestry) should have a urologic evaluation prior to treatment. Although serum PSA screening has not reduced prostate cancer-related mortality, many clinicians monitor serum PSA levels regularly in men receiving testosterone therapy. It is also prudent to monitor the hematocrit and lipid profile of men receiving testosterone, since therapy can cause erythrocytosis and hyperlipidemia. Testosterone therapy can also cause gynecomastia. Testosterone therapy is not given to men with untreated sleep apnea or heart failure. In men who have coronary risk factors or are over age 65, special attention should be given to improving cardiac risk factors (eg, controlling hypertension or hyperlipidemia) and administering low-dose aspirin while receiving testosterone replacement.

Drug interactions can occur. Testosterone should be administered cautiously to men receiving coumadin, since the combination can increase the INR and risk of bleeding. Similarly, testosterone therapy can increase serum levels of cyclosporine, tacrolimus, and tolvaptan. Testosterone can predispose to hypoglycemia in diabetic men receiving insulin or oral hypoglycemic agents, so close monitoring of blood sugars is advisable during initiation of testosterone therapy.

Oral androgen therapy with methyltestosterone is not advisable due to the potential for causing liver tumors, peliosis hepatis, and cholestatic jaundice.

A. Therapies for Male Hypogonadism

1. Testosterone topical gels—Topical testosterone is usually applied once daily in the morning after showering. Topical testosterone should not be applied to the breast or genitals. The gel should be allowed to air-dry (about 10 minutes) before donning a shirt. The patient should avoid swimming, showering, or washing the application area for at least 2 hours following application. **Testosterone topical generic 1% gel** is available in packets (12.5 mg/1.25 g, 25 mg/2.5 g, or 50 mg/5g) or tubes (50 mg/5 g). The recommended dose is 50–100 mg daily. **Testosterone topical generic 2% gel** is available in a gel pump (10 mg/0.5 g actuation). The recommended dose is 40–70 mg daily. **AndroGel 1% gel** is available in 2.5-g packets (25 mg testosterone) and 5-g packets (50 mg testosterone) and in a pump that dispenses 12.5 mg testosterone per pump actuation; the recommended dose is 50–100 mg applied daily to the shoulders. **AndroGel 1.6% gel** is available in a pump that dispenses 20.25 mg testosterone per pump actuation; the recommended dose is 40.5–81 mg daily. **Testim 1% gel** is available in 5-g tubes (50 mg testosterone); the recommended dose is 50–100 mg applied daily. **Fortesta 2% gel** is available in a pump that dispenses 10 mg testosterone per pump actuation; the recommended dose is 40–70 mg daily. **Testogel** is distributed in 5-g sachets (50 mg testosterone); this brand is not available in the United States. Testim, Fortesta, and Testogel may be applied to shoulders, upper arms, or abdomen. **Axiron 2% solution** is available in a pump that dispenses 30 mg per actuation; the recommended dose is 30–60 mg applied to each axilla daily. **Vogelxo** is a 1% testosterone gel that is available in packets or tubes (50 mg/5 g) or a gel pump (12.5 mg/1.25 g); it is applied to the shoulders in doses of 50–100 mg once daily.

The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 1.5 to 2 times the initial dose. Unfortunately, serum testosterone levels vary considerably during the day after topical testosterone gel application, such that a single serum testosterone level may not accurately reflect the average serum testosterone for that individual. After the application of topical testosterone, the hands should be washed. The application site should be allowed to dry for 10 minutes before dressing. Before close contact with women or children, a shirt must be worn or the areas of application washed with soap and water to prevent transfer of testosterone to them.

2. Transdermal testosterone patches—Testosterone transdermal systems (skin patches) are applied to nongenital skin. Androderm (2 or 4 mg/day) patches may be applied at bedtime in doses of 4–8 mg; it adheres tightly to the skin and may cause skin irritation.

3. Parenteral testosterone—The dose and injection intervals of injections are adjusted according to the patient's clinical response and serum testosterone levels drawn just before the next injection is due. A target serum testosterone level of 500 ng/dL (17.3 nmol/L) is suggested. **Testosterone cypionate** has been in use for decades; it is an intramuscular testosterone formulation that is available in solutions containing 200 mg/mL. Its main advantage is low cost. The usual dose is 200 mg every 2 weeks or 300 mg every 3 weeks. It is usually injected into the gluteus medius muscle in the upper lateral buttock, alternating sides.

Testosterone pellets (Testopel) is a very long-lasting depot testosterone formulation that is available as individual vials containing a single 75 mg implantable pellet in each vial. With sterile technique, the skin of the upper-outer buttock is anesthetized with lidocaine; using a trochar, the pellets are injected subcutaneously in doses of 150–450 mg every 3–6 months as an in-office procedure.

Testosterone undecanoate (Aveed, Nebido) is a long-lasting depot testosterone formulation. Its use is restricted to qualified healthcare facilities. It is usually injected into the gluteus medius muscle in the upper lateral buttock, alternating sides. Care must be taken to avoid intravascular injection by pulling back on the syringe plunger before injection; if any blood appears in the syringe, the needle is withdrawn and the syringe is discarded. Testosterone undecanoate (Aveed) is formulated as individual vials containing 750 mg/3 mL oily solution for intramuscular injection. The initial injection of 750 mg is followed by another 750 mg injection 4 weeks later and maintenance doses of 750 mg every 10 weeks. Testosterone undecanoate (Nebido) is formulated as individual vials containing 1000 mg/4 mL oily solution for intramuscular injection. The initial injection of 1000 mg is followed by another 1000 mg injection 6 weeks later and maintenance doses of 1000 mg every 12 weeks. A serum testosterone level is measured before the fourth dose; if the serum testosterone remains low, the dosing interval is shortened to every 10 weeks.

Caution: Testosterone undecanoate injections have caused serious pulmonary oil microembolism reactions

that present with cough, dyspnea, tight throat, chest pain, and syncope. Anaphylaxis can also occur. *Patients must be observed in the healthcare setting for 30 minutes after the injection in order to provide appropriate medical care for the complication.*

4. Buccal testosterone—Testosterone buccal tablets (Striant) are placed between the upper lip and gingivae. One or two 30-mg tablets are thus retained and changed every 12 hours. They should not be chewed or swallowed.

5. Testosterone nasal gel—An intranasal gel formulation of testosterone (Natesto) is available. It is self-administered by a metered-dose nasal pump: one pump actuation (5.5 mg) into each nostril three times daily. The nasal pump needs to be primed by inverting it and pressing the pump 10 times before it is used the first time. It should not be used concurrently with intranasal sympathomimetic decongestants. Adverse effects include nasopharyngitis, sinusitis, bronchitis, epistaxis, nasal discomfort, and headache.

6. Oral methyltestosterone—Oral testosterone supplementation is available as methyltestosterone 10 mg tablets. The usual dose is 10–50 mg daily, given either once daily or given in divided doses. Oral methyltestosterone can produce acute hepatitis and chronic high-dose use can cause peliosis hepatis, cholestatic hepatitis, and hepatocellular carcinoma. Therefore, its use is not recommended, and it is no longer available in some countries.

7. Clomiphene citrate—Men with functional hypogonadotropic hypogonadism usually respond well to clomiphene citrate that is administered orally in doses that are titrated to achieve the desired clinical response with a serum testosterone level of about 500 ng/dL (17.3 nmol/L). Treatment with clomiphene is commenced with 25 mg on alternate days and increased to 50 mg on alternate days if necessary, with a maximum dose of 50 mg daily. Serum testosterone levels usually normalize while spermatogenesis usually improves.

8. Gonadotropins—Patients with hypogonadotropic hypogonadism may require therapy with gonadotropins, particularly to induce fertility. Men may receive hCG 1000 units subcutaneously three times weekly for 6 months; if the semen analysis shows inadequate sperm, FSH 75 units subcutaneously three times weekly is added. Many men prefer long-term therapy with hCG over testosterone therapy, but cost is an issue.

9. Weight loss—When hypogonadotropic hypogonadism is due to morbid obesity, significant weight loss will improve serum testosterone levels. The rise in serum testosterone is proportionate to the weight loss. Although diet-induced weight loss is beneficial, bariatric surgery has been much more effective and serum testosterone levels may normalize after dramatic weight loss.

B. Benefits of Testosterone Replacement Therapy

Testosterone therapy usually benefits men with low serum testosterone and at least three manifestations of hypogonadism. Testosterone therapy can improve overall mood,

sense of well-being, sexual desire, and erectile function. It also increases physical vigor and muscle strength as manifested in measurements of leg-press and chest-press strength. Testosterone replacement also improves exercise endurance and stair climbing ability. Long-term testosterone replacement causes significant weight loss and a reduction in waist circumference. After 2 years of testosterone replacement, muscle mass increases about 4.5%, while fat mass decreases by about 9.1%. Testosterone replacement therapy also appears to improve overall survival.

C. Risks of Testosterone Replacement Therapy

Testosterone therapy can **aggravate benign prostatic hyperplasia** (BPH). However, aggravation of voiding problems is uncommon. In men with BPH, finasteride may be coadministered with testosterone to reduce prostate size. There have been no sufficient long-term trials studying the effect of testosterone supplementation on the incidence and mortality from prostate cancer. However, a meta-analysis of 19 smaller studies showed no statistically significant increased risk for prostate cancer among men receiving testosterone supplementation. Nevertheless, concern remains. Testosterone therapy is contraindicated in the presence of active prostate cancer, and it is prudent to screen for prostate cancer with a serum PSA before commencing therapy. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring serum PSA levels.

Erythrocytosis develops in some men who are treated with testosterone. Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. However, no increase in the incidence of thromboembolic events has been reported.

Testosterone therapy tends to **aggravate sleep apnea** in older men, likely through CNS effects. Surveillance for sleep apnea is recommended during testosterone therapy and a formal evaluation with nocturnal pulse oximetry recording is recommended for all high-risk patients with snoring, obesity, partner's report of apneic episodes, nocturnal awakening, unrefreshing sleep with daytime fatigue, or hypertension.

Men who are treated with testosterone frequently experience some increase in **acne** that is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. **Increases in intraocular pressure** have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, **gynecomastia** develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

D. Risks of Performance-enhancing Anabolic Steroids

Performance-enhancing agents, particularly androgenic anabolic steroids, are used by up to 2% of young athletes and by 20–65% of power sport athletes. They are often used

as part of a “stacking” polypharmacy that may include nandrolone decanoate, dimethandrolone, testosterone propionate, or testosterone enanthate. These androgens are usually illegal and often contaminated by toxic substances and can produce toxic hepatitis, dependence, aggression, depression, dyslipidemias, gynecomastia, acne, male pattern baldness, hepatitis, thromboembolism, and cardiomyopathy. Shared needles may transmit hepatitis or HIV. Arsenic contamination has been reported to cause multiorgan failure and death.

▶ Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given.

CRYPTORCHISM

One or both testes may be absent from the scrotum at birth in about 20% of premature or low-birth-weight male infants and in 3–6% of full term infants. Cryptorchism is found in 1–2% of males after 1 year of age but must be distinguished from retractile testes, which require no treatment. Infertility or subfertility occurs in up to 75% of men with bilateral cryptorchism and in 50% of men with unilateral cryptorchism. Some patients have underlying hypogonadism, including hypogonadotropic hypogonadism.

If the testes are not palpable, it is important to determine whether they are cryptorchid or intra-abdominal. MRI is more reliable than ultrasound for locating cryptorchid testes. Surgery for cryptorchid testes (orchiopexy)

should be performed by age 12–24 months and is generally successful. Alternatively, hCG, 1500 units intramuscularly daily for 3 days, causes a significant rise in testosterone if the testes are present. Therapy with hCG results in a testicular descent rate of about 25%.

The lifetime risk of testicular neoplasia is 0.002% in normal males. The risk of malignancy is higher for cryptorchid testes (0.06%) and for intra-abdominal testes (5%). Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

GYNECOMASTIA

ESSENTIALS OF DIAGNOSIS

- ▶ Palpable enlargement of the male breast, often asymmetric or unilateral.
- ▶ Glandular gynecomastia characterized by tenderness.
- ▶ Fatty gynecomastia typically nontender.
- ▶ Must be distinguished from carcinoma or mastitis.

▶ General Considerations

Gynecomastia is defined as the presence of palpable glandular breast tissue in males. Pubertal gynecomastia develops in about 60% of boys; the swelling usually subsides spontaneously within a year. Gynecomastia is particularly common in teenagers who are very tall or overweight. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. About 20% of adult gynecomastia is caused by drug therapy. Gynecomastia can develop in HIV-infected patients treated with antiretroviral therapy, especially in men receiving efavirenz or didanosine; breast enlargement resolves spontaneously in 73% of patients within 9 months. Fatty pseudogynecomastia is common among elderly men, particularly when there is associated weight gain. However, true glandular gynecomastia can be the first sign of a serious disorder in older men.

The causes of gynecomastia are multiple and diverse (Table 26–16).

▶ Clinical Findings

A. Symptoms and Signs

The male breasts must be palpated carefully to distinguish true glandular gynecomastia from fatty pseudogynecomastia in which only adipose tissue is felt. The breasts are best examined both seated and supine. Using the thumb and forefinger as pincers, the subareolar tissue is compared to nearby adipose tissue. Fatty tissue is usually diffuse and nontender. True glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola. The following characteristics

Table 26–16. Causes of gynecomastia.

Idiopathic	Clomiphene
Physiologic causes	Cyclophosphamide
Neonatal period	Diazepam
Puberty	Diethylstilbestrol
Aging	Digitalis preparations
Obesity	Dutasteride
Endocrine diseases	Estrogens (oral or topical)
Androgen resistance syndromes	Ethionamide
Aromatase excess syndrome (sporadic or familial)	Famotidine (rare)
Diabetic lymphocytic mastitis	Fenofibrate (rare)
Hyperprolactinemia	Finasteride
Hyperthyroidism	Flutamide
Klinefelter syndrome	Goserelin
Male hypogonadism	Growth hormone
Partial 17-ketosteroid reductase deficiency	Haloperidol
Systemic diseases	Hydroxyzine
Androgen insensitivity	Isoniazid
Chronic liver disease	Ketoconazole
Chronic kidney disease	Lavender oil (topical)
Hansen disease (leprosy)	Leuprolide and other GnRH analogs
Neurologic disorders	Marijuana
Refeeding after starvation	Meprobamate
Spinal cord injury	Methadone
Neoplasms	Methotrexate (rare)
Adrenal tumors	Methyl dopa
Bronchogenic carcinoma	Metoclopramide
Carcinoma of the breast	Metronidazole
Ectopic hCG: lung, hepatocellular, gastric, renal carcinomas	Mirtazapine
Pituitary prolactinoma	Nucleotide reverse transcriptase inhibitors
Testicular hCG-secreting tumors	Nilutamide
Drugs (partial list)	Omeprazole
Alcohol	Opioids
Alkylating agents	Penicillamine
Amiodarone	Phenothiazines
Anabolic steroids	Progestins
Androgens	Protease inhibitors
Anti-androgens	Proton pump inhibitors (uncommon)
Antiretroviral agents	Ranitidine (rare)
Bicalutamide	Reserpine
Busulfan	Risperidone
Calcium channel blockers (rare)	Somatotropin (growth hormone)
Chorionic gonadotropin	Soy ingestion
Cimetidine	Statins (rare)
	Spironolactone
	Tea tree oil (topical)
	Testosterone
	Thioridazine
	Tricyclic antidepressants
	Verapamil

are worrisome for malignancy: asymmetry; location not immediately below the areola; unusual firmness; or nipple retraction, bleeding, or discharge.

B. Laboratory Findings

In the presence of true glandular gynecomastia, serum determinations for PRL and beta-hCG are obtained. Detectable levels of beta-hCG implicate a testicular tumor

(germ cell or Sertoli cell) or other malignancy (usually lung or liver), though detectable low levels (less than 5 milli-units/mL) may be reported in primary hypogonadism and high serum LH levels if the assay for beta-hCG cross-reacts with LH. Measurements of serum free testosterone and LH are valuable in the diagnosis of primary or secondary hypogonadism. A low serum free testosterone and high LH are seen in primary hypogonadism. High testosterone levels plus high LH levels characterize partial androgen resistance. Serum estradiol is determined but is usually normal; increased levels may result from testicular tumors, increased beta-hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or aromatase gene gain-of-function mutations (rare). Serum TSH and FT₄ levels are also recommended. A karyotype (for Klinefelter syndrome) is obtained in men with persistent gynecomastia without obvious cause.

Investigation of unclear cases should include a chest radiograph to search for bronchogenic or metastatic carcinoma. Needle biopsy with cytologic examination may be performed on suspicious male breast enlargement (especially when unilateral or asymmetric) to distinguish gynecomastia from breast cancer or mastitis.

▶ Treatment

Pubertal gynecomastia often resolves spontaneously within 1–2 years. Drug-induced gynecomastia resolves after the offending drug is removed (eg, spironolactone stopped, with substitution of eplerenone). Patients with painful or persistent gynecomastia may be treated with medical therapy, usually for 9–12 months. Generally, it is prudent to treat patients for gynecomastia only when it becomes a troubling and continuing problem for them.

Selective estrogen receptor modulator (SERM) therapy is effective for true glandular gynecomastia. Raloxifene, 60 mg orally daily, may be somewhat more effective than tamoxifen, 10–20 mg orally daily.

Aromatase inhibitor (AI) therapy is also reasonably effective. For example, anastrozole reduces breast volume significantly over 6 months in adolescents given in a dose of 1 mg orally daily. Serum estradiol levels fall slightly while serum testosterone levels rise. Long-term AI therapy in adolescents is not recommended because of the possibility of inducing osteoporosis and of delaying epiphyseal fusion, which could cause an increase in adult height.

Testosterone therapy for men with hypogonadism may improve or worsen preexistent gynecomastia.

Radiation therapy has been used prophylactically to prevent gynecomastia in men with prostate cancer being treated with antiandrogen therapy. Low-dose prophylactic radiation therapy reduces its incidence from 71% to 28%. Existing gynecomastia improves in 33% with radiation therapy. However, the long-term breast and other cancer risks of such radiation are unknown.

Surgical correction is reserved for patients with persistent or severe gynecomastia.

HIRSUTISM & VIRILIZATION

ESSENTIALS OF DIAGNOSIS

- ▶ Hirsutism, acne, menstrual disorders.
- ▶ Virilization: increased muscularity, androgenic alopecia, deepening of the voice, clitoromegaly.
- ▶ Rarely, a palpable pelvic tumor.
- ▶ Urinary 17-ketosteroids and serum DHEAS and androstenedione elevated in adrenal disorders; variable in others.
- ▶ Serum testosterone is often elevated.

General Considerations

Hirsutism is defined as cosmetically unacceptable terminal hair growth that appears in women in a male pattern. Significant hirsutism affects about 5–10% of non-Asian women of reproductive age and over 40% of women at some point during their life. The amount of hair growth deemed unacceptable depends on a woman's ethnicity and familial and cultural norms. Virilization is defined as the development of male physical characteristics, such as pronounced muscle development, deep voice, male pattern baldness, and more severe hirsutism.

Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), ovarian hyperthecosis, steroidogenic enzyme defects, neoplastic disorders; or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a strong familial predisposition to hirsutism that may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

B. Polycystic Ovary Syndrome (PCOS, Hyperthecosis, Stein-Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries, affecting about 4–6% of premenopausal women in the

United States and accounting for at least 50% of all cases of hirsutism associated with elevated testosterone levels. It is familial and transmitted as a modified autosomal dominant trait. Affected women have elevated serum testosterone or free testosterone level and have signs of androgen excess, including hirsutism, acne, and male-pattern thinning of scalp hair. About 50% of affected women have oligomenorrhea or amenorrhea with anovulation. Hyperandrogenism persists after natural menopause. Despite the syndrome's name, the presence of ovarian cysts is not helpful diagnostically and is actually a misnomer, since about 30% of women with PCOS do *not* have cystic ovaries and 25–30% of normal menstruating women *have* cystic ovaries. Obesity and high serum insulin levels (due to insulin resistance) contribute to the syndrome in 70% of women. The serum LH:FSH ratio is often greater than 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present. Women with PCOS have a 35% risk of depression, compared with 11% in age-matched controls. Diabetes mellitus is present in about 13% of cases. Obstructive sleep apnea is particularly common, even in slender women with PCOS. Untreated women with amenorrhea have a slightly increased risk of endometrial carcinoma. Hypertension and hyperlipidemia are often present, increasing the risk of cardiovascular disease. Women frequently regain normal menstrual cycles with aging.

C. Steroidogenic Enzyme Defects

Congenital adrenal steroidogenic enzyme defects result in reduced cortisol secretion with a compensatory increase in ACTH that causes adrenal hyperplasia. The most common enzyme defect is 21-hydroxylase deficiency, with a prevalence of about 1:18,000.

Partial deficiency in adrenal 21-hydroxylase can present in women as hirsutism. About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase. The condition is more common in Ashkenazi Jews, Yupic Alaskans, and natives of La Reunion Island. The phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt wasting. Polycystic ovaries and adrenal adenomas are more likely to develop in these women.

Some rare patients with hyperandrogenism and hypertension have 11-hydroxylase deficiency. This is distinguished from cortisol resistance by high cortisol serum levels in the latter and by high serum 11-deoxycortisol levels in the former.

Patients with an XY karyotype and a deficiency in 17-beta-hydroxysteroid dehydrogenase-3 or a deficiency in 5-alpha-reductase-2 may present as phenotypic girls in whom virilization develops at puberty.

D. Neoplastic Disorders

Ovarian tumors are very uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of Cushing syndrome and hyperandrogenism that can be quite virilizing. Pure androgen-secreting adrenal tumors occur very rarely; about 50% are malignant.

E. Rare Causes of Hirsutism & Virilization

Acromegaly and ACTH-induced Cushing syndrome are rare causes of hirsutism and virilization. Porphyria cutanea tarda can cause periorbital hair growth in addition to dermatitis in sun-exposed areas. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Acquired hypertrichosis lanuginosa is manifested by the appearance of diffuse fine lanugo hair growth on the face and body along with stomatologic symptoms; the disorder is usually associated with an internal malignancy, especially colorectal cancer, and may regress after tumor removal. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, interferon, cetuximab, diazoxide, and certain progestins.

► Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and virilization (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization points to the presence of an androgen-producing neoplasm. Hirsutism is quantitated using the Ferriman-Gallwey score in which hirsutism is graded from 0 (none) to 4 (severe) in nine areas of the body with a maximum possible score of 36; scores 8–15 indicate moderate hirsutism, while scores over 15 indicate severe hirsutism.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic. Hypertension may be present and should prompt consideration for the possible diagnosis of Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Some general guidelines are presented here, though exceptions are common.

Serum is assayed for total testosterone and free testosterone. A serum testosterone level greater than 200 ng/dL (6.9 nmol/L) or free testosterone greater than 40 ng/dL (140 pmol/L) indicates the need for pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed.

Most radioimmunoassays and enzyme-linked immunosorbent assays (ELISAs) for testosterone are inaccurate when serum testosterone levels are less than 300 ng/dL (10.4 nmol/L). The more accurate testosterone assays rely on extraction and chromatography, followed by mass spectrometry or immunoassay. Free testosterone is best measured by calculation, using accurate assays for testosterone and sex hormone-binding globulin. A serum androstenedione level greater than 1000 ng/dL (34.9 nmol/L) also

points to an ovarian or adrenal neoplasm. Patients with milder elevations of serum testosterone or androstenedione usually are treated with an oral contraceptive.

Patients with a serum DHEAS greater than 700 mcg/dL (35 nmol/L) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. An adrenal CT scan is performed.

No firm guidelines exist as to which patients (if any) with hyperandrogenism should be screened for “late-onset” 21-hydroxylase deficiency. The evaluation requires levels of serum 17-hydroxyprogesterone to be drawn at baseline and at 30–60 minutes after the intramuscular injection of 0.25 mg of cosyntropin (ACTH_{1–24}). Ideally, this test should be done during the follicular phase of a woman’s menstrual cycle. Patients with congenital adrenal hyperplasia will usually have a baseline 17-hydroxyprogesterone level greater than 300 ng/dL (9.1 nmol/L) or a stimulated level greater than 1000 ng/dL (30.3 nmol/L). Patients with any clinical signs of Cushing syndrome should receive a screening test.

Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio greater than 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. Pelvic ultrasound or MRI can usually detect virilizing tumors of the ovary. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

► Treatment

Any drugs causing hirsutism (see above) should be stopped. Any underlying medical causes of hirsutism (eg, Cushing syndrome, acromegaly) should be treated.

A. Surgery

Androgenizing tumors of the adrenal or ovary are resected laparoscopically. Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Women with classic salt-wasting congenital adrenal hyperplasia and infertility or treatment-resistant hyperandrogenism may be treated with laparoscopic bilateral adrenalectomy.

B. Laser and Topical Treatments

Laser therapy (photoepilation) can be a very effective treatment for facial hirsutism, particularly for women with dark hair and light skin; longer-wavelength lasers are used for women with darker skin. In such women, laser removal of facial hair significantly improves their appearance and quality of life. However, laser does not remove nonpigmented hairs. Potential side effects include local pain, erythema, and hyperpigmentation (20%) that usually resolves; skin hypopigmentation occurs rarely. A paradoxical increase in hair growth occurs infrequently. Repeated laser treatments are usually required.

Local treatment of facial hirsutism by shaving or depilatories, waxing, electrolysis, or bleaching should be encouraged. **Eflornithine** (Vaniqa) 13.9% topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. However, local skin irritation may occur. Hirsutism returns with discontinuation. It may be used in conjunction with laser therapy.

Topical minoxidil may be used to treat androgenic alopecia and is mildly effective when applied to the scalp twice daily. Only the 2% formulation is FDA-approved for women.

C. Medications

Spirolactone is effective for reducing hirsutism, acne, and androgenic alopecia in women and is a first-line medical strategy for these women. It may be taken in doses of 100–200 mg orally daily (taken as a single dose or in two divided doses) on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Spirolactone is contraindicated in pregnancy, so reproductive-age women must use reliable contraception during this therapy. Hyperkalemia is an uncommon side effect, but serum potassium should be checked 1 month after beginning therapy or after dosage increases. Spirolactone should be avoided or used cautiously in women who are prone to hyperkalemia, including women with kidney disease or who are taking an ACE inhibitor or ARB for hypertension. Trimethoprim-sulfamethoxazole should not be taken along with high-dose spironolactone due to the risk of hyperkalemia and sudden death. Side effects of spironolactone include breast tenderness, menstrual irregularity, headaches, nausea, and fatigue, which may improve with continued treatment or dose reduction; paradoxical scalp hair loss has been reported at higher doses. If necessary, metformin can be added and may enhance the anti-hirsutism effect of low-dose spironolactone.

Flutamide inhibits testosterone binding to androgen receptors and also suppresses serum testosterone. It is given orally in a dosage of 250 mg once or twice daily for the first year and then 125–250 mg/day for maintenance. Used with an oral contraceptive, it appears to be more effective than spironolactone in improving hirsutism, acne, and male pattern baldness. Flutamide decreases cortisol renal clearance and corticosteroid replacement doses (eg, in congenital adrenal hyperplasia) should be reduced when flutamide is added. Hepatotoxicity has been reported but is rare. Flutamide must be given only to nonpregnant women. Women must be counseled to take strict contraceptive measures, since antiandrogen drug use during pregnancy causes malformations and disorders of sexual development (pseudohermaphroditism) in male infants.

Finasteride inhibits 5- α -reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Given as 5 mg doses orally daily, it provides modest reduction in hirsutism and androgenic alopecia over 6 months. Side effects are rare, but the drug is contraindicated in pregnancy and contraceptive measures are mandatory in reproductive age women.

Newer combined oral contraceptives that contain antiandrogenic progestins such as desogestrel (Azurette, Kariva), drospirenone (Yaz, Gianvi), norgestimate (Ortho Tri-Cyclen Lo), or cyproterone acetate (Diane 35, not available in United States) reduce hirsutism and acne. These newer antiandrogenic oral contraceptives confer a six-fold risk of deep venous thromboembolism, particularly when combined with higher doses of ethinyl estradiol, and therefore, oral contraceptives with the lowest possible dose of ethinyl estradiol (less than 50 mcg) should be selected. Older combined oral contraceptives that contain the progestins norethindrone, norgestrel, or levonorgestrel are relatively ineffective for hirsutism and acne. The risk for arterial thrombosis is increased by 50–100% for all combined oral contraceptives. For this reason, combined oral contraceptives are relatively contraindicated for women who are predisposed to thromboembolism: women who are smokers or who have migraines, hypertension or a personal history thromboembolism. However, progestin-only oral contraceptives do not confer any increased risk for venous or arterial thromboembolism. Metabolic syndrome and hypertriglyceridemia are seen, particularly with antiandrogenic progestins. The risks of metabolic syndrome may be offset by metformin.

Metformin may improve menstrual function in women with PCOS and amenorrhea or oligomenorrhea but is less effective than oral contraceptives. Metformin is not effective in promoting fertility in women with PCOS. Metformin alone is ineffective in improving hirsutism, but can enhance the anti-hirsutism effect of spironolactone. Metformin therapy is usually given orally with meals and is started at a dose of 500 mg/day with breakfast for 1 week, then increased to 500 mg with breakfast and dinner. If this dose is clinically insufficient but tolerated, the dose may be increased to 850–1000 mg twice daily. The most common side effects are dose-related gastrointestinal upset and diarrhea or constipation. Metformin appears to be nonteratogenic. Although metformin reduces insulin resistance, it does not cause hypoglycemia in nondiabetic patients. Metformin is contraindicated in kidney and liver disease.

Simvastatin can reduce hirsutism in women with PCOS. In one study, simvastatin 20 mg orally daily was given to women receiving an oral contraceptive for PCOS. Besides improving their serum lipid profiles, women receiving simvastatin had greater decreases in hirsutism and serum free testosterone levels than the women receiving an oral contraceptive alone. Atorvastatin also reduced serum testosterone by an average of 25% in women with PCOS.

Clomiphene is the treatment of choice for women with PCOS and infertility. Over 6 months, clomiphene therapy resulted in a 22.5% rate of conception with live births. The rate of pregnancy with multiple fetuses is 6%.

Women with classic congenital adrenal hyperplasia (21-hydroxylase deficiency) have hirsutism and adrenal insufficiency that requires glucocorticoid and mineralocorticoid replacement. However, women with partial “late onset” 21-hydroxylase deficiency do not require hormone replacement. Treating such women with dexamethasone risks iatrogenic Cushing syndrome and is not particularly more effective than other treatments for hirsutism.

GnRH agonist therapy has been successful in treating postmenopausal women with severe ovarian hyperandrogenism when laparoscopic oophorectomy is contraindicated or declined by the patient.

AMENORRHEA & MENOPAUSE

PRIMARY AMENORRHEA

Menarche ordinarily occurs between ages 11 and 15 years (average in the United States: 12.7 years) (see also Chapter 18). The failure of any menses to appear is termed “primary amenorrhea,” and evaluation is commenced (1) at age 14 years if neither menarche nor any breast development has occurred or if height is in the lowest 3%, or (2) at age 16 years if menarche has not occurred.

► Etiology of Primary Amenorrhea

The differential diagnoses for primary amenorrhea include hypothalamic-pituitary causes, hyperandrogenism, ovarian causes, disorders of sexual development (pseudohermaphroditism), uterine causes, and pregnancy.

A. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

The most common cause of primary amenorrhea is a variant of normal known as constitutional delay of growth and puberty, which accounts for about 30% of delayed puberty cases. There is a strong genetic basis for this condition, such that over 50% of girls with it have a family history of delayed puberty. However, constitutional delay of growth and puberty is a diagnosis of exclusion and other etiologies must be considered.

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann syndrome). Hypothalamic lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete PRL or GH. Cushing syndrome may be caused by

corticosteroid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by severe illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation.

B. Uterine Causes (with Normal FSH)

Müllerian agenesis results in a missing uterus and variable degrees of upper vaginal hypoplasia. It is the most common cause of permanent primary amenorrhea and is also known as Mayer-Rokitansky-Küster-Hauser syndrome. Affected women have intact ovaries and undergo an otherwise normal puberty. Such women ovulate and fertility is possible with in vitro fertilization and surrogacy.

An imperforate hymen is occasionally the reason for the absence of visible menses.

C. Hyperandrogenism (with Low or Normal FSH)

Polycystic ovaries and ovarian tumors can secrete excessive testosterone. Excess testosterone can also be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Androgenic steroid abuse may also cause this syndrome.

D. Ovarian Causes (with High FSH)

Gonadal dysgenesis (Turner syndrome and variants) is a frequent cause of primary amenorrhea. Autoimmune ovarian failure is another cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3-beta-hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). Deficiency in P450 aromatase (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

E. 46 XY Disorders of Sexual Development (Pseudohermaphroditism)

Complete androgen insensitivity syndrome is caused by homozygous inactivating mutations in the androgen receptor. 46 XY individuals with complete androgen insensitivity syndrome are born with completely normal external female genitalia, although some may have labial or inguinal swellings due to cryptorchid testes. Affected individuals are phenotypic girls and experience normal breast development at puberty, but fail to develop sexual hair and have primary amenorrhea. Investigation of the amenorrhea reveals an absent uterus, short vagina, and intra-abdominal gonads (testes). Serum testosterone levels are high and karyotype is 46 XY. Such individuals function as normal but infertile women but may require vaginal dilatation or

surgery. Intra-abdominal testes have a low risk of developing germ cell tumors through adolescence, but the risk increases to about 5% during adulthood, when it is advisable that they be surgically removed. Following gonadectomy, such women require replacement estrogen.

Partial androgen insensitivity syndrome in 46 XY individuals results in variable degrees of ambiguous genitalia. Newborns have micropenis, hypospadias, and bifid scrotum.

F. Pregnancy (with High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient denies ever having had sexual intercourse.

Clinical Findings

A. Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure elevation, acne, and hirsutism should be noted. Short stature may be seen with an associated GH or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner syndrome. Olfactory deficits are seen in Kallmann syndrome. Obesity and short stature may be signs of Cushing syndrome. Tall stature may be due to eunuchoidism or acromegaly. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymen patency and the presence of a uterus.

B. Laboratory and Radiologic Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, FT₄, and beta-hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation. MRI of the hypothalamus and pituitary is used to evaluate teens with primary amenorrhea and low or normal FSH and LH—especially those with high PRL levels. Pelvic duplex/color sonography is very useful. Girls who have a normal uterus and high FSH without the classic features of Turner syndrome may require a karyotype to diagnose X chromosome mosaicism.

Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with HRT.

SECONDARY AMENORRHEA & MENOPAUSE

Secondary amenorrhea is defined as the absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

Etiology

The causes of secondary amenorrhea include pregnancy, hypothalamic-pituitary causes, hyperandrogenism, uterine causes, premature ovarian failure, and menopause.

A. Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in premenopausal women. The differential diagnosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

B. Hypothalamic-Pituitary Causes (with Low or Normal FSH)

The hypothalamus must release GnRH in a pulsatile manner for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary “hypothalamic” amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have non-cyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

PRL elevation due to any cause may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Corticosteroid excess of any cause suppresses gonadotropins.

C. Hyperandrogenism (with Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In PCOS, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces

Klein DA et al. Amenorrhea: an approach to diagnosis and management. *Am Fam Physician*. 2013 Jun 1;87(11):781–8. [PMID: 23939500]

Marsh CA et al. Primary amenorrhea: diagnosis and management. *Obstet Gynecol Surv*. 2014 Oct;69(10):603–12. [PMID: 25336070]

follicular maturation. Rare causes of secondary amenorrhea include adrenal P450c21 deficiency, ovarian or adrenal malignancies, and Cushing syndrome. Anabolic steroids also cause amenorrhea.

D. Uterine Causes (with Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal.

E. Early and Premature Menopause (with High FSH)

Early menopause refers to primary ovarian failure that occurs before age 45. It affects approximately 5% of women. About 1% of women experience **premature menopause** that is defined as ovarian failure before age 40; about 30% of such cases are due to autoimmunity against the ovary. X chromosome mosaicism accounts for 8% of cases of premature menopause. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Early or premature menopause is frequently familial. Ovarian failure is usually irreversible.

F. Normal Menopause (with High FSH)

Normal menopause refers to primary ovarian failure that occurs after age 45. "Climacteric" is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40 years, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others.

► Clinical Findings

A. Symptoms and Signs

Vasomotor symptoms (hot flashes) are experienced by 60–80% of women at menopause. The duration of vasomotor symptoms can vary from seconds to many minutes. The severity can vary from mild to debilitating and many women experience drenching nocturnal sweats. Hot flashes peak in early menopause and then usually decline

gradually over a median of 10 years, but some women experience persistent severe vasomotor symptoms. African-American women tend to experience more severe vasomotor symptoms, whereas Asian women are less affected. Smokers tend to experience worse symptoms. Sleep disturbances are common and include problems initiating sleep, staying asleep, and early morning awakening. Other common symptoms of menopause include fatigue, headache, diminished libido, and rheumatologic symptoms. Psychological symptoms may include depression and irritability. Some women report mild cognitive impairment at menopause, which may be related to decreased cerebral blood flow noted in hypogonadal women, particularly during hot flashes. Estrogen deficiency causes vulvovaginal atrophy, with symptoms of vaginal dryness, dyspareunia, and irritation. Increased bone osteoclastic activity increases the risk for osteoporosis and fractures. The skin becomes more wrinkled. Increases in the LDL:HDL cholesterol ratio cause an increased risk for atherosclerosis.

A careful pelvic examination is useful to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect. Vulvovaginal complaints are not always due to estrogen deficiency and direct inspection of the vulva is necessary to detect other conditions, such as lichen sclerosis, contact dermatitis, squamous hyperplasia, or malignancy.

B. Laboratory Findings

1. Premature amenorrhea—An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Further laboratory evaluation for women who are not pregnant includes serum PRL, FSH, LH, and TSH. Hyperprolactinemia or hypopituitarism (without obvious cause) should prompt an MRI study of the pituitary region. Routine testing of kidney and liver function (BUN, serum creatinine, bilirubin, alkaline phosphatase, and alanine aminotransferase) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening. Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/day); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

2. Typical menopause—No laboratory testing is required to diagnose menopause, when amenorrhea occurs at the expected age. The expected age of menopause correlates with a woman's mother's age at menopause and varies among different kindreds and ethnic groups. An elevated serum FSH with a low or low-normal serum estradiol helps confirm the diagnosis.

► Treatment

A. Nonpharmacologic Approaches

Hot flashes may be reduced with low room temperatures, dressing coolly, and consuming cold beverages. Night

sweats may be reduced by sleeping in a cool room and by avoiding the use of excessively warm blankets or down comforters. Slow, deep breathing can ameliorate hot flushes. Women may try avoiding known triggers for hot flushes, such as smoking, alcohol, caffeine, and hot spicy foods. Idiosyncratic triggers for hot flushes may be discerned and avoided. **Aerobic training** for 50 minutes four times weekly reduced all menopausal symptoms except vaginal dryness in a randomized controlled trial. **Clinical hypnosis** reduced hot flushes over 12 weeks in one study. Acupuncture may help alleviate symptoms in some women. **Replens** is a vaginal lubricant that can be used daily or 2 hours prior to intercourse. It improves vaginal moisture and elasticity and reduces vaginal irritation and dyspareunia.

B. Nonhormonal Medications

For women with severe hot flushes who cannot take estrogen, SSRIs may offer modest relief effective within a week; escitalopram (10–20 mg/day) can reduce hot flushes significantly, but must not be used by women taking tamoxifen for breast cancer, since it inhibits its metabolism to its active metabolite. Venlafaxine extended release (75 mg/day) may also be effective and does not have a drug interaction with tamoxifen. Sexual dysfunction has not been as significant with the latter drugs when used for vasomotor symptoms, compared to their use for depression. Gabapentin is also quite effective in oral doses titrated up to 200–800 mg every 8 hours. Side effects such as drowsiness, fatigue, dizziness, and headache, which are most pronounced during the first 2 weeks of therapy, often improve within 4 weeks. An herb, black cohosh, may possibly relieve hot flushes. Tamoxifen and raloxifene offer bone protection but aggravate hot flushes. Women with postmenopausal osteoporosis may be treated with bisphosphonates or denosumab. Women with low serum testosterone levels may experience hypoactive sexual desire disorder that may respond to low-dose testosterone replacement.

▶ Hormone Replacement Therapy (HRT)

Overall survival is improved among women who begin HRT before age 60 or within 10 years of menopause. However, no survival advantage was found in older women, according to a meta-analysis of 43 randomized controlled trials. Specifically, HRT does not increase the risk of cardiac death or stroke. **Breast cancer risk** is increased among women taking combined daily estrogen and progestin HRT, whereas breast cancer risk is reduced in women taking estrogen alone. **Venous thromboembolic disease** and **stroke** are increased by oral but not transdermal estrogen. **Osteoporosis risk** is reduced by even low-dose systemic estrogen replacement.

In light of these considerations, estrogen replacement is most commonly prescribed for women in early menopause, when symptoms are worst and the benefits are greatest. Transdermal estrogen is favored over oral therapy to reduce the risk of thromboembolism. In women with an intact uterus, estrogen replacement without a progestin risks endometrial hypertrophy and dysfunctional uterine

bleeding. The addition of a progestin, however, increases the risk of breast cancer. Therefore, only the smallest effective dose of estrogen should be used to avoid the need for progestins or use them in lower doses or intermittently. Also, progestin may be delivered directly to uterus with progesterone-eluting intrauterine devices. The decision to prescribe menopausal hormonal therapy and its type and duration are dictated by individual symptoms, risk profile, and personal preferences, while considering potential benefits and risks.

A. Benefits of HRT

Estrogen replacement is the best treatment for hot flushes and sweats and eliminates these symptoms or improves them by more than 70%, usually within a month. Vaginal moisture is improved and libido is enhanced in some women. Estradiol vaginal rings can improve symptoms of an overactive bladder and vaginal dryness. Sleep disturbances are common in menopause and can be reversed with estrogen replacement. Some women notice a mild impairment in memory and cognitive function at menopause that may improve with HRT that is commenced soon after menopause. HRT does not reduce the risk of Alzheimer dementia. However, short-term transdermal estradiol has been demonstrated to slightly improve memory in women with existent mild to moderate Alzheimer disease. Estrogen replacement may also improve the body pain and reduced physical function experienced by some women at the time of menopause. Women with perimenopausal depression typically experience a significantly improved mood and overall sense of well being with estrogen replacement. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy.

Estrogen replacement prevents postmenopausal osteoporosis. The WHI study also found that women who received estrogen therapy experienced a reduced number of hip fractures (six fewer fractures/year per 10,000 women) compared with placebo. Even “microdose” transdermal estradiol (0.014 mg/day) preserves bone density.

Women aged 50–59 years in the WHI who received estrogen alone developed significantly lower CT coronary calcium scores (a marker for coronary atherosclerosis) than women receiving placebo. In the California Teachers Study, HRT in women under age 60 was associated with a dramatic 46% reduction in all-cause mortality, particularly cardiovascular disease. This association of HRT and lower mortality may suffer from self-selection bias. Nevertheless, there appears to be a survival advantage of HRT that requires longer-term administration (more than 5 years) to become apparent. The survival advantage is particularly strong for women under age 60 and diminishes with age; no reduction in mortality was noted in the group of women aged 85–94 years. The reduction in cardiovascular disease among younger postmenopausal women taking HRT may be explained by the reduction in serum levels of atherogenic lipoprotein(a) with HRT, with or without a progestin. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin.

1. Estrogen replacement without progestin (unopposed HRT)—Interestingly, the WHI study found that postmenopausal women taking unopposed estrogen had a 23% *reduction* in breast cancer risk. Unopposed estrogen replacement improves glycemic control in women with type 2 diabetes mellitus. Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a progestin may negate this effect. A 20-year study of 8801 women living in a retirement community found that estrogen use was associated with improved survival. Age-adjusted mortality rates were 56.4 (per 1000 person-years) among nonusers and 50.4 among women who had used estrogen for 15 years or longer.

2. Estrogen replacement therapy with progestins (combined HRT)—Women receiving conventional-dose daily conjugated estrogen and medroxyprogesterone acetate (0.625 mg and 2.5 mg, respectively) for an average of 5.6 years, experienced a lower risk of developing diabetes mellitus (3.5%) versus those taking a placebo (4.2%).

B. Risks of HRT

Oral estrogen increases the risk of arterial and venous thrombotic events in a dose-dependent manner, although the absolute risk is small. The WHI study found that women who received long-term conventional oral combined HRT had an increased risk of deep venous thrombosis (3.5 per 1000 person-years) compared with women receiving placebo (1.7 per 1000 person-years). Oral estrogen also increases the risk of ischemic stroke by about 30%. Oral estrogen causes a particularly increased risk for thromboembolic disease among older women and those with increased stroke proclivity (current smokers and those with hypertension, atrial fibrillation, prior thromboembolic event). Long-term use of oral conjugated estrogens in women over age 65 has been associated with poorer cognitive performance, perhaps due to small strokes. Transdermal or vaginal estrogen administration avoids this risk. Urinary stress incontinence appears to be increased by conventional-dose oral estrogen replacement, whereas topical vaginal estrogen may have a beneficial effect. Estrogen replacement may cause mastalgia that typically responds to dose reduction. Estrogen replacement also appears to increase the risk of seizures in women with epilepsy. Estrogen can stimulate the growth of untreated large pituitary prolactinomas. Oral estrogen and SERMs also increase the risk of gastroesophageal reflux disease. Oral HRT can increase the size of hepatic hemangiomas, but significant enlargement is uncommon. Conventional doses of estrogen carry higher risks than lower doses. The risks for HRT also depend on whether estrogen is administered alone (unopposed HRT) or with a progestin (combined HRT).

1. Estrogen replacement without progestin (unopposed HRT)—Surprisingly, the WHI study found that postmenopausal women who received conventional-dose estrogen-only therapy had a reduced risk of breast cancer (7 fewer cases/year per 10,000 women) compared with a placebo group. However, the California Teachers Study monitored women for a longer period; a group of 37,000

women who had been taking conventional-dose estrogen-only therapy for 20 years or longer did have a slightly increased risk of breast cancer. Women taking lower-dose unopposed estrogen therapy would be expected to have lower long-term risk of breast cancer.

Conventional-dose unopposed conjugated estrogen replacement (0.625–1.25 mg daily) increases the risk of endometrial hyperplasia and dysfunctional uterine bleeding, which often prompts patients to stop the estrogen. However, lower-dose unopposed estrogen confers a much lower risk of dysfunctional uterine bleeding. Recurrent dysfunctional bleeding necessitates a pelvic examination and possibly an endometrial biopsy. There has been considerable concern that unopposed estrogen replacement might increase the risk for endometrial carcinoma. However, a Cochrane Database Review found no increased risk of endometrial carcinoma in a review of 30 randomized controlled trials. Therefore, lower-dose unopposed estrogen replacement does not appear to confer any significant increased risk for endometrial cancer.

Long-term conventional-dose unopposed estrogen increases the mortality risk from ovarian cancer, although the absolute risk is small. The annual age-adjusted ovarian cancer death rates for women taking estrogen replacement for 10 years or longer are 64:100,000 for current users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Lower-dose estrogen replacement is believed to confer a negligible increased risk for ovarian cancer.

The WHI trial was stopped in 2002 because of an increased risk of stroke among women taking conjugated oral estrogens in doses of 0.625 mg daily; the risk was about 44 strokes per 10,000 person-years versus about 32 per 10,000 person-years in women taking placebo. Transdermal or transvaginal estrogen is not thought to increase the risk of stroke.

Oral estrogens can cause hypertriglyceridemia, particularly in women with preexistent hyperlipidemia, rarely resulting in pancreatitis. Postmenopausal estrogen therapy also slightly increases the risk of gallstones and cholecystitis. These side effects may be reduced or avoided by using transdermal or vaginal estrogen replacement.

2. Estrogen replacement with a progestin (combined HRT)—Long-term conventional-dose oral combined HRT increases breast density and the risk for abnormal mammograms (9.4% versus 5.4% for placebo). There is also a higher risk of breast cancer (8 cases per 10,000 women/year versus 6.5 cases per 10,000 women/year for placebo); the increased risk of breast cancer is highest shortly after menopause (about 2 cases per 1000 women annually). This increased risk for breast cancer appears to mostly affect relatively thin women with a BMI less than 24.4. The Iowa Women's Health Study reported an increase in breast cancer with HRT only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of HRT who have benign breast disease or a family history of breast cancer. Women in whom new-onset breast tenderness develops with combined HRT have an increased risk of breast cancer, compared with women without breast tenderness.

The Women's Health Initiative Mental Study (WHIMS) followed the effect of combined conventional-dose oral HRT on cognitive function in women 65–79 years old. HRT did not protect these older women from cognitive decline. In fact, they experienced an increased risk for severe dementia at a rate of 23 more cases/year for every 10,000 women over age 65 years. It is unknown whether this finding applies to younger postmenopausal women.

In the WHI study, women receiving conventional-dose combined oral HRT experienced an increased risk of stroke (31 strokes per 10,000 women/year versus 26 strokes per 10,000 women/year for placebo). Stroke risk was also increased by hypertension, diabetes, and smoking.

Women taking combined oral estrogen–progestin replacement do not experience an increased risk of ovarian cancer. They do experience a slightly increased risk of developing asthma.

Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled progestins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progestins include thromboembolic disorders, liver disease, breast cancer, and pregnancy.

C. HRT Agents

Hormone replacement needs to be individualized. Ideally, in women with an intact uterus, very low-dose transdermal estradiol may be used alone or with intermittent progestin or a progesterone-eluting intrauterine device, in order to reduce the risk of endometrial hyperplasia, while avoiding the need for daily oral progestin. Vaginal estrogen can be added if low-dose systemic estradiol replacement is insufficient to relieve symptoms of vulvovaginal atrophy. Women who have had a hysterectomy may receive transdermal estrogen at whatever is the lowest dose that adequately relieves symptoms. However, some women cannot find sufficient relief with transdermal estradiol and must use an oral preparation.

1. Transdermal estradiol—Estradiol can be delivered systemically with different systems of skin patches, mists, or gels. Transdermal estradiol works for most women, but some women have poor transdermal absorption. If a woman has a skin reaction to an estradiol patch, then a gel or mist may be tried at different doses until the ideal formulation is found.

A. ESTRADIOL PATCHES MIXED WITH ADHESIVE—These systems tend to cause minimal skin irritation. Generic estradiol transdermal (0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/day) is replaced weekly. Brand products include: Vivelle-Dot (0.025) or Minivivelle (0.0375, 0.05, 0.075, or 0.1 mg/day) or Alora (0.025, 0.05, 0.075, or 0.1 mg/day), replaced twice weekly; Climara (0.025, 0.0375, 0.05, 0.06, 0.075, or 0.1 mg/day), replaced weekly; and Menostar (0.014 mg/day), replaced weekly. This type of estradiol skin patch can be cut in half and applied to the skin without proportionately greater loss of potency. Minivivelle patches are the smallest.

B. ESTRADIOL MISTS AND GELS—Evamist is available as a topical mist dispenser that dispenses 1.53 mg estradiol/spray; 1–3 sprays are applied to the inner forearm daily; a single daily spray may provide sufficiently low-dose estradiol to possibly obviate the need for daily progestin in women with an intact uterus. EstroGel 0.06% is available in a metered-dose pump that dispenses 1.25 g gel per actuation (half–2 actuations/day). Elestrin 0.06% is available in a metered-dose pump that dispenses 0.87 g gel per activation (half–2 actuations/day). These gels are applied daily to one arm from the wrist to the shoulder after bathing. Divigel 0.1% gel (0.25, 0.5, 1 g/packet) is applied to the upper thigh daily. Estrasorb 2.5% is available in 1.74 g pouches (4.35 mg estradiol); 1–2 pouches of lotion are applied to the thigh/calf daily. To avoid spreading topical estradiol to others, the hands should be washed and precautions taken to avoid prolonged skin contact with children. Application of sunscreen prior to estradiol gel has been reported to *increase* the transdermal absorption of estradiol.

C. ESTRADIOL PATCHES WITH PROGESTIN MIXED WITH ADHESIVE—These preparations mix estradiol with either norethindrone acetate or levonorgestrel. Combipatch (0.05 mg E with 0.14 mg norethindrone acetate daily or 0.05 mg E with 0.25 mg norethindrone acetate daily) is replaced twice weekly. Climara Pro (0.045 mg E with 0.015 mg levonorgestrel daily) is replaced once weekly. The addition of a progestin reduces the risk of endometrial hyperplasia, but breakthrough bleeding occurs commonly. The combined patch increases the risk of breast cancer. Scalp hair loss, acne, weight gain, skin reactions, and poor skin adherence have been reported with these patches.

2. Oral estrogen—

A. ORAL ESTROGEN-ONLY PREPARATIONS—These preparations include conjugated equine estrogens that are available as Premarin (0.3, 0.45, 0.625, 0.9, and 1.25 mg), conjugated plant-derived estrogens (eg, Menest, 0.3, 0.625, and 2.5 mg), and conjugated synthetic estrogens that are available as Cenestin (0.3, 0.45, 0.625, 0.9, and 1.25 mg) and Enjuvia (0.3, 0.45, 0.625, 0.9, and 1.25 mg). Other preparations include estradiol (0.5, 1, and 2 mg), and estropipate (0.75, 1.5, and 3 mg).

B. ORAL ESTROGEN PLUS PROGESTIN PREPARATIONS—Conjugated equine estrogens with medroxyprogesterone acetate is available as Prempro (0.3/1.5, 0.45/1.5, 0.625/2.5, and 0.625 mg/5 mg); conjugated equine estrogens for 14 days cycled with conjugated equine estrogens plus medroxyprogesterone acetate for 14 days is available as Premphase (0.625/0, then 0.625 mg/5 mg); estradiol with norethindrone acetate (0.5/0.1 and 1 mg/0.5 mg); ethinyl estradiol with norethindrone acetate is available as Femhrt (2.5/0.5 and 5 mcg/1 mg) and Jinteli (5 mcg/1 mg); estradiol with drospirenone is available as Angeliq (0.5 mg/0.25 mg, and 1.0 mg/0.5 mg); estradiol with norgestimate is available as Prefest (estradiol 1 mg/day for 3 days, alternating with 1 mg estradiol/0.09 mg norgestimate daily for 3 days). Oral contraceptives can also be used for combined HRT.

3. Vaginal estrogen—Urogenital atrophy commonly develops in postmenopausal women and can cause dryness of the vagina, genital itching, burning, dyspareunia, and recurrent urinary tract infections. Urinary symptoms can include urgency and dysuria. Vaginal estrogen is intended to deliver estrogen directly to local tissues and is moderately effective in reducing these symptoms, while minimizing systemic estrogen exposure. Some estrogen is absorbed systemically and can relieve menopausal symptoms. Manufacturers recommend that these preparations be used for only 3–6 months in women with an intact uterus, since vaginal estrogen can cause endometrial proliferation. However, most clinicians use them for longer periods. Vaginal estrogen can be administered in three different ways: creams, tablets, and rings.

A. ESTROGEN VAGINAL CREAMS—These creams are administered intravaginally with a measured-dose applicator daily for 2 weeks for atrophic vaginitis, then administered one to three times weekly. Available preparations include conjugated equine estrogens, which is available as Premarin Vaginal (0.625 mg/g cream), dosed as 0.25–2 g cream administered vaginally one to three times weekly. Estradiol is available as Estrace Vaginal (0.1 mg/g cream), 1 g cream administered vaginally one to two times weekly.

B. ESTRADIOL VAGINAL TABLETS—These tablets are sold prepackaged in a disposable applicator and can be administered deep intravaginally daily for 2 weeks for atrophic vaginitis, then twice weekly. The tablets dissolve into a gel that gradually releases estradiol. This preparation is available as Vagifem (10 mcg/tablet), administered vaginally two times weekly.

C. ESTRADIOL VAGINAL RINGS—These rings are inserted manually into the upper third of the vagina, worn continuously, and replaced every 3 months. Only a small amount of the released estradiol enters the systemic circulation. Vaginal rings do not usually interfere with sexual intercourse. If a ring is removed or descends into the introitus, it may be washed in warm water and reinserted. Estring (2 mg estradiol/ring) releases estradiol 7.5 mcg/day; Femring releases estradiol acetate 0.05 mg/day or 0.1 mg/day. Both rings are replaced every 90 days. For women with postmenopausal urinary urgency and frequency, even the low-dose Estring can successfully reduce urinary symptoms.

D. ESTRADIOL WITH PROGESTIN VAGINAL RINGS—The available preparation is NuvaRing that releases a mixture of ethinyl estradiol 0.015 mg/day and etonogestrel 0.12 mg/day. It is a contraceptive vaginal ring that is placed in the vagina on or before day 5 of the menstrual cycle, left for 3 weeks, removed for 1 week, and then replaced.

4. Estradiol injections—Parenteral estradiol should be used only for particularly severe menopausal symptoms when other measures have failed or are contraindicated. Estradiol cypionate (Depo-Estradiol 5 mg/mL) may be administered intramuscularly in doses of 1–5 mg every 3–4 weeks. Estradiol valerate (20 or 40 mg/mL) may be administered intramuscularly in doses of 10–20 mg every

4 weeks. Women with an intact uterus should receive a progestin for the last 10 days of each cycle.

5. Oral progestins—For a woman with an intact uterus, long-term conventional-dose unopposed systemic estrogen therapy can cause endometrial hyperplasia, which typically results in dysfunctional uterine bleeding and might rarely lead to endometrial cancer. Progestin therapy transforms proliferative into secretory endometrium, causing a possible menses when given intermittently or no bleeding when given continuously.

The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation. Progestins may be given daily, monthly, or at longer intervals. When given episodically, progestins are usually administered for 7–14 day periods. Bedtime administration may improve sleep. Some women find that progestins produce adverse effects, such as irritability, nausea, fatigue, or headache; long-term progestins given with estrogen replacement increase the risk for breast cancer.

Oral progestins are available in different formulations: Micronized progesterone (100 mg and 200 mg/capsule), medroxyprogesterone (2.5, 5.0, and 10 mg/tablet), norethindrone acetate (5 mg/tablet), and norethindrone (0.35 mg/tablet). Topical progesterone (20–50 mg/day) may reduce hot flashes in women who are intolerant to oral HRT. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown. Progesterone is also available as vaginal gels (eg, Prochieve, 4% = 45 mg/applicatorful, and 8% = 90 mg/applicatorful) that are typically given for secondary amenorrhea and administered vaginally every other day for six doses.

6. Progestin-releasing intrauterine devices—Intrauterine devices that release progestins can be useful for women receiving ERT, since they can reduce the incidence of dysfunctional uterine bleeding and endometrial carcinoma without exposing women to the significant risks of systemic progestins. The Mirena intrauterine device releases levonorgestrel and is inserted into the uterus by a clinician within 7 days of the onset of menses. It is equally effective at reducing endometrial hyperplasia as cycled medroxyprogesterone acetate and is associated with less hirsutism. It remains effective for up to 5 years. Parous women are generally better able to tolerate the Mirena intrauterine device than nulliparous women.

7. Selective estrogen receptor modulators—SERMs (eg, raloxifene, ospemifene, tamoxifen) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects. Raloxifene (Evista) does not reduce hot flashes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/day orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Raloxifene does not stimulate the endometrium and actually reduces the

risk of endometrial carcinoma, so concomitant progesterone therapy is not required. Another advantage to raloxifene is that it reduces the risk of invasive breast cancer by about 50%. Raloxifene slightly increases the risk of venous thromboembolism (though less so than tamoxifen), so it should not be used by women at prolonged bed rest or otherwise prone to thrombosis. Ospemifene (Osphena) is a SERM that has unique estrogen-like effects on the vaginal epithelium and is indicated for the treatment of postmenopausal dyspareunia when other therapies are ineffective. Given orally in doses of 60 mg/day, it commonly aggravates hot flashes, increases the risks of thromboembolism, and increases endometrial hyperplasia. Ospemifene has unknown long-term effects upon bone and breast.

Tibolone (Livial) is an SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to HRT for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

8. Testosterone replacement therapy in women—In premenopausal women, serum testosterone levels decline with age. Between 25 and 45 years of age, women's testosterone levels fall 50%. After natural menopause, the ovaries remain a significant source for testosterone and serum testosterone levels do not fall abruptly. In contrast, very low serum testosterone levels are found in women after bilateral oophorectomy, autoimmune ovarian failure, or adrenalectomy, and in hypopituitarism. Testosterone deficiency contributes to hot flashes, loss of sexual hair, muscle atrophy, osteoporosis, and diminished libido, also known as hypoactive sexual desire disorder. **Flibanserin** is a drug that is modestly effective for treating premenopausal women with acquired hypoactive sexual desire disorder. It is administered orally 100 mg at bedtime; side effects may include hypotension, appendicitis, nausea, xerostomia, sleep disorders, and fatigue.

In women, diminished libido is common and multifactorial. Although low serum testosterone levels may contribute to hypoactive sexual desire disorder, hysterectomy and sexual isolation are major causes. Low serum testosterone levels may also cause fatigue, a diminished sense of well being, and a dulled enthusiasm for life. Androgen replacement may improve these problems.

Selected women may be treated with low-dose testosterone. Methyltestosterone can be compounded into capsules and taken orally in doses of 1.25–2.5 mg daily. Testosterone can also be compounded as a cream containing 1 mg/mL, with 1 mL applied to the abdomen daily. Methyltestosterone also is available combined with esterified estrogens: 1.25 mg methyltestosterone/0.626 mg esterified estrogens or 2.5 mg methyltestosterone/1.25 mg esterified estrogens. The latter formulations are convenient but carry the same disadvantages as oral estrogen—particularly an increased risk of thromboembolism.

Women receiving testosterone therapy must be monitored for the appearance of any acne or hirsutism, and serum testosterone levels are determined periodically if

women feel that they are benefitting and long-term testosterone therapy is instituted. Side effects of low-dose testosterone therapy are usually minimal but may include erythrocytosis, emotional changes, hirsutism, acne, an adverse effect on lipids, and potentiation of warfarin anticoagulation therapy. Testosterone therapy tends to reduce both triglyceride and HDL cholesterol levels. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with oral methyltestosterone doses of 2.5 mg or less daily.

Vaginal testosterone is an option for postmenopausal women who cannot use systemic or vaginal estrogen due to breast cancer. Testosterone 150–300 mcg/day vaginally appears to reduce vaginal dryness and dyspareunia without increasing systemic estrogen levels.

Caution: Androgens should not be given to women with liver disease or during pregnancy or breastfeeding. Testosterone replacement therapy for women should be used judiciously, since long-term prospective clinical trials are lacking. An analysis of the Nurses' Health Study found that women who had been taking conjugated equine estrogens plus methyltestosterone experienced an increased risk of breast cancer, so breast cancer screening is recommended.

TURNER SYNDROME (Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS

- ▶ Short stature with normal GH levels.
- ▶ Primary amenorrhea or early ovarian failure.
- ▶ Epicanthal folds, webbed neck, short fourth metacarpals.
- ▶ Renal and cardiovascular anomalies.

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies (Table 26–17). It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two X chromosomes (45,XO karyotype). Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO).

1. Classic Turner Syndrome (45,XO Gonadal Dysgenesis)

▶ Clinical Findings

A. Symptoms and Signs

Features of Turner syndrome are variable and may be subtle in girls with mosaicism. Turner syndrome may be diagnosed in infant girls at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Girls and women with Turner syndrome have an increased risk of aortic coarctation (11%) and bicuspid aortic valves (16%); these cardiac abnormalities are more common in patients with a webbed neck. If a woman with Turner syndrome becomes pregnant, there is a 2% risk of death from aortic dissection or rupture. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and renal abnormalities (Table 26–17). Emotional disorders are common. Affected women are also more prone to autoimmune disease, particularly thyroiditis (37%), inflammatory bowel disease (4%), and celiac disease (3%).

Hypogonadism presents as “delayed adolescence” (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner (blood karyotyping) who enter puberty are typically found to have mosaicism if other tissues are karyotyped.

Table 26–17. Manifestations of Turner syndrome.

Short stature
Distinctive facial features
Ptosis
Micrognathia
Low-set ears
Epicanthal folds
Sexual infantilism due to gonadal dysgenesis with primary amenorrhea (80%)
Early ovarian failure with secondary amenorrhea (20%)
Webbed neck (40%)
Low hairline
High-arched palate
Cubitus valgus
Short fourth metacarpals (50%)
Lymphedema of hands and feet (30%)
Hypoplastic widely spaced nipples
Hyperconvex nails
Pigmented nevi
Keloid formation (eg, surgical scars or after ear piercing)
Recurrent otitis media
Renal abnormalities (60%)
Horseshoe kidney
Hydronephrosis
Hypertension (idiopathic or due to coarctation or kidney disease)
Cardiovascular anomalies
Coarctation of the aorta (10–20%)
Partial anomalous pulmonary venous connection
Bicuspid aortic valve (with aortic stenosis or regurgitation)
Aortic dissection due to coarctation and cystic medial necrosis of the aorta
Gastrointestinal disorders
Telangiectasias with bleeding
Celiac disease
Inflammatory bowel disease
Colon carcinoma
Liver disease
Impaired space-form recognition, direction sense, and mathematical reasoning
Associated conditions
Obesity
Diabetes mellitus (types 1 and 2)
Dyslipidemia
Hyperuricemia
Hashimoto thyroiditis
Achlorhydria
Cataracts, corneal opacities
Neuroblastoma (1%)
Rheumatoid arthritis

B. Laboratory Findings

Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. A blood karyotype showing 45,XO (or X chromosome abnormalities or mosaicism) establishes the diagnosis. GH and IGF-1 levels are normal.

C. Imaging

An ultrasound and MRI scan of the chest and abdomen should be done in all patients with Turner syndrome to determine whether cardiac, aortic, and renal abnormalities are present.

Treatment

Treatment of short stature with daily injections of GH (0.1 unit/kg/day) plus an androgen (eg, oxandrolone) for at least 4 years before epiphyseal fusion increases final height by a mean of about 10.3 cm over the mean predicted height of 144.2 cm. Rarely, such GH treatment causes pseudotumor cerebri. After age 12 years, estrogen therapy is begun with low doses of conjugated estrogens (0.3 mg) or ethinyl estradiol (5 mcg) given on days 1–21 per month. When growth stops, HRT is begun with estrogen and progestin; transdermal estrogen may be used to initiate pubertal development.

Complications & Surveillance

Bicuspid aortic valves are associated with an increased risk of infective endocarditis, aortic valvular stenosis or regurgitation, and ascending aortic aneurysm and dissection. Partial anomalous pulmonary vein connections occur in 13% and can lead to left-to-right shunting of blood. Adults with Turner syndrome have a high incidence of ECG abnormalities.

Women with Turner syndrome have a reduced life expectancy due in part to their increased risk of diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis.

Diagnostic vigilance and aggressive treatment of these conditions reduce the risk of aortic aneurysm dissection, ischemic heart disease, stroke, and fracture. Patients are prone to keloid formation after surgery or ear piercing. Yearly ocular examinations and periodic thyroid evaluations are recommended.

Repeat cardiovascular evaluations should be done every 3–4 years. Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46,X/abnormal X are more prone to malformations of the urinary collecting system. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome, particularly those with pronounced neck webbing and shield chest. Patients with aortic root enlargement are usually treated with beta-blockade and serial imaging. About 5% of women with Turner syndrome experience natural pregnancy and even more can become pregnant with oocyte donation. Such pregnancies are very high-risk, with high rates of fetal morbidity, preeclampsia, and aortic dissection. Women are usually advised to deliver via cesarean section because of the risk of aortic aneurysm rupture during vaginal delivery.

2. Turner Syndrome Variants

A. 46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp-) that include the *SHOX* gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure. Transmission of Turner syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner syndrome. Patients with deletions of the long arm of the X chromosome (distal to Xq24) often have amenorrhea without short stature or other features of Turner syndrome.

Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

B. 45,XO/46,XX and 45,XO/46,XY Mosaicism

45,XO/46,XX mosaicism results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

45,XO/46,XY mosaicism can produce some manifestations of Turner syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype. Germ cell tumors, such as gonadoblastomas and seminomas, develop in about 10% of patients with 45,XO/46,XY mosaicism; most such tumors are benign.

CLINICAL USE OF CORTICOSTEROIDS

Prolonged treatment with systemic high-dose corticosteroids causes a variety of adverse effects that can be life threatening. Patients should be thoroughly informed of the major possible side effects of treatment such as insomnia, cognitive and personality changes, weight gain with central obesity, bruising, striae, muscle weakness, polyuria, renal calculi, diabetes mellitus, glaucoma, cataracts, sex hormone suppression, candidiasis and opportunistic infections. High-dose corticosteroids have adverse cardiovascular effects, increasing the risk of hypertension, dyslipidemia, myocardial infarction, stroke, atrial fibrillation or flutter, and heart failure. Prolonged corticosteroid therapy for systemic inflammatory disorders commonly suppresses pituitary ACTH secretion, causing secondary adrenal insufficiency.

In pregnancy, maternal corticosteroids are transmitted across the placenta to the fetus, causing adverse effects on fetal growth and development as well as childhood cognition and behavior. Therefore, women who are to receive high-dose corticosteroids should be screened for pregnancy and counseled to use contraception.

Bone fractures (especially spine and hip) ultimately occur in about 40% of patients receiving long-term corticosteroid therapy. Osteoporotic fractures can also occur in patients who receive extensive topical, inhaled, or intermittent oral

Table 26–18. Management of patients receiving systemic corticosteroids.**Recommendations for prescribing**

- Do not administer corticosteroids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.

Monitoring recommendations

- Screen for tuberculosis with a purified protein derivative (PPD) test or chest radiograph before commencing long-term corticosteroid therapy.
- Screen for pregnancy in reproductive age women; recommend contraceptive measures.
- Screen for diabetes mellitus before treatment and at each clinician visit.
- Teach patient about the symptoms of hyperglycemia.
- Screen for hypertension before treatment and at each clinician visit.
- Screen for glaucoma and cataracts before treatment, 3 months after treatment inception, and then at least yearly.
- Monitor plasma potassium for hypokalemia and treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently to document the degree of axial spine demineralization and compression.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- With dosage reduction, watch for signs of adrenal insufficiency or corticosteroid withdrawal syndrome.

Patient information

- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function.
- Inform the patient about other possible side effects, particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Counsel to avoid smoking and excessive ethanol consumption.

Prophylactic measures

- Institute a vigorous physical exercise and isometric regimen tailored to each patient's abilities or disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D₃, 400–800 units orally daily.
 - Check spot morning urines for calcium; alter dosage to keep urine calcium concentration < 30 mg/dL (< 7.5 mmol/L).
 - If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily.
- If the patient has pre-existent osteoporosis or has been receiving glucocorticoids for ≥ 3 months, consider prophylaxis:
 - Bisphosphonate such as alendronate (70 mg every week orally), zoledronate (5 mg every year intravenously) for up to 3–5 years;
 Or
 - Denosumab (60 mg every 6 months subcutaneously) for up to 3–5 years.
- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Fall prevention strategies: walking assistance (cane, walker, wheelchair, handrails) when required due to weakness or balance problems; avoid activities that could cause falls or other trauma.
- For ulcer prophylaxis, if administering corticosteroids with nonsteroidals, prescribe a proton pump inhibitor (not required for corticosteroids alone). Avoid large doses of antacids containing aluminum hydroxide (many popular brands) because aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound corticosteroid osteoporosis.
- Treat hypogonadism.
- Treat infections aggressively. Consider unusual pathogens.
- Treat edema as indicated.

corticosteroids (eg, prednisone 10 mg/day or more and cumulative dose greater than 1 g). Osteoporotic fractures can occur even in patients receiving long-term corticosteroid therapy at relatively low doses (eg, 5–7.5 mg prednisone daily). Vertebral fractures occur at higher bone densities compared to patients without corticosteroid exposure. Patients at increased risk for corticosteroid osteoporotic fractures include those who are over age 60 or who have a low body mass index, pretreatment osteoporosis, a family history of osteoporosis, or concurrent disease that limits mobility. Avascular necrosis of bone (especially hips) develops in about 15% of patients who receive corticosteroids at high doses (eg, prednisone 15 mg daily or more) for more than 1 month with cumulative prednisone doses of 10 g or more.

Bisphosphonates (eg, alendronate, 70 mg orally weekly) prevent the development of osteoporosis among patients receiving prolonged courses of corticosteroids. For patients who are unable to tolerate oral bisphosphonates

(due to esophagitis, hiatal hernia, or gastritis), periodic intravenous infusions of pamidronate, 60–90 mg, or zoledronate, 4 mg, should also be effective. Teriparatide, 20 mcg subcutaneously daily for up to 2 years, is also effective against corticosteroid-induced osteoporosis. It is wise to follow an organized treatment plan such as the one outlined in Table 26–18.

Diabetes Mellitus & Hypoglycemia

Umesh Masharani, MB, BS, MRCP(UK)

DIABETES MELLITUS

ESSENTIALS OF DIAGNOSIS

Type 1 diabetes

- ▶ Polyuria, polydipsia, and weight loss associated with random plasma glucose of 200 mg/dL (11.1 mmol/L) or more.
- ▶ Plasma glucose of 126 mg/dL (7.0 mmol/L) or more after an overnight fast, documented on more than one occasion.
- ▶ Ketonemia, ketonuria, or both.
- ▶ Islet autoantibodies are frequently present.

Type 2 diabetes

- ▶ Many patients are over 40 years of age and obese.
- ▶ Polyuria and polydipsia. Ketonuria and weight loss generally are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- ▶ Plasma glucose of 126 mg/dL or more after an overnight fast on more than one occasion. Two hours after 75 g oral glucose, diagnostic values are 200 mg/dL (11.1 mmol) or more.
- ▶ HbA_{1c} 6.5% or more.
- ▶ Hypertension, dyslipidemia, and atherosclerosis are often associated.

▶ Epidemiologic Considerations

An estimated 29.1 million people (9.3%) in the United States have diabetes mellitus, of which approximately 1.25 million have type 1 diabetes and most of the rest have type 2 diabetes. A third group designated as “other specific types” by the American Diabetes Association (ADA) (Table 27-1) number only in the thousands.

▶ Classification & Pathogenesis

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate for the resistance.

A. Type 1 Diabetes Mellitus

This form of diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process in over 95% of cases (type 1A) and idiopathic in less than 5% (type 1B). The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. Type 1 diabetes is usually associated with ketosis in its untreated state. It occurs at any age but most commonly arises in children and young adults with a peak incidence before school age and again at around puberty. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

1. Immune-mediated type 1 diabetes mellitus (type 1A)—Approximately one-third of the disease susceptibility is due to genes and two-thirds to environmental factors. Genes that are related to the HLA locus contribute about 40% of the genetic risk. About 95% of patients with type 1 diabetes possess either HLA-DR3 or HLA-DR4, compared with 45–50% of white controls. *HLA-DQ* genes are even more specific markers of type 1 susceptibility, since a particular variety (*HLA-DQB1*0302*) is found in the DR4 patients with type 1, while a “protective” gene (*HLA-DQB1*0602*) is often present in the DR4 controls. The other important gene that contributes to about 10% of the genetic risk is found at the 5′ polymorphic region of the insulin gene. Mutations in genes associated with T cell tolerance can also cause autoimmune diabetes. The autoimmune regulatory gene (*AIRE*) product regulates the expression of several proteins in the thymus causing the

Table 27–1. Other specific types of diabetes mellitus.

Genetic defects of pancreatic B cell function
MODY 1 (HNF-4alpha); rare
MODY 2 (glucokinase); less rare
MODY 3 (HNF-1alpha); accounts for two-thirds of all MODY
MODY 4 (PDX1); very rare
MODY 5 (HNF-1beta); very rare
MODY 6 (neuroD1); very rare
Mitochondrial DNA
Genetic defects in insulin action
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
Diseases of the exocrine pancreas
Endocrinopathies
Drug- or chemical-induced diabetes
Other genetic syndromes (Down, Klinefelter, Turner, others)
sometimes associated with diabetes

MODY, maturity-onset diabetes of the young; PDX1, pancreatic duodenal homeobox 1.

deletion of self-reactive T cells. Type 1 diabetes mellitus as well as other autoimmune disorders (autoimmune polyglandular syndrome 1) develop in 20% of individuals with homozygote mutations in *AIRE*. Most patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), glutamic acid decarboxylase 65 (GAD65), insulin (IAA), tyrosine phosphatase IA2 (ICA-512), and zinc transporter 8 (ZnT8) at the time the diagnosis is made (Table 27–2). These antibodies facilitate screening for an autoimmune cause of diabetes, particularly screening siblings of affected children, as well as adults with atypical features of type 2 diabetes mellitus. Also, low levels of anti-insulin antibodies develop in almost all patients once they are treated with insulin.

Family members of diabetic probands are at increased lifetime risk for developing type 1 diabetes mellitus. A child whose mother has type 1 diabetes has a 3% risk of developing the disease and a 6% risk if the child's father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the diabetic proband. If one haplotype is shared, the risk is 6% and if two haplotypes are

shared, the risk increases to 12–25%. The highest risk is for identical twins, where the concordance rate is 25–50%.

Some patients with a milder expression of type 1 diabetes mellitus initially retain enough B cell function to avoid ketosis, but as their B cell mass diminishes later in life, dependence on insulin therapy develops. Islet cell antibody surveys among northern Europeans indicate that up to 15% of “type 2” diabetic patients may actually have this mild form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA). Evidence for environmental factors playing a role in the development of type 1 diabetes include the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer and nearer to the equator. Also, the risk for type 1 diabetes increases when individuals who normally have a low risk emigrate to the Northern Hemisphere. For example, Pakistani children born and raised in Bradford, England have a higher risk for developing type 1 diabetes compared with children who lived in Pakistan all their lives.

Which environmental factor is responsible for the increased risk is not known. There have been a number of different hypotheses including infections with certain viruses (mumps, rubella, Coxsackie B4) and consumption of cow's milk. Also, in developed countries, childhood infections have become less frequent and so perhaps the immune system becomes dysregulated with development of autoimmunity and conditions such as asthma and diabetes. This theory is referred to as the **hygiene hypothesis**. Part of the difficulty in determining the causative environmental factor is that autoimmune injury is initiated many years before the clinical presentation of diabetes.

2. Idiopathic type 1 diabetes mellitus (type 1B)—Approximately 5% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoacidosis. This subgroup has been classified as “idiopathic type 1 diabetes” and designated as “type 1B.” Although only a minority of patients with type 1 diabetes fall into this group, most of these individuals are of Asian or African origin. About 4% of the West Africans with ketosis-prone diabetes are homozygous for a mutation in *PAX-4* (*Arg133Trp*)—a transcription factor that is essential for the development of pancreatic islets.

B. Type 2 Diabetes Mellitus

This represents a heterogeneous group of conditions that used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity (insulin resistance).

Genetic and environmental factors combine to cause both the insulin resistance and the beta cell loss. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever type 2 diabetes develops in one twin. So far, more than 30

Table 27–2. Diagnostic sensitivity and specificity of autoimmune markers in patients with newly diagnosed type 1 diabetes mellitus.

	Sensitivity	Specificity
ICA antibody	44–100%	96%
Glutamic acid decarboxylase (GAD65)	70–90%	99%
Insulin (IAA)	40–70%	99%
Tyrosine phosphatase (IA-2)	50–70%	99%
Zinc transporter 8 (ZnT8)	50–70%	99%

genetic loci have been associated with an increased risk of type 2 diabetes. A significant number of the identified loci appear to code for proteins that have a role in beta cell function or development. One of the genetic loci with the largest risk effect is *TCF7L2*. This gene codes for a transcription factor involved in the WNT signaling pathway that is required for normal pancreatic development.

Early in the disease process, hyperplasia of pancreatic B cells occurs and probably accounts for the fasting hyperinsulinism and exaggerated insulin and proinsulin responses to glucose and other stimuli. With time, chronic deposition of amyloid in the islets may combine with inherited genetic defects progressively to impair B cell function.

Obesity is the most important environmental factor causing insulin resistance. The degree and prevalence of obesity varies among different racial groups with type 2 diabetes. While obesity is apparent in no more than 30% of Chinese and Japanese patients with type 2, it is found in 60–70% of North Americans, Europeans, or Africans with type 2 and approaches 100% of patients with type 2 among Pima Indians or Pacific Islanders from Nauru or Samoa.

Visceral obesity, due to accumulation of fat in the omental and mesenteric regions, correlates with insulin resistance; subcutaneous abdominal fat seems to have less of an association with insulin insensitivity. There are many patients with type 2 diabetes who, while not overtly obese, have increased visceral fat; they are termed the “metabolically obese.” Exercise may affect the deposition of visceral fat as suggested by CT scans of Japanese wrestlers, whose extreme obesity is predominantly subcutaneous. Their daily vigorous exercise program prevents accumulation of visceral fat, and they have normal serum lipids and euglycemia despite daily intakes of 5000–7000 kcal and development of massive subcutaneous obesity.

C. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—This subgroup is a relatively rare monogenic disorder characterized by non-insulin-dependent diabetes with **autosomal dominant inheritance** and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described (Table 27–1). Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression.

2. Diabetes due to mutant insulins or insulin receptors—Less than 10 families have been described with a subtype of nonobese type 2 diabetes from mutant insulins. Since affected individuals were heterozygous and possessed one normal insulin gene, diabetes was mild, did not appear until middle age, and showed autosomal dominant genetic transmission. Defects in one of their insulin receptor genes have been found in more than 40 people with diabetes, and most have extreme insulin resistance associated with acanthosis nigricans (Figure 27–1). In very rare instances when both insulin receptor genes are abnormal, newborns present with a leprechaun-like phenotype and seldom live through infancy.

▲ **Figure 27–1.** Acanthosis nigricans of the nape of the neck, with typical dark and velvety appearance. (Used, with permission, from Umesh Masharani, MB, BS, MRCP (UK).)

3. Diabetes mellitus associated with a mutation of mitochondrial DNA—Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to mutations of mitochondrial DNA occurs in less than 2% of patients with diabetes. The most common cause is the A3243G mutation in the gene coding for the tRNA (Leu, UUR). Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]).

4. Wolfram syndrome—Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DIDMOAD. It is due to mutations in a gene named *WFS1*, which encodes a 100.3 kDa transmembrane protein localized in the endoplasmic reticulum. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

5. Autosomal recessive syndromes—Homozygous mutations in a number of pancreatic transcription factors, *NEUROG3*, *PTF1A*, *RFX6*, and *GLI-similar 3 (GLIS3)*, cause neonatal or childhood diabetes. Homozygous *PTF1A* mutations result in absent pancreas and cerebellar atrophy; *NEUROG3* mutations cause severe malabsorption and diabetes before puberty. Homozygous mutations in *RFX6* cause the Mitchell-Riley syndrome characterized by absence of all islet cell types apart from pancreatic polypeptide cells, hypoplasia of the pancreas and gallbladder, and intestinal atresia. *GLIS3* gene plays a role in transcription of insulin gene, and homozygous mutations cause neonatal diabetes and congenital hypothyroidism. The gene *EIF2AK3* encodes PKR-like ER kinase (PERK), which controls one of the pathways of the unfolded protein response. Absence of PERK leads to inadequate response to

ER stress and accelerated beta cell apoptosis. Patients with mutation in this gene have neonatal diabetes, epiphyseal dysplasia, developmental delay, and hepatic and renal dysfunction (Wolcott-Rallison syndrome).

6. Diabetes mellitus secondary to other causes—Endocrine tumors secreting growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin can cause glucose intolerance (Table 27–3). In the first four of these situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with somatostatin, inhibition of insulin secretion is the major factor. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is resolved.

High-titer anti-insulin receptor antibodies that inhibit insulin binding cause a clinical syndrome characterized by severe insulin resistance, glucose intolerance or diabetes mellitus, and acanthosis nigricans. These patients usually have other autoimmune disorders. There are reports of spontaneous remission or remission with cytotoxic therapy.

Many medications are associated with carbohydrate intolerance or frank diabetes (Table 27–3). The medications act by decreasing insulin secretion or by increasing insulin resistance or both. Cyclosporine and tacrolimus impair insulin secretion; sirolimus principally increases insulin resistance. These agents contribute to the development of new-onset diabetes after transplantation. Corticosteroids increase insulin resistance but may also have an effect on beta cell function; in a case control study and a large population cohort study, oral corticosteroids doubled the risk for development of diabetes. Thiazide diuretics and beta-blockers modestly increase the risk for diabetes. Treating the hypokalemia due to thiazides may reverse the hyperglycemia. Atypical antipsychotics, particularly olanzapine and clozapine, have been associated with increased

risk of glucose intolerance. These medications cause weight gain and insulin resistance but may also impair beta cell function; an increase in rates of diabetic ketoacidosis has been reported.

Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed.

► Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome)

Twenty-five percent of the general nonobese, nondiabetic population has insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant nondiabetic individuals are at much higher risk for developing type 2 diabetes than insulin-sensitive persons. In addition to diabetes, these individuals have a cluster of abnormalities termed **syndrome X** or **metabolic syndrome** that significantly increases their risk of atherosclerotic disease: elevated plasma triglycerides and small, dense, low-density lipoproteins (LDL); lower high-density lipoproteins (HDLs); higher blood pressure; hyperuricemia; abdominal obesity; prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1); and proinflammatory state.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. Although hyperinsulinism and hypertension often coexist in whites, that is not the case in blacks or Pima Indians. Moreover, patients with hyperinsulinism due to insulinoma are not hypertensive, and there is no fall in blood pressure after surgical removal of the insulinoma restores normal insulin levels. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients.

American Diabetes Association. Standards of medical care in diabetes—2016. *Diabetes Care*. 2016 Jan;39(Suppl):S1–119. [PMID: 26696680]

Table 27–3. Secondary causes of hyperglycemia.

Hyperglycemia due to tissue insensitivity to insulin
Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma)
Pharmacologic agents (corticosteroids, sympathomimetic drugs, niacin)
Liver disease (cirrhosis, hemochromatosis)
Muscle disorders (myotonic dystrophy)
Adipose tissue disorders (lipodystrophy, truncal obesity)
Insulin receptor disorders (acanthosis nigricans syndromes, leprechaunism)
Hyperglycemia due to reduced insulin secretion
Hormonal tumors (somatostatinoma, pheochromocytoma)
Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis)
Pharmacologic agents (thiazide diuretics, phenytoin, pentamidine, calcineurin inhibitors)

► Clinical Findings

A. Symptoms and Signs

1. Type 1 diabetes—A characteristic symptom complex of hyperosmolality and hyperketonemia from the accumulation of circulating glucose and fatty acids typically presents in patients with type 1 diabetes who have an absolute deficiency of insulin. Increased urination and thirst are consequences of osmotic diuresis secondary to sustained hyperglycemia. The diuresis results in a loss of glucose as well as free water and electrolytes in the urine. Blurred vision often develops as the lenses are exposed to hyperosmolar fluids.

Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces symptoms of postural hypotension. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.

When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.

The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mOsm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of diabetic ketoacidosis.

Hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted.

2. Type 2 diabetes—While increased urination and thirst may be presenting symptoms in some patients with type 2 diabetes, many other patients have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, when the disease has been occult for some time, patients with type 2 diabetes may have evidence of neuropathic or cardiovascular complications at the time of presentation. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis as well as in those who have delivered babies larger than 9 lb (4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses. Balanoposthitis (inflammation of the foreskin and glans in uncircumcised males) may occur.

Many patients with type 2 diabetes are overweight or obese. Even those who are not significantly obese often have characteristic localization of fat deposits on the upper segment of the body (particularly the abdomen, chest,

neck, and face) and relatively less fat on the appendages, which may be quite muscular. This centripetal fat distribution is characterized by a high waist circumference; a waist circumference larger than 40 inches (102 cm) in men and 35 inches (88 cm) in women is associated with an increased risk of diabetes. Some patients may have acanthosis nigricans, which is associated with significant insulin resistance; the skin in the axilla, groin, and back of neck is hyperpigmented and hyperkeratotic (Figure 27-1). Mild hypertension is often present in obese patients with diabetes. Eruptive xanthomas on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia.

Hyperglycemic hyperosmolar coma can also be present; in these cases, patients are profoundly dehydrated, hypotensive, lethargic or comatose but without Kussmaul respirations.

B. Laboratory Findings

1. Urine glucose—A specific and convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 100 mg/dL (5.5 mmol) glucose in urine. Diastix can be directly applied to the urinary stream, and differing color responses of the indicator strip reflect glucose concentration.

A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation.

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from mutations in the *SGLT2* gene coding for sodium-glucose transporter 2 (familial renal glycosuria) to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, chronic kidney disease), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate (GFR) during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

2. Urine and blood ketones—Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect beta-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories measure beta-hydroxybutyric acid, and there are meters available (Precision Xtra; Nova Max Plus) for patient use that measures beta-hydroxybutyric acid levels in capillary glucose samples. Beta-hydroxybutyrate levels greater than 0.6 mmol/L require evaluation. Patients with levels greater than 3.0 mmol/L, equivalent to very large urinary ketones, require hospitalization.

3. Plasma or serum glucose—The glucose concentration is 10–15% higher in plasma or serum than in whole blood

Table 27–4. Criteria for the diagnosis of diabetes.

	Normal Glucose Tolerance	Impaired Glucose Tolerance	Diabetes Mellitus ²
Fasting plasma glucose mg/dL (mmol/L)	< 100 (5.6)	100–125 (5.6–6.9)	≥ 126 (7.0)
Two hours after glucose load ¹ mg/dL (mmol/L)	< 140 (7.8)	≥ 140–199 (7.8–11.0)	≥ 200 (11.1)
HbA _{1c} (%)	< 5.7	5.7–6.4	≥ 6.5

¹Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before the test.

²A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) or HbA_{1c} of ≥ 6.5% is diagnostic of diabetes if confirmed by repeat testing.

because structural components of blood cells are absent. A plasma glucose level of 126 mg/dL (7 mmol/L) or higher on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 27–4). Fasting plasma glucose levels of 100–125 mg/dL (5.6–6.9 mmol/L) are associated with increased risk of diabetes (impaired fasting glucose tolerance).

4. Oral glucose tolerance test—If the fasting plasma glucose level is less than 126 mg/dL (7 mmol/L) when diabetes is nonetheless suspected, then a standardized oral glucose tolerance test may be done (Table 27–4). In order to optimize insulin secretion and effectiveness, especially when patients have been on a low-carbohydrate diet, a minimum of 150–200 g of carbohydrate per day should be included in the diet for 3 days preceding the test. The patient should eat nothing after midnight prior to the test day. On the morning of the test, adults are then given 75 g of glucose in 300 mL of water; children are given 1.75 g of glucose per kilogram of ideal body weight. The glucose load is consumed within 5 minutes. The test should be performed in the morning because there is some diurnal variation in oral glucose tolerance, and patients should not smoke or be active during the test.

Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. An oral glucose tolerance test is normal if the fasting venous plasma glucose value is less than 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). A fasting value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of greater than 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus. Patients with 2-hour value of 140–199 mg/dL (7.8–11.1 mmol/L) have impaired glucose tolerance. False-positive results may occur in patients who are malnourished, bedridden, or afflicted with an infection or severe emotional stress.

5. Glycated hemoglobin (hemoglobin A1) measurements—Hemoglobin becomes glycated by ketoamine reactions between glucose and other sugars and the free

amino groups on the alpha and beta chains. Only glycation of the N-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge dependent techniques. These charge separated hemoglobins are collectively referred to as hemoglobin A₁ (HbA₁). The major form of HbA₁ is hemoglobin A_{1c} (HbA_{1c}) where glucose is the carbohydrate. HbA_{1c} comprises 4–6% of total hemoglobin A₁. HbA_{1c} is abnormally elevated in diabetic persons with chronic hyperglycemia. Office-based immunoassays using capillary blood give a result in about 9 minutes and this allows for nearly immediate feedback to the patients regarding their glycemic control.

Since glycohemoglobins circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycemia over the preceding 8–12 weeks, thereby providing an improved method of assessing diabetic control. The HbA_{1c} value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA_{1c} are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals. In patients monitoring their own blood glucose levels, HbA_{1c} values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, HbA_{1c} values are essential for adjusting therapy. There is a linear relationship between the HbA_{1c} and the average glucose levels in the previous 3 months. In a study using a combination of intermittent seven-point capillary blood glucose profiles (preprandial, postprandial, and bedtime) and intermittent continuous glucose monitoring data, the change in glucose values was 28.7 mg/dL for every 1% change in HbA_{1c}. Substantial individual variability exists, however, between HbA_{1c} and mean glucose concentration. For HbA_{1c} values between 6.9% and 7.1%, the glucose levels ranged from 125 mg/dL to 205 mg/dL (6.9–11.4 mmol/L; 95% CIs). For HbA_{1c} of 6%, the mean glucose levels ranged from 100 mg/dL to 152 mg/dL (5.5–8.5 mmol/L); and for 8% they ranged from 147 mg/dL to 217 mg/dL (8.1–12.1 mmol/L). For this reason, caution should be exercised in estimating average glucose levels from measured HbA_{1c}.

The accuracy of HbA_{1c} values can be affected by hemoglobin variants or traits; the effect depends on the specific hemoglobin variant or derivative and the specific assay used. In patients with high levels of hemoglobin F, immunoassays give falsely low values of HbA_{1c}. The National Glycohemoglobin Standardization Program website (www.ngsp.org) has information on the impact of frequently encountered hemoglobin variants and traits on the results obtained with the commonly used HbA_{1c} assays.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA_{1c} irrespective of the assay method used. Intravenous iron and erythropoietin therapy for treatment of anemia in chronic kidney disease also falsely lower HbA_{1c} levels. Alternative methods such as fructosamine should be considered for these patients. Vitamins C and E are reported to

falsely lower test results possibly by inhibiting glycation of hemoglobin. Conditions that increase erythrocyte survival such as splenectomy for hereditary spherocytosis will falsely raise HbA_{1c} levels. Iron deficiency anemia is also associated with higher HbA_{1c} levels.

HbA_{1c} is endorsed by the ADA as a diagnostic test for type 1 and type 2 diabetes (Table 27-4). A cutoff value of 6.5% was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA_{1c} to diagnose diabetes is that there is no need to fast; it has lower intraindividual variability than the fasting glucose test and the oral glucose tolerance test; and it provides an estimate of glucose control for the preceding 2–3 months. People with HbA_{1c} levels of 5.7–6.4% should be considered at high risk for developing diabetes (prediabetes). The diagnosis should be confirmed with a repeat HbA_{1c} test, unless the patient is symptomatic with plasma glucose levels greater than 200 mg/dL (11.1 mmol/L). This test is not appropriate to use in populations with high prevalence of hemoglobinopathies or in conditions with increased red cell turnover. Also, the testing is performed using a National Glycohemoglobin Standardization Program (NGSP) certified method and standardized to the Diabetes Control and Complication Trial assay. In the European Union, the tests are standardized to the International Federation of Clinical Chemistry (IFCC), which defines HbA_{1c} as mmol glycated hexapeptide per mol (glycated and nonglycated hexapeptides) and reported as mmol HbA_{1c}/mol Hb. The conversion factor for NGSP and IFCC results is NGSP (USA) result = (0.09148*IFCC result) + 2.152. There is worldwide consensus that HbA_{1c} should be reported in both NGSP (%) and IFCC (mmol/mol) units.

6. Serum fructosamine—Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 1–2 weeks. Reductions in serum albumin (eg, nephrotic state, protein-losing enteropathy, or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 200–285 μmol/L when the serum albumin level is 5 g/dL. HbA_{1c} values and serum fructosamine are highly correlated. Serum fructosamine levels of 300, 367, and 430 μmol/L approximate to HbA_{1c} values of 7%, 8%, and 9%, respectively. Substantial individual variability exists, though, when estimating the likely HbA_{1c} value from the fructosamine measurement.

7. Self-monitoring of blood glucose—Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom “tight” metabolic control is attempted, they are indispensable. There are several paper strip (glucose

oxidase, glucose dehydrogenase, or hexokinase) methods for measuring glucose on capillary blood samples. A reflectance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, reporting capability, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Breeze, Contour), Roche Diagnostics (Accu-Chek), Sanofi Aventis (iBGStar), and Abbott Laboratories (Precision, FreeStyle). These blood glucose meters are relatively inexpensive, ranging from \$50 to \$100 each. Test strips remain a major expense, costing about \$.25 to \$1.50 apiece. Each glucose meter also comes with a lancet device and disposable 26- to 33-gauge lancets. Most meters can store from 100 to 1000 glucose values in their memories and have capabilities to download the values into a computer spreadsheet for review by the patients and their health care team. iBGStar is a glucose meter that connects directly to the iPhone. Some meters are designed to communicate with a specific insulin pump. Contour Next Link meter, for example, communicates with the MiniMed Medtronic pump). The accuracy of data obtained by home glucose monitoring does require education of the patient in sampling and measuring procedures as well as in properly calibrating the instruments.

The clinician should be aware of the limitations of the self-monitoring glucose systems. The strips have limited lifespans and improper storage (high temperature; open vial) can affect their function. Patients should also be advised not to use expired strips. Some of the older meters require input of a code for each batch of strips and failure to enter the code can result in misleading results. The newer meters no longer require this step. Increases or decreases in hematocrit can decrease or increase the measured glucose values. The mechanism underlying this effect is not known but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Meters and the test strips are calibrated over the glucose concentrations ranging from 60 mg/dL (3.3 mmol/L) to 160 mg/dL (8.9 mmol/L) and the accuracy is not as good for higher and lower glucose levels. When the glucose is less than 60 mg/dL (3.3 mmol/L), the difference between the meter and the laboratory value may be as much as 20%. Glucose oxidase–based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in the critically ill who are receiving supplemental oxygen; under these circumstances, a glucose dehydrogenase–based system may be preferable. Glucose dehydrogenase pyrroloquinoline quinone (GDH-PQQ) systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a

delay in detection of rapidly developing hypoglycemia. Impaired circulation to the fingers (for example, in patients with Raynaud disease) will artificially lower finger-stick glucose measurements (pseudohypoglycemia).

8. Continuous glucose monitoring systems—A number of continuous glucose monitoring systems are available for clinical use. The systems manufactured by Medtronic Minimed, DexCom systems, and Abbott Diagnostics (outside the United States), involve inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3–7 days. The MiniMed system can only be used in conjunction with the Minimed pump and the glucose data are displayed on the screen of the pump. The DexCom system transmits glucose data wirelessly to a separate pager-like device with a screen. The DexCom system also has the option of displaying data on smart phones or smart watches or on the screens of several insulin pumps. The systems allow the patient to set “alerts” for low and high glucose values and rate of change of glucose levels. Patients still have to calibrate the devices with periodic fingerstick glucose levels, and since there are concerns regarding reliability, it is still necessary to confirm the displayed glucose level with a fingerstick glucose before making interventions such as injecting extra insulin or eating extra carbohydrates. A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of continuous glucose monitoring during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. The MiniMed insulin pump can be programmed to automatically suspend insulin delivery for up to 2 hours when the glucose levels on its continuous glucose monitoring device falls to a preset level and the patient does not respond to the alert. This insulin suspension feature has been shown to reduce the amount of time patients are in the hypoglycemic range at night. Many of these systems are covered by insurance. The initial cost is about \$800 to \$1000, and the sensor, which has to be changed every 3 to 7 days, costs \$35 to \$60; the out-of-pocket expense of about \$4000 annually.

There is great interest in using the data obtained from these continuous glucose monitoring systems to automatically deliver insulin by continuous subcutaneous insulin infusion pump. Algorithms have been devised to link continuous glucose monitoring to insulin delivery. These closed loop systems (artificial pancreas) have been shown in short-term clinical studies to improve nighttime glucose control and reduce the risk of nocturnal hypoglycemia.

9. Lipoprotein abnormalities in diabetes—Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient

control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in patients with type 2 diabetes, a distinct “diabetic dyslipidemia” is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300–400 mg/dL [3.4–4.5 mmol/L]), a low HDL cholesterol (less than 30 mg/dL [0.8 mmol/L]), and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Since a low HDL cholesterol is a major feature predisposing to macrovascular disease, the term “dyslipidemia” has preempted the term “hyperlipidemia,” which mainly denoted the elevated triglycerides. Measures designed to correct the obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. Chapter 28 discusses these matters in detail.

Haidar A et al. Comparison of dual-hormone artificial pancreas, single-hormone artificial pancreas, and conventional insulin pump therapy for glycaemic control in patients with type 1 diabetes: an open-label randomised controlled crossover trial. *Lancet Diabetes Endocrinol.* 2015 Jan;3(1):17–26. [PMID: 25434967]

► Clinical Trials in Diabetes

Findings of the Diabetes Complications and Control Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS), have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes.

The Diabetes Control and Complications Trial, a long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus, reported that “near” normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA_{1c} determinations or the glucose results.

In half of the patients, a mean hemoglobin A_{1c} of 7.2% (normal: less than 6%) and a mean blood glucose of 155 mg/dL (8.6 mmol/L) were achieved using intensive therapy, while in the conventionally treated group HbA_{1c} averaged 8.9% with an average blood glucose of 225 mg/dL

(12.5 mmol/L). Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, -10 to 68). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Even though the between-group differences in mean HbA_{1c} narrowed over 4 years, the group assigned to intensive therapy had a lower risk of retinopathy at 4 years, microalbuminuria at 7 to 8 years, and impaired GFR (less than 60 mL/min/1.73 m²) at 22 years of continued study follow-up. Moreover, by the end of the 11-year follow-up period, the intensive therapy group had significantly reduced their risk of any cardiovascular disease events by 42% (95% CI, 9% to 23%; *P* = 0.02). Thus, it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and the elderly, since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control.

The Diabetes Prevention Program was aimed at discovering whether treatment with either diet and exercise or metformin could prevent the onset of type 2 diabetes in people with impaired glucose tolerance; 3234 overweight men and women aged 25–85 years with impaired glucose tolerance participated in the study. Intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduced the risk of progression to type 2 diabetes by 71% compared with a matched control group. Participants taking 850 mg of metformin twice a day reduced their risk of developing type 2 diabetes by 31%, but this intervention was relatively ineffective in those who were either less obese or in the older age group.

With the demonstration that intervention can be successful in preventing progression to diabetes in these subjects, a recommendation has been made to change the terminology from the less comprehensible “impaired glucose tolerance” to “prediabetes.” The latter is a term that the public can better understand and thus respond to by implementing healthier diet and exercise habits.

The United Kingdom Prospective Diabetes Study, a multicenter study, was designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage.

Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreased the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No adverse cardiovascular outcomes were noted regardless of the therapeutic agent. In the overweight or obese subgroup, metformin therapy was more beneficial than diet alone in reducing the number of cases that progressed to diabetes as well as decreasing the number of patients who suffered myocardial infarctions and strokes. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

Tight control of blood pressure (median value 144/82 mm Hg vs 154/87 mm Hg) substantially reduced the risk of microvascular disease and stroke but not myocardial infarction. In fact, reducing blood pressure by this amount had substantially greater impact on microvascular outcomes than that achieved by lowering HbA_{1c} from 7.9% to 7%. An epidemiologic analysis of the UKPDS data did show that every 10 mm Hg decrease in updated mean systolic blood pressure was associated with 11% reduction in risk for myocardial infarction. More than half of the patients needed two or more medications for adequate therapy of their hypertension, and there was no demonstrable advantage of angiotensin-converting enzyme (ACE) inhibitor therapy over therapy with beta-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the literature about its safety in patients with diabetes.

Like the DCCT trialists, the UKPDS researchers performed post-trial monitoring to determine whether there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The intensively treated group had significantly reduced risk of myocardial infarction (15%, *P* = 0.01) and death from any cause (13%, *P* = 0.007) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. Unlike the sustained benefits seen with glucose control, there were no sustained benefits from having been in the more tightly controlled blood pressure group. Both blood pressure groups were at similar risk for microvascular events and diabetes-related end points during the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

The Steno-2 study was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors

(diet, smoking cessation, exercise, and pharmacologic interventions) for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded end point design was used where 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. The intensively treated group had stepwise introduction of lifestyle and pharmacologic interventions aimed at keeping glycated hemoglobin less than 6.5%, blood pressure lower than 130/80 mm Hg; total cholesterol under 175 mg/dL (4.5 mmol/L), and triglycerides less than 150 mg/dL (1.7 mmol/L). All the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II-receptor blocker. The lifestyle component of intensive intervention included reduction in dietary fat intake to less than 30% of total calories; smoking cessation program; light to moderate exercise; daily vitamin-mineral supplement of vitamin C, E, and chromium picolinate. Initially, aspirin was only given as secondary prevention to patients with a history of ischemic cardiovascular disease; later, all patients received aspirin. After a mean follow-up of 7.8 years, cardiovascular events (eg, myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions) developed in 44% of patients in the conventional arm and only in 24% in the intensive multifactorial arm—about a 50% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm by 62% and 63%, respectively.

The data from the UKPDS and this study provide support for guidelines recommending vigorous treatment of concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

Results from three subsequent trials, the ACCORD, ADVANCE, and VADT, do not provide support for the hypothesis that near-normal glucose control in patients with type 2 diabetes will reduce cardiovascular events. It is, however, important not to over-interpret the results of these three studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of post-trial follow-up. Specific subgroups of type 2 diabetic patients may also have different outcomes. The ACCORD, ADVANCE, and VADT studies recruited patients who had diabetes for 8–10 years and one-third of them already had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD, ADVANCE, and VADT studies; the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in the intensive treatment group.

A formal meta-analysis performed of the raw trial data from the ACCORD, ADVANCE, VADT, and UKPDS studies found that allocation to more intensive glucose control reduced the risk of myocardial infarction by 15% (hazard ratio 0.85, 95% CI 0.76–0.94). This benefit occurred in patients who did not have preexisting macrovascular disease.

► Treatment Regimens

A. Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. There is no specific recommendation on the percentage of calories that should come from carbohydrate, protein, and fat. The macronutrient proportions should be individualized based on the patient's eating patterns, preferences, and metabolic goals. In general, most patients with diabetes consume about 45% of their total daily calories in the form of carbohydrates, 25–35% in the form of fat, and 10–35% in the form of protein. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. A Mediterranean-style eating pattern (a diet supplemented with walnuts, almonds, hazelnuts, and olive oil) has been shown to improve glycemic control and lower combined endpoints for cardiovascular events and stroke. In those patients with obesity and type 2 diabetes, weight reduction by caloric restriction is an important goal of the diet (see Chapter 29). Patients with type 1 diabetes or type 2 diabetes who take insulin should be taught “carbohydrate counting,” so they can administer their insulin bolus for each meal based on its carbohydrate content.

The current recommendations for saturated fats and dietary cholesterol intake for people with diabetes are the same as for the general population. Saturated fats should be limited to less than 10% of daily calories and dietary cholesterol intake should be less than 300 mg/day. For those patients with kidney disease, dietary protein should be maintained at the recommended daily allowance of 0.8g/kg/day. Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association (<http://www.eatright.org>), 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040).

1. Dietary fiber—Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary “fiber.” Insoluble fibers such as cellulose or

hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

2. Glycemic index—The glycemic index of a carbohydrate containing food is determined by comparing the glucose excursions after consuming 50 g of test food with glucose excursions after consuming 50 g of reference food (white bread):

$$\text{Glycemic index} = \frac{\text{Blood glucose area under the curve (3h) for test food}}{\text{Blood glucose area under the curve (3h) for reference food}} \times 100$$

Eating low glycemic index foods results in lower glucose levels after meals. Low glycemic index foods have values of 55 or less and include many fruits, vegetables, grainy breads, pasta, and legumes. High glycemic index foods have values of 70 or greater and include baked potato, white bread, and white rice. Glycemic index is lowered by presence of fats and protein when food is consumed in a mixed meal. Even though it may not be possible to accurately predict the glycemic index of a particular food in the context of a meal, it is reasonable to choose foods with low glycemic index.

3. Artificial and other sweeteners—Saccharin (Sweet 'N Low), sucralose (Splenda), acesulfame potassium (Sweet One), and rebiana (Truvia) are “artificial” sweeteners that can be used in cooking and baking. Aspartame (NutraSweet) lacks heat stability, so it cannot be used in cooking. None of these sweeteners raise blood glucose levels.

Fructose represents a “natural” sugar substance that is a highly effective sweetener, induces only slight increases in plasma glucose levels, and does not require insulin for its metabolism. However, because of potential adverse effects of large amounts of fructose on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much. Therefore, sugar

alcohols are often used in food products that are labeled as “sugar free,” such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can cause bloating and diarrhea.

B. Medications for Treating Hyperglycemia

The medications for treating type 2 diabetes are listed in Table 27–5.

1. Medications that primarily stimulate insulin secretion by binding to the sulfonylurea receptor on the beta cell—

A. SULFONYLUREAS—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells. Specific receptors on the surface of pancreatic B cells bind sulfonylureas in the rank order of their insulinotropic potency (glyburide with the greatest affinity and tolbutamide with the least affinity). It has been shown that activation of these receptors closes potassium channels, resulting in depolarization of the B cell. This depolarized state permits calcium to enter the cell and actively promote insulin release.

Sulfonylureas are used in patients with type 2 but not type 1 diabetes, since these medications require functioning pancreatic B cells to produce their effect on blood glucose. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Sulfonylureas are generally contraindicated in patients with severe liver or kidney impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

(1) First-generation sulfonylureas (tolbutamide, tolazamide, acetohexamide, chlorpropamide)—**Tolbutamide** is rapidly oxidized in the liver to inactive metabolites, and its approximate duration of effect is relatively short (6–10 hours). Tolbutamide is probably best administered in divided doses (eg, 500 mg before each meal and at bedtime); however, some patients require only one or two tablets daily with a maximum dose of 3000 mg/day. Because of its short duration of action, which is independent of kidney function, tolbutamide is relatively safe to use in kidney impairment. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving certain antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal medications to treat candidiasis. These medications apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

Table 27-5. Drugs for treatment of type 2 diabetes mellitus.

Drug	Tablet Size	Daily Dose	Duration of Action
Sulfonylureas			
Acetohexamide (Dymelor)	250 and 500 mg	0.25–1.5 g as single dose or in two divided doses	8–24 hours
Chlorpropamide (Diabinese)	100 and 250 mg	0.1–0.5 g as single dose	24–72 hours
Gliclazide (not available in United States)	80 mg	40–80 mg as single dose; 160–320 mg as divided dose	12 hours
Glimepiride (Amaryl)	1, 2, and 4 mg	1–4 mg once a day is usual dose; 8 mg once a day is maximal dose	Up to 24 hours
Glipizide			
(Glucotrol)	5 and 10 mg	2.5–40 mg as a single dose or in two divided doses 30 minutes before meals	6–12 hours
(Glucotrol XL)	2.5, 5, and 10 mg	2.5 to 10 mg once a day is usual dose; 20 mg once a day is maximal dose	Up to 24 hours
Glyburide			
(Dia Beta, Micronase)	1.25, 2.5, and 5 mg	1.25–20 mg as single dose or in two divided doses	Up to 24 hours
(Glynase)	1.5, 3, and 6 mg	1.5–12 mg as single dose or in two divided doses	Up to 24 hours
Tolazamide (Tolinase)	100, 250, and 500 mg	0.1–1 g as single dose or in two divided doses	Up to 24 hours
Tolbutamide (Orinase)	250 and 500 mg	0.5–2 g in two or three divided doses	6–12 hours
Meglitinide analogs			
Mitiglinide (available in Japan)	5 and 10 mg	5 or 10 mg three times a day before meals	2 hours
Repaglinide (Prandin)	0.5, 1, and 2 mg	0.5 to 4 mg three times a day before meals	3 hours
D-Phenylalanine derivative			
Nateglinide (Starlix)	60 and 120 mg	60 or 120 mg three times a day before meals	1.5 hours
Biguanides			
Metformin (Glucophage)	500, 850, and 1000 mg	1–2.5 g; 1 tablet with meals two or three times daily	7–12 hours
Extended-release metformin (Glucophage XR)	500 and 750 mg	500–2000 mg once a day	Up to 24 hours
Thiazolidinediones			
Pioglitazone (Actos)	15, 30, and 45 mg	15–45 mg daily	Up to 24 hours
Rosiglitazone (Avandia)	2, 4, and 8 mg	4–8 mg daily (can be divided)	Up to 24 hours
Alpha-glucosidase inhibitors			
Acarbose (Precose)	50 and 100 mg	25–100 mg three times a day just before meals	4 hours
Miglitol (Glyset)	25, 50, and 100 mg	25–100 mg three times a day just before meals	4 hours
Voglibose (not available in United States)	0.2 and 0.3 mg	0.2–0.3 mg three times a day just before meals	4 hours
GLP-1 receptor agonists			
Exenatide (Byetta)	1.2 mL and 2.4 mL pre-filled pens containing 5 mcg and 10 mcg (subcutaneous injection)	5 mcg subcutaneously twice a day within 1 hour of breakfast and dinner. Increase to 10 mcg subcutaneously twice a day after about a month. Do not use if calculated creatinine clearance is < 30 mL/min.	6 hours
Exenatide, long-acting release (Byetta LAR, Bydureon)	2 mg (powder)	Suspend in provided diluent and inject subcutaneously.	1 week
Liraglutide (Victoza)	Pre-filled, multi-dose pen that delivers doses of 0.6 mg, 1.2 mg, or 1.8 mg	0.6 mg subcutaneously once a day (starting dose). Increase to 1.2 mg after a week if no adverse reactions. Dose can be further increased to 1.8 mg, if necessary.	24 hours
Albiglutide (Tanzeum)	30, 50 mg single dose pen (powder)	Mix with diluent and inject subcutaneously. 30 mg is usual dose. Dose can be increased to 50 mg if necessary.	1 week

(continued)

Table 27-5. Drugs for treatment of type 2 diabetes mellitus. (Continued)

Drug	Tablet Size	Daily Dose	Duration of Action
Dulaglutide (Trulicity)	0.75, 1.5 mg single dose pen or prefilled syringe	0.75 mg subcutaneously. Dose can be increased to 1.5 mg if necessary.	1 week
DPP-4 inhibitors			
Alogliptin (Nesina)	6.25, 12.5, and 25 mg	25 mg once daily; dose is 12.5 mg daily if calculated creatinine clearance is 30–59 mL/min and 6.25 mg daily if clearance < 30 mL/min.	24 hours
Saxagliptin (Onglyza)	2.5 and 5 mg	2.5 mg or 5 mg once daily. Use 2.5 mg dose if calculated creatinine clearance is ≤ 50 mL/min or if also taking drugs that are strong CYP3A4/5 inhibitors such as ketoconazole.	24 hours
Sitagliptin (Januvia)	25, 50, and 100 mg	100 mg once daily is usual dose; dose is 50 mg once daily if calculated creatinine clearance is 30 to 50 mL/min and 25 mg once daily if clearance is < 30 mL/min.	24 hours
Vildagliptin (Galvus) (not available in United States)	50 mg	50 mg once or twice daily. Contraindicated in patients with calculated creatinine clearance ≤ 60 mL/min or AST/ALT three times upper limit of normal.	24 hours
Linagliptin (Tradjenta)	5 mg	5 mg daily	24 hours
SGLT2 inhibitors			
Canagliflozin (Invokana)	100 and 300 mg	100 mg daily is usual dose. Do not use if eGFR < 45 mL/min/1.72 m ² . 300 mg dose can be used if normal eGFR, resulting in lowering the HbA _{1c} an additional ~ 0.1–0.25%.	24 hours
Dapagliflozin (Farxiga)	5 and 10 mg	10 mg daily. Use 5 mg dose in hepatic failure.	24 hours
Empagliflozin (Jardiance)	10 and 25 mg	10 mg daily. 25 mg dose can be used if necessary.	24 hours
Others			
Bromocriptine (Cycloset)	0.8 mg	0.8 mg daily. Increase weekly by 1 tablet until maximal tolerated dose of 1.6–4.8 mg daily.	24 hours
Colesevelam (Welchol)	625 mg	3 tablets twice a day	24 hours
Pramlintide (Symlin)	5 mL vial containing 0.6 mg/mL; also available as prefilled pens. Symlin pen 60 or Symlin pen 120 (subcutaneous injection)	For insulin-treated type 2 patients, start at 60 mcg dose three times a day (10 units on U100 insulin syringe). Increase to 120 mcg three times a day (20 units on U100 insulin syringe) if no nausea for 3–7 days. Give immediately before meal. For type 1 patients, start at 15 mcg three times a day (2.5 units on U100 insulin syringe) and increase by increments of 15 mcg to a maximum of 60 mcg three times a day, as tolerated. To avoid hypoglycemia, lower insulin dose by 50% on initiation of therapy.	2 hours

AST/ALT, aspartate aminotransferase/alanine aminotransferase; eGFR, estimated glomerular filtration rate.

(2) **Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)**—Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. These medications should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

The usual starting dose of **glyburide** is 2.5 mg/day, and the average maintenance dose is 5–10 mg/day given as a single morning dose; maintenance doses higher than 20 mg/day are not recommended. Some reports suggest that 10 mg is a maximum daily therapeutic dose, with 15–20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia.

A “Press Tab” formulation of “micronized” glyburide—easy to divide in half with slight pressure if necessary—is available. Glyburide is metabolized in the liver into products with hypoglycemic activity, which probably explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1–2 hours, yet the biologic effects of glyburide are clearly persistent 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide should not be used in patients with liver failure and chronic kidney disease because of the risk of hypoglycemia. Elderly patients are at particular risk for hypoglycemia even with relatively small daily doses.

The recommended starting dose of **glipizide** is 5 mg/day, with up to 15 mg/day given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be less effective than smaller doses. For maximum effect in reducing postprandial hyperglycemia, glipizide should be ingested 30 minutes before meals, since rapid absorption is delayed when the medication is taken with food.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy should therefore not be used in patients with liver failure. Because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients and for those patients with kidney disease. Glucotrol-XL provides extended release of glipizide during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. The recommended starting dose is 40–80 mg/day with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The medication is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride has a long duration of effect with a half-life of 5 hours allowing once or twice daily dosing. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/day has been shown to be effective, and the

maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

B. MEGLITINIDE ANALOGS—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the adenosine triphosphate (ATP)-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The medication therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximum daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the medication was compared with a long-duration sulfonylurea (glyburide), there was a trend toward less hypoglycemia. Like the sulfonylureas, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other medications that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The medication may be useful in patients with kidney impairment or in the elderly.

Mitiglinide is a benzylsuccinic acid derivative that binds to the sulfonylurea receptor and is similar to repaglinide in its clinical effects. It is approved for use in Japan.

C. D-PHENYLALANINE DERIVATIVE—Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. This compound is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Use 60 mg in patients who have mild elevations in HbA_{1c}. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

2. Medications that primarily lower glucose levels by their actions on the liver, muscle, and adipose tissue—

A. METFORMIN—Metformin (1,1-dimethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes.

Metformin's therapeutic effects primarily derive from the increasing hepatic adenosine monophosphate-activated protein kinase activity, which reduces hepatic gluconeogenesis and lipogenesis.

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins or metabolized, being excreted unchanged by the kidneys.

Metformin is the first-line therapy for patients with type 2 diabetes. The current recommendation is to start this medication at diagnosis. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese

patients with diabetes without the weight gain associated with insulin or sulfonylurea therapy. Metformin is ineffective in patients with type 1 diabetes. Patients with chronic kidney disease should not be given this medication because failure to excrete it would produce high blood and tissue levels of metformin that could stimulate lactic acid overproduction. In the United States, metformin use is not recommended at or above a serum creatinine level of 1.4 mg/dL in women and 1.5 mg/dL in men. In the United Kingdom, the recommendations are to review metformin use when the serum creatinine exceeds 130 $\mu\text{mol/L}$ (1.5 mg/dL) or the estimated glomerular filtration rate (eGFR) falls below 45 mL/min per 1.73 m². The medication should be stopped if the serum creatinine exceeds 150 $\mu\text{mol/L}$ (1.7 mg/dL) or the eGFR is below 30 mL/min per 1.73 m². Patients with liver failure or persons with excessive alcohol intake should not receive this medication—lactic acid production from the gut and other tissues, which rises during metformin therapy, could result in lactic acidosis when defective hepatocytes cannot remove the lactate or when alcohol-induced reduction of nucleotides interferes with lactate clearance.

The maximum dosage of metformin is 2550 mg, although little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500 mg tablet three times a day with meals or one 850 mg or 1000 mg tablet twice daily at breakfast and dinner. Up to 2000 mg of the extended-release preparation can be given once a day. Lower doses should be used in patients with eGFRs between 30 and 45 mL/min per 1.73 m².

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3–5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients switched from immediate-release metformin to comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a “euglycemic” or “antihyperglycemic” medication rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare. Metformin interferes with the calcium dependent absorption of vitamin B₁₂-intrinsic complex in the terminal ileum; vitamin B₁₂ deficiency can occur after many years of metformin use. Periodic screening with vitamin B₁₂ levels should be considered, especially in patients with peripheral neuropathy or if a macrocytic anemia develops. Increased intake of dietary calcium may prevent the metformin-induced B₁₂ malabsorption.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. Almost all reported cases have involved persons with associated risk factors that should have contraindicated its use

(kidney, liver, or cardiorespiratory insufficiency; alcoholism; advanced age). Acute kidney injury can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of radiocontrast administration and restarted a day or two later after confirmation that renal function has not deteriorated.

B. THIAZOLIDINEDIONES—Two medications of this class, rosiglitazone and pioglitazone, are available for clinical use. These medications sensitize peripheral tissues to insulin. They bind a nuclear receptor called peroxisome proliferator-activated receptor gamma (PPAR-gamma) and affect the expression of a number of genes. Like the biguanides, this class of medications does not cause hypoglycemia.

Both rosiglitazone and pioglitazone are effective as monotherapy and in combination with sulfonylureas or metformin or insulin, lowering HbA_{1c} by 1–2%. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4–8 mg daily and of pioglitazone, 15–45 mg daily, and the medications do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone.

These medications have some additional effects apart from glucose lowering. Rosiglitazone therapy is associated with increases in total cholesterol, LDL cholesterol (15%), and HDL cholesterol (10%). There is a reduction in free fatty acids of about 8–15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL cholesterol (15%) but did not cause a consistent change in total cholesterol and LDL cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone showed similar effects on HbA_{1c} and weight gain. Pioglitazone-treated persons, however, had lower total cholesterol, LDL cholesterol, and triglycerides when compared with rosiglitazone-treated persons. Small prospective studies have demonstrated that treatment with these medications leads to improvements in the biochemical and histologic features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury, and there are reports that pioglitazone can reduce neointimal proliferation after coronary stent placement. In one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine excretion.

Safety concerns and some troublesome side effects have emerged about this class of medications that significantly limit their use. A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this medication increases the risk of angina pectoris or myocardial infarction. A meta-analysis of clinical trials with pioglitazone did not show similar findings. Although conclusive data were

lacking, the European Medicines Agency suspended the use of rosiglitazone in Europe. In the United States, the FDA established a restricted distribution program. A subsequent large prospective clinical trial (the RECORD study) failed to confirm the meta-analysis finding and the restrictions were lifted in the United States. It is unlikely, however, that there is going to be a resurgence in its use and pioglitazone is likely to remain the preferred agent.

Edema occurs in about 3–4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10–15%) in patients receiving concomitant insulin therapy and may result in heart failure. The medications are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also been reported as being associated with new onset or worsening macular edema. Apparently, this is a rare side effect, and most of these patients also had peripheral edema. The macular edema resolved or improved once the medication was discontinued.

An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione compared to 1.1 per 100 patient years on comparison treatment. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women.

Other side effects include anemia, which occurs in 4% of patients treated with these medications; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the medication is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass. Initial reports in male rats and humans raised concern about bladder tumors. A 10-year observational cohort study of patients taking pioglitazone, however, failed to find an association with bladder cancer. Reassuringly, a large multipopulation pooled analysis (1.01 million persons over 5.9 million person years) also failed to find an association between cumulative exposure of pioglitazone or rosiglitazone and incidence of bladder cancer.

Troglitazone, the first medication in this class to go into widespread clinical use, was withdrawn from clinical use because of medication-associated fatal liver failure. Although rosiglitazone and pioglitazone have not been reported to cause liver injury, the FDA recommends that they should not be used in patients with clinical evidence of active liver disease or pretreatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

3. Medications that affect absorption of glucose—Alpha-glucosidase inhibitors competitively inhibit the alpha-glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these medications—acarbose and miglitol—are available for clinical use in the United States. Voglibose, another alpha-glucosidase inhibitor is available in Japan, Korea, and India. Acarbose and miglitol are potent inhibitors of glucoamylase, alpha-amylase, and

sucrase but have less effect on isomaltase and hardly any on trehalase and lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference between acarbose and miglitol is in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (about 2%) crosses the microvillar membrane. Miglitol, however, has a structural similarity with glucose and is absorbable. Both medications delay the absorption of carbohydrate and lower postprandial glycemic excursion.

A. ACARBOSE—The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA_{1c} by 0.5–1%.

The principal adverse effect, seen in 20–30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% versus 2% in placebo controls, and particularly with doses greater than 300 mg/day). The levels generally return to normal on stopping the medication.

B. MIGLITOL—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The medication is not metabolized and is excreted unchanged by the kidney. Miglitol should not be used in end-stage chronic kidney disease, when its clearance would be impaired.

4. Incretins—Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is because the oral glucose causes a release of gut hormones, principally glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP1), that amplify the glucose-induced insulin release. This “incretin effect” of GLP-1 secretion (but not GIP1 secretion) is reduced in patients with type 2 diabetes and when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 also has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in people with diabetes and improve postprandial hyperglycemia. GLP-1 acts on the stomach delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the deceleration of gastric emptying markedly reduces the glucose lowering effect of GLP-1. GLP-1 receptors are present in the central nervous system and may play a role in the anorectic effect of the drugs. Type 2 diabetic patients undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a central nervous system effect as well.

A. GLP-1 RECEPTOR AGONISTS—GLP-1 is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4) and by other enzymes, such as endopeptidase 24.11, and is also cleared rapidly by the kidney. As a result, GLP-1's half-life is only 1–2 minutes. The native peptide, therefore, cannot be used therapeutically and the approach taken has been to develop metabolically stable analogs or derivatives of GLP-1 that are not subject to the same enzymatic degradation or renal clearance. Four GLP-1 receptor agonists, exenatide, liraglutide, albiglutide, and dulaglutide are available for clinical use.

Exenatide (Exendin 4) is a GLP-1 receptor agonist isolated from the saliva of the Gila monster (a venomous lizard) that is more resistant to DPP-4 action and cleared by the kidney. Its half-life is 2.4 hours, and its glucose lowering effect is about 6 hours. Exenatide is dispensed as two fixed-dose pens (5 mcg and 10 mcg). It is injected 60 minutes before breakfast and before dinner. Patients with type 2 diabetes should be prescribed the 5 mcg pen for the first month and, if tolerated, the dose can then be increased to 10 mcg twice a day. The medication is not recommended in patients with GFR less than 30 mL/min. In clinical trials, adding exenatide therapy to patients with type 2 diabetes already taking metformin or a sulfonylurea, or both, further lowered the HbA_{1c} value by 0.4% to 0.6% over a 30-week period. These patients also experienced a weight loss of 3–6 pounds. Exenatide LAR is a once weekly preparation that is dispensed as a powder (2 mg). It is suspended in the provided diluent just prior to injection. In comparative clinical trials, the long-acting drug lowers the HbA_{1c} level a little more than the twice daily drug. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

Liraglutide is a soluble fatty acid acylated GLP-1 analog (with replacement of lysine with arginine at position 34 and the attachment of a C16 acyl chain to a lysine at position 26). The fatty-acyl GLP-1 retains affinity for GLP-1 receptors but the addition of the C16 acyl chain allows for noncovalent binding to albumin, both hindering DPP-4 access to the molecule and contributing to a prolonged half-life and duration of action. The half-life is approximately 12 hours, allowing the medication to be injected once a day. The dosing is initiated at 0.6 mg daily, increased

after 1 week to 1.2 mg daily. Some patients may benefit from increasing the dose to 1.8 mg. In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA_{1c} value. Depending on the dose and design of the study, the HbA_{1c} decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1–6 pounds. Liraglutide at a dose of 3 mg daily has been approved for weight loss.

Albiglutide is a human GLP-1 dimer fused to human albumin. It is rendered resistant to DPP-4 action by a glycine substitution for alanine at position 8. The half-life of albiglutide is about 5 days and a steady state is reached after 4–5 weeks of once weekly administration. The usual dose is 30 mg weekly by subcutaneous injection. The dose can be increased to 50 mg weekly if necessary. The pen contains a lyophilized powder that is reconstituted just prior to administration. Albiglutide monotherapy and combination therapy lowers HbA_{1c} by about 0.8%. Weight loss is much less than with exenatide and liraglutide.

Dulaglutide consists of two GLP-1 analog molecules covalently linked to an Fc fragment of human IgG₄. The GLP-1 molecule has amino acid substitutions that resist DPP-4 action. The half-life of dulaglutide is about 5 days. The usual dose is 0.75 mg weekly by subcutaneous injection. The maximum recommended dose is 1.5 mg weekly. Dulaglutide monotherapy and combination therapy lowers HbA_{1c} by about 0.7% to 1.6%. Weight loss ranged from 2 pounds to 7 pounds.

The most frequent adverse reactions of the GLP1 receptor agonists are nausea (11–40%), vomiting (4–13%), and diarrhea (9–17%). The reactions are more frequent at the higher doses. Albiglutide tends to have the lowest rates of these reactions. In clinical trials about 1–5% of participants withdrew from the studies because of the gastrointestinal symptoms.

All the GLP-1 receptor agonists are associated with increased risk of pancreatitis. The FDA reported 30 post-marketing reports of acute pancreatitis in patients taking exenatide. The pancreatitis was severe (hemorrhagic or necrotizing) in 6 instances, and 2 of these patients died. In the liraglutide, albiglutide, and dulaglutide clinical trials, there were 13, 6, and 5 cases of pancreatitis in the drug-treated groups versus 1, 2, and 1 case(s) in the comparator groups, respectively. This translates to about 1.4–2.2 vs 0.6–0.9 cases of pancreatitis per 1000 patient years. Patients taking GLP-1 receptor agonists should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain.

There have been rare reports of acute kidney injury in patients taking exenatide. Some of these patients had pre-existing kidney disease, and others had one or more risk factors for kidney disease. A number of the patients reported nausea, vomiting, and diarrhea, and it is possible that these side effects caused volume depletion and contributed to the development of the kidney injury. For this reason, the GLP-1 receptors agonists should be prescribed cautiously in patients with kidney impairment.

GLP-1 receptor agonists stimulate C-cell neoplasia and cause medullary thyroid carcinoma in rats. Human C-cells

express very few GLP1-receptors, and the relevance to human therapy is unclear. The medications, however, should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia (MEN) syndrome type 2.

B. DPP-4 INHIBITORS—An alternate approach to the use of GLP-1 receptor agonists is to inhibit the enzyme DPP-4 and prolong the action of endogenously released GLP-1 and GIP. Four oral DPP-4 inhibitors, sitagliptin, saxagliptin, linagliptin, and alogliptin, are available in the United States for the treatment of type 2 diabetes. An additional DPP-4 inhibitor, vildagliptin, is available in Europe.

Sitagliptin, when used in clinical trials alone and in combination with metformin and pioglitazone, improved HbA_{1c} from 0.5% to 1.4%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30–50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nasopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of ~200 cells/mcL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions including Stevens-Johnson syndrome. There have also been reports of pancreatitis (88 cases including 2 cases of hemorrhagic or necrotizing pancreatitis). The frequency of these events is unclear.

Saxagliptin, when added to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes, further lowered the HbA_{1c} value by about 0.7–0.9%. The dose is 2.5 mg or 5 mg orally once a day. The 2.5-mg dose should be used in patients with calculated creatinine clearance less than 50 mL/min. It lowers HbA_{1c} by about 0.6% when added to metformin or glyburide or thiazolidine in various 24-week clinical trials. The medication does not cause weight gain or loss. The main adverse reactions were upper respiratory tract infection, nasopharyngitis, headache, and urinary tract infection. There is also small reversible dose-dependent reduction in absolute lymphocyte count, which remains within normal limits. Hypersensitivity reactions, such as urticaria and facial edema, occurred in 1.5% of patients taking the medication compared with 0.4% receiving placebo. The metabolism of saxagliptin is by CYP3A4/5; thus, strong inhibitors or inducers of CYP3A4/5 will affect the pharmacokinetics of saxagliptin and its active metabolite. Saxagliptin may increase the risk of heart failure. In a post marketing study of 16,492 type 2 diabetes patients, there were 289 cases of heart failure in the saxagliptin group (3.5%) and 228 cases in the placebo group (2.8%)—a hazard ratio of 1.27. Patients at the highest risk for failure were those who had a history of heart failure or had elevated levels of N-terminal of the prohormone brain natriuretic peptide (NT-pBNP) or had kidney impairment.

Alogliptin lowers HbA_{1c} by about 0.5–0.6% when added to metformin, sulfonylurea, or pioglitazone. The usual dose is 25 mg orally daily. The 12.5-mg dose is used

in patients with calculated creatinine clearance of 30 to 60 mLs/min; and 6.25 mg for clearance less than 30 mL/min. In clinical trials, pancreatitis occurred in 11 of 5902 patients on alogliptin (0.2%) and in 5 of 5183 patients receiving all comparators (<0.1%). There have been reports of hypersensitivity reactions (anaphylaxis, angioedema, Stevens-Johnson syndrome). Cases of hepatic failure have been reported but it is unclear if alogliptin was the cause. The medication, however, should be discontinued in the event of liver failure.

In a large post-marketing study, alogliptin, like saxagliptin, was associated with a slightly increased rate of heart failure.

Linagliptin lowers HbA_{1c} by about 0.4–0.6% when added to metformin, sulfonylurea, or pioglitazone. The dose is 5 mg orally daily, and, since it is primarily excreted unmetabolized via the bile, no dose adjustment is needed in patients with renal failure. The adverse reactions include nasopharyngitis and hypersensitivity reactions (urticaria, angioedema, localized skin exfoliation, bronchial hyperreactivity). In one study, there were eight cases of pancreatitis in 4687 patients exposed to drug (4311 patient years) with 0 cases in 1183 patients receiving placebo (433 patient years).

Vildagliptin lowers HbA_{1c} by about 0.5–1% when added to the therapeutic regimen of patients with type 2 diabetes. The dose is 50 mg once or twice daily. Adverse reactions include upper respiratory tract infections, nasopharyngitis, dizziness, and headache. Rare cases of hepatic dysfunction, including hepatitis, have been reported. Liver function testing is recommended quarterly during the first year of use and periodically thereafter.

5. Sodium-glucose co-transporter 2 inhibitors—Glucose is freely filtered by the renal glomeruli and is reabsorbed in the proximal tubules by the action of sodium-glucose co-transporters (SGLT). Sodium-glucose co-transporter 2 (SGLT2) accounts for about 90% of glucose reabsorption and its inhibition causes glycosuria in people with diabetes, lowering plasma glucose levels. The SGLT2 inhibitors canagliflozin, dapagliflozin, and empagliflozin are approved for clinical use in the United States.

Canagliflozin reduces the threshold for glycosuria from a plasma glucose threshold of ~180 mg/dL to 70–90 mg/dL. It has been shown to reduce HbA_{1c} by 0.6–1% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of 2–5 kg. The usual dose is 100 mg daily but up to 300 mg daily can be used in patients with normal kidney function.

Dapagliflozin is an SGLT2 inhibitor that has been shown to reduce HbA_{1c} levels by 0.5–0.8% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of about 2–4 kg. The usual dose is 10 mg daily but 5 mg daily is the recommended initial dose in patients with hepatic failure.

Empagliflozin reduces HbA_{1c} by 0.5–0.7% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of about 2–3 kg. The usual dosage is 10 mg daily but a higher dose of 25 mg daily can be used. In a postmarketing multinational study of

7020 patients with type 2 diabetes with known cardiovascular disease, the addition of empagliflozin was associated with a lower primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke (hazard ratio 0.86, $P = 0.04$). The mechanisms regarding the benefit remain unclear. Weight loss, lower blood pressure, and diuresis may have played a role since there were fewer deaths from heart failure in the treated group whereas the rates of myocardial infarction were unaltered. Additional studies with empagliflozin and other SGLT2 inhibitors are needed to confirm this result.

As might be expected, the efficacy of the SGLT2 inhibitors is reduced in chronic kidney disease. They can also increase creatinine and decrease eGFR, especially in patients with kidney impairment. Canagliflozin is contraindicated in patients with eGFR less than 45 mL/min/1.73 m². The main side effects are increased incidence of genital mycotic infections and urinary tract infections affecting ~8–9% of patients. There have also been reports of cases of pyelonephritis and septicemia requiring hospitalization. The glycosuria can cause intravascular volume contraction and hypotension.

Canagliflozin has been reported to cause a decrease in bone mineral density at the lumbar spine and the hip. In a pooled analysis of eight clinical trials (mean duration 68 weeks), a 30% increase in fractures was observed in patients taking canagliflozin. It is likely that the effect on the bones is a class effect and not restricted to canagliflozin. All the SGLT2 inhibitors cause a modest increase in LDL cholesterol levels (3–8%). Also, in clinical trials, patients taking dapagliflozin had higher rates of breast cancer (nine cases vs none in comparator arms) and bladder cancer (10 cases vs 1 in placebo arm). These cancer rates exceeded the expected rates in age-matched reference diabetes population.

Cases of diabetic ketoacidosis have been reported with off-label use of SGLT2 inhibitors in patients with type 1 diabetes. Type 1 patients are taught to give less insulin if their glucose levels are not elevated. SGLT2 inhibitors lower glucose levels by changing the renal threshold and not by insulin action. Type 1 patients taking an SGLT2 inhibitor, because the glucose levels are not elevated, may either withhold or reduce their insulin doses to such a degree as to induce ketoacidosis. SGLT2 inhibitors should not be used in patients with type 1 diabetes and in those patients labelled as having type 2 diabetes but who are very insulin deficient and ketosis-prone.

6. Others—Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). When given subcutaneously, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those taking the medication had an approximately 0.4% reduction in HbA_{1c} and about 1.7 kg weight loss compared with placebo. The HbA_{1c} reduction was sustained for 2 years but some of the weight was regained. The medication is given by injection immediately before the meal. Hypoglycemia can occur, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the medication is started. Since the

medication slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of fast-acting carbohydrates. Nausea was the other main side effect, affecting 30–50% of persons but tended to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15 mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg premeals increased to 120 mcg in 3 to 7 days if no significant nausea occurs.

Bromocriptine, a dopamine 2 receptor agonist, has been shown to modestly lower HbA_{1c} by 0.1–0.5% when compared to baseline and 0.4–0.5% compared to placebo. The tablet dose is 0.8 mg and the daily dose is 2 (1.6 g) to 6 (4.8 mg) tablets as tolerated. Common side effects are nausea, vomiting, dizziness, and headache.

Colesevelam, the bile acid sequesterant, when added to metformin or sulfonylurea or insulin lowered HbA_{1c} 0.3–0.4% when compared to baseline and 0.5–0.6% compared to placebo. HbA_{1c} lowering, however, was not observed in a single monotherapy clinical trial comparing colesevelam to placebo. Colesevelam use is associated with ~20% increase in triglyceride levels. Other adverse effects include constipation and dyspepsia.

With their modest glucose lowering and significant side effects, using bromocriptine or colesevelam to treat diabetes is not recommended.

7. Medication combinations—Several medication combinations are available in different dose sizes, including glyburide and metformin (Glucoavance); glipizide and metformin (Metaglip); repaglinide and metformin (Prandi-Met); rosiglitazone and metformin (Avandamet); pioglitazone and metformin (ACTOplusMet); rosiglitazone and glimepiride (Avandaryl); pioglitazone and glimepiride (Duetact); sitagliptin and metformin (Janumet); saxagliptin and metformin XR (Kombiglyze XR); linagliptin and metformin (Jentadueto); alogliptin and metformin (Kazano); alogliptin and pioglitazone (Oseni); dapagliflozin and metformin (Xigduo); canagliflozin and metformin (Invokamet); empagliflozin and metformin (Synjardy); and empagliflozin and linagliptin (Glyxambi). These medication combinations, however, limit the clinician's ability to optimally adjust dosage of the individual medications and for that reason are not recommended.

8. Safety of the antihyperglycemic agents—The UKPDS has put to rest previous concerns regarding the safety of sulfonylureas. It did not confirm any cardiovascular hazard among over 1500 patients treated intensively with sulfonylureas for over 10 years, compared with a comparable number who received either insulin or diet therapy. Analysis of a subgroup of obese patients receiving metformin also showed no hazard and even a slight reduction in cardiovascular deaths compared with conventional therapy.

C. Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with other hypoglycemic medications.

Table 27-6. Summary of bioavailability characteristics of the insulins.

Insulin Preparations	Onset of Action	Peak Action	Effective Duration
Insulins lispro, aspart, glulisine	5–15 minutes	1–1.5 hours	3–4 hours
Human regular	30–60 minutes	2 hours	6–8 hours
Human NPH	2–4 hours	6–7 hours	10–20 hours
Insulin glargine	0.5–1 hour	Flat	~24 hours
Insulin detemir	0.5–1 hour	Flat	17 hours
Insulin degludec	0.5–1.5 hours	Flat	More than 42 hours
Technosphere inhaled insulin	5–15 minutes	1 hour	3 hours

1. Characteristics of available insulin preparations—

Commercial insulin preparations differ with respect to the time of onset and duration of their biologic action (Table 27-6).

Human insulin is dispensed as either regular (R) or NPH (N) formulations. Six analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and three long-acting (insulin glargine, insulin detemir, and insulin degludec)—are approved by the FDA for clinical use (Table 27-7). Animal insulins are no longer available in the United States. All currently available insulins contain less than 10 ppm of proinsulin and are labeled as “purified.” These purified insulins preserve their potency, so that refrigeration is recommended but not crucial.

During travel, reserve supplies of insulin can be readily transported for weeks without losing potency if protected from extremes of heat or cold. All the insulins in the United States are available in a concentration of 100 units/mL (U100) and dispensed in 10 mL vials or 0.3 mL cartridges or prefilled disposable pens. Several insulins are available at higher concentrations: insulin glargine, 300 units/mL (U300); insulin degludec, 200 units/mL (U200); insulin lispro, 200 units/mL (U200); and regular insulin, 500 units/mL (U500).

2. Insulin preparations—The short-acting preparations are regular insulin and the rapidly acting insulin analogs (Table 27-7). They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting preparations are NPH insulin and the long-acting insulin analogs. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer. The long-acting insulin analogs are also dispensed as clear solutions; insulin glargine is at acidic pH and insulin detemir is at neutral pH. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously.

Table 27-7. Insulin preparations available in the United States.¹

Rapidly acting human insulin analogs
Insulin lispro (Humalog, Lilly)
Insulin aspart (Novolog, Novo Nordisk)
Insulin glulisine (Apidra, Sanofi Aventis)
Short-acting regular insulin
Regular insulin (Lilly, Novo Nordisk)
Technosphere inhaled regular insulin (Afrezza)
Intermediate-acting insulins
NPH insulin (Lilly, Novo Nordisk)
Premixed insulins
70% NPH/30% regular (70/30 insulin—Lilly, Novo Nordisk)
70% NPL/25% insulin lispro (Humalog Mix 75/25—Lilly)
50% NPL/50% insulin lispro (Humalog Mix 50/50—Lilly)
70% insulin aspart protamine/30% insulin aspart (Novolog Mix 70/30—Novo Nordisk)
70% insulin degludec/30% insulin aspart (Ryzodeg, Novo Nordisk)
Long-acting human insulin analogs
Insulin glargine (Lantus (U100), Toujeo (U300), Sanofi Aventis; Basaglar (U100), Lilly)
Insulin detemir (Levemir, Novo Nordisk)
Insulin degludec (Tresiba, Novo Nordisk)

¹All insulins available in the United States are recombinant human or human insulin analog origin. All the above insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin; U300 preparation of insulin glargine; U200 preparation of insulin lispro; U200 preparation of insulin degludec. NPH, neutral protamine Hagedorn.

A. SHORT-ACTING INSULIN PREPARATIONS—

(1) Regular insulin—Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5–7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of patients with diabetes who require insulin. Regular insulin is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the rapidly acting insulin analogs may be preferable in these situations.

For markedly insulin-resistant persons who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available in a 10 mL vial. Since a U500 syringe is not available, when U500 insulin is required in cases of severe insulin resistance, a U100 insulin syringe or tuberculin syringe must be used to measure doses. The clinician should carefully note dosages in both units and volume to avoid overdosage. The U500 preparation is much more expensive and is rarely needed.

(2) **Rapidly acting insulin analogs**—Insulin lispro (Humalog), is an insulin analog where the proline at position B28 is reversed with the lysine at B29. Insulin aspart (Novolog), is a single substitution of proline by aspartic acid at position B28. In insulin glulisine (Apidra) the asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These three analogs have less of a tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this more rapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of rapidly acting insulin analogs is that their duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. In the event of pump failure, however, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route. A U200 concentration of insulin lispro is available in a disposable prefilled pen. The only advantage of the U200 over the U100 insulin lispro preparation is that it delivers the same dose in half the volume.

B. LONG-ACTING INSULIN PREPARATIONS—

(1) **NPH (neutral protamine Hagedorn or isophane) insulin**—NPH is an intermediate-acting insulin whose onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form (“isophane”).

Its onset of action is delayed to 2–4 hours, and its peak response is generally reached in about 6–7 hours. Because its duration of action is often less than 24 hours (with a range of 10–20 hours), most patients require at least two injections daily to maintain a sustained insulin effect.

(2) **Insulin glargine**—In this insulin, the asparagine at position 21 of the insulin A chain is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin, which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients in clinical trials, fasting hyperglycemia was better controlled with less nocturnal hypoglycemia when compared to NPH insulin.

A more concentrated form of insulin glargine (U300) is available as an insulin pen. In pharmacodynamic studies in type 1 patients, the U300 compared to the U100 preparation had approximately 5 hours longer duration of action. In clinical trials in type 1 patients, U300 use did not result in better control or reduce the rates of hypoglycemia. Although limited clinical data suggest that insulin glargine is safe in pregnancy, it is not approved for this use.

(3) **Insulin detemir**—In this insulin analog, the threonine at position B30 has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. Its prolonged action is due to dihexamerization and binding of hexamers and dimers to albumin at the injection site as well as binding of the monomer via its fatty acid side chain to albumin in the circulation. The affinity of insulin detemir is fourfold to fivefold lower than that of human soluble insulin and therefore the U100 formulation of insulin detemir has an insulin concentration of 2400 nmol/mL compared with 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. It has been approved for use during pregnancy.

(4) **Insulin degludec**—In this insulin analog, the threonine at position B30 has been removed, and the lysine at position B29 is conjugated to hexadecanoic acid via a gamma-L-glutamyl spacer. In the vial, in the presence of phenol and zinc, the insulin is in the form of dihexamers but when injected subcutaneously, it self associates into large multihexameric chains consisting of thousands of dihexamers. The chains slowly dissolve in the subcutaneous tissue and insulin monomers are steadily released into the systemic circulation. The half-life of the insulin is 25 hours. Its onset of action is in 30–90 minutes and its duration of action is more than 42 hours. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. Insulin degludec is available in two concentrations, U100 and U200, and dispensed in prefilled disposable pens.

C. **MIXED INSULIN PREPARATIONS**—Patients with type 2 diabetes can sometimes achieve reasonable glucose control with just pre-breakfast and pre-supper injections of

mixtures of short acting and NPH insulins. The regular insulin or rapidly acting insulin analog is withdrawn first, then the NPH insulin and then injected immediately. Stable premixed insulins (70% NPH and 30% regular) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or impairment of manual dexterity. Premixed preparations of insulin lispro and NPH insulins are unstable. In an attempt to remedy this, an intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed called NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (75% NPL/25% insulin lispro mixture [Humalog Mix 75/25] and 50% NPL/50% insulin lispro mixture [Humalog Mix 50/50]) are available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLog Mix 70/30) is available. The main advantages of these mixtures are that they can be given within 15 minutes of starting a meal and they are superior in controlling the postprandial glucose rise after a carbohydrate rich meal. These benefits have not translated into improvements in HbA_{1c} levels when compared with the usual 70% NPH/30% regular mixture. The longer-acting insulin analogs, insulin glargine and insulin detemir, cannot be mixed with either regular insulin or the rapidly acting insulin analogs. Insulin degludec, however, can be mixed and is available as 70% insulin degludec/30% insulin aspart and is injected once or twice a day.

3. Methods of insulin administration—

A. INSULIN SYRINGES AND NEEDLES—Plastic disposable syringes are available in 1 mL, 0.5 mL, and 0.3 mL sizes. The “low-dose” 0.3 mL syringes are popular, because many patients with diabetes do not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Three lengths of needles are available: 6 mm, 8 mm, and 12.7 mm. Long needles are preferable in obese patients to reduce variability of insulin absorption. The needles are of 28, 30, and 31 gauges. The 31 gauge needles are almost painless. “Disposable” syringes may be reused until blunting of the needle occurs (usually after three to five injections). Sterility adequate to avoid infection with reuse appears to be maintained by recapping syringes between uses. Cleansing the needle with alcohol may not be desirable since it can dissolve the silicone coating and can increase the pain of skin puncturing.

Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is not required prior to injection as long as the skin is clean. Rotation of sites is recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs from repeated use of a single site. However, considerable variability of absorption rates from different sites, particularly with exercise, may contribute to the instability of glycemic control in certain type 1 patients if injection sites are rotated too frequently in different areas of the body. Consequently, it is best to limit injection sites to a single region of the body and rotate sites within that region. The abdomen is recommended for subcutaneous injections, since regular insulin has been

shown to absorb more rapidly from there than from other subcutaneous sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

B. INSULIN PEN INJECTOR DEVICES—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro and insulin aspart are available for reusable pens (Eli Lilly, Novo Nordisk, and Owen Mumford). Disposable prefilled pens are also available for insulin lispro, insulin aspart, insulin glulisine, insulin detemir, insulin glargine, insulin degludec, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, 50% NPL/50% insulin lispro, 70% insulin aspart protamine/30% insulin aspart, and 70% insulin degludec/30% insulin aspart. Pen needles are available in 29, 31, and 32 gauges and 4, 5, 6, 8, and 12.7 mm lengths (Novofine; BD).

C. INSULIN PUMPS—In the United States, Medtronic Mini-Med, Animas, Insulet, Roche, and Tandem make battery operated continuous subcutaneous insulin infusion (CSII) pumps. These pumps are small (about the size of a pager) and very easy to program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). Ominpod (Insulet Corporation) is an insulin infusion system in which the insulin reservoir and infusion set are integrated into one unit (pod), so there is no catheter (electronic patch pump). The pod, placed on the skin, delivers subcutaneous basal and bolus insulin based on wirelessly transmitted instructions from a personal digital assistant. The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient therefore is able to eat with less regard to timing because the basal insulin infusion should maintain constant blood glucose between meals. Also the ability to adjust the basal insulin infusion makes it easier for the patient to manage glycemic excursions that occur with exercise. The pumps also have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. They keep track of the time elapsed since last insulin bolus and the patient is reminded of this when he or she attempts to give additional correction bolus before the effect of the previous bolus has worn off (“insulin on board” feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients with type 1 diabetes who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another disadvantage is its cost and the time demanded of the clinician and staff in initiating therapy.

V-go (Valeritas) is a mechanical patch pump designed specifically for people with type 2 diabetes who employ a

basal/bolus insulin regimen. The device is preset to deliver one of three fixed and flat basal rates (20, 30, or 40 units) for 24 hours (at which point it must be replaced) and there is a button that delivers two units per press to help cover meals.

D. INHALED INSULIN—The dry-powder formulation of recombinant human regular insulin that is delivered by inhalation (technosphere insulin, Afrezza) is approved for use in adults with diabetes. Pharmacokinetic studies show that technosphere insulin is rapidly absorbed with peak insulin levels reached in 12–15 minutes and declining to baseline in 3 hours. Pharmacodynamic studies show that median time to maximum effect with inhaled insulin is approximately 1 hour and declines to baseline by about 3 hours. In contrast, the median time to maximum effect with subcutaneous insulin lispro is about 2 hours and declines to baseline by 4 hours. In clinical trials, technosphere insulin combined with basal insulin was as effective in glucose lowering as rapid-acting insulin analogs combined with basal insulin. It is formulated as a single-use, color-coded cartridge delivering 4, 8, or 12 units immediately before the meal. The manufacturer provides a dose conversion table; patients injecting up to 4 units of rapid-acting insulin analog should use the 4-unit cartridge. Those injecting 5 to 8 units should use the 8-unit cartridge. If the dose is 9–12 units of rapid-acting insulin premeal then one 4-unit cartridge and one 8-unit cartridge or one 12-unit cartridge should be used. The inhaler is about the size of a referee's whistle.

The most common adverse reaction of the inhaled insulin was a cough affecting about 27% of patients. A small decrease in pulmonary function (forced expiratory volume in 1 second [FEV₁]) was seen in the first 3 months of use, which persisted over 2 years of follow-up. Inhaled insulin is contraindicated in smokers and patients with chronic lung disease, such as asthma and chronic obstructive pulmonary disease. Spirometry should be performed to identify potential lung disease prior to initiating therapy. During the clinical trials, there were two cases of lung cancer in patients who were taking inhaled insulin and none in the comparator-treated patients. All the patients in whom lung cancer developed had a history of prior cigarette smoking. There were also two cases of squamous cell carcinoma of the lung in nonsmokers exposed to inhaled insulin; these cases occurred after completion of the clinical trials. Cases of lung cancer were also reported in cigarette smokers using a previously available inhaled insulin preparation (Exubera). The incidence rate in the Exubera treated group was 0.13 per 1000 patient years and 0.03 per 1000 patient years in the comparator-treated group.

D. Transplantation

1. Pancreas transplantation—All uremic patients with type 1 diabetes who are candidates for a kidney transplant should be considered potential candidates for a pancreas transplant. Eligibility criteria include age younger than 55 and minimal cardiovascular risk. Contraindications include noncorrectable coronary artery disease, extensive peripheral vascular disease, and significant obesity (weight greater than 100 kg). The pancreas transplant may occur at the same time as kidney transplant or after kidney

transplant. Patients undergoing simultaneous pancreas and kidney transplantation have an 83% chance of pancreatic graft survival at 1 year and 69% at 5 years. Solitary pancreatic transplantation in the absence of a need for kidney transplantation is considered only in those rare patients who do not respond to all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control. Pancreas transplant alone graft survival is 78% at 1 year and 54% at 5 years.

2. Islet transplantation—Total pancreatectomy is curative for severe pain syndrome associated with chronic pancreatitis. The pancreatectomy, however, results in surgical diabetes. Harvesting islets from the removed pancreas and autotransplanting them into the liver (via portal vein) can prevent the development of diabetes or result in “mild” diabetes (partial islet function) that is easier to manage. Since the islets are autologous no immunosuppression is required. The number of islets transplanted is the main predictor of insulin independence.

People with type 1 diabetes can become insulin independent after receiving islets isolated from a donor pancreas (alloislet transplant). The islets are infused into the portal vein using a percutaneous transhepatic approach, and they lodge in the liver releasing insulin in response to physiologic stimuli. Long-term immunosuppression is necessary to prevent allograft rejection and to suppress the autoimmune process that led to the disease in the first place. Insulin independence for more than 5 years has been demonstrated in patients who got anti-CD3 antibody or anti-thymocyte globulin induction immunosuppression and calcineurin inhibitors, mTor inhibitors, and mycophenolate mofetil as maintenance immunosuppression. One major limitation is the need for more than one islet infusion to achieve insulin independence. This is because of significant loss of islets during isolation and the period prior to engraftment. Alloislet transplantation is currently an experimental procedure and widespread application will depend on improving insulin independence rates with one infusion and also demonstrating that the long-term outcomes are as good as those of pancreas transplant alone.

► Steps in the Management of the Diabetic Patient

A. Diagnostic Examination

An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether or not ketonuria accompanies the glycosuria.

Features that suggest end-organ insulin insensitivity to insulin, such as visceral obesity, acanthosis nigricans, or both, must be identified. The family history should document not only the incidence of diabetes in other members of the family but also the age at onset, association with obesity, the need for insulin, and whether there were complications. For the occasional patient, measurement of GAD65, IAA, ICA 512, and zinc transporter 8 antibodies can help distinguish between type 1 and type 2 diabetes. Many patients with newly diagnosed type 1 diabetes still have significant endogenous insulin production, and C peptide levels do not reliably distinguish between type 1 and type 2 diabetes. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis of diabetes should document fasting plasma glucose levels above 126 mg/dL (7 mmol/L) or postprandial values consistently above 200 mg/dL (11.1 mmol/L) or HbA_{1c} of at least 6.5% and whether ketonuria accompanies the glycosuria. An HbA_{1c} measurement is also useful for assessing the effectiveness of future therapy. Baseline values include fasting plasma triglycerides, total cholesterol and HDL-cholesterol, electrocardiography, kidney function studies, peripheral pulses, and neurologic, podiatric, and ophthalmologic examinations to help guide future assessments.

B. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The “teaching curriculum” should include explanations by the clinician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data.

Patients taking insulin should have an understanding of the actions of basal and bolus insulins. They should be taught to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families and friends should be taught to recognize signs and symptoms of hypoglycemia and how to treat low glucose reactions. Strenuous exercise can precipitate hypoglycemia, and patients must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in the exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin and insulin doses should be adjusted accordingly. Infections can cause

insulin resistance, and patients should be instructed on how to manage the hyperglycemia with supplemental rapidly acting insulin.

The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Advice on personal hygiene, including detailed instructions on foot and dental care, should be provided. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists, such as catecholamines or glucagon, and thus bring about a marked increase in insulin requirements. Patients who are taking oral agents may decompensate and temporarily require insulin. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade patients with newly diagnosed diabetes who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

C. Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 1 diabetes—Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT (see above) should be provided about the advantages of taking multiple injections of insulin in conjunction with self-blood glucose monitoring. If near-normalization of blood glucose is attempted, at least four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. The rapidly acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for preprandial use. However, because of their relatively short duration (no more than 3–4 hours), the rapidly acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the rapidly acting insulin analog dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. Table 27–8 illustrates a regimen with a rapidly acting insulin analog and insulin detemir or insulin glargine that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Table 27–8. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and insulin detemir, or insulin glargine or degludec in a 70-kg man with type 1 diabetes.^{1–3}

	Pre-Breakfast	Pre-Lunch	Pre-Dinner	At Bedtime
Rapidly acting insulin analog	5 units	4 units	6 units	
Insulin detemir	6–7 units			8–9 units
OR				
Rapidly acting insulin analog	5 units	4 units	6 units	—
Insulin glargine or degludec		—		15–16 units

¹Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

²The dose of rapidly acting insulin can be raised by 1 or 2 units if extra carbohydrate (15–30 g) is ingested or if premeal blood glucose is > 170 mg/dL (9.4 mmol/L).

³Insulin glargine or insulin detemir must be given as a separate injection.

Insulin glargine is usually given once in the evening to provide 24-hour coverage. This insulin *cannot be mixed* with any of the other insulins and must be given as a separate injection. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day. As shown, insulin detemir may also need to be given twice a day to get adequate 24-hour basal coverage. Alternatively, small doses of NPH (~3–4 units) can be given with each meal to provide daytime basal coverage with a larger dose at night. Unlike the long-acting insulin analogs, NPH can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine.

Continuous subcutaneous insulin infusion (CSII) by portable battery-operated “open loop” devices currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting patients to delay or skip meals and vary meal size and

composition. The dosage is usually based on providing 50% of the estimated insulin dose as basal and the remainder as intermittent boluses prior to meals. For example, a 70-kg man requiring 35 units of insulin per day may require a basal rate of 0.7 units per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 units per hour might be appropriate (given the “dawn phenomenon”—reduced tissue sensitivity to insulin between 5 AM and 8 AM). The meal bolus would depend on the carbohydrate content of the meal and the premeal blood glucose value. **One unit per 15 g of carbohydrate plus 1 unit for 50 mg/dL (2.8 mmol/L) of blood glucose above a target value (eg, 120 mg/dL [6.7 mmol/L]) is a common starting point.** Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. The majority of patients use the rapidly acting insulin analogs in the pumps. One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the Somogyi effect, in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning. Also, the dawn phenomenon is present in as many as 75% of type 1 patients and can aggravate the hyperglycemia.

The diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements (Table 27–9). This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by eliminating the dose of intermediate insulin at dinnertime and giving it at a lower dosage at bedtime or by supplying more food at bedtime. When a waning insulin level is the cause, then either increasing the evening dose or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required.

Table 27–9. Prebreakfast hyperglycemia: Classification by blood glucose and insulin levels.

	Blood Glucose (mg/dL) [mmol/L]			Free Immunoreactive Insulin (microunit/mL)		
	10:00 PM	3:00 AM	7:00 AM	10:00 PM	3:00 AM	7:00 AM
Somogyi effect	90 [5]	40 [2.2]	200 [11.1]	High	Slightly high	Normal
Dawn phenomenon	110 [6.1]	110 [6.1]	150 [8.3]	Normal	Normal	Normal
Waning of insulin dose plus dawn phenomenon	110 [6.1]	190 [10.6]	220 [12.2]	Normal	Low	Low
Waning of insulin dose plus dawn phenomenon plus Somogyi effect	110 [6.1]	40 [2.2]	380 [21.1]	High	Normal	Low

2. Type 2 diabetes—Therapeutic recommendations are based on the relative contributions of beta cell insufficiency and insulin insensitivity in individual patients. The possibility that the individual patient has a specific etiologic cause for their diabetes should always be considered, especially when the patient does not have a family history of type 2 diabetes or does not have any evidence of central obesity or insulin resistance. Such patients should be evaluated for other types of diabetes such as LADA or MODY. Patients with LADA should be prescribed insulin when the disease is diagnosed and treated like patients with type 1 diabetes. It is also important to note that many patients with type 2 diabetes mellitus have a progressive loss of beta cell function and will require additional therapeutic interventions with time.

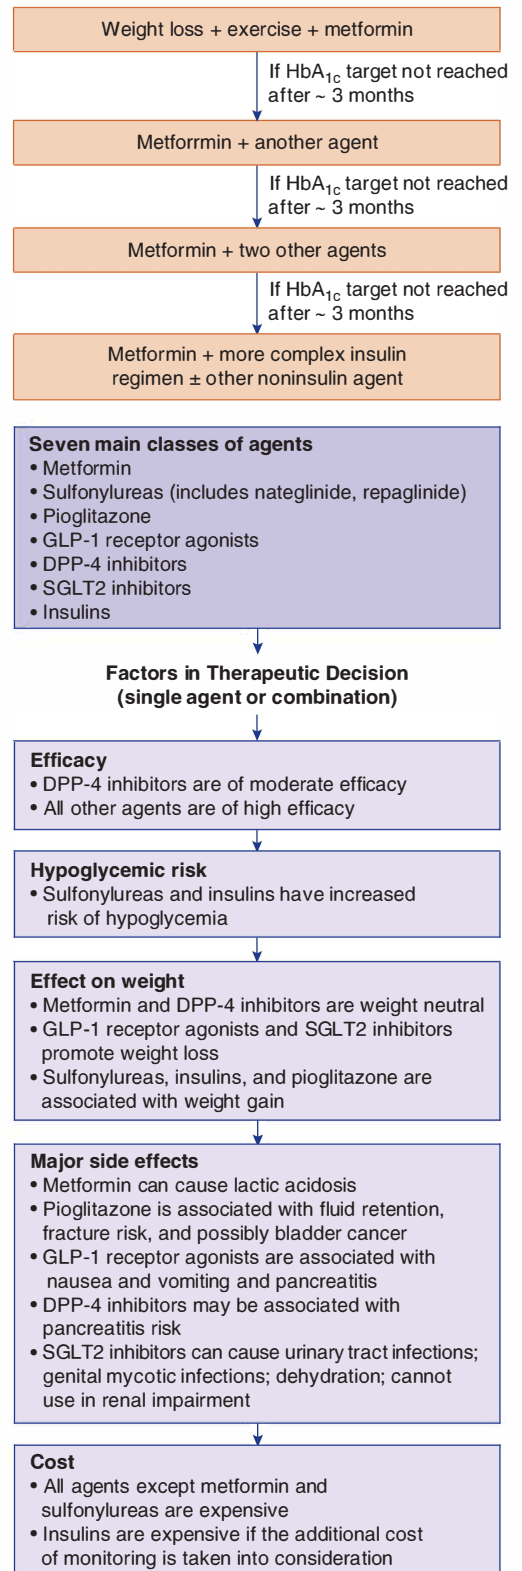

A. WEIGHT REDUCTION—One of the primary modes of therapy in the obese patient with type 2 diabetes is weight reduction. Normalization of glycemia can be achieved by weight loss and improvement in tissue sensitivity to insulin. A combination of caloric restriction, increased exercise, and behavior modification is required if a weight reduction program is to be successful. Understanding the risks associated with the diagnosis of diabetes may motivate the patient to lose weight.

For selected patients, medical or surgical options for weight loss should be considered. Orlistat, phentermine/topiramate, lorcaserin, naltrexone/extended-release bupropion, and high-dose liraglutide (3 mg daily) are weight loss medications approved for use in combination with diet and exercise (see Chapter 29).

Bariatric surgery (Roux-en-Y, gastric banding, gastric sleeve, biliopancreatic diversion/duodenal switch) typically results in substantial weight loss and improvement in glucose levels. A meta-analysis examining the impact of bariatric surgery on patients with diabetes and BMI of 40 kg/m² or greater noted that 82% of patients had resolution of clinical and laboratory manifestations of diabetes in the first 2 years after surgery and 62% remained free of diabetes more than 2 years after surgery. The improvement was most marked in the procedure that caused the greatest weight loss (biliopancreatic diversion/duodenal switch). There was, however, a high attrition of patients available for follow-up, and there was little information about different ethnic types. Weight regain does occur after bariatric surgery, and it can be expected that 20–25% of the lost weight will be regained over 10 years. The impact of this weight gain on diabetes recurrence depends principally on the degree of beta cell dysfunction.

Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically obese normal weight patient. There is less emphasis on weight loss, but exercise remains an important aspect of treatment.

B. GLUCOSE LOWERING AGENTS—Figure 27–2 outlines the treatment approach based on the consensus algorithm proposed by the American Diabetes Association and the European Association for the Study of Diabetes. The current recommendation is to start **metformin** therapy at diagnosis and not wait to see whether the patient can

▲ **Figure 27–2.** Algorithm for the treatment of type 2 diabetes based on the 2012 and 2015 recommendations of the consensus panel of the American Diabetes Association/European Association for the Study of Diabetes.

achieve target glycemic control with weight management and exercise. See discussion of the individual medications, above.

When diabetes is not well controlled with initial therapy (usually metformin), then a second agent should be added. **Sulfonylureas** have been available for many years and their use in combination with metformin is well established. They do, however, have the propensity of causing hypoglycemia and weight gain. In patients who experience hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue (repaglinide or nateglinide) before meals may suffice to get the glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Patients who are very concerned about weight gain may benefit from a trial of GLP-1 receptor agonist or DPP-4 inhibitor or SGLT2 inhibitor. If two agents are inadequate, then a third agent is added, although data regarding efficacy of such combined therapy are limited.

When the combination of oral agents (and injectable GLP-1 receptor agonists) fail to achieve euglycemia in patients with type 2 diabetes, then insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this medication when insulin therapy is instituted. Pioglitazone, which improves peripheral insulin sensitivity, can be used together with insulin but this combination is associated with more weight gain and peripheral edema. The sulfonylureas also continue to be of benefit. There is limited information on the benefits of continuing the GLP-1-receptor agonists or the DPP-4 inhibitors or the SGLT2 inhibitors once insulin therapy is initiated. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

D. Acceptable Levels of Glycemic Control

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. **Criteria for “acceptable” control** includes the following: (1) blood glucose levels of 90–130 mg/dL (5–7.2 mmol/L) before meals and after an overnight fast, (2) levels no higher than 180 mg/dL (10 mmol/L) 1 hour after meals and 150 mg/dL (8.3 mmol/L) 2 hours after meals, and (3) HbA_{1c} levels less than 7% for nonpregnant adults. Less

stringent HbA_{1c} goals may be appropriate in children, those with a history of severe hypoglycemia, limited life expectancy, and advanced microvascular and macrovascular disease. In the elderly frail patient, an HbA_{1c} target of approximately 8% (preprandial blood glucose levels in the range of the 150–159 mg/dL) may be reasonable although formal evidence is lacking. **The UKPDS study demonstrated that blood pressure control was as significant or more significant than glycemic control in patients with type 2 diabetes regarding the prevention of microvascular as well as macrovascular complications.**

E. Complications of Insulin Therapy

1. Hypoglycemia—Hypoglycemic reactions are the most common complications that occur in patients with diabetes who are treated with insulin. The signs and symptoms of hypoglycemia may be divided into those resulting from stimulation of the autonomic nervous system and those from neuroglycopenia (insufficient glucose for normal central nervous system function). When the blood glucose falls to around 54 mg/dL (3 mmol/L), the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL [2.8 mmol/L]), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose can then lead to loss of consciousness or even a seizure. With repeated episodes of hypoglycemia, there is adaptation, and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition is referred to as “hypoglycemic unawareness.” It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving beta-blocking agents. Though not absolutely contraindicated, these medications must be used with caution in patients with diabetes who require insulin, and beta-1-selective blocking agents are preferred.

Hypoglycemia can occur in patient taking sulfonylureas, repaglinide, and nateglinide, particularly if the patient is elderly, has kidney or liver disease, or is taking certain other medications that alter metabolism of the sulfonylureas (eg, phenylbutazone, sulfonamides, or warfarin). It occurs more frequently with the use of long-acting sulfonylureas than when shorter-acting agents are used. Otherwise, hypoglycemia in insulin-treated patients with

diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who “stack” their insulin—that is, give another dose of insulin before the first injection has had its full action—can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response, sympatho-adrenal responses, and cortisol deficiency. Patients with diabetes of greater than 5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and end-stage chronic kidney disease. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In addition, in patients with gastroparesis, if insulin is given before a meal, the peak of insulin action may occur before the food is absorbed causing the glucose levels to fall. Finally, in end-stage chronic kidney disease, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of renal contribution to gluconeogenesis in the postabsorptive state.

To prevent and treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 grams of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is receiving insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The medication can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. The glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL (2 mmol/L) in about 15 minutes. After the patient recovers consciousness, additional

oral carbohydrate should be given. People with diabetes receiving hypoglycemic medication therapy should also wear an identification MedicAlert bracelet or necklace or carry a card in his or her wallet (1-800-ID-ALERT, www.medicalert.org).

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous access is not available, 1 mg of glucagon can be injected intramuscularly.

2. Immunopathology of insulin therapy—At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the switch to human and purified pork insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low.

A. INSULIN ALLERGY—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

B. IMMUNE INSULIN RESISTANCE—A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a small extent develops in most insulin-treated patients. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to human or highly purified pork insulins and has not been reported with the analogs.

C. LIPODYSTROPHY—Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection. This complication results from an immune reaction, and it has become rarer with the development of human and highly purified insulin preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly. It can occur with purified insulins as well. Rotation of injection sites will prevent lipohypertrophy.

► Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and

the lens of the eye. These lesions lead to hypertension, end-stage chronic kidney disease, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, end-stage chronic kidney disease develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. Proliferative retinopathy ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years' duration). In patients with type 1 diabetes, complications from end-stage chronic kidney disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

A. Ocular Complications

1. Diabetic cataracts—Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonglycosylated glycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

2. Diabetic retinopathy—There are two main categories of diabetic retinopathy: nonproliferative and proliferative (see Chapter 7). Diabetic macular edema can occur at any stage. **Nonproliferative (“background”) retinopathy** represents the earliest stage of retinal involvement by diabetes and is characterized by such changes as microaneurysms, dot hemorrhages, exudates, and retinal edema. The prevalence of nonproliferative retinopathy in patients with type 2 diabetes is 60% after 16 years.

Proliferative retinopathy involves the growth of new capillaries and fibrous tissue within the retina and into the vitreous chamber. It is a consequence of small vessel occlusion, which causes retinal hypoxia; this in turn stimulates new vessel growth. New vessel formation may occur at the optic disk or elsewhere on the retina. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifested as cotton-wool spots (small infarcted areas of retina). Vision is usually normal until vitreous hemorrhage or retinal detachment occurs.

Proliferative retinopathy can occur in both types of diabetes but is more common in type 1, developing about 7–10 years after onset of symptoms, with a prevalence of 25% after 15 years' duration. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3–5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis, because many were probably diabetic for an extensive period of time before diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3–5 years and for all patients with type 2 diabetes. Chapter 7 describes

the treatment of retinopathy and macular edema. There is no contraindication to using aspirin in patients with proliferative retinopathy.

3. Glaucoma—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in patients with diabetes can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

B. Diabetic Nephropathy

As many as 4000 cases of end-stage chronic kidney disease occur each year among diabetic people in the United States.

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes have a 30–40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in type 2 diabetes patients, in whom only about 15–20% develop clinical kidney disease. However, since there are many more individuals affected with type 2 diabetes, end-stage chronic kidney disease is much more prevalent in type 2 than in type 1 diabetes in the United States and especially throughout the rest of the world.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood. Sensitive radioimmunoassay methods detect small amounts of urinary albumin—in contrast to the less sensitive dipstick strips, whose minimal detection limit is 0.3–0.5%. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, an albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. In the early morning spot urine, a ratio of albumin (mcg/L) to creatinine (mg/L) of less than 30 mcg/mg creatinine is normal, and a ratio of 30–300 mcg/mg creatinine suggests abnormal microalbuminuria. At least two early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified. Short-term hyperglycemia, exercise, urinary tract infections, heart failure, and acute febrile illness can cause transient albuminuria and so testing for microalbuminuria should be postponed until resolution of these problems.

Subsequent end-stage chronic kidney disease can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/mg creatinine. Glycemic control as well as a protein diet of 0.8 g/kg/day may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in

addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetic patients impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated *nocturnal* systolic blood pressure, it is possible that “normotensive” diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitors in reducing microalbuminuria in “normotensive” patients.

If treatment is inadequate, then the disease progresses with proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol, as well as progressive azotemia. In contrast to all other kidney disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive end-stage chronic kidney disease (patients continue to excrete 10–11 g daily as creatinine clearance diminishes). As end-stage chronic kidney disease progresses, there is an elevation in the renal threshold at which glycosuria appears (see Chapter 22).

C. Diabetic Neuropathy

Diabetic neuropathies are the most common complications of diabetes affecting up to 50% of older patients with type 2 diabetes.

1. Peripheral neuropathy—

A. DISTAL SYMMETRIC POLYNEUROPATHY—This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable, hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms. The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes-Weinstein filament and those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot results in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Figure 27–3). Peripheral neuropathy, autonomic neuropathy, and trauma also predisposes to the development of Charcot arthropathy. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a “rocker

▲ **Figure 27–3.** Diabetic foot ulcer over head of first metatarsal (arrow). (Used, with permission, from Dean SM, Satiani B, Abraham WT. *Color Atlas and Synopsis of Vascular Diseases*. McGraw-Hill, 2014.)

bottom” deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot. Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, **platelet-derived growth factor** (becaplermin [Regranex]) should be considered for local application. A post-marketing epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, resulting in a “black box” warning on the medication label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

In some patients, hypersensitivity to light touch and occasionally severe “burning” pain, particularly at night, can become physically and emotionally disabling. Nortriptyline or desipramine in doses of 25–150 mg/day orally may provide dramatic relief for pain from diabetic neuropathy, often within 48–72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to having a full night’s sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This medication should not be continued if improvement has not occurred after 5 days of therapy.

Amitriptyline, 25–75 mg orally at bedtime can also be used but has more anticholinergic effects. Tricyclic antidepressants, in combination with the phenothiazine, fluphenazine, have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg orally daily in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic medications prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this medication was not compared with an active control. Also, because of its abuse potential, it has been categorized as a schedule V controlled substance. Duloxetine (60–120 mg), a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this medication reduced the pain sensitivity score by 40–50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia. Application of a 5% lidocaine patch over an area of maximal pain has been reported to be of benefit. It is approved for treatment of postherpetic neuralgia and is in clinical trials for the treatment of painful diabetic neuropathy.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

B. ISOLATED PERIPHERAL NEUROPATHY—Involvement of the distribution of only one nerve (“mononeuropathy”) or of several nerves (“mononeuropathy multiplex”) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

2. Autonomic neuropathy—Neuropathy of the autonomic system occurs principally in patients with diabetes of long duration. It affects many diverse visceral functions including blood pressure and pulse, gastrointestinal activity,

bladder function, and erectile dysfunction. Treatment is directed specifically at each abnormality.

Involvement of the gastrointestinal system may be manifested by nausea, vomiting, postprandial fullness, reflux or dysphagia, constipation or diarrhea (or both), and fecal incontinence. Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Metoclopramide has been of some help in treating diabetic gastroparesis. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur, especially when used for longer than 3 months, and the FDA has cautioned against the long-term use of metoclopramide.

Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying over the short term in doses of 250 mg three times daily, but its effectiveness seems to diminish over time. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy (such as rifaximin, metronidazole, amoxicillin/clavulanate, ciprofloxacin, or doxycycline), although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60 mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to lower blood pressure in these patients who already have autonomic neuropathy, resulting in orthostatic hypotension. Constipation usually responds to stimulant laxatives such as senna.

Incomplete emptying of the bladder can sometimes occur. Bethanechol in doses of 10–50 mg orally three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter.

Use of Jobst fitted stockings, tilting the head of the bed, and arising slowly from the supine position can be helpful in treating symptoms of orthostatic hypotension. When such measures are inadequate, then treatment with fludrocortisone 0.1–0.2 mg orally daily can be considered. This medication, however, can result in supine hypertension and hypokalemia. Midodrine (10 mg orally three times a day), an alpha-agonist, can also be used.

Erectile dysfunction can result from neurologic, psychological or vascular causes, or a combination of these

causes. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5–2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50–60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. Low doses are available for daily use. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision. Priapism can occur with these medications, and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. These phosphodiesterase type 5 (PDE5) inhibitors potentiate the hypotensive effects of nitrates and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of heart failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive medications causes penile engorgement and erection. Medications most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E₁). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intraurethral pellets of alprostadil avoid the problem of injection of the medication.

External vacuum therapy (Erec-Aid System) is a non-surgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection that is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20–30 minutes. While this method is generally effective, its cumbersome nature limits its appeal.

Surgical implants of penile prostheses remain an option for those patients in whom the nonsurgical approaches are ineffective.

D. Cardiovascular Complications

1. Heart disease—Microangiopathy occurs in the heart and may explain the etiology of congestive cardiomyopathies in diabetic patients who do not have demonstrable coronary artery disease. More commonly, however, heart disease in patients with diabetes is due to coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as

well, although the absolute risk is lower than in patients with type 2 diabetes. Premenopausal women who normally have lower rates of coronary artery disease lose this protection once diabetes develops. The increased risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation. Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have a beneficial effect. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of LDL cholesterol lowering was apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of less than 100 mg/dL (2.6 mmol/L). Lowering LDL cholesterol to 70 mg/dL (1.8 mmol/L) may have additional benefit and is a reasonable target for most patients with type 2 diabetes who have multiple risk factors for cardiovascular disease.

The ADA also recommends lowering systolic blood pressure to less than 140 mm Hg and diastolic pressure to less than 90 mm Hg in patients with diabetes. The systolic target of 130 mm Hg or less and diastolic of 80 mm Hg or less is recommended for the younger patient if it can be achieved without undue treatment burden. The Systolic Blood Pressure Intervention Trial (SPRINT) reported that treating to a systolic blood pressure of less than 120 mm Hg reduced cardiovascular events by 25% and death from cardiovascular causes by 43% during 3.26 years of follow-up. People with diabetes, however, were excluded from this study, and it is unclear if the results are applicable to this population. Patients with type 2 diabetes who already have cardiovascular disease or microalbuminuria should be considered for treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes who do not have cardiovascular disease or microalbuminuria would specifically benefit from ACE inhibitor treatment.

Aspirin at a dose of 81–325 mg daily is effective in reducing cardiovascular morbidity and mortality in patients who have a history of myocardial infarction or stroke (secondary prevention). It is unclear if aspirin prevents primary cardiovascular events in people with diabetes. The current recommendation is to give aspirin to people with diabetes who have a greater than 10% 10-year risk of cardiovascular events. Typically, this includes most diabetic men aged 50 years or older and diabetic women aged 60 years or older with one or more additional risk factors (smoking, hypertension, dyslipidemia, family history of premature cardiovascular disease, or albuminuria). Contraindications for aspirin therapy are patients with aspirin allergy, bleeding tendency, recent gastrointestinal bleeding, or active hepatic disease. Based on the Early Treatment Diabetic Retinopathy Study (ETDRS), there does not appear to be a contraindication to aspirin use to

achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy. Aspirin also does not seem to affect the severity of vitreous/preretinal hemorrhages or their resolution.

2. Peripheral vascular disease—Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, erectile dysfunction, and intestinal angina.

The incidence of **gangrene of the feet** in patients with diabetes is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco should be avoided. Control of other risk factors such as hypertension is essential. Beta-blockers are relatively contraindicated because of presumed negative peripheral hemodynamic consequences but data that support this are lacking. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. **Candidal infection** can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in women with chronically uncontrolled diabetes who have persistent glucosuria and is a frequent cause of pruritus. While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

In some patients with type 2 diabetes, poor glycemic control can cause a severe hypertriglycemia, which can present as **eruptive cutaneous xanthomas** and pancreatitis. The skin lesions appear as yellow morbilliform eruptions 2–5 mm in diameter with erythematous areolae. They occur on extensor surfaces (elbows, knees, buttocks) and disappear after triglyceride levels are reduced.

Necrobiosis lipoidica diabetorum is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men. Pathologically, the lesions show degeneration

of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes, and also in patients without diabetes. First-line therapy includes topical and subcutaneous corticosteroids. Improving glycemic control may help the condition.

“**Shin spots**” are not uncommon in adults with diabetes. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

F. Bone and Joint Complications

Long-standing diabetes can cause progressive stiffness of the hand secondary to contracture and tightening of skin over the joints (diabetic cheiroarthropathy), frozen shoulder (adhesive capsulitis), carpal tunnel syndrome, and Dupuytren contractures. These complications are believed to be due to glycosylation of collagen and perhaps other proteins in connective tissue. There may also be an inflammatory component.

Data on bone mineral density and fracture risk in people with diabetes are contradictory. Patients with type 2 diabetes do appear to be at increased risk for nonvertebral fractures. Women with type 1 diabetes have an increased risk of fracture when compared with women without diabetes. Other factors, such as duration of diabetes, and diabetes complications, such as neuropathy and kidney disease, likely affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by ossification of the anterior longitudinal ligaments of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia and acute and tophaceous gout are more common in type 2 diabetes.

Bursitis, particularly of the shoulders and hips, occurs more frequently than expected in patients with diabetes.

Special Situations

A. Diabetes Management in the Hospital

Most patients with diabetes are hospitalized for reasons other than their diabetes. Indeed, up to 10–15% of all hospitalized patients have diabetes. Audits suggest that as many as a 30% of these hospitalized patients have inappropriate management of their diabetes, with such errors as being given metformin where contraindicated, failure to act on high blood glucose levels, omission of diabetes medication, no record of diabetes complications, and inappropriate insulin management or blood glucose monitoring. It is challenging using outpatient oral therapies or insulin regimens in the hospital because patients are not eating as usual; they are often fasting for procedures; clinical events increase adverse reactions associated with diabetes medicines, eg, thiazolidinediones can cause fluid retention and worsen heart failure; metformin should not be used in patients with significant chronic kidney or liver disease, or those getting contrast for radiographic studies. Subcutaneous or intravenous insulin therapy is frequently substituted for other diabetes medicines because the insulin dose can be adjusted to match changing inpatient needs and it is safe to use insulin in patients with heart, kidney, and liver disease.

Surgery represents a stress situation during which most of the insulin antagonists (eg, catecholamines, growth hormone, and corticosteroids) are mobilized. In the diabetic patient, this can lead to a worsening of hyperglycemia and perhaps even ketoacidosis. The aim of medical management of people with diabetes during the perioperative period is to minimize these stress-induced changes. Recommendations for management depend both on the patient's usual diabetic regimen and on the type of surgery (major or minor) to be done (see also Chapter 3).

For people with diabetes controlled with diet alone, no special precautions must be taken unless diabetic control is markedly disturbed by the procedure. If this occurs, small doses of short-acting insulin as needed will correct the hyperglycemia.

Patients taking oral agents should not take them on the day of surgery. If there is significant hyperglycemia, small doses of short-acting insulin are given as needed. If this

approach does not provide adequate control, an insulin infusion should be started in the manner indicated below. The oral agents can be restarted once the patient is eating normally after the operation. It is important to order a postoperative serum creatinine level to ensure adequate kidney function prior to restarting metformin therapy.

Patients taking insulin represent the only serious challenge to management of diabetes when surgery is necessary. However, with careful attention to changes in the clinical or laboratory picture, glucose control can be managed successfully. The protocol used to control the glucose depends on the kind of diabetes (type 1 or type 2); whether it is minor surgery (lasting less than 2 hours and patient eating afterwards) or major surgery (lasting more than 2 hours, with invasion of a body cavity, and patient not eating afterwards); and the preoperative insulin regimen (basal bolus or premixed insulin twice a day or premeal bolus only or regular insulin before meals and NPH at bedtime). Patients with type 1 diabetes must be receiving some insulin to prevent the development of diabetic ketoacidosis. Many patients with type 2 diabetes who are taking insulin do well perioperatively without insulin for a few hours. Ideally, patients with diabetes should undergo surgery early in the morning. Table 27–10 summarizes the approach for these patients.

One insulin infusion method adds 10 units of regular insulin to 1 L of 5% dextrose in 0.45% saline, and this is infused intravenously at a rate of 100–180 mL/h. This gives the patient 1–1.8 units of insulin per hour which, except in the most severe cases, generally keeps the blood glucose within the range of 100–250 mg/dL (5.5–13.9 mmol/L). The infusion may be continued for several days, if necessary. Perioperatively, plasma glucose or blood glucose should be determined every 2–4 hours to be sure metabolic control is adequate. If it is not, adjustments in the ratio of insulin to dextrose in the intravenous solution can be made.

An alternative method consists of separate infusions of insulin and glucose delivered by pumps to permit independent adjustments of each infusion rate, depending on hourly variation of blood glucose values. There are a number of different algorithms available for insulin infusions (see <http://www.hospitalmedicine.org>).

Table 27–10. Recommendations for management of insulin-treated diabetes during surgery.

Type of Diabetes	Minor Surgical Procedures (< 2 hours; eating afterwards)	Major Surgical Procedures (> 2 hours; invasion of body cavity; not eating immediately after recovery)
Type 2: Patients taking basal bolus insulin regimen; twice daily premixed insulin	No insulin on the day of operation. Start 5% dextrose infusion; monitor fingerstick blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours	Same regimen as minor procedure. If control is not satisfactory, then intravenous insulin infusion
Type 1: Patients taking basal bolus insulin regimen or using insulin pump	Patients using pump should discontinue the pump the evening before procedure and given 24-hour basal insulin. On day of procedure, start 5% dextrose; monitor blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours	Initiate insulin infusion on morning of procedure and transition back to usual regimen when eating

After surgery, when the patient has resumed an adequate oral intake, subcutaneous administration of insulin can be resumed and intravenous administration of insulin and dextrose can be stopped 30 minutes after the first subcutaneous dose. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of short-acting insulin plus some long-acting basal insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control.

In the **intensive care units (ICUs)**, glucose levels are controlled most frequently using insulin infusions. Patients receiving total parenteral nutrition can have insulin added to the bag. Standard total parenteral nutrition contains 25% dextrose so an infusion rate of 50 mL/h delivers 12.5 g of dextrose per hour.

On the **general surgical and medical wards**, most patients are treated with subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate- or long-acting insulins. Standardized order sets can reduce errors, and they often include algorithms for recognition and treatment of hypoglycemia (see <http://ucsfpatientdiabetes.pbworks.com> for examples).

The morbidity and mortality in diabetic patients is twice that of nondiabetic patients. Those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have even higher mortality—almost eightfold that of nondiabetic patients in one study. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

A large multicenter, multinational study (NICE-SUGAR) recruited 6104 surgical and medical ICU patients with hyperglycemia (20% had diabetes) and randomized them to tight control (blood glucose levels of 81–108 mg/dL [4.5–6 mmol/L]) or less tight control (glucose levels less than 180 mg/dL [10 mmol/L]). The tight group achieved blood glucose levels of 115 ± 18 mg/dL (6.4 ± 1.0 mmol/L) and the conventional group, 144 ± 23 mg/dL (8 ± 1.3 mmol/L). There were more deaths (829 versus 751 deaths) in the tight glucose control group compared with the less tight glucose control group ($P = 0.02$). The excess deaths in the intensive group were due to cardiovascular events. The intensively treated group also had more cases of severe hypoglycemia (206 versus 15 cases).

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered.

Thus, based on the evidence available, ICU patients with diabetes and new-onset hyperglycemia with blood glucose levels above 180 mg/dL (10 mmol/L) should be treated with insulin, aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL

(10 mmol/L). In the ICU setting, aiming for blood glucose levels close to 100 mg/dL (5.6 mmol/L) is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL (5.6 mmol/L) and 180 mg/dL (10 mmol/L) may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

B. Pregnancy and the Diabetic Patient

Tight glycemic control with normal HbA_{1c} levels is very important during pregnancy. Early in pregnancy, poor control increases the risk of spontaneous abortion and congenital malformations. Late in pregnancy, poor control can result in polyhydramnios, preterm labor, stillbirth, and fetal macrosomia with its associated problems. Diabetes complications can impact both maternal and fetal health. Diabetic retinopathy can first develop during pregnancy or retinopathy that is already present can worsen. Diabetic women with microalbuminuria can have worsening albuminuria during pregnancy and are at higher risk for preeclampsia. Patients who have preexisting kidney failure (prepregnancy creatinine clearance less than 80 mL/min) are at high risk for further decline in kidney function during the pregnancy, and this may not reverse after delivery. Diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy and some patients may require fluid and nutritional support.

Although there is evidence that glyburide is safe during pregnancy, the current practice is to control diabetes with insulin therapy. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia.

Regular and NPH insulin and the insulin analogs lispro, aspart, and detemir are labeled pregnancy category B. Insulin glargine, glulisine, and degludec are labeled category C because of lack of clinical safety data. A small study using insulin glargine in 32 pregnancies did not reveal any problems.

Unless there are fetal or maternal complications, diabetic women should be able to carry the pregnancy to full-term, delivering at 38 to 41 weeks. Induction of labor before 39 weeks may be considered if there is concern about increasing fetal weight. See Chapter 19 for further details.

► Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and

endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

▶ When to Refer

- All patients should receive self-management education when diabetes is diagnosed and at intervals thereafter. The instructional team must include a registered dietitian and registered nurse; they must be Certified Diabetes Educators (CDEs).
- Patients with type 1 diabetes should be referred to an endocrinologist for comanagement with a primary care provider.
- Patients with type 2 diabetes should be referred to an endocrinologist if treatment goals are not met or if the patient requires an increasingly complex regimen to maintain glycemic control.
- Patients with type 2 diabetes should be referred to an ophthalmologist or optometrist for a dilated eye examination when the diabetes is diagnosed, and patients with type 1 diabetes should be referred 5 years after the diagnosis is made.
- Patients with peripheral neuropathy, especially those with loss of protective threshold (unable to detect 5.07 Semmes-Weinstein filament) or structural foot problems, should be referred to a podiatrist.
- Referrals to other specialists may be required for management of chronic complications of diabetes.

DIABETIC COMA

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (diabetic ketoacidosis) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in patients with diabetes stricken with severe infections or with cardiovascular collapse.

DIABETIC KETOACIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Hyperglycemia greater than 250 mg/dL (13.9 mmol/L).
- ▶ Acidosis with blood pH < 7.3.
- ▶ Serum bicarbonate less than 15 mEq/L.
- ▶ Serum positive for ketones.

▶ General Considerations

Diabetic ketoacidosis may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in the elderly, who have mortality rates over 20%. The National Data Group reports an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which would signal the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance, either for psychological reasons or because of inadequate education, is one of the most common causes of recurrent diabetic ketoacidosis.

▶ Clinical Findings

A. Symptoms and Signs

The appearance of diabetic ketoacidosis is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. If untreated, mental stupor ensues that can progress to coma. Drowsiness is fairly common, but frank coma only occurs in about 10% of patients. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a

“fruity” breath odor of acetone would strongly suggest the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

Typically, the patient with moderately severe diabetic ketoacidosis has a plasma glucose of 350–900 mg/dL (19.4–50 mmol/L), serum ketones at a dilution of 1:8 or greater or beta-hydroxybutyrate more than 4 nmol/L, hyperkalemia (serum potassium level of 5–8 mEq/L), slight hyponatremia (serum sodium of approximately 130 mEq/L), hyperphosphatemia (serum phosphate level of 6–7 mg/dL [1.9–2.3 mmol/L]), and elevated blood urea nitrogen and serum creatinine levels (Table 27–11). Acidosis may be severe (pH ranging from 6.9 to 7.2 and serum bicarbonate ranging from 5 mEq/L to 15 mEq/L); PCO_2 is low (15–20 mm Hg) related to hyperventilation. Fluid depletion is marked, typically about 100 mL/kg.

The difference between venous and arterial pH is 0.02 to 0.15 pH units and venous and arterial bicarbonate is 1.88 mEq/L. These small differences will not affect either the diagnosis or the management of diabetic ketoacidosis, and there is no need to collect arterial blood for measuring the acid-base status.

The hyperkalemia occurs despite total body potassium depletion because of the shift of potassium from the intracellular to extracellular spaces that occurs in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3–5 mEq/kg. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced due to loss of sodium ions (7–10 mEq/kg) by polyuria and vomiting and because

severe hyperglycemia shifts intracellular water into the interstitial compartment. There is some controversy about the correction factor for the serum sodium in the presence of hyperglycemia. Many guidelines recommend a correction factor, whereby the serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL (5.56 mmol/L) rise in plasma glucose above normal, but there is evidence that the decrease may be greater when patients have more severe hyperglycemia (greater than 400 mg/dL or 22.2 mmol/L) and/or volume depletion. One group has suggested (based on short-term exposure of normal volunteers to markedly elevated glucose levels) that, when the serum glucose is greater than 200 mg/dL (11.1 mmol/L), the serum sodium concentration decreases by at least 2.4 mEq/L. Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mOsm/kg):

$$mOsm/kg = 2 [\text{measured } Na^+] + \frac{\text{Glucose (mg/dL)}}{18}$$

These calculated estimates are usually 10–20 mOsm/kg lower than values measured by standard cryoscopic techniques. Central nervous system depression or coma occurs when the effective serum osmolality exceeds 320–330 mOsm/L. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality (see Chapter 21).

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to increases in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, reduced ketolysis by insulin-deficient peripheral tissues

Table 27–11. Laboratory diagnosis of coma in diabetic patients.

	Urine Glucose	Urine Ketones	Plasma Glucose	Plasma Bicarbonate	Plasma Ketones
Related to diabetes					
Hypoglycemia	0 ¹	0 or +	Low	Normal	0
Diabetic ketoacidosis	++++	++++	High	Low	++++
Hyperglycemic hyperosmolar state coma	++++	0	High	Normal or slightly low	0
Lactic acidosis	0 or +	0 or +	Normal or low or high	Low	0 or +
Unrelated to diabetes					
Alcohol or other toxic drugs	0 or +	0 or +	May be low	Normal or low ²	0 or +
Cerebrovascular accident or head trauma	+ or 0	0	Often high	Normal	0
Uremia	0 or +	0	High or normal	Low	0 or +

¹Leftover urine in bladder might still contain glucose from earlier hyperglycemia.

²Alcohol can elevate plasma lactate as well as keto acids to reduce pH.

contributes to the ketoacidemia. The only true “keto” acid present is acetoacetic acid which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol/L, which is seldom reached in the plasma of ketoacidotic patients—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent beta-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase beta-hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents are then unreliable, suggesting no ketonemia in cases where beta-hydroxybutyric acid is a major factor in producing the acidosis. Combined glucose and ketone meter (Precision Xtra, Nova Max Plus) that measure blood beta-hydroxybutyrate concentration on capillary blood are now available. Many clinical laboratories also offer direct blood beta-hydroxybutyrate measurement.

Nonspecific elevations of serum amylase and lipase occurs in about 16–25% of cases of diabetic ketoacidosis, and an imaging study may be necessary if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

▶ Treatment

Patients with mild diabetic ketoacidosis are alert and have pH levels between 7.25 and 7.30 and beta-hydroxybutyrate levels of 3–4 mmol/L; those with moderate ketoacidosis are either alert or little drowsy and have pH levels between 7.0 and 7.24 and beta-hydroxybutyrate levels of 4–8 mmol/L; and those with severe ketoacidosis are stuporose and have a pH < 7.0 and beta-hydroxybutyrate levels of greater than 8 mmol/L. Those with mild ketoacidosis can be treated in the emergency department, but those with moderate or severe ketoacidosis require admission to the ICU or step-down unit. Therapeutic goals are to restore plasma volume and tissue perfusion, reduce blood glucose and osmolality toward normal, correct acidosis, replenish electrolyte losses, and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of diabetic ketoacidosis. An indwelling catheter may also be necessary. In patients with preexisting heart or kidney failure or those in severe cardiovascular collapse, a central venous pressure catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the

clinician responsible for the patient's care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2–3 hours during the initial treatment period. Bedside glucose meters should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids in order to avoid masking signs and symptoms of impending cerebral edema.

A. Fluid Replacement

In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9% (“normal”) saline unless the serum sodium is greater than 150 mEq/L, when 0.45% (“half normal”) saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL (13.9–16.7 mmol/L). This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose.

B. Insulin Replacement

Immediately after initiation of fluid replacement, regular insulin should be given intravenously in a loading dose of 0.1 unit/kg as a bolus to prime the tissue insulin receptors. Following the initial bolus, intravenous doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. A prospective randomized study showed that a bolus dose is not required if patients are given hourly insulin infusion at 0.14 unit/kg. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin dose should be “piggy-backed” into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a

repeat loading dose (0.1 or 0.14 unit/kg) is recommended. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin. The insulin dose should be adjusted to lower the glucose concentration by about 50–70 mg/dL (2.8–3.9 mmol/L). Patients who are normally take insulin glargine or insulin detemir can be given their usual maintenance doses during initial treatment of their diabetic ketoacidosis. The continuation of their subcutaneous basal insulins means that lower doses of intravenous insulin will be needed, and there will be a smoother transition from intravenous insulin infusion to the subcutaneous regimen.

C. Potassium

Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. Occasionally, a patient may present with a serum potassium level less than 3.5 mEq/L, in which case insulin therapy should be delayed until the potassium level is corrected to greater than 3.5 mEq/L. An ECG can be of help in monitoring the patient's potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

D. Sodium Bicarbonate

The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected; (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve); and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when very severe acidosis exists. Therefore, it is recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection.

One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline with 20 mEq KCl or to 400 mL of sterile water with 20 mEq KCl and infused over 1 to 2 hours. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) It can be repeated until the arterial pH reaches 7.1, but *it should not be given if the pH is 7.1 or greater* since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

E. Phosphate

Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. However, three randomized studies in which phosphate was replaced in patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3–4 mmol/h* in a 60–70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL (0.8 mmol/L) after this infusion, a repeat 5-hour infusion can be given.

F. Hyperchloremic Acidosis During Therapy

Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered. Using a balanced electrolyte solution similar to serum in chloride concentration and pH during resuscitation instead of normal saline has been reported to prevent the hyperchloremic acidosis.

G. Treatment of Associated Infection

Antibiotics are prescribed as indicated. Cholecystitis and pyelonephritis may be particularly severe in these patients.

H. Transition to Subcutaneous Insulin Regimen

Once the diabetic ketoacidosis is controlled and the patient is awake and able to eat, subcutaneous insulin therapy can be initiated. The patient with type 1 diabetes may have persistent significant tissue insulin resistance and may require a total daily insulin dose of approximately 0.6 units/kg. The amount of insulin required in the previous 8 hours can also be helpful in estimating the initial insulin doses. Half the total daily dose can be given as a long-acting basal insulin and the other half as short-acting insulin premeals. The patient should receive subcutaneous basal insulin and rapid-acting insulin analog with the first meal and the insulin infusion discontinued an hour later. The overlap of the subcutaneous insulin action and insulin infusion is necessary to prevent relapse of the diabetic ketoacidosis. The increased insulin resistance is only present for a few days, and it is important to reduce both the basal and bolus insulins to avoid hypoglycemia. A patient with new-onset type 1 diabetes usually still has significant beta cell function and may not need any basal insulin and only very low doses of rapid-acting insulin before meals after recovery from the ketoacidosis. Patients with type 2 diabetes and diabetes ketoacidosis due to severe illness may initially require insulin therapy but can often transition back to oral agents during outpatient follow-up.

Prognosis

Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients' clinical and laboratory responses to therapy have dramatically reduced the mortality rates of diabetic ketoacidosis to less than 5%. However, this complication remains a significant risk in the aged who have mortality rates greater than 20% and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is end-stage chronic kidney disease, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for its development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intravenous mannitol at a dosage of 1–2 g/kg given over 15 minutes is the mainstay of treatment. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment of diabetic ketoacidosis.

After recovery and stabilization, patients should be instructed on how to recognize the early symptoms and signs of ketoacidosis. Urine ketones or capillary blood

beta-hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose remains unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental rapid acting insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the clinician if ketonuria persists, and especially if there is vomiting and inability to keep down fluids. Recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive counseling.

HYPERGLYCEMIC HYPEROSMOLAR STATE

ESSENTIALS OF DIAGNOSIS

- ▶ Hyperglycemia greater than 600 mg/dL (33.3 mmol/L).
- ▶ Serum osmolality greater than 310 mOsm/kg.
- ▶ No acidosis; blood pH > 7.3.
- ▶ Serum bicarbonate greater than 15 mEq/L.
- ▶ Normal anion gap (less than 14 mEq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are typically middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than diabetic ketoacidosis even in older age groups. Underlying chronic kidney disease or heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain medications such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As the plasma volume contracts,

kidney function becomes impaired, limiting the urinary glucose losses and exacerbating the hyperglycemia. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

▶ Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. Lethargy and confusion develop as serum osmolality exceeds 310 mOsm/kg, and convulsions and coma can occur if osmolality exceeds 320–330 mOsm/kg. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

Severe hyperglycemia is present, with blood glucose values ranging from 800 mg/dL to 2400 mg/dL (44.4 mmol/L to 133.2 mmol/L) (Table 27–11). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mOsm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL (35.7 mmol/L) being typical.

▶ Treatment

A. Fluid Replacement

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolality is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. Once blood glucose reaches 250 mg/dL (13.9 mmol/L), fluid replacement

should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL (13.9–16.7 mmol/L) in order to reduce the risk of cerebral edema. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (beta-hydroxybutyrate more than 1 mmol/L). Start the insulin infusion rate at 0.05 units/kg/h (bolus is not needed) and titrate to lower blood glucose levels by 50–70 mg/dL per hour (2.8–3.9 mmol/L/h). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in diabetic ketoacidosis, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it has been recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate less than 1 mg/dL [0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

▶ Prognosis

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid replacement remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication and should be looked for and treated.

The overall mortality rate of hyperglycemic hyperosmolar state coma is more than ten times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is

often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (nausea and vomiting, infection) that predispose to recurrence of the hyperglycemic, hyperosmolar state, as well as detailed information on how to prevent the escalating dehydration that culminates in hyperosmolar coma (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the clinician).

LACTIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Severe acidosis with hyperventilation.
- ▶ Blood pH below 7.30.
- ▶ Serum bicarbonate less than 15 mEq/L.
- ▶ Anion gap greater than 15 mEq/L.
- ▶ Absent serum ketones.
- ▶ Serum lactate greater than 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Overproduction of lactic acid (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse) can cause accumulation. Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of bowel or extremities. Lactic acidosis in patients with diabetes mellitus is

uncommon but occasionally occurs in metformin-treated patients (see above) and it still must be considered in the acidotic diabetic patient, especially if the individual is seriously ill. Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular kidney failure.

Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from medication overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See also Chapter 21.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.¹

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent.

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by

¹ In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated and in cases associated with metformin toxicity.

► Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

Lalau JD. Lactic acidosis induced by metformin: incidence, management and prevention. *Drug Saf.* 2010 Sep 1;33(9):727–40. [PMID: 20701406]

THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL (3.3 mmol/L) and impairment of brain function at approximately 50 mg/dL (2.8 mmol/L). Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

► Differential Diagnosis (Table 27–12)

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or

Table 27–12. Common causes of hypoglycemia in adults.¹

Fasting hypoglycemia
Pancreatic B cell tumor
Surreptitious administration of insulin or sulfonylureas
Extrapancreatic tumors
Postprandial hypoglycemia
Alimentary
Noninsulinoma pancreatogenous hypoglycemia syndrome
Functional
Occult diabetes mellitus
Alcohol-related hypoglycemia
Immunopathologic hypoglycemia
Idiopathic anti-insulin antibodies (which release their bound insulin)
Antibodies to insulin receptors (which act as agonists)
Drug-induced hypoglycemia

¹In the absence of clinically obvious endocrine, renal, or hepatic disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.

inborn metabolic diseases from childhood, the principal diagnostic possibilities include: (1) hyperinsulinism, due to either pancreatic B cell tumors, iatrogenic or surreptitious administration of insulin or sulfonylurea and (2) hypoglycemia due to extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. Occult diabetes very occasionally present with postprandial hypoglycemia. Rarely, it occurs with islet cell hyperplasia—the so-called noninsulinoma pancreatogenous hypoglycemia syndrome.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished alcohol abusers but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously. In the former case, the mechanism appears to relate to increasing dissociation of insulin from circulating pools of bound insulin. When antibodies to insulin receptors are found, most patients do not have hypoglycemia but rather severe insulin-resistant diabetes and acanthosis nigricans. However, during the course of the disease in these patients, certain anti-insulin receptor antibodies with agonist activity mimicking insulin action may develop, producing severe hypoglycemia.

HYPOGLYCEMIA DUE TO PANCREATIC B CELL TUMORS

ESSENTIALS OF DIAGNOSIS

- ▶ Hypoglycemic symptoms—frequently neuroglycopenic (confusion, blurred vision, diplopia, anxiety, convulsions).
- ▶ Immediate recovery upon administration of glucose.
- ▶ Blood glucose less than 45 mg/dL (2.5 mmol/L) with a serum insulin level of 6 microunit/mL or more.

► General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (MEN type 1 [MEN 1]). It has been reported that about 30% of sporadic insulinoma tumors have a somatic mutation in the YY1 gene (T372R)

that encodes the transcriptional repressor YY1. Over 99% of insulinomas are located within the pancreas and less than 1% in ectopic pancreatic tissue.

Clinical Findings

A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In long-standing cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called Whipple triad is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated fasting blood glucose of 45 mg/dL (2.5 mmol/L) or less, and (3) immediate recovery upon administration of glucose. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise. They typically begin with evidence of central nervous system glucose lack and can include blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Sweating and palpitations may not occur.

Hypoglycemic unawareness is very common in patients with insulinoma. They adapt to chronic hypoglycemia by increasing their efficiency in transporting glucose across the blood-brain barrier, which masks awareness that their blood glucose is approaching critically low levels. Counterregulatory hormonal responses as well as neurogenic symptoms such as tremor, sweating, and palpitations are therefore blunted during hypoglycemia. If lack of these warning symptoms prevents recognition of the need to eat to correct the problem, patients can lapse into severe hypoglycemic coma. However, symptoms and normal hormone responses during experimental insulin-induced hypoglycemia have been shown to be restored after successful surgical removal of the insulinoma. Presumably with return of euglycemia, adaptive effects on glucose transport into the brain are corrected, and thresholds of counterregulatory responses and neurogenic autonomic symptoms are therefore restored to normal.

B. Laboratory Findings

B cell adenomas do not reduce secretion of insulin in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin, proinsulin, and C-peptide levels at a time when plasma glucose level is below 45 mg/dL.

The diagnostic criteria for insulinoma after a 72-hour fast are listed in Table 27–13. Other causes of hyperinsulinemic hypoglycemia must be considered, including factitious

Table 27–13. Diagnostic criteria for insulinoma after a 72-hour fast.

Laboratory Test	Result
Plasma glucose	< 45 mg/dL (2.5 mmol/L)
Plasma insulin (RIA) ¹	≥ 6 microunit/mL (36 pmol/L)

administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and low C-peptide levels. In patients who have injected insulin, the insulin/C-peptide ratio (pmol/L) will be greater than 1. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide levels (by immunochemiluminometric assays [ICMA]) of greater than 200 pmol/L and proinsulin levels (by radioimmunoassay [RIA]) of greater than 5 pmol/L are characteristic of insulinomas. In patients with insulinoma, plasma beta-hydroxybutyrate levels are suppressed to 2.7 mmol/L or less. No single hormone measurement (insulin, proinsulin, C-peptide) is 100% sensitive and specific for the diagnosis of insulinoma, and insulinoma cases have been reported with insulin levels below 3 microunit/mL (ICMA assay) or proinsulin level below 5 pmol/L. These hormonal assays are also not standardized between laboratories, and there can be significant variation in the results. Therefore, the diagnosis should be based on multiple biochemical parameters.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms and before consumption of carbohydrates, if this can be done safely. Patients with insulinomas frequently report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis, however, cannot be made based on a fingerstick blood glucose. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin, and C-peptide levels and a negative sulfonylurea screen. When patients give

a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 mg/dL (2.8 mmol/L) then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient supervised 72-hour fast. A suggested protocol for the supervised fast is shown in Table 27–14.

In 30% of patients with insulinoma, the blood glucose levels often drop below 45 mg/dL (2.5 mmol/L) after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term “72-hour fast” is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL (3.1–3.3 mmol/L) during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL (1.9 mmol/L). In these cases,

however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level of 6 microunit/mL or more using a RIA assay (greater than 3 microunit/mL using an ICMA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis.

Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine has been devised to demonstrate exaggerated and prolonged insulin secretion in the presence of insulinomas. However, because insulin-secreting tumors have a wide range of granule content and degrees of differentiation, they are variably responsive to these secretagogues; and a negative response does not necessarily rule out an insulinoma. For these reasons, stimulation tests are not recommended in the diagnostic work-up of insulinoma.

An oral glucose tolerance test is of no value in the diagnosis of insulin secreting tumors. HbA_{1c} levels may be low but there is considerable overlap with normal patients and no particular value is diagnostic.

D. Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate.

Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all of them. A pancreatic dual phase helical CT scan with thin section can identify 82–94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially for those with no hypervascular pattern. The imaging study used will depend on local availability and local radiologic skill. If the imaging study is normal, then an endoscopic ultrasound should be performed. In experienced hands, about 80–90% of tumors can be detected with this procedure. Fine-needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or the imaging result is equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to a particular region of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Calcium gluconate 10% solution diluted to a volume

Table 27–14. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.

- (1) Obtain baseline plasma glucose, insulin, proinsulin, and C-peptide measurements at onset of fast and place intravenous cannula.
- (2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
- (3) Measure urine for ketones at the beginning and every 12 hours and at end of fast.
- (4) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is < 45 mg/dL send a venous blood sample to the laboratory for plasma glucose,¹ insulin, proinsulin, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.
- (5) If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is < 45 mg/dL, or if 72 hours have elapsed then conclude the fast with a final blood sample for plasma glucose,¹ insulin, proinsulin, C-peptide, beta-hydroxybutyrate and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, then administer 50 mL of 50% dextrose intravenously over 3 to 5 minutes. Do not conclude a fast based simply on a capillary blood glucose measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.

¹Glucose sample should be collected in sodium fluoride containing tube on ice to prevent glycolysis and the plasma separated immediately upon receipt at the laboratory. Arrange for the laboratory to run the glucose samples “stat.”

of 5 mL with 0.95% saline is bolused into the selected artery at a dose of 0.0125 mmol calcium/kg (0.005 mmol calcium/kg for obese patients). Small samples of blood (5 mL) are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after the calcium injection. Fingertick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure to prevent hypoglycemia. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up from baseline in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery calcium infusions. A less than twofold elevation of insulin in the 120-second sample may represent effects of recirculating calcium and is not considered a positive localization. In a single insulinoma, the response is in one artery alone unless the tumor resides in an area fed by two arteries or if there are multiple insulinomas (eg, in MEN 1). Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatogenous hypoglycemia syndrome) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48–72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

► Treatment

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given oral diazoxide. Divided doses of 300–400 mg/day usually suffice although an occasional patient may require up to 800 mg/day. Side effects include edema due to sodium retention, gastric irritation, and mild hirsutism. Hydrochlorothiazide, 25–50 mg daily, can be used to counteract the sodium retention and edema as well potentiate diazoxide's hyperglycemic effect.

In patients with a single benign pancreatic B cell adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Diazoxide should be administered on the day of the surgery because it reduces the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose should be monitored throughout surgery, and 5% or 10% dextrose infusion should be used to maintain euglycemia. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and

enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

In patients with inoperable functioning islet cell carcinoma with and without hepatic metastasis and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, the treatment approach is the same as for other types of pancreatic neuroendocrine tumors (pNETs). Diazoxide is the treatment of choice in preventing hypoglycemia. Frequent carbohydrate feedings (every 2–3 hours) can also be helpful, although weight gain can become a problem. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, verapamil (which inhibits insulin release from insulinoma cells) can be tried. Somatostatin analogs, octreotide or lanreotide, should be considered if diazoxide is ineffective or if there is tumor progression. These drugs not only inhibit insulin secretion but also have antiproliferative activity. Surgery or embolization (bland, chemo- and radio-) or thermal ablation (radiofrequency, microwave, and cryoablation) can be used to reduce tumor burden and also provide symptomatic relief. There are also chemotherapy regimens that can be considered. Regimens include combination of streptozocin, 5-fluorouracil, and doxorubicin; capecitabine and oxaliplatin; and capecitabine and temozolomide. There is only limited data regarding efficacy of these regimens. Targeted therapies against multiple steps in PI3K/AKT/mTor pathway have been shown to be helpful; everolimus, an inhibitor of mTor, has been approved for treatment of advanced pNETs. Sunitinib, a monoclonal antibody against VEGF receptors 2 and 3, PDGFR alpha and beta and c-kit, has been shown to slow growth of pNETs. Treatment with radioisotopes (indium-111 or yttrium-90 or lutetium-177) linked to a somatostatin analog have been reported to show benefit in a proportion of patients.

NONISLET CELL TUMOR HYPOGLYCEMIA

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

In many cases the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor 2 (IGF-2) by the tumor. This immature form of the IGF-II molecule (pro-IGF-2 or “big IGF-2”) binds IGF-binding protein-3 (IGFBP-3) but not to the acid-labile subunit. As a consequence, this pro-IGF-II remains active and binds to insulin receptors in muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. It also binds to receptors for IGF-1 in the pancreatic B cell to inhibit insulin secretion

and in the pituitary to suppress growth hormone release. With the reduction of growth hormone, there is a consequent lowering of IGF-1 levels as well as IGFBP-3 and acid-labile subunit.

The diagnosis is supported by laboratory documentation of serum insulin levels below 5 microunit/mL with plasma glucose levels of 45 mg/dL (2.5 mmol/L) or lower. Values for growth hormone and IGF-1 are also decreased. Levels of IGF-2 may be increased but often are “normal” in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can only be detected by special laboratory techniques.

Not all the patients with nonislet cell tumor hypoglycemia have elevated pro-IGF-II. Ectopic insulin production has been described in bronchial carcinoma, ovarian carcinoma, and small cell carcinoma of the cervix. Hypoglycemia due to IgF-1 released from a metastatic large cell carcinoma of the lung has also been reported. GLP-1 secreting tumors (ovarian and pNETs) can also cause hypoglycemia by stimulating insulin release from normal pancreatic islets.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

POSTPRANDIAL HYPOGLYCEMIA

1. Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes develops in patients who have undergone gastric surgery (eg, gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, Nissan fundoplication, Bilroth II procedure and Roux-en-Y), especially when they consume foods containing high levels of carbohydrates. This late dumping syndrome occurs about 1–3 hours after a meal and is a result of rapid delivery of high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. The hyperinsulinemic response to the high carbohydrate load causes hypoglycemia. The symptoms include lightheadedness, sweating, confusion and even loss of consciousness after eating a high carbohydrate meal. It is likely that excessive release of gastrointestinal hormones such as GLP-1 play a role in the hyperinsulinemic response. It has been reported that treatment with exendin 9-39, a GLP-1 receptor agonist can prevent post gastric bypass hypoglycemia. The incidence of secondary dumping syndrome declined with the advent of medical therapy for peptic ulcer disease. There has been resurgence of cases, however, with the popularity of Roux-en-Y gastric bypass surgery for the treatment of morbid obesity. Patients typically complain of symptoms that are more severe after consumption of large amounts of readily absorbable carbohydrates. In terms of documenting hypoglycemia, it is reasonable to request the patient to consume

a meal that leads to symptoms during everyday life. An oral glucose tolerance test is not recommended because many normal persons have false-positive test results. There have been case reports of insulinoma and noninsulinoma pancreatogenous hypoglycemia syndrome in patients with hypoglycemia post Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify patients who have a history of hypoglycemia with exercise or missed meals, and these individuals may require a formal 72-hour fast to rule out an insulinoma.

Treatment for secondary dumping includes dietary modification, but this may be difficult to sustain. Patients can try more frequent meals with smaller portions of less rapidly digested carbohydrates. Alpha-glucosidase therapy may be a useful adjunct to a low carbohydrate diet. Octreotide 50 mcg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms due to late dumping syndrome. Various surgical procedures to delay gastric emptying have been reported to improve symptoms but long-term efficacy studies are lacking.

2. Noninsulinoma Pancreatogenous Hypoglycemia Syndrome (Islet Cell Hyperplasia)

In a very small number of patients with organic hyperinsulinism, islet cell hyperplasia is present rather than an adenoma. This condition is referred to as noninsulinoma pancreatogenous hypoglycemia syndrome. These patients typically have documented hyperinsulinemic hypoglycemia after meals but not with fasting up to 72 hours. The patients have a positive response to calcium-stimulated angiography. A gradient-guided partial pancreatectomy leads to clinical remission, and the pathology of the pancreas shows evidence of islet cell hyperplasia and nesidioblastosis. These patients do not have mutations in the pancreatic islet beta-cell ATP-sensitive potassium channel inward rectifier (*Kir 6.2*) and the sulfonylurea receptor-1 (*SURI*) genes, which have been reported in children with familial hyperinsulinemic hypoglycemia.

3. Functional Alimentary Hypoglycemia

Patients have symptoms suggestive of increased sympathetic activity, including anxiety, weakness, tremor, sweating or palpitations after meals. Physical examination and laboratory tests are normal. It is not recommended that patients with symptoms suggestive of increased sympathetic activity undergo either a prolonged oral glucose tolerance test or a mixed meal test. Instead, the patients should be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (less than 50 mg/dL) and who have resolution of symptoms when the glucose is raised by eating rapidly released carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays in therapy, with dietary manipulation only an adjunct.

4. Occult Diabetes

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are often obese and frequently have a family history of diabetes mellitus.

Patients with this type of postprandial hypoglycemia often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. In the obese, treatment is directed at weight reduction to achieve ideal weight. These patients should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

5. Autoimmune Hypoglycemia

Patients with autoimmune hypoglycemia have early postprandial hyperglycemia followed by hypoglycemia 3–4 hours later. The hypoglycemia is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin.

The disorder is associated with methimazole treatment for Graves disease, although it can also occur in patients treated with various other sulfhydryl-containing medications (captopril, penicillamine) as well as other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis as well as in multiple myeloma and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin. There is also an association with the HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302). These alleles are 10 to 20 times more common in Japanese and Korean populations, which explains why the disorder has been reported mostly in Japanese patients.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases, the hypoglycemia is transient and usually resolves spontaneously within 3–6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with small, frequent low-carbohydrate meals. Prednisone (30–60 mg orally daily) has been used to lower the titer of insulin antibodies.

Lupsa BC et al. Autoimmune forms of hypoglycemia. *Medicine* (Baltimore). 2009 May;88(3):141–53. [PMID: 19440117]

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has

access to insulin or sulfonylurea medications taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C peptide immunoreactivity is pathognomonic of exogenous insulin administration. Insulin and C peptide is secreted in a 1:1 molar ratio. A large fraction of the endogenous insulin is cleared by the liver whereas C peptide, which is cleared by the kidney, has a lower metabolic clearance rate. For this reason, the molar ratio of insulin and C peptide in a hypoglycemic patient should be less than 1.0 in cases of insulinoma and is greater than 1.0 in cases of exogenous insulin administration. When sulfonylureas, repaglinide and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

HYPOGLYCEMIA DUE TO INSULIN RECEPTOR ANTIBODIES

Hypoglycemia due to insulin receptor autoantibodies is an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to corticosteroid therapy but not to plasmapheresis or immunosuppression.

Kim CH et al. Autoimmune hypoglycemia in a type 2 diabetic patient with anti-insulin and insulin receptor antibodies. *Diabetes Care*. 2004 Jan;27(1):288–9. [PMID: 14694017]

MEDICATION-INDUCED HYPOGLYCEMIA

A number of medications apart from the sulfonylureas can occasionally cause hypoglycemia. Common offenders include the fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, ACE inhibitors, salicylates and beta-adrenergic blocking agents. The fluoroquinolones, particularly gatifloxacin, have been associated with both hypoglycemia and hyperglycemia. It is thought that the drug acts on the ATP sensitive potassium channels in the beta cell. Hypoglycemia is an early event, and hyperglycemia occurs several days into therapy. Intravenous pentamidine is cytotoxic to beta cells and causes acute hyperinsulinemia and hypoglycemia followed by insulinopenia and hyperglycemia. Fasting patients taking noncardioselective beta-blockers can have an exaggerated hypoglycemic response to starvation. The beta-blockade inhibits fatty acids and gluconeogenesis substrate release and reduces plasma glucagon response. Therapy with ACE inhibitors increases the risk of hypoglycemia in patients who are taking insulin or sulfonylureas presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to the muscle.

Ethanol-associated hypoglycemia may be due to hepatic depletion of NADH and altered NADH:NAD ratio. This in turn limits conversion of lactate to pyruvate, the main substrate for hepatic gluconeogenesis. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL (9.8 mmol/L) can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

Lipid Disorders

Robert B. Baron, MD, MS

28

For patients with known cardiovascular disease (secondary prevention), cholesterol lowering leads to a consistent reduction in total mortality and recurrent cardiovascular events in men and women and in middle-aged and older patients. Among patients without cardiovascular disease (primary prevention), the data are less conclusive, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Nonetheless, treatment guidelines have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their overall risk of developing cardiovascular disease.

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In fasting serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

$$\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}$$

Most clinical laboratories measure the total cholesterol, the total triglycerides, and the amount of cholesterol found in the HDL fraction, which is easily precipitated from serum. Most triglyceride is found in VLDL particles, which contain five times as much triglyceride by weight as

cholesterol. The amount of cholesterol found in the VLDL fraction can be estimated by dividing the triglyceride by 5:

$$\text{VLDL cholesterol} = \frac{\text{Triglycerides}}{5}$$

Because the triglyceride level is used as a proxy for the amount of VLDL, this formula works only in fasting samples and when the triglyceride level is less than 400 mg/dL (4.52 mmol/L). At higher triglyceride levels, LDL and VLDL cholesterol levels can be determined after ultracentrifugation or by direct chemical measurement.

The total cholesterol is reasonably stable over time; however, measurements of HDL and especially triglycerides may vary considerably because of analytic error in the laboratory and biologic variation in a patient's lipid level. Thus, the LDL should always be estimated as the mean of at least two determinations; if those two estimates differ by more than 10%, a third lipid profile is obtained. The LDL is estimated as follows:

$$\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides (mg/dL)}}{5}$$

When using SI units, the formula becomes

$$\text{LDL cholesterol} = \text{Total cholesterol} - \text{HDL cholesterol} - \frac{\text{Triglycerides (mmol/L)}}{2.2}$$

Some authorities use the ratio of the total to HDL cholesterol as an indicator of lipid-related coronary risk: the lower this ratio is, the better. Although ratios are useful predictors within populations of patients, they may obscure important information in individual patients. (A total cholesterol of 300 mg/dL [7.76 mmol/L] and an HDL of 60 mg/dL [1.56 mmol/L] result in the same ratio as a total cholesterol of 150 mg/dL [3.88 mmol/L] with an HDL of 30 mg/dL [0.78 mmol/L].) Moreover, the total

cholesterol-to-HDL cholesterol ratio will magnify the importance of variations in HDL measurement.

There is no true “normal” range for serum lipids. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL (7.76 mmol/L) in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL (5.17 mmol/L). Total and LDL cholesterol levels tend to rise with age in persons who are otherwise in good health.

Declines are seen in acute illness, and lipid studies in such patients are of little value with the exception of the serum triglyceride level in a patient with pancreatitis. Cholesterol levels (even when expressed as an age-matched percentile rank, such as the highest 20%) do not remain constant over time, especially from childhood through adolescence and young adulthood. Thus, children and young adults with relatively high cholesterol may have lower levels later in life, whereas those with low cholesterol may show increases.

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Reducing cholesterol levels in healthy middle-aged men without CHD (primary prevention) reduces their risk in proportion to the reduction in LDL cholesterol. Treated adults have statistically significant and clinically important reductions in the rates of myocardial infarctions, strokes, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent a nonfatal myocardial infarction or a coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in persons with hypertension and other risk factors but without CHD demonstrated a 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes in both men and women. The NNT for 1 year to prevent one event was 169.

Primary prevention studies have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically

significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400.

In patients with CHD, the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a nonfatal myocardial infarction or a coronary artery disease death in these studies was between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Results with other classes of medications have been less consistent. For example, patients treated with gemfibrozil had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo.

The disparities in results between primary and secondary prevention studies highlight several important points. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects will generalize to other classes of medication. Second, the net benefits from cholesterol lowering depend on the underlying risk of CHD and of other disease. In patients with atherosclerosis, morbidity and mortality rates associated with CHD are high, and measures that reduce it are more likely to be beneficial even if they have no effect—or even slightly harmful effects—on other diseases.

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including drugs, can influence serum lipids. These are important for two reasons: abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Diabetes and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with cardiovascular disease or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL or 10 mmol/L) result in the formation of **eruptive xanthomas** (Figure 28–1) (red-yellow papules, especially on the buttocks). High LDL concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. **Lipemia retinalis** (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL or 20 mmol/L).

SCREENING & TREATMENT OF HIGH BLOOD CHOLESTEROL

All patients with cardiovascular disease and diabetes should have their lipids measured. The only exceptions are patients in whom lipid lowering is not indicated for other

▲ **Figure 28–1.** Eruptive xanthoma on the arm of a man with untreated hyperlipidemia and diabetes mellitus. (Reproduced, with permission, from Richard P. Usatine, MD.)

reasons. Patients who already have evidence of atherosclerosis are the group at highest risk for suffering additional manifestations in the near term and thus have the most to gain from lipid lowering. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of the disease.

In patients with cardiovascular disease, a complete lipid profile (total cholesterol, HDL cholesterol, and triglyceride levels) after an overnight fast should be obtained. According to the 2013 American College of Cardiology/American Heart Association (ACC/AHA) guidelines, however, such patients are treated with statins independent of their lipid levels. Similarly, patients aged 40–75 with diabetes should also have a complete lipid profile. Those with diabetes and LDL greater than or equal to 70 mg/dL (1.81 mmol/L) should be treated with statins.

The best screening and treatment strategy for adults who do not have atherosclerotic cardiovascular disease is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions are individualized based on the patient's risk.

Although the 2013 ACC/AHA guidelines recommend screening of all adults aged 21 years or older for high blood cholesterol, the United States Preventive Services Task Force (USPSTF) suggests beginning at age 20 years only if there are other cardiovascular risk factors such as tobacco use, diabetes, hypertension, obesity, or a family history of premature cardiovascular disease. For men without other risk factors, screening is recommended beginning at age 35 years. For women and for men aged 20 to 35 without increased risk, the USPSTF makes no recommendation for or against routine screening for lipid disorders. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds.

Individuals without cardiovascular disease should have their 10-year risk of CHD calculated. Although those with LDL cholesterol greater than 190 mg/dL (4.91 mmol/L) are recommended for treatment independent of their 10-year risk of cardiovascular disease, all other patients are recommended for treatment based on their overall cardiovascular risk. The best method for estimating 10-year risk is controversial. The 2013 ACC/AHA guidelines include a risk calculator that measures cardiovascular risk. It can be downloaded at myamericanheart.org under Statements & Guidelines and then Prevention Guidelines. It has been criticized by some authors as overestimating risk. The older Framingham 10-year calculator includes CHD but not stroke risk. One approach is to use both risk calculators until better data are available.

Numerous other risk factors have been studied in an attempt to better predict future CHD events. These include high-sensitivity C-reactive protein (hs-CRP), electron beam computed tomography (EBCT), homocysteine, fibrinogen, lipoprotein (a), LDL subfractions, ankle-brachial index, and others. Several of these, particularly hs-CRP and EBCT, may add additional prognostic ability after accounting for traditional risk factors, but no clinical

trials have adequately examined the effect of these on health outcomes. Clinical guidelines suggest limiting the use of additional risk factors such as hs-CRP to selected patients if additional data are likely to change a therapeutic decision.

Several strategies for obtaining the initial cholesterol measurement have been proposed, including: (1) measuring total cholesterol alone, (2) measuring total cholesterol and HDL cholesterol, or (3) measuring LDL cholesterol. Initial measurement of the LDL cholesterol is least likely to lead to patient misinformation and misclassification and is the strategy recommended by the 2013 ACC/AHA guidelines.

Treatment decisions are based on the presence of clinical cardiovascular disease or diabetes, patient age, LDL cholesterol greater than 190 mg/dL (4.91 mmol/L), and the estimated 10-year risk of developing cardiovascular disease. The 2013 ACC/AHA guidelines define four groups of patients who benefit from statin medications: (1) individuals with clinical atherosclerotic cardiovascular disease; (2) individuals with primary elevation of LDL cholesterol greater than 190 mg/dL (4.91 mmol/L); (3) individuals aged 40–75 with diabetes and LDL greater than or equal to 70 mg/dL (1.81 mmol/L); and (4) individuals aged 40–75 without clinical atherosclerotic cardiovascular disease or diabetes, with LDL 70–189 mg/dL (1.81–4.91 mmol/L), and estimated 10-year CVD risk of 7.5% or higher.

► Screening & Treatment in Women

The foregoing screening and treatment guidelines are designed for both men and women. Yet several observational studies suggest that a low HDL cholesterol is a more important risk factor for CHD in women than a high LDL cholesterol. Meta-analysis of studies including women with known heart disease, however, has found that statins prevent recurrent myocardial infarctions in women. There is insufficient evidence to be certain of a similar effect from statins in women without evidence of CHD. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Estimating the 10-year cardiovascular risk is particularly important in women since a larger percentage of women than men will have estimated 10-year cardiovascular risks below 7.5% per year and be advised not to take statins unless their LDL is very high (greater than 190 mg/dL [4.91 mmol/L]).

► Screening & Treatment in Older Patients

Meta-analysis of evidence relating cholesterol to CHD in the elderly suggests that cholesterol is not a risk factor for CHD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with cardiovascular disease (secondary prevention) benefited from statin therapy, whereas those without cardiovascular disease (primary prevention) did not. The 2013 ACC/AHA guidelines suggest continuing statin treatment in patients over age 75 who have cardiovascular disease. The guidelines, however,

suggest not screening or treating patients over the age of 75 who do not have evidence of cardiovascular disease. Individual patient decisions to discontinue statin therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

TREATMENT OF HIGH LDL CHOLESTEROL

Reduction of LDL cholesterol with statins is just one part of a program to reduce the risk of cardiovascular disease. Other measures—including smoking cessation, hypertension control, and aspirin—are also of central importance. Less well studied but of potential value is raising the HDL cholesterol level. Quitting smoking reduces the effect of other cardiovascular risk factors (such as a high cholesterol level); it may also increase the HDL cholesterol level. Exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL. Modest alcohol use (1–2 ounces a day) also raises HDL levels and appears to have a salutary effect on CHD rates.

The use of medications to raise the HDL cholesterol has not been demonstrated to provide additional benefit. For example, cholesteryl ester transfer protein inhibitors are a class of medicines being investigated to raise HDL levels. Agents in this class, however, have not been shown to be

effective. The use of niacin in addition to statins has also been carefully studied in the AIM-HIGH study and the HPS2-THRIVE study and shown not to be effective.

► Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, with even less in the long term. The effect of diet therapy, however, varies considerably among individuals, as some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Cholesterol-lowering diets may also have a variable effect on lipid fractions. Diets very low in total fat or in saturated fat may lower HDL cholesterol as much as LDL cholesterol. It is not known how these diet-induced changes affect coronary risk.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. A traditional cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to less than 7% of calories. These diets replace fat, particularly saturated fat, with carbohydrate. In most instances, this approach will also result in fewer total calories consumed and will facilitate weight loss in overweight patients. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in reductions in HDL cholesterol.

An alternative strategy is the Mediterranean diet, which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol but is less likely to lead to reductions in HDL cholesterol. Several studies have suggested that this approach may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets. A clinical trial demonstrated reduced cardiovascular events in persons on a Mediterranean diet supplemented with additional nuts or extra-virgin olive oil compared to persons on a less intensive Mediterranean diet.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Plant stanols and sterols can reduce LDL cholesterol by 10%. Intake of garlic, soy protein, vitamin C, and pecans, may also yield modest reductions of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29). Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

► Pharmacologic Therapy

Most patients whose risk from CHD is considered high enough to warrant pharmacologic therapy of an elevated LDL cholesterol should be given aspirin prophylaxis at a dose of 81 mg/day unless there are contraindications such as aspirin sensitivity, bleeding diatheses, or active peptic ulcer disease. Other CHD risk factors, such as hypertension and smoking, should also be controlled.

The 2013 ACC/AHA guidelines suggest treatment with statins for all patients who require drug treatment. As discussed above, the guidelines define four groups of patients who benefit from statin medications.

A. Statins (Hydroxymethylglutaryl-Coenzyme A [HMG-CoA] Reductase Inhibitors)

The statins (HMG-CoA reductase inhibitors) work by inhibiting the rate-limiting enzyme in the formation of cholesterol. They reduce myocardial infarctions and total mortality in secondary prevention, as well as in older middle-aged men free of CHD. A meta-analysis has demonstrated significant reduction in risk of stroke. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by up to 35%. There are also modest increases in HDL levels and decreases in triglyceride levels.

The 2013 ACC/AHA guidelines divide statins into high-intensity and moderate-intensity statin therapy (Table 28–1). High intensity statins lower LDL cholesterol by approximately 50%. Examples include atorvastatin 40–80 mg and rosuvastatin 20–40 mg/day (Table 28–2). Moderate intensity statins lower LDL cholesterol by approximately 30–50%. Examples include atorvastatin 10–20 mg, rosuvastatin 5–10 mg, simvastatin 20–40 mg, pravastatin 40–80 mg, and lovastatin 40 mg. All statins are given once daily in the morning or evening. The most common side effects are muscle aches, occurring in up to 10% of patients, and mild gastrointestinal effects. Statins are

Table 28–1. Indications for high intensity and moderate intensity statins: Recommendations of the 2013 ACC/AHA Guidelines.

Indications	Treatment Recommendation
Presence of clinical atherosclerotic cardiovascular disease	High intensity statin or moderate intensity statin if over age 75
Primary elevation of LDL cholesterol \geq 190 mg/dL (4.91 mmol/L)	High intensity statin
Age 40–75 Presence of diabetes LDL \geq 70 mg/dL (1.81 mmol/L)	Moderate intensity statin or high intensity statin if 10-year CVD risk 7.5% or higher
Aged 40–75 No clinical atherosclerotic cardiovascular disease or diabetes LDL 70–189 mg/dL (1.81–4.91 mmol/L) Estimated 10-year CVD risk 7.5% or higher	Treat with moderate-to-high intensity statin

ACC/AHA, American College of Cardiology/American Heart Association; CVD, cardiovascular disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

associated with a 10% increase in the risk of diabetes. Other serious, but extremely uncommon, side effects include liver failure and muscle disease including myositis and rhabdomyolysis. Some patients experience muscle pain even when the serum creatine kinase levels are normal. Liver disease is more common in patients who are also taking fibrates or niacin. Manufacturers of statins recommend monitoring liver enzymes before initiating therapy and as clinically indicated thereafter. Muscle disease is more common with statins and fibrates and niacin as well as with erythromycin, antifungal medications, nefazadone, and cyclosporine. Simvastatin at the highest approved dose—80 mg—is associated with a higher risk of muscle injury or myopathy. This dose should only be used in those who have been taking the medication for longer than 1 year without muscle toxicity.

B. Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial of middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events. A meta-analysis of 10 randomized trials using niacin has also shown a 27% reduction in cardiovascular events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL

cholesterol levels. The average effect of full-dose niacin therapy, 3–4.5 g/day, is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/day. Niacin will also reduce triglycerides by half and will lower lipoprotein(a) (Lp[a]) levels and will increase plasma homocysteine levels. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as “hot flashes” or pruritus and that can be decreased with aspirin (81–325 mg/day) or other nonsteroidal anti-inflammatory agents taken during the same day. Flushing may also be decreased by initiating niacin therapy with a very small dose, eg, 100 mg with the evening meal. The dose can be doubled each week until 1.5 g/day is tolerated. After rechecking blood lipids, the dose is increased and divided over three meals until the goal of 3–4.5 g/day is reached (eg, 1 g with each meal). Extended-release niacin is better tolerated by most patients. It is not known whether routine monitoring of liver enzymes results in early detection and thus reduced severity of hepatocellular hepatitis with jaundice. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that niacin can be safely used in diabetic patients.

C. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colestelam, and colestipol. Treatment with these agents reduces the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid–binding resins; they should be used with caution in those with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

The usual dose of cholestyramine is 12–36 g of resin per day in divided doses with meals, mixed in water or, more palatably, juice. Doses of colestipol are 20% higher (each packet contains 5 g of resin). The dose of colestelam is 625 mg, 6–7 tablets per day.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

D. Fibric Acid Derivatives

The fibrates are peroxisome proliferative-activated receptor- α (PPAR- α) agonists that result in potent reductions of plasma triglycerides and increases in HDL

Table 28–2. Effects of selected lipid-modifying drugs.

Drug	Lipid-Modifying Effects		Triglyceride	Initial Daily Dose	Maximum Daily Dose	Cost for 30 Days Treatment with Dose Listed ¹
	LDL	HDL				
Alirocumab (Praluent)	–45 to –60%	±	±	75 mg once every 2 weeks	150 mg once every 2 weeks	\$1344.00 (75 mg every 2 weeks)
Atorvastatin (Lipitor)	–25 to –40%	+5 to 10%	↓↓	10 mg once	80 mg once	\$164.70 (20 mg once)
Cholestyramine (Questran, others)	–15 to –25%	+5%	±	4 g twice a day	24 g divided	\$201.06 (8 g divided)
Colesevelam (WelChol)	–10 to –20%	+10%	±	625 mg, 6–7 tablets once	625 mg, 6–7 tablets once	\$622.08 (6 tablets once)
Colestipol (Colestid)	–15 to –60%	+5%	±	5 g twice a day	30 g divided	\$236.00 (10 g divided)
Evolocumab (Repatha)	–50 to –60%	±	±	140 mg once every 2 weeks	420 mg once monthly	\$1301.54 (140 mg every 2 weeks)
Ezetimibe (Zetia)	–20%	+5%	±	10 mg once	10 mg once	\$311.95 (10 mg once)
Fenofibrate (Tricor, others)	–10 to –15%	+15 to 25%	↓↓	48 mg once	145 mg once	\$171.60 (145 mg once)
Fenofibric Acid (Lilipix)	–10 to –15%	+15 to 25%	↓↓	45 mg once	135 mg once	\$180.00 (135 mg once)
Fluvastatin (Lescol)	–20 to –30%	+5 to 10%	↓	20 mg once	40 mg once	\$113.40 (20 mg once)
Gemfibrozil (Lopid, others)	–10 to –15%	+15 to 20%	↓↓	600 mg once	1200 mg divided	\$71.40 (600 mg twice a day)
Lovastatin (Mevacor, others)	–25 to –40%	+5 to 10%	↓	10 mg once	80 mg divided	\$71.10 (20 mg once)
Niacin (OTC, Niaspan)	–15 to –25%	+25 to 35%	↓↓	100 mg once	3–4.5 g divided	\$22.20 (1.5 g twice a day, OTC) \$449.40 (2 g Niaspan)
Pitavastatin (Livalo)	–30 to 40%	+10 to 25%	↓↓	2 mg once	4 mg once	\$252.00 (2 mg once)
Pravastatin (Pravachol)	–25 to –40%	+5 to 10%	↓	20 mg once	80 mg once	\$98.10 (20 mg once)
Rosuvastatin (Crestor)	–40 to –50%	+10 to 15%	↓↓	10 mg once	40 mg once	\$298.20 (20 mg once)
Simvastatin (Zocor, others)	–25 to –40%	+5 to 10%	↓↓	5 mg once	80 mg once	\$84.60 (10 mg once)

HDL, high-density lipoprotein; LDL, low-density lipoprotein; ± variable, if any; others, indicates availability of less expensive generic preparations; OTC, over the counter.

cholesterol. They reduce LDL levels by about 10–15%, although the result is quite variable, and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally.

Gemfibrozil reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower HDL cholesterol levels and high triglyceride levels. In a VA study, gemfibrozil was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. In the largest clinical trial that used clofibrate, there were significantly more deaths—especially due to cancer—in the treatment group; it should not be used.

E. Ezetimibe

Ezetimibe is a lipid-lowering drug that inhibits the intestinal absorption of dietary and biliary cholesterol by blocking passage across the intestinal wall by inhibiting a cholesterol transporter. The usual dose of ezetimibe is

10 mg/day orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy and can further reduce LDL in patients taking statins who are not yet at therapeutic goal. However, beneficial effects of ezetimibe monotherapy on cardiovascular outcomes has not been demonstrated.

One study has shown that adding ezetimibe to a statin resulted in a small incremental benefit on cardiovascular outcomes. At the end of 7 years of study, patients taking ezetimibe-simvastatin had a 2% absolute reduction in cardiovascular events compared to patients taking simvastatin alone.

F. Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors

PCSK9 inhibitors are monoclonal antibodies that reduce liver LDL-receptor degradation and lower LDL cholesterol levels by 50–60%. Two agents, alirocumab and evolocumab, are approved for use in the United States for patients with familial hypercholesterolemia or cardiovascular disease who require additional lowering of LDL cholesterol. The medications are injected subcutaneously every 2–4 weeks. No significant increase in adverse events has been observed compared to placebo. Studies designed to demonstrate a reduction in cardiovascular events have not been published, but analysis of existing studies does suggest a substantial reduction in death from cardiovascular disease and myocardial infarction. However, cost effectiveness models suggest that these medications, at current prices, are not cost-effective.

▶ Initial Selection of Medication

For patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor is recommended. Although other medications will also have beneficial effects on lipids, there is little evidence demonstrating the desired effects on cardiovascular disease and all-cause mortality. Resins are the only lipid-modifying medication considered safe in pregnancy.

Combination therapy is rarely indicated. Despite improvements in the lipid profile, there are few data demonstrating improved clinical outcomes of combination therapy when compared with HMG-CoA reductase inhibitors alone. The AIM-High Study of niacin added to simvastatin, for example, was stopped early due to a lack of efficacy. The use of extended-release niacin with laropiprant (a prostaglandin antagonist) in high-risk patients taking a statin also did not reduce the risk of cardiovascular events. The addition of ezetimibe to simvastatin in the IMPROVE-IT study resulted in a statistically significant benefit on cardiovascular events but the absolute reduction was small.

Combinations may also increase the risk of complications of drug therapy. The combination of gemfibrozil and HMG-CoA reductase inhibitors increases the risk of muscle and liver disease more than either drug alone. An increase in adverse events was also seen when niacin plus laropiprant was added to statins.

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides (greater than 1000 mg/dL) are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL (5 mmol/L). The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels may also be helpful. In patients with fasting triglycerides greater than or equal to 500 mg/dL (5 mmol/L) despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, niacin, a fibric acid derivative, omega-3-acid ethyl esters, or an HMG-CoA reductase inhibitor) is indicated. Combinations of these medications may also be used.

Whether patients with triglycerides greater than 150 mg/dL (1.5 mmol/L) should be treated to prevent CHD is not known. Meta-analysis of 17 observational studies suggests that after adjustment for other risk factors, elevated triglycerides increased CHD risk in men by 14% and in women by 37%. Elevated triglycerides are also an important feature of the metabolic syndrome. Other data, however, suggest that triglyceride measurements do not improve discrimination between those with and without CHD events, and clinical trial data are not available to support the routine treatment of high triglycerides in all patients.

Nutritional Disorders

Robert B. Baron, MD, MS

PROTEIN-ENERGY MALNUTRITION

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- ▶ **Kwashiorkor:** caused by protein deficiency.
- ▶ **Marasmus:** caused by combined protein and energy deficiency.
- ▶ Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

▶ General Considerations

Protein-energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein-energy malnutrition remains among the most significant health problems. It occurs in two distinct syndromes. **Kwashiorkor**, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficient. **Marasmus**, caused by combined protein and energy deficiency, is seen where adequate quantities of food are simply not available.

In industrialized societies, protein-energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein-energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein-energy malnutrition** typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), heart failure, cancer, or AIDS. These two syndromes are estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in them. In both syndromes, protein-energy malnutrition is caused either by decreased intake of energy and protein or

by increased nutrient losses or increased nutrient requirements from the underlying illness. For example, diminished energy intake may result from poor dentition or various gastrointestinal disorders. Increased nutrient losses result from malabsorption, diarrhea, and glycosuria. Increased nutrient requirements occur with fever, surgery, neoplasia, and burns.

▶ Clinical Findings

Clinical manifestations of protein-energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. In the developing world, children manifest marasmus and kwashiorkor. In industrialized nations, clinical manifestations of secondary protein-energy malnutrition are affected by the patient's nutritional status prior to illness, illness resulting in the protein and energy deficiency, and degree of the deficiency.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein-energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseous muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to less than 2.8 g/dL (28 g/L). In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein-energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient is obese, even in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often less than 2.8 g/dL (28 g/L). Dependent edema, ascites, or anasarca may develop. As with primary protein-energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

▶ Treatment

The treatment of severe protein-energy malnutrition is a slow process requiring great care. Initial efforts should be

directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid–base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated based on the patient's actual body weight. Adult patients are given 1 g/kg of protein and 30 kcal/kg of calories. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein–calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein–energy malnutrition require close follow-up. In adults, both calories and protein are advanced as tolerated, adults to 1.5 g/kg/day of protein and 40 kcal/kg/day of calories.

Patients who are re-fed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with carbohydrate refeeding can result in heart failure in persons with depressed cardiac function. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein–energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

OBESITY

ESSENTIALS OF DIAGNOSIS

- ▶ Excess adipose tissue; body mass index (BMI) greater than 30.
- ▶ Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).
- ▶ Associated with health consequences, including diabetes mellitus, hypertension, and hyperlipidemia.

General Considerations

Obesity is one of the most common disorders in medical practice and among the most frustrating and difficult to manage. Little progress has been made in prevention or treatment, yet major changes have occurred in our understanding of its causes and its implications for health.

Definition & Measurement

Obesity is defined as an excess of adipose tissue. Physical examination is usually sufficient to detect excess body fat. More quantitative evaluation is performed by calculating the BMI.

The **BMI** closely correlates with excess adipose tissue. It is calculated by dividing measured body weight in kilograms by the height in meters squared.

The National Institutes of Health (NIH) define a normal BMI as 18.5–24.9. Overweight is defined as BMI = 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III (extreme) obesity is BMI greater than 40. Factors other than total weight, however, are also important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (greater than 102 cm in men and 88 cm in women) or with high waist–hip ratios (greater than 1.0 in men and 0.85 in women) have a greater risk of diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Furthermore, visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen.

US survey data demonstrate that 68% of Americans are overweight and 33.8% are obese. Women in the

United States are more apt to be obese than men, and African-American and Mexican-American women are more obese than whites. The poor are more obese than the rich regardless of race. Approximately 60% of individuals with obesity in the United States have the metabolic syndrome (including three or more of the following factors: elevated abdominal circumference, blood pressure, blood triglycerides, and fasting blood sugar, and low high-density lipoprotein [HDL] cholesterol).

▶ Etiology

Obesity has been considered to be the direct result of a sedentary lifestyle plus chronic ingestion of excess calories. Yet, as much as 40–70% of obesity may be explained by genetic influences. Twin studies demonstrate substantial genetic influences on BMI with little influence from the childhood environment.

Five genes affecting control of appetite have been identified in mice. Mutations of each gene result in obesity, and each has a human homolog. One gene codes for a protein expressed by adipose tissue—leptin—and another for the leptin receptor in the brain. The other three genes affect brain pathways downstream from the leptin receptor. Numerous other candidate genes for human obesity have been identified. Only a small percentage of human obesity is thought to be due to single gene mutations. Most human obesity undoubtedly develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades clearly points to major roles for environmental and behavioral factors in its development.

▶ Medical Evaluation of the Obese Patient

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders. Particular attention should be directed at use of laxatives, diuretics, hormones, nutritional supplements, and over-the-counter medications.

Physical examination should assess the BMI, degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity.

Less than 1% of obese patients have an identifiable secondary, nonpsychiatric, cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can usually be diagnosed by physical examination in patients with unexplained recent weight gain. Such patients require further endocrinologic evaluation, including serum thyroid-stimulating hormone (TSH) determination and dexamethasone suppression testing (see Chapter 26).

All obese patients should be assessed for medical consequences of their obesity by screening for the metabolic syndrome. Blood pressure, waist circumference, fasting glucose, low-density lipoprotein (LDL) and HDL cholesterol, and triglycerides should be measured.

▶ Treatment

Using conventional dietary techniques, only 20% of patients will lose 20 lb and maintain the loss for over 2 years; only 5% maintain a 40-lb loss. Average weight loss is approximately 7% of baseline weight. Continued close provider–patient contact appears to be more important for success of treatment than the specific features of any given treatment regimen. Careful patient selection improves success rates and decreases frustration of both patients and therapists. Only sufficiently motivated patients should enter active treatment programs. Specific attempts to identify motivated patients—eg, requesting a 3-day diet record—are often useful.

Most successful programs employ a multidisciplinary approach to weight loss, with hypocaloric diets, behavior modification to change eating behavior, aerobic exercise, and social support. Emphasis must be on *maintenance* of weight loss.

Dietary instructions for most patients incorporate the same principles that apply to healthy people who are not obese. These instructions emphasize intake of a wide variety of predominantly “unprocessed” foods, with special attention to limiting foods that provide large amounts of calories without other nutrients, ie, fat, sucrose, and alcohol. There is no physiologic advantage to diets that restrict carbohydrates, advocate relatively larger amounts of protein or fats, or recommend ingestion of foods one at a time. Diets that are restricted in carbohydrates (such as the Atkins and South Beach diets), however, can be effective in achieving a lower total calorie intake. Several studies have demonstrated that low-carbohydrate diets can be used safely and effectively for weight loss without adverse effects on lipids or other metabolic parameters. Meal replacement diets can also be used effectively and safely to achieve weight loss.

Long-term changes in eating behavior are required to maintain weight loss. Although formal **behavior modification** programs are available to which patients can be referred, the clinician caring for obese patients can teach a number of useful behavioral techniques. The most important technique is to emphasize planning and record keeping. Patients can be taught to plan menus and exercise sessions and to record their actual behavior. Record keeping not only aids in behavioral change, but also helps the provider to make specific suggestions for problem solving. Patients can be taught to recognize “eating cues” (emotional, situational, etc) and how to avoid or control them. Regular self-monitoring of weight is also associated with improved long-term weight maintenance.

Exercise offers a number of advantages to patients trying to lose weight and keep it off. Aerobic exercise directly increases the daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise will also preserve lean body mass and partially prevent the decrease in basal energy expenditure (BEE) seen with semistarvation. Compared to no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in slightly greater weight loss than diet alone. A greater intensity of exercise is associated with a greater

amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight. **Social support** is essential for a successful weight loss program. Continued close contact with clinicians and involvement of the family and peer group are useful techniques for reinforcing behavioral change and preventing social isolation.

Patients with severe obesity may require more aggressive treatment regimens. **Very-low-calorie diets** (typically 800–1000 kcal/day) result in rapid weight loss and marked initial improvement in obesity-related metabolic complications. Patients are commonly maintained on such programs for 4–6 months. Patients who adhere to the program lose an average of 2 lb per week. Average maximum weight loss is approximately 15% of initial weight. Most programs use meal replacement diets to achieve the very-low-calorie intake. Long-term weight maintenance following meal replacement programs is less predictable and requires concurrent behavior modification, long-term use of low-calorie diets, careful self-monitoring, and regular exercise. Side effects such as fatigue, orthostatic hypotension, cold intolerance, and fluid and electrolyte disorders are observed in proportion to the degree of calorie reduction and require regular supervision by a clinician. Other less common complications include gout, gallbladder disease, and cardiac arrhythmias. Although weight loss is more rapidly achieved with very-low-calorie diets as compared with traditional diets, long-term outcomes are equivalent.

Medications for the treatment of obesity are available both over the counter and by prescription. Considerable controversy exists as to the appropriate use of medications for obesity. NIH clinical obesity guidelines state that obesity drugs may be used as part of a comprehensive weight loss program for patients with BMI greater than 30 or those with BMI greater than 27 with obesity-related risk factors. However, few data suggest that medications can improve long-term outcomes associated with obesity.

Several medications are approved by the US Food and Drug Administration (FDA) for treatment of obesity. Catecholaminergic medications (eg, phentermine, diethylpropion, benzphetamine, and phendimetrazine) are approved for short-term use only and have limited utility. **Orlistat** (120 mg orally up to three times daily with each fat-containing meal) is available by prescription for longer-term treatment of obesity. A nonprescription lower-dose formulation (60 mg) is available. Rather than in the central nervous system, orlistat works in the gastrointestinal tract to inhibit intestinal lipase, reducing fat absorption. Not unexpectedly, it may cause diarrhea, gas, and cramping and perhaps reduced absorption of fat-soluble vitamins. In randomized trials with up to 2 years of follow-up, orlistat resulted in 2–4 kg greater weight loss than placebo. A beneficial impact on long-term obesity-related clinical outcomes has not been established.

Four additional medications are approved for use in the United States. **Lorcaserin**, a selective serotonin receptor agonist given in a dose of 10 mg orally twice daily, is associated with modest weight loss, about 3% of initial weight more than placebo. Approximately twice as many

patients (38% vs 16%) lose more than 5% of initial weight on lorcaserin compared to placebo. Post-marketing surveillance is focused on concerns about increased breast tumors in animal studies, valvular heart disease in patients receiving earlier drugs of this class, and psychiatric side effects.

The combination of **phentermine hydrochloride** and **topiramate** (3.75 mg/23 mg orally daily for 14 days, then 7.5 mg/46 mg orally daily, to a maximum dosage of 15 mg/92 mg orally daily) results in dose-dependent weight loss. In clinical trials, patients receiving the lowest dose lost 7.8% more weight than those receiving placebo; with the higher dose, 9.8% more weight was lost. Common side effects include mood changes, fatigue, and insomnia. Since the medications increase heart rate, a large clinical trial to assess cardiovascular risk is being conducted. The combination is also associated with increased birth defects and should not be used during pregnancy. Its distribution is restricted in the United States (telephone 1-888-998-4887 or visit www.QsymiaREMS.com).

The combination of **naltrexone** and **bupropion hydrochloride** (8 mg ER/90 mg ER, increasing from 1 tablet orally daily by 1 additional daily tablet each week to a maximum of 2 tablets twice daily) is also approved by the FDA for weight loss. Clinical trials demonstrated a 2–4% weight loss compared to placebo after 1 year. Concerns include an increased risk of suicidal thoughts and behaviors, other neuropsychiatric events, seizures, and elevation of blood pressure and heart rate. Other side effects include nausea and vomiting, diarrhea and constipation, headache, and dry mouth. A cardiovascular outcome trial to further assess safety is in progress.

Liraglutide (Saxenda), an injectable incretin (a glucagon-like peptide-1 receptor agonist), is FDA approved for obesity treatment in a dose of 0.6 mg subcutaneously daily, increasing by 0.6 mg daily each week to a maximum of 3 mg subcutaneously daily. Clinical trials demonstrated a 3.7–4.5% weight loss compared to placebo at 1 year. Concerns include thyroid tumors in animal studies, pancreatitis, gallbladder disease, renal impairment, increased heart rate, and suicidal thoughts. Common side effects include nausea and vomiting, diarrhea and constipation, and hypoglycemia. A cardiovascular outcomes trial is being conducted.

Bariatric surgery is an increasingly prevalent treatment option for patients with severe obesity. In the United States, gastric operations are considered the procedures of choice. Most popular is the Roux-en-Y gastric bypass (RYGB). In most centers, the operation can be done laparoscopically. RYGB typically results in substantial amounts of weight loss—over 30% of initial body weight in some studies. Complications occur in up to 40% of persons undergoing RYGB surgery and include peritonitis due to anastomotic leak; abdominal wall hernias; staple line disruption; gallstones; neuropathy; marginal ulcers; stomal stenosis; wound infections; thromboembolic disease; gastrointestinal symptoms; and nutritional deficiencies, including iron, vitamin B₁₂, folate, calcium, and vitamin D. Operative mortality rates within 30 days are nil to 1% in low-risk populations but have been reported to be substantially

higher in Medicare beneficiaries. One-year mortality rates have been reported as high as 7.5% in men with Medicare. Surgical volume (number of cases performed by the surgeon or hospital) has been demonstrated to be an important predictor of outcome.

Another operation is gastric banding. Gastric banding results in less dramatic weight loss than RYGB and has fewer short-term complications. Frequent follow-up, however, is required to adjust the gastric band. Longer-term follow-up has shown a 39% rate of major complications and a 60% rate of re-operation.

A third operation, sleeve gastrectomy, is gaining in popularity. With this procedure, approximately three-quarters of the stomach is resected, but the gastrointestinal tract is otherwise left intact. Weight loss results are somewhat less than RYGB but greater than gastric banding.

NIH consensus panel recommendations are to limit obesity surgery to patients with BMIs over 40, or over 35 if obesity-related comorbidities are present. The procedure is cost-effective for patients with severe obesity and most third-party payers cover the procedure in selected patients. A large Swedish study suggested that bariatric surgery is associated with a significant reduction in deaths at 11-year follow-up. The number needed to treat to prevent one death in 11 years was 77 operations. A US Veterans Administration study, however, did not show a mortality benefit.

▶ When to Refer

Patients with BMI over 40 (or over 35 with obesity-related morbidities) who are interested in considering weight loss surgery.

EATING DISORDERS

ANOREXIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- ▶ Disturbance of body image and intense fear of becoming fat.
- ▶ Weight loss leading to body weight 15% below expected.
- ▶ In females, absence of three consecutive menstrual cycles.

▶ General Considerations

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are females, most from the middle and upper socioeconomic strata.

The prevalence of anorexia nervosa is greater than previously suggested. In Rochester, Minnesota, for example, the prevalence per 100,000 population is estimated to be 270 for females and 22 for males. Many other adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal and achievement oriented. Interpersonal relationships may be inadequate or destructive. The parents are usually overly directive and concerned with slimmness and physical fitness, and much of the family conversation centers around dietary matters. One theory holds that the patient's refusal to eat is an attempt to regain control of her body in defiance of parental control. The patient's unwillingness to inhabit an "adult body" may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are commonly perfectionistic in behavior and exhibit obsessional personality characteristics. Marked depression or anxiety may be present.

▶ Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

▶ Diagnosis & Differential Diagnosis

The diagnosis is based on weight loss to a body weight 15% below expected, distorted body image, fear of weight gain or of loss of control over food intake and, in females, absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

Behavioral features required for the diagnosis include intense fear of becoming obese, disturbance of body image, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders (eg, panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus); gastrointestinal disorders (eg, Crohn disease and gluten enteropathy); chronic infections (eg, tuberculosis); cancers, (eg, lymphoma); and rare central nervous system disorders (eg, hypothalamic tumor).

▶ Treatment

The goal of treatment is restoration of normal body weight and resolution of psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. One-half continue to experience difficulties with eating behavior and psychiatric problems. Two to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by clinicians and family is probably the most important feature of therapy. Cognitive behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, selected serotonin reuptake inhibitors (SSRIs), and lithium carbonate are effective in some cases; overall, however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish normal eating behavior.

▶ When to Refer

- Adolescents and young adults with otherwise unexplained weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

▶ When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein-energy malnutrition.
- Failure to improve with outpatient management.

BULIMIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- ▶ Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- ▶ Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- ▶ Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain such as self-induced vomiting, diuretic or cathartic use, or strict dieting or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day for a few days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weights may fluctuate but generally are within 20% of desirable weights.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those of patients with anorexia nervosa. Bulimic patients, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse also cause electrolyte abnormalities or dehydration. Constipation and hemorrhoids are common.

Treatment

Treatment of bulimia nervosa requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine hydrochloride and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

DISORDERS OF VITAMIN METABOLISM

THIAMINE (B₁) DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ Most common in patients with chronic alcoholism.
- ▶ Early symptoms of anorexia, muscle cramps, paresthesias, irritability.
- ▶ Advanced syndromes of high output heart failure (“wet beriberi”), peripheral nerve disorders, and Wernicke-Korsakoff syndrome (“dry beriberi”).

General Considerations

Most thiamine deficiency in the United States is due to chronic alcoholism, with poor dietary intake of thiamine and impaired thiamine absorption, metabolism, and storage. Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein-calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status with intravenous dextrose solutions.

Clinical Findings

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system (“wet beriberi”) or the nervous system (“dry beriberi”). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intake. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, and pulmonary and peripheral edema, with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke-Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

▶ Diagnosis

In most instances, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used biochemical tests measure erythrocyte transketolase activity and urinary thiamine excretion. A transketolase activity coefficient greater than 15–20% suggests thiamine deficiency.

▶ Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/day is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/day. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

▶ When to Refer

Patients with signs of beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist.

THIAMINE TOXICITY

There is no known toxicity of thiamine.

Yang JD et al. Beriberi disease: is it still present in the United States? *Am J Med*. 2012 Oct;125(10):e5. [PMID: 22800868]

RIBOFLAVIN (B₂) DEFICIENCY

▶ Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and

other causes of protein-calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

▶ Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2–1.3 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

▶ Treatment

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/day until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

RIBOFLAVIN TOXICITY

There is no known toxicity of riboflavin.

Aubuchon-Endsley NL et al. Relationships among socioeconomic status, dietary intake, and stress in breastfeeding women. *J Acad Nutr Diet*. 2015 Jun;115(6):939–46.e1. [PMID: 25687029]

NIACIN DEFICIENCY

▶ General Considerations

Niacin is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are protein foods containing tryptophan and numerous cereals, vegetables, and dairy products.

Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient-drug interactions. Niacin deficiency can also occur in inborn errors of metabolism. Niacin in the form of nicotinic acid is used therapeutically for the treatment of

hypercholesterolemia and hypertriglyceridemia. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid.

Clinical Findings

As with other B vitamins, early manifestations of niacin deficiency are nonspecific—anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

Diagnosis

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly *N*-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized under-nutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide (10–150 mg/day).

NIACIN TOXICITY

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 81–325 mg/day, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

HPS2-THRIVE Collaborative Group; Landray MJ et al. Effects of extended-release niacin with laropiprant in high-risk patients. *N Engl J Med*. 2014 Jul 17;371(3):203–12. [PMID: 25014686]

VITAMIN B₆ DEFICIENCY

Vitamin B₆ deficiency most commonly occurs as a result of interactions with medications—especially isoniazid, cycloserine, penicillamine, and oral contraceptives—or of alcoholism. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin. Patients with common variable immunodeficiency may have concomitant vitamin B₆ deficiency.

Clinical Findings

Vitamin B₆ deficiency results in clinical symptoms similar to those of other B vitamin deficiencies, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures. Studies have suggested a potential relationship of low vitamin B₆ levels and a variety of clinical conditions including cardiovascular diseases, inflammatory diseases, and certain cancers.

Diagnosis

The diagnosis of vitamin B₆ deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels are greater than 50 ng/mL.

Treatment

Vitamin B₆ deficiency can be effectively treated with vitamin B₆ supplements (10–20 mg/day orally). Some patients taking medications that interfere with pyridoxine metabolism (such as isoniazid) may need doses as high as 50–100 mg/day orally to prevent vitamin B₆ deficiency. This is particularly true for patients who are more likely to have diets marginally adequate in vitamin B₆, such as the elderly, alcoholic patients, or the urban poor. Inborn errors of metabolism and pyridoxine-responsive syndromes often require doses up to 600 mg/day orally.

VITAMIN B₆ TOXICITY

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B₆ (200–2000 mg/day).

Kulkantrakorn K. Pyridoxine-induced sensory ataxic neuropathy and neuropathy: revisited. *Neurol Sci*. 2014 Nov;35(11):1827–30. [PMID: 25056196]

VITAMIN B₁₂ & FOLATE

Vitamin B₁₂ (cobalamin) and folate are discussed in Chapter 13.

VITAMIN C (Ascorbic Acid) DEFICIENCY

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in the urban poor, the elderly, and patients with chronic alcoholism. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

▶ Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

▶ Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.1 mg/dL.

▶ Treatment

Adult scurvy can be treated with ascorbic acid 300–1000 mg/day orally. Improvement typically occurs within days.

VITAMIN C TOXICITY

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretic concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative results for some fecal occult blood tests and both false-negative and false-positive results for urine glucose.

VITAMIN A DEFICIENCY

▶ Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of

blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in the elderly and urban poor.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

▶ Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

▶ Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated with vitamin A 30,000 international units orally daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 international units/kg orally for at least 5 days. The potential antioxidant effects of beta-carotene can be achieved with supplements of 25,000–50,000 international units of beta-carotene.

VITAMIN A TOXICITY

Excess intake of beta-carotenes (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international units/day for more than 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure, with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A is also related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

Sommer A et al. A global clinical view on vitamin A and carotenoids. *Am J Clin Nutr.* 2012 Nov;96(5):1204S–6S. [PMID: 23053551]

VITAMIN D

Vitamin D is discussed in Chapter 26.

VITAMIN E DEFICIENCY

Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption or abetalipoproteinemia in adults or chronic cholestatic liver disease, biliary atresia, or cystic fibrosis in children. Manifestations of deficiency include areflexia, disturbances of gait, decreased vibration and proprioception, and ophthalmoplegia.

Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipid levels.

Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. Several trials of supplemental vitamin E have shown slower cognitive decline in patients with Alzheimer disease.

VITAMIN E TOXICITY

Clinical trials have suggested an increase in all-cause mortality with high dose (400 international units/day or more) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

VITAMIN K

Vitamin K is discussed in Chapter 14.

DIET THERAPY

In consultation with a registered dietician, specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. Diet therapy is a difficult process, though, and not all patients are able to cooperate fully. Requesting the patient to record dietary intake for 3–5 days may provide useful insight into the patient's motivation as well as providing nutrient information about the current diet.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B₆—may be inadequate and should be provided in the form of supplements. Dairy products, soups, eggs, and soft cereals are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty in chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables and coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a general diet, in head and

neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, and protein. Other restrictive diets include gluten restriction in gluten enteropathy, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

► Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction is beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with diets of 2 or 1 g of sodium per day. Diets with more severe restriction are poorly accepted by patients and are rarely used. Current Institute of Medicine guidelines recommend 2.3 g of sodium per day, which is approximately 1 teaspoon of salt.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About 80% of the current US dietary intake is from processed and pre-prepared foods. Diets designed for 2.3 g of sodium per day require elimination of most processed foods, added salt, and foods with particularly high sodium content. Patients who follow such diets for 2–3 months lose their craving for salty foods and can often continue to restrict their sodium intake indefinitely. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction.

Diets allowing 1 g of sodium require further restriction of commonly eaten foods. Special “low-sodium” products are available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients, most commonly those with severe liver disease and ascites.

► Fat-Restricted Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve

the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

In general, fat-restricted diets require broiling, baking, or boiling meat and fish; discarding the skin of poultry and fish and using those foods as the main protein source; using nonfat dairy products; and avoiding desserts, sauces, and gravies.

► Low-Cholesterol, Low-Saturated-Fat Diets

Fat-restricted diets that specifically restrict saturated fats and dietary cholesterol are the mainstay of dietary treatment of hyperlipidemia (see Chapter 28). Similar diets are often recommended for diabetes mellitus (see Chapter 27) and for the prevention of coronary artery disease (see Chapter 10). The large Women’s Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer. In contrast, a study of Mediterranean diets, supplemented by nuts or extra-virgin olive oil, did demonstrate a reduction in cardiovascular events.

The aim of low-cholesterol, low-fat diets is to restrict total fat to less than 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories and dietary cholesterol to 200 mg/day. Saturated fat can be replaced either with complex carbohydrates or, if energy balance permits, with monounsaturated fats. Saturated fat, total fat, and dietary cholesterol can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Cholesterol-lowering diets can be further augmented with the addition of plant stanols and sterols and with soluble dietary fiber.

► Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/day of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

DIETS THAT SUPPLEMENT NUTRIENTS

▶ High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Guidelines suggest that men eat 30–38 g/day and women 21–25 g/day. Typical US diets, however, contain about half of that amount. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and, in some studies, colon cancer and a lower risk of cardiovascular disease. A meta-analysis of 22 studies suggested that each 7 g of dietary fiber was associated with a 9% decrease in first cardiovascular events.

Diets high in dietary fiber (21–38 g/day) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber, particularly soluble fiber, may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Good sources of soluble fiber are oats, nuts, seeds, legumes and most fruits. Foods with insoluble fiber include whole wheat, brown rice, other whole grains, and most vegetables. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be a useful adjunct to increase dietary fiber.

▶ High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and supplement dietary potassium.

▶ High-Calcium Diets

Additional intakes of dietary calcium have been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The Women's Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Observational studies have also suggested that calcium supplements, especially when taken without vitamin D, may be associated with an increased risk of coronary heart

disease. The recommended dietary allowance for the total calcium intake (from food and supplements) in adults ranges from 1000 mg/day to 1200 mg/day. Average American daily intakes are approximately 700 mg/day.

Dairy products are the primary dietary sources of calcium in the United States. An 8-ounce glass of milk, for example, contains approximately 300 mg of calcium. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to use lactose-free milk, take supplemental lactase enzyme supplements, or tolerate non-liquid products such as cheese and yogurt. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

NUTRITIONAL SUPPORT

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to most patients. Nutrition support should be utilized, however, only if it is likely to improve the patient's clinical outcome. The financial costs and risks of side effects must be balanced against the

potential advantages of improved nutritional status in each clinical situation.

INDICATIONS FOR NUTRITIONAL SUPPORT

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring prolonged therapeutic bowel rest, and (4) those with severe protein-calorie undernutrition with a treatable disease who have sustained a loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

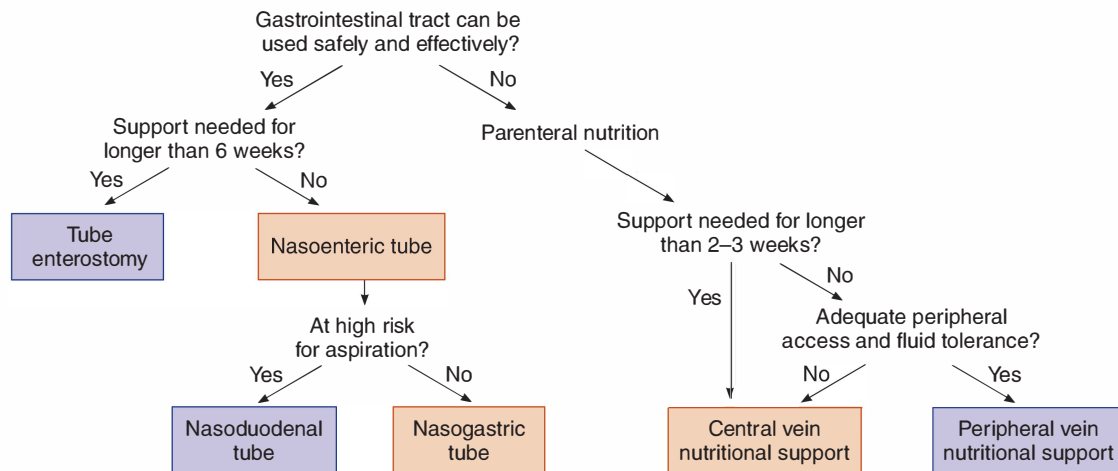

Nutritional Support Methods

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29-1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient preferences, timing of meals and diagnostic procedures and use of medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements. Fiber and lactose content, caloric density, protein level, amino acid profiles, vitamin K, and calcium can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for **liquid artificial nutrition** ("tube feedings"). Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally (though, as noted below, this may not prevent all aspirations, particularly if the pylorus is patulous). Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally, patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Feeding tubes can also be placed directly into the gastrointestinal tract using **tube enterostomies**. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require

▲ Figure 29-1. Nutritional support method decision tree.

continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced to jejunostomies. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive **parenteral nutritional support**. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but because of the high osmolality of parenteral solutions this is rarely tolerated for more than a few weeks.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate non-protein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

NUTRITIONAL REQUIREMENTS

Each patient's nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

▶ Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required.

▶ Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the **Harris–Benedict equation**: for men, $BEE = 666 + (13.7 \times \text{weight in kg}) + (5 \times \text{height in cm}) - (6.8 \times \text{age in years})$. For women, $BEE = 655 + (9.5 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$. For undernourished patients, actual body weight should be used; for obese patients, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of BEE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for obese patients, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For accurate determination of energy expenditure, indirect calorimetry should be used.

▶ Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/day. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

▶ Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/day of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/day; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/day. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies.

Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/day) and copper (about 2 mg/day). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B₁₂, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

▶ Essential Fatty Acids

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

ENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–1). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most “elemental” form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Table 29–1. Enteral solutions.

Complete

- Blenderized (eg, Compleat Regular, Compleat Modified,¹ Vitaneed¹)
- Whole protein, lactose-containing (eg, Mentene, Carnation and Delmark Instant Breakfast, Forta Shake)
- Whole protein, lactose-free, low-residue:
 - 1 kcal/mL (eg, Ensure, Isocal, Osmolite, Nutren 1.0,¹ Nutrilan, Isolan,¹ Sustacal, Resource)
 - 1.5 kcal/mL (eg, Ensure Plus, Sustacal HC, Comply, Nutren 1.5, Resource Plus)
 - 2 kcal/mL (eg, Isocal HCN, Magnacal, TwoCal HN)
- High-nitrogen: > 15% total calories from protein (eg, Ensure HN, Attain,¹ Osmolite HN,¹ Replete, Entrition HN,¹ Isolan,¹ Isocal HN,¹ Sustacal HC, Isosource HN,¹ Ultralan)
- Whole protein, lactose-free, high-residue:
 - 1 kcal/mL (eg, Jevity,¹ Profiber,¹ Nutren 1.0 with fiber,¹ Fiberian,¹ Sustacal with fiber, Ultracal,¹ Ensure with fiber, Fibersource)
- Chemically defined peptide- or amino acid-based (eg, Accupeg HPF, CriticareHN, Peptamen,¹ Reabfin, Vital HN, AlitraQ, Tolorex, Vivonex TEN)

“Disease-specific” formulas

- Advanced chronic kidney disease: with essential amino acids (eg, Amin-Aid, Travasorb Renal, Aminess)
- Malabsorption: with medium-chain triglycerides (eg, Portagen,¹ Travasorb MCT)
- Respiratory failure: with > 50% calories from fat (eg, Pulmocare, NutriVent)
- Hepatic encephalopathy: with high amounts of branched-chain amino acids (eg, Hepatic-Acid II, Travasorb Hepatic)

Incomplete (modular)

- Protein (eg, Nutrisource Protein, Promed, Propac)
- Carbohydrate (eg, Nutrisource Carbohydrate, Polycose, Sumacal)
- Fat (eg, MCT Oil, Microlipid, Nutrisource Lipid)
- Vitamins (eg, Nutrisource Vitamins)
- Minerals (eg, Nutrisource Minerals)

¹Isotonic.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO₂ retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25–33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Minor complications of tube feedings occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding.

Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but in most cases are easily managed. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, CO₂ production, and acid–base balance may also occur.

PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient's estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mOsm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–2.

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–4.25% amino acids. These solutions have osmolalities between 800 and 1200 mOsm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins.

Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Table 29–2. Typical parenteral nutrition solution (for stable patients without organ failure).

Dextrose (3.4 kcal/g)	25%
Amino acids (4 kcal/g)	6%
Na ⁺	50 mEq/L
K ⁺	40 mEq/L
Ca ²⁺	5 mEq/L
Mg ²⁺	8 mEq/L
Cl ⁻	60 mEq/L
P	12 mEq/L
Acetate	Balance
MVI-12 (vitamins)	10 mL/day
MTE (trace elements)	5 mL/day
Fat emulsion 20%	250 mL five times a week
Typical rate	Day 1: 30 mL/h
	Day 2: 60 mL/h
By day 2, solution provides:	Calories: 1925 kcal total
	Protein: 86 g
	Fat: 19% of total kcal
	Fluid: 1690 mL

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. The maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

COMPLICATIONS OF PARENTERAL NUTRITIONAL SUPPORT

Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, significant complications will develop in about 5% of patients. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Table 29–3. Metabolic complications of parenteral nutritional support.

Complication	Common Causes	Possible Solutions
Hyperglycemia	Too rapid infusion of dextrose, “stress,” corticosteroids	Decrease glucose infusion; insulin; replacement of dextrose with fat
Hyperosmolar nonketotic dehydration	Severe, undetected hyperglycemia	Insulin, hydration, potassium
Hyperchloremic metabolic acidosis	High chloride administration	Decrease chloride
Azotemia	Excessive protein administration	Decrease amino acid concentration
Hyperphosphatemia, hypokalemia, hypomagnesemia	Extracellular to intracellular shifting with refeeding	Increase solution concentration
Liver enzyme abnormalities	Lipid trapping in hepatocytes, fatty liver	Decrease dextrose
Acalculous cholecystitis	Biliary stasis	Oral fat
Zinc deficiency	Diarrhea, small bowel fistulas	Increase concentration
Copper deficiency	Biliary fistulas	Increase concentration

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1–2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients (Table 29–3). Most are minor and easily managed, and termination of support is seldom necessary.

PATIENT MONITORING DURING NUTRITIONAL SUPPORT

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be

evaluated for nitrogen balance by means of the following equation:

$$\text{Nitrogen balance} = \frac{\text{24-hour protein intake(g)}}{6.25} - \left(\frac{\text{24-hour urinary nitrogen(g)}}{4} + 4 \right)$$

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

Common Problems in Infectious Diseases & Antimicrobial Therapy

Peter V. Chin-Hong, MD
B. Joseph Guglielmo, PharmD

30

COMMON PROBLEMS IN INFECTIOUS DISEASES

FEVER OF UNKNOWN ORIGIN (FUO)

ESSENTIALS OF DIAGNOSIS

- ▶ Illness of at least 3 weeks duration.
- ▶ Fever over 38.3°C on several occasions.
- ▶ Diagnosis has not been made after 3 outpatient visits or 3 days of hospitalization.

General Considerations

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. Because of costs of hospitalization and the availability of most screening tests on an outpatient basis, the original criterion requiring 1 week of hospitalization has been modified to accept patients in whom a diagnosis has not been made after 3 outpatient visits or 3 days of hospitalization.

Several additional categories of FUO have been added: (1) **Hospital-associated FUO** refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Health care-associated Infections below). (2) **Neutropenic FUO** includes patients with fever of 38.3°C or higher on several occasions with less than 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Chapter 2 and Infections in the Immunocompromised Patient, below). (3) **HIV-associated FUO** pertains to HIV-positive patients with fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see Chapter 31). Although not usually

considered separately, FUO in solid organ transplant recipients and FUO in the returning traveler are common scenarios, each with a unique differential diagnosis, and are also discussed in this chapter.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30–50% of cases) and cancer a rare cause (5–10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In the elderly (over 65 years of age), multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and granulomatosis with polyangiitis account for 25–30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have

no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5–1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with episodic or recurrent fever (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with prolonged fever. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infections are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, *Pneumocystis jirovecii* pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Posttransplant lymphoproliferative disorders may also present with fever. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are

seen almost exclusively in patients over 50 years of age and are nearly always associated with an elevated erythrocyte sedimentation rate (greater than 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, the diagnosis remains elusive in 15% or more of patients. Of these patients, the fever abates spontaneously in about 75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

► Clinical Findings

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. Laboratory Tests

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if *Legionella*, *Bartonella*, or nutritionally deficient streptococci are possible pathogens. “Screening tests” with immunologic or microbiologic serologies (“febrile agglutinins”) are of low yield and should not be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (*Borrelia*).

B. Imaging

All patients with FUO should have a chest radiograph. Studies such as sinus films, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings

often lead to a specific diagnosis. A normal CT scan is not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies in diagnosing FUO is variable. Some experts use positron emission tomography (PET) in conjunction with CT scans early in the investigation of FUO. However, more studies are needed before this practice can be more fully integrated into clinical practice. Theoretically, a gallium or PET scan would be more helpful than an indium-labeled white blood cell scan because gallium and fluorodeoxyglucose may be useful for detecting infection, inflammation, and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: Headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (15–25%; except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis, particularly in persons with hematologic abnormalities. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical visualization and biopsies should be considered when there is continued deterioration or lack of diagnosis.

▶ Treatment

Although it is tempting to begin an empiric course of antimicrobials for FUO, it is rarely helpful and may delay diagnosis if the etiology is infectious (eg, by reducing the sensitivity of blood cultures).

Empiric administration of corticosteroids should be discouraged because they can suppress fever and exacerbate many infections.

▶ When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and HIV-infected patients).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US Centers for Disease Control and Prevention.

▶ When to Admit

- Any patient who is rapidly declining with weight loss where hospital admission may expedite work-up.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).

INFECTIONS IN THE IMMUNOCOMPROMISED PATIENT

ESSENTIALS OF DIAGNOSIS

- ▶ Fever and other symptoms may be blunted because of immunosuppression.
- ▶ A contaminating organism in an immunocompetent individual may be a pathogen in an immunocompromised one.
- ▶ The interval since transplantation and the degree of immunosuppression can narrow the differential diagnosis.
- ▶ Empiric broad-spectrum antibiotics may be appropriate in high-risk patients whether or not symptoms are localized.

▶ General Considerations

Immunocompromised patients have defects in their natural defense mechanisms resulting in an increased risk for infection. In addition, infection is often severe, rapidly progressive, and life threatening. Organisms that are not usually problematic in the immunocompetent person may be important pathogens in the compromised patient (eg, *Staphylococcus epidermidis*, *Corynebacterium jeikeium*, *Propionibacterium acnes*, *Bacillus* species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as merely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation is required to identify a specific organism.

A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, small lymphocyte lymphoma, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk for infection with encapsulated organisms, such as *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*. Although rituximab is normally thought of as being linked to impaired cellular immunity, it has been associated with the development of *Pneumocystis jirovecii* infection as well as with hepatitis B reactivation.

B. Granulocytopenia (Neutropenia)

Granulocytopenia is common following hematopoietic cell transplantation (“stem cell transplantation”) and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/mcL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/mcL. The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, *Pseudomonas*, gram-positive cocci (particularly *Staphylococcus aureus*, *S epidermidis*, and viridans streptococci), *Candida*, *Aspergillus*, and other fungi that have recently emerged as pathogens such as *Trichosporon*, *Scedosporium*, *Fusarium*, and the mucormycoses.

C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 31); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic drugs. This latter group—those who are immunosuppressed as a result of medications—includes patients who have

undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (eg, for asthma, temporal arteritis, systemic lupus erythematosus). Patients taking tumor necrosis factor (TNF) inhibitors, such as etanercept and infliximab, are also included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as *Listeria*, *Legionella*, *Salmonella*, and *Mycobacterium*; viruses, such as herpes simplex, varicella, and CMV; fungi, such as *Cryptococcus*, *Coccidioides*, *Histoplasma*, and *Pneumocystis*; and protozoa, such as *Toxoplasma*. Patients taking TNF inhibitors have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), viral (HBV reactivation and HCV progression), and fungal infections (primary and reactivation).

D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the early (preengraftment) posttransplant period (day 1–21), patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. Between 3 weeks and 3 months posttransplant, infections with CMV, adenovirus, *Aspergillus*, and *Candida* are most common. *P jirovecii* pneumonia is possible, particularly in patients who receive additional immunosuppression for treatment of graft-versus-host disease. Patients continue to be at risk for infectious complications beyond 3 months following transplantation, particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. Varicella-zoster is common, and *Aspergillus* and CMV infections are increasingly seen in this period as well.

E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. Immediate postoperative infections often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, urinary tract infections, perinephric abscesses, and infected lymphoceles can occur.

Most infections that occur in the first 2–4 weeks posttransplant are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ. In rare instances, donor-derived infections (eg, West Nile virus, tuberculosis)

may present during this time period. Compensated organ transplants obtained abroad through “medical tourism” can introduce additional risk of infections, which vary by country and by transplant setting. Infections that occur between the first and sixth months are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella-zoster, and CMV is quite common. Opportunistic infections with fungi (eg, *Candida*, *Aspergillus*, *Cryptococcus*, *Pneumocystis*), *Listeria monocytogenes*, *Nocardia*, and *Toxoplasma* are also common. After 6 months, if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

F. Other Immunocompromised States

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, Foley catheters, dialysis catheters), central nervous system dysfunction (which predisposes patients to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

Clinical Findings

A. Laboratory Findings

Routine evaluation includes complete blood count with differential, chest radiograph, and blood cultures; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV antigen test or polymerase chain reaction), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause. Antigen-based assays may be useful for the diagnosis of aspergillosis (detected by galactomannan level in serum or bronchoalveolar lavage fluid), or other invasive fungal disease, including *Pneumocystis* infection (serum (1→3)-beta-D-glucan level).

B. Special Diagnostic Procedures

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of *Pneumocystis* pneumonia in 50–80% of AIDS patients with this infection. In

other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis. Next generation DNA-sequencing analysis is being evaluated as an option for diagnosis of infectious diseases in immunocompromised persons.

Differential Diagnosis

Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

Prevention

There is great interest in preventing infection with prophylactic antimicrobial regimens but no uniformity of opinion about optimal drugs or dosage regimens. Hand washing is the simplest and most effective means of decreasing hospital-associated infections, especially in the compromised patient. Invasive devices such as central and peripheral lines and Foley catheters are potential sources of infection. Some centers use laminar airflow isolation or high-efficiency particulate air (HEPA) filtering in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if colony-stimulating factors are used (typically in situations where the risk of febrile neutropenia is 20% or higher) during chemotherapy or during stem-cell transplantation.

A. *Pneumocystis* & Herpes Simplex Infections

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3–6 months, is frequently used to prevent *Pneumocystis* infections in transplant patients. In patients allergic to TMP-SMZ, dapsone, 50 mg orally daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be determined before therapy when the latter is instituted. Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving ganciclovir or valganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematopoietic cell transplants) to 12 weeks (other solid organ transplants).

B. CMV

No uniformly accepted approach has been adopted for prevention of CMV. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative patients who receive organs from seropositive donors. These high-risk patients usually receive oral valganciclovir, 900 mg daily for 3–6 months (longer in lung transplant recipients). Other solid organ transplant recipients (seropositive recipients) are at lower risk

for developing CMV disease but still usually receive oral valganciclovir for 3 months. The lowest risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive CMV prophylaxis during rejection therapy. Alternatively, in a preemptive approach, patients can be monitored without specific prophylaxis by having blood sampled weekly to look for CMV by polymerase chain reaction techniques. If CMV is detected, then therapy is instituted with oral valganciclovir, 900 mg orally twice daily for a minimum of 2–3 weeks.

Recipients of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Like in solid organ transplant recipients, two approaches have been used: universal prophylaxis or preemptive therapy. In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) may receive oral valganciclovir, 900 mg daily to day 100. This method is costly and associated with significant bone marrow toxicity. Because of this, many clinicians prefer the preemptive approach for recipients of hematopoietic stem cell transplants. However, while this preemptive approach is effective, it does miss a small number of patients in whom CMV disease would have been prevented had prophylaxis been used. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

C. Other Organisms

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. Prophylactic administration of antibiotics in the afebrile, asymptomatic neutropenic patient is controversial, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms is a risk. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following bone marrow transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily *Aspergillus*) and yeast (primarily *Candida*) infections is routinely used, but the optimal agent, dose, and duration have not been standardized. Lipid-based preparations of amphotericin B, aerosolized amphotericin B, intravenous and oral fluconazole or voriconazole, and oral posaconazole solution and tablets are all prophylactic options in the neutropenic patient. Because voriconazole is superior to amphotericin for documented *Aspergillus* infections and because posaconazole prophylaxis (compared with fluconazole) has been shown to result in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease, one approach to prophylaxis is to use oral fluconazole (400 mg/day) for

patients at low risk for developing fungal infections (those who receive autologous bone marrow transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg solution three times daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant *Candida* and molds (*Fusarium*, *Aspergillus*, *Mucor*) has raised concerns about its routine use as a prophylactic agent in the general solid organ transplant population. However, liver transplant recipients with additional risk factors, such as having undergone a choledochojejunostomy, having had a high transfusion requirement or having developed renal failure, may benefit from abbreviated *Candida* prophylaxis while in the ICU postoperatively.

Given the high risk of reactivation of tuberculosis in patients taking TNF inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-gamma release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF inhibitors should be delayed until treatment for LTBI is completed. There is also a marked risk of reactivation of hepatitis B and hepatitis C in patients taking TNF inhibitors; patients should also be screened for these viruses when TNF inhibitor treatment is being considered.

▶ Treatment

A. General Measures

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted.

While reduction or discontinuation of immunosuppressive medication may jeopardize the viability of the transplanted organ, this measure may be necessary if the infection is life-threatening. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with reduction in infection.

B. Specific Measures

Antimicrobial drug therapy ultimately should be tailored to culture results. While combinations of antimicrobials may be used with the intent of providing synergy or preventing resistance, the primary reason for empiric combination therapy is broad-spectrum coverage of multiple pathogens (since infections in these patients are often polymicrobial).

Empiric therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome. The antibiotic or

combination of antibiotics used depends on the degree of immune compromise and the site of infection. For example, in the febrile neutropenic patient, an algorithmic approach to therapy is often used. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against selected gram-positive bacteria, *Pseudomonas aeruginosa*, and other aerobic gram-negative bacilli (such as cefepime 2 g every 8 hours intravenously). The addition of vancomycin, 10–15 mg/kg/dose intravenously every 12 hours, should be considered in those patients with suspected infection due to methicillin-resistant *Staphylococcus aureus* (MRSA), *S epidermidis*, enterococcus, and resistant viridans streptococci. Continued neutropenic fever necessitates broadening of antibacterial coverage from cefepime to agents such as imipenem 500 mg every 6 hours or meropenem 1 g every 8 hours intravenously with or without tobramycin 5–7 mg/kg intravenously every 24 hours. Antifungal agents (such as voriconazole, 200 mg intravenously or orally every 12 hours, or caspofungin, 50 mg daily intravenously) should be added if fevers continue after 5–7 days of broad-spectrum antibacterial therapy. Regardless of whether the patient becomes afebrile, therapy is continued until resolution of neutropenia. Failure to continue antibiotics through the period of neutropenia has been associated with increased morbidity and mortality.

Patients with fever and low-risk neutropenia (neutropenia expected to persist for less than 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours. Antibiotics are continued as long as the patient is neutropenic even if a source is not identified. In the organ transplant patient with interstitial infiltrates, the main concern is infection with *Pneumocystis* or *Legionella* species, so that empiric treatment with a macrolide or fluoroquinolone (*Legionella*) and TMP-SMZ, 15 mg/kg/day orally or intravenously, based on trimethoprim component (*Pneumocystis*) would be reasonable in those patients not receiving TMP-SMZ prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures (see above) to make a specific diagnosis. By making a definite diagnosis, therapy can be specific, thereby reducing selection pressure for resistance and superinfection.

▶ When to Refer

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with latent tuberculosis, HBV, and HCV infection in whom therapy with TNF inhibitors is planned.

▶ When to Admit

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid-organ or hematopoietic

stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF inhibitors, transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

HEALTH CARE–ASSOCIATED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Health care–associated infections are acquired during the course of receiving health care treatment for other conditions.
- ▶ Hospital-associated infections are a subset of health care–associated infections defined as those not present or incubating at the time of hospital admission and developing 48 hours or more after admission.
- ▶ Most health care–associated infections are preventable.
- ▶ Hand washing is the most effective means of preventing health care–associated infections and should be done routinely even when gloves are worn.

▶ General Considerations

In the United States, approximately 5% of patients acquire a health care–associated infection, resulting in prolongation of the hospital stay, increase in cost of care, significant morbidity, and a 5% mortality rate. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream

infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and *Clostridium difficile* colitis.

Some general principles are helpful in preventing, diagnosing, and treating health care–associated infections:

1. Many infections are a direct result of the use of invasive devices for monitoring or therapy, such as intravenous catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. Early removal of such devices reduces the possibility of infection.
2. Patients in whom health care–associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, health care–associated infections are often due to multidrug resistant pathogens and are different from those encountered in community-acquired infections. For example, *S aureus* and *S epidermidis* (a frequent cause of prosthetic device infection) are often resistant to nafcillin and cephalosporins and require vancomycin for therapy; *Enterococcus faecium* resistant to ampicillin and vancomycin; gram-negative infections caused by *Pseudomonas*, *Citrobacter*, *Enterobacter*, *Acinetobacter*, and *Stenotrophomonas* may be resistant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a health care–associated infection, antimicrobial history and the “local ecology” must be considered. In the most seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibilities are known, the most narrow spectrum, least toxic, most cost-effective drug should be used.

Widespread use of antimicrobial drugs contributes to the selection of drug-resistant organisms, thus every effort should be made to limit the spectrum of coverage and unnecessary duration. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient. To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest radiograph, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent colonization, not infection.

▶ Clinical Findings

A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or

central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and if present, may indicate more disseminated disease such as bacteremia, cellulitis and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. Fever in an intensive care unit patient—Fever complicates up to 70% of patients in intensive care units, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, urinary tract infections, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the intensive care unit.

An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash.

2. Fever in the postoperative patient—Postoperative fever is very common and in many cases resolves spontaneously. Etiologies are both infectious and noninfectious. Timing of the fever in relation to the surgery and the nature of the surgical procedure may help diagnostically.

A. IMMEDIATE FEVER (IN THE FIRST FEW HOURS AFTER SURGERY)—Immediate fever can be due to medications that were given perioperatively, to the trauma of surgery itself, or to infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. Malignant hyperthermia is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can cause a chemical pneumonitis (Mendelson syndrome) that rapidly develops but is transient and does not require antibiotics. Fever due to the trauma of surgery itself usually resolves in 2–3 days, longer in more complicated operative cases and in patients with head trauma.

B. ACUTE FEVER (WITHIN 1 WEEK OF SURGERY)—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, pulmonary embolism, and pancreatitis. Atelectasis following surgery is commonly invoked as a cause of postoperative fever but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

C. SUBACUTE FEVER (AT LEAST 1 WEEK AFTER SURGERY)—Surgical site infections commonly present at least 1 week

after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Abdominal surgery may result in deep abdominal abscesses that require drainage.

B. Laboratory Findings

Blood cultures are universally recommended, and chest radiographs are frequently obtained. A properly prepared sputum Gram stain and semi-quantitative sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transesophageal echocardiogram in a patient with *S aureus* bacteremia).

Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather at least two peripherally obtained blood cultures. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for *S epidermidis*, resulting in the inappropriate use of vancomycin. Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible and unnecessary therapy may be given. Every such “pseudobacteremia” increases laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The differential time to positivity measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (about 120 minutes’ difference in time) supports a catheter-related bloodstream infection, and a negative test may permit catheters to be retained.

► Complications

Patients who have persistent bacteremia and fever despite removal of the infected catheter may have complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with *S aureus*). Additional studies such as venous Doppler studies, transesophageal echocardiogram, and chest radiographs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

► Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hematoma, pancreatitis, pulmonary embolism, myocardial infarction, and ischemic bowel disease.

► Prevention

The concept of universal precautions emphasizes that all patients are treated as though they have a potential blood-borne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections. Application of a rapid drying, alcohol-based antiseptic is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination. For prevention of transmission of *C difficile* infection, hand-washing is more effective than alcohol-based antiseptics. Even after removing gloves, providers should always wash hands in cases of proven or suspected *C difficile* infection.

Peripheral intravenous lines should be replaced every 3 days. Arterial lines and lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. Silver alloy-impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria, and antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections and bacteremia. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia. Whether the increased cost of these devices justifies their routine use should be determined by individual institutions. Catheter-related urinary tract infections and intravenous catheter-associated infections are not Medicare-reimbursable conditions. Preoperative skin preparation with chlorhexidine and alcohol (versus povidone-iodine) has been shown to reduce the incidence of infection following surgery. Another strategy that can prevent surgical-site infections is the identification and treatment of *S aureus* nasal carriers with 2% mupirocin nasal ointment and chlorhexidine soap. Daily bathing of ICU patients with chlorhexidine-impregnated washcloths versus soap and water results in lower risk of MRSA-associated clinical cultures and catheter-associated bloodstream infections. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality.

Attentive nursing care (positioning to prevent decubitus ulcers, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening (active surveillance cultures) for MRSA on admission to acute care facilities among certain subpopulations of patients (eg, those recently hospitalized, admission to the intensive care unit, patients undergoing hemodialysis).

However, outside the setting of an MRSA outbreak, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, and influenza vaccinations, are important adjuncts. (See section below on Immunization against Infectious Diseases.)

Treatment

A. Fever in an Intensive Care Unit Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature higher than 41°C, there is less physiologic need to maintain euthermia. Empiric broad-spectrum antibiotics (see Table 30–5) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.

B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.

In general, catheters should be removed if there is purulence at the exit site; if the organism is *S aureus*, gram-negative rods, or *Candida* species; if there is persistent bacteremia (more than 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulase-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg intravenously twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage may be considered in patients who are immunocompromised or who are critically ill (see Table 30–5).

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulase-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy is generally recommended for uncomplicated bacteremia caused by gram-negative rods, *Candida* species, and *S aureus*. Antibiotic lock therapy involves the instillation of supratherapeutic concentrations of antibiotics with heparin in the lumen of catheters. The purpose is to achieve adequate concentrations of antibiotics to kill microbes in the biofilm. Antibiotic lock therapy can be used for catheter-related bloodstream infections caused by coagulase-negative staphylococci or enterococci and when the catheter is being retained in a salvage situation.

When to Refer

- Any patient with multidrug-resistant infection.
- Any patient with fungemia or persistent bacteremia.
- Patients with multisite infections.

- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.
- Patients with refractory or recurrent *C difficile* colitis.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

ESSENTIALS OF DIAGNOSIS

- ▶ Central nervous system infection is a medical emergency.
- ▶ Symptoms and signs common to all central nervous system infections include headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and cerebrospinal fluid abnormalities.

Table 30–1. Typical cerebrospinal fluid findings in various central nervous system diseases.

Diagnosis	Cells/mcL	Glucose (mg/dL)	Protein (mg/dL)	Opening Pressure
Normal	0–5 lymphocytes	45–85 ¹	15–45	70–180 mm H ₂ O
Purulent meningitis (bacterial) ² community-acquired	200–20,000 polymorphonuclear neutrophils	Low (< 45)	High (> 50)	Markedly elevated
Granulomatous meningitis (mycobacterial, fungal) ³	100–1000, mostly lymphocytes ³	Low (< 45)	High (> 50)	Moderately elevated
Spirochetal meningitis	100–1000, mostly lymphocytes ³	Normal	High (> 50)	Normal to slightly elevated
Aseptic meningitis, viral or meningoencephalitis ⁴	25–2000, mostly lymphocytes ³	Normal or low	High (> 50)	Slightly elevated
“Neighborhood reaction” ⁵	Variably increased	Normal	Normal or high	Variable

¹Cerebrospinal fluid glucose must be considered in relation to blood glucose level. Normally, cerebrospinal fluid glucose is 20–30 mg/dL lower than blood glucose, or 50–70% of the normal value of blood glucose.

²Organisms in smear or culture of cerebrospinal fluid; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

³Polymorphonuclear neutrophils may predominate early.

⁴Viral isolation from cerebrospinal fluid early; antibody titer rise in paired specimens of serum; polymerase chain reaction for herpesvirus.

⁵May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. Cerebrospinal fluid culture results usually negative.

▶ General Considerations

Infections of the central nervous system can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses.

▶ Etiologic Classification

Central nervous system infections can be divided into several categories that usually can be readily distinguished

from each other by cerebrospinal fluid examination as the first step toward etiologic diagnosis (Table 30–1).

A. Purulent Meningitis

Patients with bacterial meningitis usually seek medical attention within hours or 1–2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 30–2. The diagnosis is usually based on the Gram-stained smear (positive in 60–90%) or culture (positive in over 90%) of the cerebrospinal fluid.

Table 30–2. Initial antimicrobial therapy for purulent meningitis of unknown cause.

Population	Usual Microorganisms	Standard Therapy
18–50 years	<i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i>	Vancomycin ¹ plus ceftriaxone ²
Over 50 years	<i>S pneumoniae</i> , <i>N meningitidis</i> , <i>Listeria monocytogenes</i> , gram-negative bacilli, group B streptococcus	Vancomycin ¹ plus ampicillin, ³ plus ceftriaxone ²
Impaired cellular immunity	<i>L monocytogenes</i> , gram-negative bacilli, <i>S pneumoniae</i>	Vancomycin ¹ plus ampicillin ³ plus cefepime ⁴
Postsurgical or posttraumatic	<i>Staphylococcus aureus</i> , <i>S pneumoniae</i> , aerobic gram-negative bacilli, coagulase-negative staphylococci, diphtheroids (eg, <i>Propionibacterium acnes</i>) (uncommon)	Vancomycin ¹ plus cefepime ⁴

¹ Given to cover highly penicillin- or cephalosporin-resistant pneumococci. The dose of vancomycin is 15 mg/kg/dose intravenously every 8 hours. Vancomycin trough levels should be maintained at > 15 mcg/mL. Stopped if the causative organism is susceptible to ceftriaxone.

² Ceftriaxone can often be used safely in meningitis patients with a history of penicillin allergy (aztreonam can be considered for empiric coverage of gram-negative bacilli in patients with serious penicillin and cephalosporin allergy). The usual dose of ceftriaxone is 2 g intravenously every 12 hours. If the organism is sensitive to penicillin, 3–4 million units intravenously every 4 hours is given.

³ In severely ill patients, ampicillin is used when *L monocytogenes* infection is a consideration. For confirmed infection due to *L monocytogenes*, gentamicin is sometimes added to ampicillin. (For patients allergic to penicillin, trimethoprim-sulfamethoxazole [TMP-SMZ] in a dosage of 15–20 mg/kg/day of TMP in 3 or 4 divided doses can be considered.) The dose of ampicillin is usually 2 g intravenously every 4 hours.

⁴ Cefepime is given in a dose of 2–3 g intravenously every 8 hours.

Adapted from *Treat Guide Med Lett*. 2013 Jul; 11(131):65–73.

B. Chronic Meningitis

The presentation of chronic meningitis is less acute than purulent meningitis. Patients with chronic meningitis usually have a history of symptoms lasting weeks to months. The most common pathogens are *Mycobacterium tuberculosis*, atypical mycobacteria, fungi (*Cryptococcus*, *Coccidioides*, *Histoplasma*), and spirochetes (*Treponema pallidum* and *Borrelia burgdorferi*). The diagnosis is made by culture or in some cases by serologic tests (cryptococcosis, coccidioidomycosis, syphilis, Lyme disease).

C. Aseptic Meningitis

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles-mumps-rubella (MMR) vaccines, mumps was the most common cause of viral meningitis. Drug-induced aseptic meningitis has been reported with nonsteroidal anti-inflammatory drugs, sulfonamides, and certain monoclonal antibodies.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis]), and many others, produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. Cerebrospinal fluid may be entirely normal or may show some lymphocytes and in some instances (eg, herpes simplex) red cells as well. Influenza has been associated with encephalitis, but the relationship is not clear. An autoimmune form of encephalitis associated with N-methyl-D-aspartate receptor antibodies should be suspected in younger patients with encephalitis and associated seizures, movement disorders, and psychosis.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive Gram stain results by 20% and culture by 30–40% of the cerebrospinal fluid but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

F. Neighborhood Reaction

As noted in Table 30–1, this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess,

osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain drugs—nonsteroidal anti-inflammatory drugs, OKT3, TMP-SMZ, and others—can also produce symptoms and signs of meningeal irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningismus with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should *not* be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes *S aureus*, gram-negative bacilli, streptococci, and mouth anaerobes (including anaerobic streptococci and *Prevotella* species).

I. Health Care–Associated Meningitis

This infection may arise as a result of invasive neurosurgical procedures (eg, craniotomy, internal or external ventricular catheters, external lumbar catheters), complicated head trauma, or from hospital-acquired bloodstream infections. Outbreaks have been associated with contaminated epidural or paraspinal corticosteroid injections. In general, the microbiology is distinct from community-acquired meningitis, with gram-negative organisms (eg, *Pseudomonas*), *S aureus*, and coagulase-negative staphylococci and, in the outbreaks associated with contaminated corticosteroids, mold and fungi (*Exserohilum rostratum* and *Aspergillus fumigatus*) playing a larger role.

▶ Clinical Findings

A. Symptoms and Signs

The classic triad of fever, stiff neck, and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.

B. Laboratory Tests

Evaluation of a patient with suspected meningitis includes a blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae*, *H influenzae*,

N meningitidis, and *Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been used to detect bacteria (*S pneumoniae*, *H influenzae*, *N meningitidis*, *M tuberculosis*, *B burgdorferi*, and *Tropheryma whippelii*) and viruses (herpes simplex, varicella-zoster, CMV, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex and varicella-zoster, and the tests are very sensitive (greater than 95%) and specific. Tests to detect the other organisms may not be any more sensitive than culture, but the real value is the rapidity with which results are available, ie, hours compared with days or weeks. In patients at risk for infection possibly following a contaminated corticosteroid injection, a negative fungal culture or negative PCR test from a diagnostic specimen obtained from the central nervous system or a parameningeal site does not rule out infection. Active fungal infection may be present even when these tests are negative. Consultation with an infectious disease expert is recommended.

C. Lumbar Puncture and Imaging

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings. Other indications for CT scan are an immunocompromised patient or moderate to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30–1). Antibiotics given within 4 hours before obtaining cerebrospinal fluid probably do not affect culture results. MRI with contrast of the epidural injection site and surrounding areas is recommended (sometimes repeatedly) for those with symptoms following a possibly contaminated corticosteroid injection to exclude epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis.

▶ Treatment

Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 30–2 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 3–7 days; *S pneumoniae*, 10–14 days; *L monocytogenes*, 14–21 days; and gram-negative bacilli, 21 days.

For adults with pneumococcal meningitis, dexamethasone 10 mg administered intravenously 15–20 minutes

before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (*Streptococcus pneumoniae* or *S suis*), and those who are HIV negative. It is unknown whether patients with meningitis due to *N meningitidis* and other bacterial pathogens benefit from the use of adjunctive corticosteroids. Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g intravenously as a bolus), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of intraventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) may also decrease cerebral edema.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against organisms isolated. An empiric regimen often includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours, with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. Vancomycin trough serum levels should be greater than 15 mcg/mL in such patients. In cases where abscesses are smaller than 2 cm, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks can be used without drainage.

In addition to antibiotics, in cases of health care–associated meningitis associated with an external intraventricular catheter, the probability of cure is increased if the catheter is removed. In infections associated with internal ventricular catheters, removal of the internal components and insertion of an external drain is recommended. After collecting cerebrospinal fluid, epidural aspirate, or other specimens for culture, empiric antifungal therapy with voriconazole as well as routine empiric treatment for other pathogens (as above) is recommended until the specific cause of the patient's central nervous system or parameningeal infection has been identified. In addition, early consultation with a neurosurgeon is recommended for those found to have an epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis to discuss possible surgical management (eg, debridement).

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 36; syphilis and Lyme borreliosis, Chapter 34; tuberculous meningitis, Chapter 33; herpes encephalitis, Chapter 32).

▶ When to Refer

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, *M tuberculosis*), or if the patient is immunosuppressed.
- Patients with chronic meningitis.
- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery or epidural or paraspinal corticosteroid injection).
- Patients with recurrent meningitis.

▶ When to Admit

- Patients with suspected acute meningitis, encephalitis, and brain or paraspinous abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

ANIMAL & HUMAN BITE WOUNDS

ESSENTIALS OF DIAGNOSIS

- ▶ Cat and human bites have higher rates of infection than dog bites.
- ▶ Hand bites are particularly concerning for the possibility of closed-space infection.
- ▶ Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- ▶ All infected wounds need to be cultured to direct therapy.

▶ General Considerations

About 1000 dog bite injuries require emergency department attention each day in the United States, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are provoked (ie, bites occur while playing with the animal or after surprising the animal while eating or waking it abruptly from sleep). Failure to elicit a history of provocation is important, because an unprovoked attack raises the possibility of rabies. Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determinants of whether they become infected. Cat bites are more likely to become infected than human bites—between 30% and 50% of all cat bites become infected. Infections following human bites are variable. Bites inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15–30% of cases, with a particularly high rate of infection in closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. “Through and through” bites (eg, involving the mucosa and the skin) have an infection rate similar to closed-fist injuries. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections is polymicrobial. Following dog and cat bites, over 50% of infections are caused by aerobes and anaerobes and 36% are due to aerobes alone. Pure anaerobic infections are rare. *Pasteurella* species are the single most common isolate (75% of infections caused by cat bites and 50% of infections caused by dog bites). Other common aerobic isolates include streptococci, staphylococci, *Moraxella*, and *Neisseria*; the most common anaerobes are *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*. The median number of isolates following human bites is four (three aerobes and one anaerobe). Like dog and cat bites, infections caused by most human bites are a mixture of aerobes and anaerobes (54%) or are due to aerobes alone (44%). Streptococci and *S aureus* are the most common aerobes. *Eikenella corrodens* (found in up to 30% of patients), *Prevotella*, and *Fusobacterium* are the most common anaerobes. Although the organisms noted are the most common, innumerable others have been isolated—including *Capnocytophaga* (dog and cat), *Pseudomonas*, and *Haemophilus*—emphasizing the point that all infected bites should be cultured to define the microbiology.

HIV can be transmitted from bites (either from biting or receiving a bite from an HIV-infected patient) but has rarely been reported.

▶ Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. Radiographs should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. Cat bites in any location and hand bites by any animal, including humans, should receive prophylaxis. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with *Capnocytophaga* species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily together with one of the following is recommended for 5–7 days: doxycycline 100 mg orally twice daily, or double-strength TMP-SMZ orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily). Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy at 400 mg orally once daily for 5–7 days. Agents such as dicloxacillin, cephalixin, erythromycin, and clindamycin should not be used alone because they lack activity against *Pasteurella* species. Doxycycline and TMP-SMZ have poor activity against anaerobes and should only be used in combination with clindamycin.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens require treatment with either a combination of a beta-lactam plus a beta-lactamase inhibitor (ampicillin-sulbactam [Unasyn], 1.5–3.0 g intravenously every 6–8 hours; or piperacillin-tazobactam [Zosyn], 3.375 g intravenously every 6–8 hours; or amoxicillin-clavulanate [Augmentin], 500 mg orally three times daily); or with a carbapenem (ertapenem, 1 g intravenously daily; imipenem, 500 mg intravenously every 6–8 hours; or meropenem, 1 g intravenously every 8 hours). For the patient with severe penicillin allergy, a combination of clindamycin 600–900 mg intravenously every 8 hours plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) or TMP-SMZ (10 mg/kg of trimethoprim daily in two or three divided doses) is indicated. Duration of therapy is usually 2–3 weeks unless complications such as septic arthritis or osteomyelitis are present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see Chapter 33) and rabies (see Chapter 32) prophylaxis.

▶ When to Refer

- If septic arthritis or osteomyelitis is suspected.
- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

▶ When to Admit

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

SEXUALLY TRANSMITTED DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ All sexually transmitted diseases (STDs) have subclinical or latent periods, and patients may be asymptomatic.
- ▶ Simultaneous infection with several organisms is common.
- ▶ All patients who seek STD testing should be screened for syphilis and HIV.
- ▶ Partner notification and treatment are important to prevent further transmission and reinfection of the index case.

▶ General Considerations

The most common STDs are gonorrhea,* syphilis,* human papillomavirus (HPV)–associated condyloma acuminatum, chlamydial genital infections,* herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis*; hepatitis A, B, and C*; amebiasis; giardiasis*; cryptosporidiosis*; salmonellosis*; and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in men who have sex with men. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 31). All STDs have subclinical or latent phases that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Simultaneous infection by several different agents is common.

* Reportable to public health authorities.

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

A. Genital Ulcers

Common etiologies include herpes simplex virus, primary syphilis, and chancroid. Other possibilities include lymphogranuloma venereum (see Chapter 33), granuloma inguinale caused by *Klebsiella granulomatis* (see Chapter 33), as well as lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 20), neoplasm, trauma, drugs, and irritants.

B. Urethritis with or without Urethral Discharge

The most common infections causing urethral discharge are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. *N gonorrhoeae* and *C trachomatis* are also frequent causes of prostatitis among sexually active men. Other sexually transmitted infections that can cause urethritis include *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Trichomonas vaginalis*. Noninfectious causes of urethritis include reactive arthritis (Reiter syndrome) with associated urethritis.

C. Vaginal Discharge

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as *Gardnerella vaginalis*), candidiasis, and *T vaginalis* (see Chapter 18). Less common infectious causes of vaginitis include HPV-associated condylomata acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though *N gonorrhoeae* and *C trachomatis* are frequent causes of cervicitis, they rarely produce vaginal discharge.

▶ Screening & Prevention

All persons who seek STD testing should undergo routine screening for HIV infection, using rapid HIV-testing (if patients may not follow up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. Patients in whom certain STDs have been diagnosed and treated (chlamydia or gonorrhea, and trichomonas in women) are at a high risk for reinfection and should be encouraged to be rescreened for STDs at 3 months following the initial STD diagnosis.

Asymptomatic patients often request STD screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recommended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is recommended for gonorrhea or chlamydia. There are no

recommendations to screen heterosexual men for urethral chlamydia but this could be considered in STD clinics, adolescent clinics, or correctional facilities. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults (particularly to those 25 years old and under). Clinicians should also evaluate transgender men and women for STD screening, based on current anatomy and behaviors practiced. If not immune, hepatitis B vaccination is recommended for all sexually active adults, and hepatitis A vaccination in men who have sex with men. Persons between the ages of 9 and 26 should be routinely offered vaccination against HPV (quadrivalent or 9-valent).

The risk of developing an STD following a **sexual assault** is difficult to accurately ascertain given high rates of baseline infections and poor follow-up. Victims of assault have a high baseline rate of infection (*N gonorrhoeae*, 6%; *C trachomatis*, 10%; *T vaginalis*, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant but is often lower than the preexisting rate (*N gonorrhoeae*, 6–12%; *C trachomatis*, 4–17%; *T vaginalis*, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and nucleic acid amplification tests for *N gonorrhoeae* and *C trachomatis* should be performed. Vaginal secretions are obtained for *Trichomonas* wet mount and culture, or point-of-care testing. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for *Candida* and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STDs should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune globulin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the prompt institution of postexposure prophylaxis with antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.

In addition to screening asymptomatic patients with STDs, other strategies for preventing further transmission include evaluating sex partners and administering pre-exposure vaccination of preventable STDs to individuals at risk; other strategies include the consistent use of male and female condoms and male circumcision. Adult male circumcision has been shown to decrease the transmission of HIV by 50%, and of herpes simplex virus and HPV by 30% in heterosexual couples in sub-Saharan Africa. For each patient, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute to all sexual contacts (patient-delivered therapy) is an important strategy for preventing further transmission and to prevent reinfection of the index case.

Note that vaginal spermicides and condoms containing nonoxonyl-9 provide no additional protection against STDs. Early initiation of antiretroviral therapy in HIV-infected individuals can prevent HIV acquisition in an uninfected sex partner. Also, preexposure prophylaxis with a once-daily pill containing tenofovir plus emtricitabine has been shown to be effective in preventing HIV infection among high-risk men who have sex with men.

▶ When to Refer

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory or recurrent STDs, particularly when drug resistance is suspected.

INFECTIONS IN DRUG USERS

ESSENTIALS OF DIAGNOSIS

- ▶ Common infections that occur with greater frequency in drug users include:
 - Skin infections, aspiration pneumonia, tuberculosis.
 - Hepatitis A, B, C, D; STDs; HIV/AIDS.
 - Pulmonary septic emboli, infective endocarditis.
 - Osteomyelitis and septic arthritis.

▶ General Considerations

There is a high incidence of infection among drug users, particularly those who inject drugs. Increased risk of infection is likely associated with poor hygiene and colonization with potentially pathogenic organisms, contamination of drugs and equipment, increased sexual risk behaviors, and impaired immune defenses. The use of parenterally administered recreational drugs has increased enormously in recent years. There are now an estimated 300,000 or more injection drug users in the United States.

Skin infections are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S aureus* (including community-acquired methicillin-resistant strains) and oral flora (streptococci, *Eikenella*, *Fusobacterium*, *Peptostreptococcus*) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous (“skin-popping”) or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in drug users, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is very common among habitual drug users and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

HIV/AIDS has a high incidence among injection drug users and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who use drugs intravenously is most commonly caused by *S aureus*, *Candida* (usually *C albicans* or *C parapsilosis*), *Enterococcus faecalis*, other streptococci, and gram-negative bacteria (especially *Pseudomonas* and *Serratia marcescens*). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and septic arthritis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually results from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While staphylococci—often methicillin-resistant—are common organisms, *Serratia*, *Pseudomonas*, *Candida* (often not *C albicans*), and other pathogens rarely encountered in spontaneous bone or joint disease are found in injection drug users.

Treatment

A common and difficult clinical problem is management of the parenteral drug user who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest radiograph is abnormal), empiric therapy is begun. If the chest radiograph is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with a third-generation cephalosporin, such as ceftriaxone, 1 g intravenously every 24 hours, plus azithromycin, 500 mg orally or intravenously every 24 hours, or doxycycline, 100 mg orally or

intravenously twice daily. If the chest radiograph is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococcus). If the chest radiograph is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empiric treatment with vancomycin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done.

When to Refer

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

When to Admit

- Injection drug users with fever.
- Patients with abscesses or progressive skin and soft tissue infection that require debridement.

ACUTE INFECTIOUS DIARRHEA

ESSENTIALS OF DIAGNOSIS

- ▶ **Acute diarrhea:** lasts less than 2 weeks
- ▶ **Chronic diarrhea:** lasts longer than 2 weeks.
- ▶ **Mild diarrhea:** 3 or fewer stools per day.
- ▶ **Moderate diarrhea:** 4 or more stools per day with local symptoms (abdominal cramps, nausea, tenesmus).
- ▶ **Severe diarrhea:** 4 or more stools per day with systemic symptoms (fever, chills, dehydration).

General Considerations

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), drugs, and infectious agents (including viruses, bacteria, and protozoa) (Table 30–3). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term “inflammatory diarrhea” suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients complain of frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, invasive strains of *Escherichia coli*, and other Shiga-toxin–producing strains of *coli* (STEC), *Entamoeba histolytica*, and *C difficile*. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. Noninflammatory diarrhea is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, norovirus, astrovirus, enteric adenoviruses), vibriones (*Vibrio cholerae*, *Vibrio parahaemolyticus*), enterotoxin-producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis. In developed countries, viruses (particularly norovirus) are an important cause of hospitalizations due to acute gastroenteritis among adults.

The term “food poisoning” denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested. Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that

due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. *Cyclospora*, cryptosporidia, and *Isospora* are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests *Salmonella*, *Shigella*, *Campylobacter*, *E coli*, or *V cholerae*; undercooked hamburger suggests STEC; outbreak in long-term care facility, school, or cruise ship suggests norovirus (including newly identified strains, eg, GII.4 Sydney); and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in Table 30–3.

Treatment

A. General Measures

In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures. Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural lightheadedness, decreased urination), oral glucose-based rehydration solutions can be used (CeraLyte, Pedialyte).

B. Specific Measures

When symptoms persist beyond 3–4 days, initial presentation is accompanied by fever or bloody diarrhea, or if the patient is immunocompromised, cultures of stool are usually obtained. Symptoms have often resolved by the time cultures are completed. In this case, even if a pathogen is isolated, therapy is not needed (except for *Shigella*, since the infecting dose is so small that therapy to eradicate organisms from the stool is indicated for epidemiologic reasons). If symptoms persist and a pathogen is isolated, it is reasonable to institute specific treatment even though therapy has not been conclusively shown to alter the natural history of disease for most pathogens. Exceptions include infection with *Shigella* where antibiotic therapy has been shown to shorten the duration of symptoms by 2–3 days, and *Campylobacter* infections (early therapy, within 4 days of onset of symptoms, shortens the course of disease). Conversely, antibiotic therapy for infections with STEC does not ameliorate symptoms and may increase the risk of developing hemolytic-uremic syndrome. Uncomplicated gastroenteritis due to *Salmonella* does not require therapy because the disease is usually self-limited and therapy may prolong carriage and perhaps increase

Table 30–3. Acute bacterial diarrheas and “food poisoning.”

Organism	Incubation Period	Vomiting	Diarrhea	Fever	Associated Foods	Diagnosis	Clinical Features and Treatment
<i>Staphylococcus</i> (preformed toxin)	1–8 hours	+++	±	±	Staphylococci grow in meats, dairy, and bakery products and produce enterotoxin.	Clinical. Food and stool can be tested for toxin.	Abrupt onset, intense nausea and vomiting for up to 24 hours, recovery in 24–48 hours. Supportive care.
<i>Bacillus cereus</i> (preformed toxin)	1–8 hours	+++	±	–	Reheated fried rice causes vomiting or diarrhea.	Clinical. Food and stool can be tested for toxin.	Acute onset, severe nausea and vomiting lasting 24 hours. Supportive care.
<i>B cereus</i> (diarrheal toxin)	10–16 hours	±	+++	–	Toxin in meats, stews, and gravy.	Clinical. Food and stool can be tested for toxin.	Abdominal cramps, watery diarrhea, and nausea lasting 24–48 hours. Supportive care.
<i>Clostridium perfringens</i>	8–16 hours	±	+++	–	Clostridia grow in rewarmed meat and poultry dishes and produce an enterotoxin.	Stools can be tested for enterotoxin or cultured.	Abrupt onset of profuse diarrhea, abdominal cramps, nausea; vomiting occasionally. Recovery usual without treatment in 24–48 hours. Supportive care; antibiotics not needed.
<i>C. botulinum</i>	12–72 hours	±	–	–	Clostridia grow in anaerobic acidic environment eg, canned foods, fermented fish, foods held warm for extended periods.	Stool, serum, and food can be tested for toxin. Stool and food can be cultured.	Diplopia, dysphagia, dysphonia, respiratory embarrassment. Treatment requires clear airway, ventilation, and intravenous polyvalent antitoxin (see text). Symptoms can last for days to months.
<i>C. difficile</i>	Usually occurs after 7–10 days of antibiotics. Can occur after a single dose or several weeks after completion of antibiotics.	–	+++	++	Associated with antimicrobial drugs; clindamycin and beta-lactams most commonly implicated. Fluoroquinolones associated with hypervirulent strains.	Stool tested for toxin.	Abrupt onset of diarrhea that may be bloody; fever. Oral metronidazole for mild to moderate cases. Oral vancomycin for more severe disease.
Enterohemorrhagic <i>Escherichia coli</i> , including Shiga-toxin producing <i>E coli</i> strains (STEC)	1–8 days	+	+++	–	Undercooked beef, especially hamburger; unpasteurized milk and juice; raw fruits and vegetables.	Shiga-toxin–producing <i>E coli</i> can be cultured on special medium. Other toxins can be detected in stool.	Usually abrupt onset of diarrhea, often bloody; abdominal pain. In adults, it is usually self-limited to 5–10 days. In children, it is associated with hemolytic-uremic syndrome (HUS). Antibiotic therapy may increase risk of HUS. Plasma exchange may help patients with STEC-associated HUS.

Enterotoxigenic <i>E coli</i> (ETEC)	1–3 days	±	+++	±	Water, food contaminated with feces.	Stool culture. Special tests required to identify toxin-producing strains.	Watery diarrhea and abdominal cramps, usually lasting 3–7 days. In travelers, fluoroquinolones shorten disease.
<i>Vibrio parahaemolyticus</i>	2–48 hours	+	+	±	Undercooked or raw seafood.	Stool culture on special medium.	Abrupt onset of watery diarrhea, abdominal cramps, nausea and vomiting. Recovery is usually complete in 2–5 days.
<i>V. cholerae</i>	24–72 hours	+	+++	–	Contaminated water, fish, shellfish, street vendor food.	Stool culture on special medium.	Abrupt onset of liquid diarrhea in endemic area. Needs prompt intravenous or oral replacement of fluids and electrolytes. Tetracyclines and azithromycin shorten excretion of vibrios.
<i>Campylobacter jejuni</i>	2–5 days	±	+++	+	Raw or undercooked poultry, unpasteurized milk, water.	Stool culture on special medium.	Fever, diarrhea that can be bloody, cramps. Usually self-limited in 2–10 days. Treat with azithromycin or fluoroquinolones for severe disease. May be associated with Guillain-Barré syndrome.
<i>Shigella</i> species (mild cases)	24–48 hours	±	+	+	Food or water contaminated with human feces. Person to person spread.	Routine stool culture.	Abrupt onset of diarrhea, often with blood and pus in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Therapy depends on sensitivity testing, but the fluoroquinolones are most effective. Do not give opioids. Often mild and self-limited.
<i>Salmonella</i> species	1–3 days	–	++	+	Eggs, poultry, unpasteurized milk, cheese, juices, raw fruits and vegetables.	Routine stool culture.	Gradual or abrupt onset of diarrhea and low-grade fever. No antimicrobials unless high risk (see text) or systemic dissemination is suspected, in which case give a fluoroquinolone. Prolonged carriage can occur.
<i>Yersinia enterocolitica</i>	24–48 hours	±	+	+	Undercooked pork, contaminated water, unpasteurized milk, tofu.	Stool culture on special medium.	Severe abdominal pain (appendicitis-like symptoms), diarrhea, fever. Polyarthrits, erythema nodosum in children. If severe, give tetracycline or fluoroquinolone. Without treatment, self-limited in 1–3 weeks.
Rotavirus	1–3 days	++	+++	+	Fecally contaminated foods touched by infected food handlers.	Immunoassay on stool.	Acute onset, vomiting, watery diarrhea that lasts 4–8 days. Supportive care.
Noroviruses and other caliciviruses	12–48 hours	++	+++	+	Shellfish and fecally contaminated foods touched by infected food handlers.	Clinical diagnosis with negative stool cultures. PCR available on stool.	Nausea, vomiting (more common in children), diarrhea (more common in adults), fever, myalgias, abdominal cramps. Lasts 12–60 hours. Supportive care.

PCR, polymerase chain reaction.

relapses. Because bacteremia with complications can occur in high-risk patients, some experts have recommended therapy for *Salmonella* in patients over the age of 50, in organ transplant recipients, in those with HIV, in patients taking corticosteroids, in those with lymphoproliferative diseases, and in those with vascular grafts. Ciprofloxacin, 500 mg orally every 12 hours for 5 days, is effective in shortening the course of illness compared with placebo in patients presenting with diarrhea, whether a pathogen is isolated or not. However, because of concerns about selecting for resistant organisms (especially *Campylobacter*, where increasing resistance to fluoroquinolones has been documented and erythromycin is the drug of choice) coupled with the fact that most infectious diarrhea is self-limited, routine use of antibiotics for all patients with diarrhea is not recommended. Antibiotics should be considered in patients with evidence of invasive disease (white cells in stool, dysentery), with symptoms 3–4 days or more in duration, with multiple stools (eight to ten or more per day), and in those with impaired immune responses. Antimotility drugs are useful in mild cases. Their use should be limited to patients without fever and without dysentery (bloody stools), and they should be used in low doses because of the risk of producing toxic megacolon. Postinfectious irritable bowel syndrome can follow infection and is approached in a similar fashion as in non-infectious irritable bowel syndrome.

Therapeutic recommendations for specific agents can be found elsewhere in this book.

INFECTIOUS DISEASES IN THE RETURNING TRAVELER

ESSENTIALS OF DIAGNOSIS

- ▶ Most infections are common and self-limited.
- ▶ Identify patients with transmissible diseases that require isolation.
- ▶ The incubation period may be helpful in diagnosis.
- ▶ Less than 3 weeks following exposure may suggest dengue, leptospirosis, and yellow fever; more than 3 weeks suggest typhoid fever, malaria, and tuberculosis.

General Considerations

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral infections to life-threatening illness. The evaluation is best done by identifying whether a particular syndrome is present, then refining the differential diagnosis based on an exposure history. The travel history should include directed questions regarding geography (rural versus urban, specific country visited), animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, historical or pretravel immunizations, and adherence to malaria prophylaxis.

Etiologies

The most common infectious causes of fever—excluding simple causes such as upper respiratory infections, bacterial pneumonia and urinary tract infections—in returning travelers are malaria (see Chapter 35), diarrhea (see next section), and dengue (see Chapter 32). Others include respiratory infections, including seasonal influenza, influenza A/H1N1 “swine” influenza, and influenza A/H5N1 or A/H7N9 “avian” influenza (see Chapter 32); leptospirosis (see Chapter 34); typhoid fever (see Chapter 33); and rickettsial infections (see Chapter 32). Foreign travel is increasingly recognized as a risk factor for colonization and disease with resistant pathogens, such as extended-spectrum beta-lactamases (ESBL)—producing gram-negative organisms. Systemic febrile illnesses without a diagnosis also occur commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

A. Fever and Rash

Potential etiologies include dengue, Ebola, Chikungunya, and Zika viruses, viral hemorrhagic fever, leptospirosis, meningococemia, yellow fever, typhus, *Salmonella typhi*, and acute HIV infection.

B. Pulmonary Infiltrates

Tuberculosis, ascaris, *Paragonimus*, and *Strongyloides* can all cause pulmonary infiltrates.

C. Meningoencephalitis

Etiologies include *N meningitidis*, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

D. Jaundice

Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

E. Fever without Localizing Symptoms or Signs

Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

F. Traveler's Diarrhea

See next section.

▶ Clinical Findings

Fever and rash in the returning traveler should prompt blood cultures and serologic tests based on the exposure history. The work-up of a **pulmonary infiltrate** should include the placement of a PPD or use of an interferon-gamma release assay, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of **meningoencephalitis** should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rabies is suspected). **Jaundice** in a returning traveler should be evaluated for hemolysis (for malaria), and the following tests should be performed: liver tests, thick/thin smears of peripheral blood, and directed serologic testing. The work-up of **traveler's diarrhea** is presented in the following section. Finally, patients with **fever** but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver tests, urinalysis, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, chest radiograph, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, *Strongyloides*). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient.

▶ When to Refer

Travelers with fever, particularly if immunocompromised.

▶ When to Admit

Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

TRAVELER'S DIARRHEA

ESSENTIALS OF DIAGNOSIS

- ▶ Usually a benign, self-limited disease occurring about 1 week into travel.
- ▶ Prophylaxis not recommended unless there is a comorbid disease (inflammatory bowel syndrome, HIV, immunosuppressive medication).
- ▶ Single-dose therapy of a fluoroquinolone usually effective if significant symptoms develop.

▶ General Considerations

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea may develop within 2–10 days. Bacteria cause 80% of cases of traveler's diarrhea, with enterotoxigenic *E coli*, *Shigella* species, and *Campylobacter jejuni* being the most common pathogens. Less common are *Aeromonas*, *Salmonella*, noncholera vibrios, *E histolytica*, and *G lamblia*. Contributory causes include unusual food

and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

▶ Clinical Findings

A. Symptoms and Signs

There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic *E coli*. With invasive bacterial pathogens (*Shigella*, *Campylobacter*, *Salmonella*) stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler's diarrhea is also a significant risk factor for developing irritable bowel syndrome.

B. Laboratory Findings

In patients with fever and bloody diarrhea, stool culture is indicated, but in most cases, cultures are reserved for those who do not respond to antibiotics.

▶ Prevention

A. General Measures

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

B. Specific Measures

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, the currently recommended approach is to provide the traveler with a supply of antimicrobials to be taken if significant diarrhea occurs during the trip. In areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose, then 2 mg after each loose stool to a maximum of 16 mg/day) with a single oral dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (200 mg), cures most cases of traveler's diarrhea. If diarrhea is associated with bloody stools or persists despite a single dose of a fluoroquinolone, 1000 mg of azithromycin should be taken. In pregnant women and in areas where invasive bacteria more commonly cause diarrhea (Indian subcontinent, Asia, especially Thailand where fluoroquinolone-resistant *Campylobacter* is prevalent), azithromycin is the drug of choice. Rifaximin, a nonabsorbable agent, is also approved for therapy of traveler's diarrhea at a dose of 200 mg orally three times per day or 400 mg twice a day for 3 days. Because luminal concentrations are high, but tissue levels are insufficient, it should not be used in situations where there is a high likelihood of invasive disease (eg, fever, systemic toxicity, or

bloody stools). Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes mellitus, heart disease in the elderly, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable.

Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, numerous oral antimicrobial once-daily regimens are effective, such as norfloxacin, 400 mg; ciprofloxacin, 500 mg; or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

▶ Treatment

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever 39°C or higher) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

▶ When to Refer

- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

▶ When to Admit

Patients who are severely dehydrated or hemodynamically unstable should be admitted to the hospital.

ANTIMICROBIAL THERAPY

SELECTED PRINCIPLES OF ANTIMICROBIAL THERAPY

Specific steps (outlined below) are required when considering antibiotic therapy for patients. Drugs within classes, drugs of first choice, and alternative drugs are presented in Table 30–4.

A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can often be predicted. See Tables 30–5 and 30–6.

Table 30–4. Drugs of choice for suspected or proved microbial pathogens.

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Gram-negative cocci		
<i>Moraxella catarrhalis</i>	Cefuroxime, a fluoroquinolone ¹	Ceftriaxone, cefuroxime axetil, an erythromycin, ² a tetracycline, ³ azithromycin, amoxicillin-clavulanic acid, TMP-SMZ ⁴
<i>Neisseria gonorrhoeae</i> (gonococcus)	Ceftriaxone plus azithromycin or doxycycline	Cefixime plus azithromycin or doxycycline ⁵
<i>Neisseria meningitidis</i> (meningococcus)	Penicillin ⁶	Ceftriaxone, ampicillin
Gram-positive cocci		
<i>Streptococcus pneumoniae</i> ⁷ (pneumococcus)	Penicillin ⁶	An erythromycin, ² a cephalosporin, ⁸ vancomycin, clindamycin, azithromycin, a tetracycline, ³ respiratory fluoroquinolones ¹
<i>Streptococcus</i> , hemolytic, groups A, B, C, G	Penicillin ⁶	An erythromycin, ² a cephalosporin, ⁸ vancomycin, clindamycin, azithromycin
Viridans streptococci	Penicillin ⁶ ± gentamicin	Cephalosporin, ⁸ vancomycin
<i>Staphylococcus</i> , methicillin-resistant	Vancomycin	TMP-SMZ, ⁴ doxycycline, minocycline, linezolid ¹¹ , tedizolid ¹¹ , daptomycin ¹¹ , telavancin ¹¹ , dalbavancin ¹¹ , oritavancin ¹¹ , ceftaroline
<i>Staphylococcus</i> , non-penicillinase-producing	Penicillin ⁶	A cephalosporin, ⁸ clindamycin
<i>Staphylococcus</i> , penicillinase-producing	Penicillinase-resistant penicillin ⁹	Vancomycin, a cephalosporin, ⁸ clindamycin, amoxicillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam, TMP-SMZ ⁴
<i>Enterococcus faecalis</i>	Ampicillin ± gentamicin ¹⁰	Vancomycin ± gentamicin
<i>Enterococcus faecium</i>	Vancomycin ± gentamicin ¹⁰	Linezolid, ¹¹ quinupristin-dalfopristin, ¹¹ daptomycin, ¹¹ tigecycline, ¹¹ tedizolid, ¹¹ oritavancin ¹¹
Gram-negative rods		
<i>Acinetobacter</i>	Imipenem, meropenem	Tigecycline, minocycline, doxycycline, aminoglycosides, ¹² colistin
<i>Prevotella</i> , oropharyngeal strains	Clindamycin	Metronidazole
<i>Bacteroides</i> , gastrointestinal strains	Metronidazole	Ticarcillin-clavulanate, ampicillin-sulbactam, piperacillin-tazobactam, carbapenem
<i>Brucella</i>	Doxycycline + rifampin ³	TMP-SMZ ⁴ ± gentamicin; ciprofloxacin + rifampin
<i>Campylobacter jejuni</i>	Erythromycin ² or azithromycin	Tetracycline, ³ a fluoroquinolone ¹
<i>Enterobacter</i>	Ertapenem, imipenem, meropenem, cefepime	Aminoglycoside, a fluoroquinolone, ¹ TMP-SMZ ⁴
<i>Escherichia coli</i> (sepsis) ¹³	Cefotaxime, ceftriaxone	Ertapenem ¹³ imipenem ¹³ or meropenem, ¹³ aminoglycosides, ¹² a fluoroquinolone, ¹ aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime-avibactam, ¹³ ceftolozane-tazobactam ¹³
<i>Escherichia coli</i> (uncomplicated outpatient urinary infection)	Nitrofurantoin, fosfomycin	Fluoroquinolones, ¹ TMP-SMZ, ⁴ oral cephalosporin
<i>Haemophilus</i> (meningitis and other serious infections)	Ceftriaxone	Aztreonam
<i>Haemophilus</i> (respiratory infections, otitis)	Ampicillin-clavulanate	Doxycycline, azithromycin, ceftriaxone, cefuroxime, cefuroxime axetil, TMP-SMZ ⁴
<i>Helicobacter pylori</i>	Amoxicillin, clarithromycin and PPI	Bismuth subsalicylate, tetracycline, metronidazole and PPI
<i>Klebsiella</i> ¹³	A cephalosporin	TMP-SMZ, ⁴ aminoglycoside, ¹² ertapenem, ¹³ imipenem ¹³ or meropenem, ¹³ a fluoroquinolone, ¹ aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime-avibactam, ¹³ ceftolozane-tazobactam ¹³
<i>Legionella</i> species (pneumonia)	Azithromycin, or fluoroquinolones ¹ ± rifampin	Doxycycline ± rifampin

(continued)

Table 30–4. Drugs of choice for suspected or proved microbial pathogens. (continued)

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
<i>Proteus mirabilis</i>	Ampicillin	An aminoglycoside, ¹² TMP-SMZ, ⁴ a fluoroquinolone, ¹ a cephalosporin ⁸
<i>Proteus vulgaris</i> and other species (<i>Morganella</i> , <i>Providencia</i>)	Ceftriaxone	Aminoglycoside, ¹² ertapenem, imipenem or meropenem, TMP-SMZ, ⁴ a fluoroquinolone ¹
<i>Pseudomonas aeruginosa</i>	Piperacillin-tazobactam or ceftazidime or cefepime, or imipenem or meropenem or doripenem or aztreonam ± aminoglycoside ¹²	Ciprofloxacin (or levofloxacin) ± piperacillin-tazobactam; ciprofloxacin (or levofloxacin) ± ceftazidime; ciprofloxacin (or levofloxacin) ± cefepime; ceftazidime-avibactam ¹³ ; ceftolozane-tazobactam ¹³
<i>Burkholderia pseudomallei</i> (melioidosis)	Ceftazidime	Tetracycline, ³ TMP-SMZ, ⁴ amoxicillin-clavulanic acid, imipenem or meropenem
<i>Burkholderia mallei</i> (glanders)	Streptomycin + tetracycline ³	Chloramphenicol + streptomycin
<i>Salmonella</i> (bacteremia)	Ceftriaxone	A fluoroquinolone ¹
<i>Serratia</i>	Carbapenem	TMP-SMZ, ⁴ aminoglycosides, ¹² a fluoroquinolone, ¹ ceftriaxone
<i>Shigella</i>	A fluoroquinolone ¹	Azithromycin, ampicillin, TMP-SMZ, ⁴ ceftriaxone
<i>Vibrio</i> (cholera, sepsis)	A tetracycline ³	TMP-SMZ, ⁴ a fluoroquinolone ¹
<i>Yersinia pestis</i> (plague)	Streptomycin ± a tetracycline ³	Chloramphenicol, TMP-SMZ ⁵
Gram-positive rods		
<i>Actinomyces</i>	Penicillin ⁶	Tetracycline, ³ clindamycin
<i>Bacillus</i> (including anthrax)	Penicillin ⁶	Erythromycin, ² a fluoroquinolone ¹
<i>Clostridium</i> (eg, gas gangrene, tetanus)	Penicillin ⁶	Metronidazole, clindamycin, imipenem or meropenem
<i>Corynebacterium diphtheria</i>	Erythromycin ²	Penicillin ⁶
<i>Corynebacterium jeikeium</i>	Vancomycin	Linezolid
<i>Listeria</i>	Ampicillin ± aminoglycoside ¹²	TMP-SMZ ⁴
Acid-fast rods		
<i>Mycobacterium tuberculosis</i> ¹⁵	Isoniazid (INH) + rifampin + pyrazinamide ± ethambutol	Other antituberculous drugs (see Tables 9–15 and 9–16)
<i>Mycobacterium leprae</i>	Dapsone + rifampin ± clofazimine	Minocycline, ofloxacin, clarithromycin
<i>Mycobacterium kansasii</i>	INH + rifampin ± ethambutol	Clarithromycin, azithromycin, ethionamide, cycloserine
<i>Mycobacterium avium</i> complex	Clarithromycin or azithromycin + ethambutol, ± rifabutin	Amikacin, ciprofloxacin
<i>Mycobacterium fortuitum-chelonae</i>	Cefoxitin + clarithromycin	Amikacin, rifampin, sulfonamide, doxycycline, linezolid
<i>Nocardia</i>	TMP-SMZ ⁴	Minocycline, imipenem or meropenem, linezolid
Spirochetes		
<i>Borrelia burgdorferi</i> (Lyme disease)	Doxycycline, amoxicillin, cefuroxime axetil	Ceftriaxone, penicillin, azithromycin
<i>Borrelia recurrentis</i> (relapsing fever)	Doxycycline ³	Penicillin ⁶
<i>Leptospira</i>	Penicillin ⁶	Doxycycline, ³ ceftriaxone
<i>Treponema pallidum</i> (syphilis)	Penicillin ⁶	Doxycycline, ceftriaxone
<i>Treponema pertenue</i> (yaws)	Penicillin ⁶	Doxycycline

(continued)

Table 30–4. Drugs of choice for suspected or proved microbial pathogens. (continued)

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Mycoplasmas	Clarithromycin or azithromycin or doxycycline	A fluoroquinolone, ¹ erythromycin ²
Chlamydiae		
<i>C psittaci</i>	Doxycycline	Chloramphenicol
<i>C trachomatis</i> (urethritis or pelvic inflammatory disease)	Doxycycline or azithromycin	Levofloxacin, ofloxacin
<i>C pneumoniae</i>	Doxycycline ³	Erythromycin, ² azithromycin, a fluoroquinolone ^{1,16}
Rickettsiae	Doxycycline ³	Chloramphenicol, a fluoroquinolone ¹

¹Fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and others (see text). Gemifloxacin, levofloxacin, and moxifloxacin, the so-called “respiratory fluoroquinolones,” demonstrate the most reliable activity against gram-positive organisms, including penicillin-resistant *S pneumoniae* and methicillin-sensitive *S aureus*. Activity against enterococci and *S epidermidis* is variable.

²Erythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.

³All tetracyclines have similar activity against most microorganisms. Minocycline (the most active tetracycline), doxycycline, have increased activity over tetracycline against *S aureus*.

⁴TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

⁵Test of cure required if ceftriaxone not used.

⁶Penicillin G is preferred for parenteral injection; penicillin V for oral administration—to be used only in treating infections due to highly sensitive organisms.

⁷Infections caused by isolates with intermediate resistance may respond to high doses of penicillin or ceftriaxone, as well as the respiratory fluoroquinolones (gemifloxacin, levofloxacin, and moxifloxacin). Infections caused by highly resistant strains should be treated with vancomycin. Many strains of penicillin-resistant pneumococci are resistant to macrolides, cephalosporins, tetracyclines, and TMP-SMZ.

⁸Most intravenous cephalosporins (with the exception of ceftazidime) have good activity against streptococci and staphylococci.

⁹Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

¹⁰Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

¹¹Linezolid, tedizolid, daptomycin, telavancin, dalbavancin, oritavancin should be reserved for the treatment of vancomycin-resistant isolates or in patients intolerant of vancomycin. Daptomycin, tigecycline, tedizolid, and oritavancin are not approved by FDA for treatment of vancomycin-resistant strains of enterococci but are frequently active in vitro.

¹²Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.

¹³Extended beta-lactamase–producing isolates should be treated with a carbapenem. If a carbapenem cannot be used, either ceftazidime-avibactam or ceftolozane-tazobactam can be considered.

¹⁴Ceftazidime-avibactam and ceftolozane-tazobactam often active in multidrug-resistant *P aeruginosa*.

¹⁵Resistance is common and susceptibility testing should be done.

¹⁶Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin.

Key: ±, alone or combined with.

B. “Best Guess”

Select an empiric regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent,

and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before drugs are abandoned that were judiciously selected on a “best guess” basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably inhibited by certain drugs; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns have now become resistant

Table 30–5. Examples of initial antimicrobial therapy for acutely ill, hospitalized adults pending identification of causative organism.

Suspected Clinical Diagnosis	Likely Etiologic Diagnosis	Drugs of Choice
Meningitis, bacterial, community-acquired	<i>Streptococcus pneumoniae</i> (pneumococcus), ¹ <i>Neisseria meningitidis</i> (meningococcus)	Ceftriaxone, 2 g intravenously every 12 hours ² ; plus vancomycin, 15 mg/kg intravenously every 8 hours
Meningitis, bacterial, age > 50, community-acquired	Pneumococcus, meningococcus, <i>Listeria monocytogenes</i> , ² gram-negative bacilli, group B streptococcus	Ampicillin, 2 g intravenously every 4 hours, plus ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 15 mg/kg intravenously every 8 hours
Meningitis, postoperative (or posttraumatic)	<i>S aureus</i> , gram-negative bacilli, coagulase-negative staphylococci, diphtheroids (eg, <i>Propionibacterium acnes</i>) (uncommon) pneumococcus (in posttraumatic)	Vancomycin, 15 mg/kg intravenously every 8 hours, plus cefepime, 3 g intravenously every 8 hours
Brain abscess	Mixed anaerobes, pneumococci, streptococci	Ceftriaxone, 2 g intravenously every 12 hours plus metronidazole, 500 mg orally every 8 hours plus vancomycin, 15 mg/kg intravenously every 8 hours
Pneumonia, acute, community-acquired, non-ICU hospital admission	Pneumococci, <i>M pneumoniae</i> , <i>Legionella</i> , <i>C pneumoniae</i>	Ceftriaxone, 1 g intravenously every 24 hours or ampicillin 2 g intravenously every 6 hours) plus azithromycin 500 mg intravenously every 24 hours; or a respiratory fluoroquinolone ³ alone
Pneumonia, postoperative or nosocomial	<i>S aureus</i> , mixed anaerobes, gram-negative bacilli	Cefepime, 1 g intravenously every 8 hours; or ceftazidime, 2 g intravenously every 8 hours; or piperacillin-tazobactam, 4.5 g intravenously every 6 hours; or imipenem, 500 mg intravenously every 6 hours; or meropenem, 1 g intravenously every 8 hours plus tobramycin, 5–7 mg/kg intravenously every 24 hours; or ciprofloxacin, 400 mg intravenously every 12 hours; or levofloxacin, 500 mg intravenously every 24 hours plus vancomycin, 15 mg/kg intravenously every 12 hours
Endocarditis, acute (including injection drug user)	<i>S aureus</i> , <i>E faecalis</i> , gram-negative aerobic bacteria, viridans streptococci	Vancomycin, 15 mg/kg intravenously every 12 hours, plus gentamicin, 1 mg/kg every 8 hours
Septic thrombophlebitis (eg, IV tubing, IV shunts)	<i>S aureus</i> , gram-negative aerobic bacteria	Vancomycin, 15 mg/kg intravenously every 12 hours, plus ceftriaxone, 1 g intravenously every 24 hours
Osteomyelitis	<i>S aureus</i>	Nafcillin, 2 g intravenously every 4 hours; or cefazolin, 2 g intravenously every 8 hours
Septic arthritis	<i>S aureus</i> , <i>N gonorrhoeae</i>	Ceftriaxone, 1–2 g intravenously every 24 hours
Pyelonephritis with flank pain and fever (recurrent urinary tract infection)	<i>E coli</i> , <i>Klebsiella</i> , <i>Enterobacter</i> , <i>Pseudomonas</i>	Ceftriaxone, 1 g intravenously every 24 hours; or ciprofloxacin, 400 mg intravenously every 12 hours (500 mg orally); or levofloxacin, 500 mg once daily (intravenously/orally)
Fever in neutropenic patient receiving cancer chemotherapy	<i>S aureus</i> , <i>Pseudomonas</i> , <i>Klebsiella</i> , <i>E coli</i>	Ceftazidime, 2 g intravenously every 8 hours; or cefepime, 2 g intravenously every 8 hours
Intra-abdominal sepsis (eg, postoperative, peritonitis, cholecystitis)	Gram-negative bacteria, <i>Bacteroides</i> , anaerobic bacteria, streptococci, clostridia	Piperacillin-tazobactam, 4.5 g intravenously every 6 hours, or ertapenem, 1 g every 24 hours

¹Some strains may be resistant to penicillin.²TMP-SMZ can be used to treat *Listeria monocytogenes* in patients allergic to penicillin in a dosage of 15–20 mg/kg/day of TMP in three or four divided doses.³Levofloxacin 750 mg/day, moxifloxacin 400 mg/day.

Table 30–6. Examples of empiric choices of antimicrobials for adult outpatient infections.

Suspected Clinical Diagnosis	Likely Etiologic Agents	Drugs of Choice	Alternative Drugs
Erysipelas, impetigo, cellulitis, ascending lymphangitis	Group A streptococcus	Phenoxymethyl penicillin, 0.5 g orally four times daily for 7–10 days	Cephalexin, 0.5 g orally four times daily for 7–10 days; or azithromycin, 500 mg on day 1 and 250 mg on days 2–5
Furuncle with surrounding cellulitis	<i>Staphylococcus aureus</i>	Dicloxacillin, 0.5 g orally four times daily for 7–10 days for MSSA. However, in many areas of the United States, CA-MRSA has become predominant: TMP-SMZ two double-strength tablets twice daily for 7–10 days; or clindamycin 0.3 g orally four times daily for 7–10 days	Cephalexin, 0.5 g orally four times daily for 7–10 days for MSSA. For CA-MRSA, tetracyclines, but not fluoroquinolones, are reasonable alternatives
Pharyngitis	Group A streptococcus	Phenoxymethyl penicillin, 0.5 g orally four times daily, or amoxicillin, 0.5–1 g orally three times daily, for 10 days	For patients with history of non-anaphylactic penicillin allergy, cephalexin, 0.5 g orally four times daily for 10 days; for patients with more severe penicillin allergy, clindamycin, 300 mg orally four times daily for 10 days; or azithromycin, 500 mg on day 1 and 250 mg on days 2–5; or azithromycin for susceptible isolates
Otitis media	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i>	Amoxicillin, 0.5–1 g orally three times daily for 10 days	Augmentin, ² 0.875 g orally twice daily; or cefuroxime, 0.5 g orally twice daily; or cefpodoxime, 0.2–0.4 g daily; or doxycycline, 100 mg twice daily; or TMP-SMZ, ¹ one double-strength tablet twice daily (all regimens for 10 days)
Acute sinusitis	<i>S pneumoniae</i> , <i>H influenzae</i> , <i>M catarrhalis</i>	Augmentin, ² 0.875 g orally twice daily,	For patients allergic to penicillin, doxycycline, 100 mg twice daily for 10 days, or some fluoroquinolones ⁵ can be considered. Due to increasing resistance among pneumococci, monotherapy with a macrolide, a cephalosporin, or TMP-SMZ is not recommended
Aspiration pneumonia	Mixed oropharyngeal flora, including anaerobes	Clindamycin, 0.3 g orally four times daily for 10–14 days	Phenoxymethyl penicillin, 0.5 g orally four times daily for 10–14 days
Pneumonia	<i>S pneumoniae</i> , <i>Mycoplasma pneumoniae</i> , <i>Legionella pneumophila</i> , <i>Chlamydomphila pneumoniae</i>	Doxycycline, 100 mg orally twice daily, or azithromycin (erythromycin, clarithromycin), 0.5 g orally on day 1 and 0.25 g on days 2–5	Amoxicillin, 0.5–1.0 g orally three times daily. A respiratory fluoroquinolone ⁵ for patients at high risk for infection due to resistant pneumococci
Cystitis	<i>Escherichia coli</i> , <i>Staphylococcus saprophyticus</i> , <i>Klebsiella pneumoniae</i> , <i>Proteus</i> species, other gram-negative rods or enterococci	Nitrofurantoin monohydrate macrocrystals 100 mg twice daily for 5–7 days (unless pregnant); fosfomycin 3 g orally as a single dose	Cephalexin, 0.5 g orally four times daily for 7 days, for uncomplicated cystitis. Due to increasing resistance, TMP-SMZ and fluoroquinolones should not be used as first-line therapy for empiric treatment
Pyelonephritis	<i>E coli</i> , <i>K pneumoniae</i> , <i>Proteus</i> species, <i>S saprophyticus</i>	Fluoroquinolones ⁴ for 7 days if prevalence of resistance among uropathogens is < 10%	TMP-SMZ, ¹ one double-strength tablet twice daily for 7–14 days for susceptible pathogens. Oral beta-lactams are considered less effective
Gastroenteritis	<i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Entamoeba histolytica</i>	See footnote 3	

(continued)

Table 30–6. Examples of empiric choices of antimicrobials for adult outpatient infections. (continued)

Suspected Clinical Diagnosis	Likely Etiologic Agents	Drugs of Choice	Alternative Drugs
Urethritis, epididymitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>	Ceftriaxone, 250 mg intramuscularly once plus azithromycin (or doxycycline) for <i>N gonorrhoeae</i> ; azithromycin 1 g orally once, or doxycycline, 100 mg orally twice daily for 7 days, for <i>C trachomatis</i>	Cefixime 400 mg orally once for <i>N gonorrhoeae</i> ⁶
Pelvic inflammatory disease	<i>N gonorrhoeae</i> , <i>C trachomatis</i> , anaerobes, gram-negative rods	Levofloxacin 500 mg orally daily, or ofloxacin, 400 mg orally twice daily, for 14 days, plus metronidazole, 500 mg orally twice daily, for 14 days	Cefoxitin, 2 g intramuscularly, with probenecid, 1 g orally, followed by doxycycline, 100 mg orally twice daily for 14 days; or ceftriaxone, 250 mg intramuscularly once, followed by doxycycline, 100 mg orally twice daily for 14 days
Syphilis			
Early syphilis (primary, secondary, or latent of < 1 year's duration)	<i>Treponema pallidum</i>	Benzathine penicillin G, 2.4 million units intramuscularly once	Doxycycline, 100 mg orally twice daily for 2 weeks
Latent syphilis of > 1 year's duration or cardiovascular syphilis	<i>T pallidum</i>	Benzathine penicillin G, 2.4 million units intramuscularly once a week for 3 weeks (total: 7.2 million units)	Doxycycline, 100 mg orally twice daily, for 4 weeks
Neurosyphilis	<i>T pallidum</i>	Aqueous penicillin G, 12–24 million units/day intravenously for 10–14 days	

¹TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.

²Augmentin is a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.

³The diagnosis should be confirmed by culture before therapy. *Salmonella* gastroenteritis does not require therapy. For susceptible *Shigella* isolates, give ciprofloxacin, 0.5 g orally twice daily for 5 days; or TMP-SMZ double-strength tablets twice daily for 5 days; or ampicillin, 0.5 g orally four times daily for 5 days. For *Campylobacter* infection, give azithromycin, 1 g orally times one dose, or ciprofloxacin, 0.5 g orally twice daily for 5 days. For *E histolytica* infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by diiodohydroxyquinoline, 600 mg orally three times daily for 3 weeks.

⁴Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 500 mg orally daily.

⁵Fluoroquinolones with activity against *S pneumoniae*, including penicillin-resistant isolates, include gemifloxacin (320 mg orally once daily), levofloxacin (500–750 mg orally once daily) and moxifloxacin (400 mg orally once daily). Use fluoroquinolones as drug of choice if recent antibiotic use within 3 months or comorbidities present.

⁶Test of cure recommended if ceftriaxone is not used.

Adapted from *Treat Guide Med Lett*. 2013 Jul; 11(131):65–73.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *S aureus*; MSSA, methicillin-sensitive *S aureus*; TMP-SMZ, trimethoprim-sulfamethoxazole.

and require testing. Examples include the pneumococci, which may be resistant to multiple drugs (including penicillin, macrolides, and TMP-SMZ); the enterococci, which may be resistant to penicillin, aminoglycosides, and vancomycin; and extended-spectrum beta-lactamase producing-*E coli* resistant to third-generation cephalosporins and fluoroquinolones.

Over the past several years, the pharmaceutical industry has shifted away from developing and producing antibacterial medications, particularly those active against

gram-negative pathogens. However, in 2015, two beta-lactamase inhibitor combinations have been approved by the FDA which offer much-needed options in the treatment of resistant *Pseudomonas aeruginosa* and ESBL-producing Enterobacteriaceae. Nonetheless, the paucity of new drugs and increasing bacterial resistance reinforce the need to use all antimicrobials judiciously. When culture and susceptibility results have been finalized, it is important to utilize the most narrow spectrum agent possible to decrease the selection pressure for antibacterial resistance.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth, in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC (minimal inhibitory concentration). In most infections, the MIC is the appropriate *in vitro* test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate drug, drug dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug resistance in the original pathogen or superinfection with a new more resistant organism.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for drug selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes mellitus.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as *S aureus* respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used. When potentially toxic drugs (eg, aminoglycosides, flucytosine) are used, serum levels of the drug are measured to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of drugs, the dosage or frequency of administration must be adjusted; it is best to measure levels in the elderly, morbidly obese patients, or those with altered kidney function when possible and adjust therapy accordingly.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active

infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient. Recommendations about duration of therapy are often given based on clinical experience, not prospective controlled studies of large numbers of patients.

H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life threatening and treatment cannot be stopped, the reactions are managed symptomatically or another drug is chosen that does not cross-react with the offending one (Table 30-4). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

I. Route of Administration

Intravenous therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain drugs (eg, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMZ, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines and the quinolones chelate multivalent cations resulting in decreased antibacterial absorption. Azithromycin capsules are associated with decreased bioavailability when taken with food and should be given 1 hour before or 2 hours after meals. Posaconazole solution should always be administered with food.

A major complication of intravenous antibiotic therapy is catheter infections. Peripheral catheters are changed every 48–72 hours to prevent phlebitis, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of catheter-related infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20–23F) peripherally inserted silicone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition costs and monitoring costs (drug levels, liver tests, electrolytes, etc), the cost of treating adverse

reactions, the cost of treatment failure, and the costs associated with drug administration must be considered.

HYPERSENSITIVITY TESTS & DESENSITIZATION

▶ Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. Skin tests with penicilloyl-polylysine, with minor antigenic determinants, and with undegraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). Among positive reactors to skin tests, the incidence of subsequent immediate severe penicillin reactions is high. A history of a penicillin reaction in the past is often not reliable. Only a small proportion (less than 20%) of patients with a history of penicillin allergy have an adverse reaction when challenged with the drug. The decision to administer penicillin or related drugs (other beta-lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative drugs. For patients with a history of severe reaction (anaphylaxis), alternative drugs should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin or may be given another beta-lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other beta-lactam) rashes are not allergic in origin. The non-allergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with challenge. Rarely, penicillins can induce nephritis with primary tubular lesions associated with anti-basement membrane antibodies.

If the intradermal test described below is negative, desensitization is not necessary, and a full dose of the

material may be given. If the test is positive, alternative drugs should be strongly considered. If that is not feasible, desensitization is necessary.

Patients with a history of allergy to penicillin are also at an increased risk for having a reaction to **cephalosporins** or **carbapenems**. A common approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction to penicillin can be excluded by history, a cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, the cephalosporin or carbapenem can be given. If the test is positive, there is a 5–10% chance of cross reactivity with cephalosporins, and the decision whether to use cephalosporins depends on the availability of alternative agents and the severity of the infection. While carbapenems historically have been considered highly cross reactive with penicillins, the cross reactivity appears to be minimal (1%).

▶ Intradermal Test for Hypersensitivity

Penicillin is the drug that most frequently serves as an indication for sensitivity testing and desensitization. A clinical history of penicillin allergy has a positive predictive value of only 15%. IgG-mediated delayed reactions such as erythematous or maculopapular skin rash or serum sickness should be distinguished from immediate-type IgE-mediated reactions, such as urticaria, angioedema, and anaphylaxis.

▶ Desensitization

A. Precautions

1. The desensitization procedure is not innocuous—deaths from anaphylaxis have been reported. If extreme hypersensitivity is suspected, it is advisable to use an alternative structurally unrelated drug and to reserve desensitization for situations when treatment cannot be withheld and no alternative drug is available.
2. An antihistaminic drug (25–50 mg of hydroxyzine or diphenhydramine intramuscularly or orally) should be administered before desensitization is begun in order to lessen any reaction that occurs.
3. Desensitization should be conducted in an intensive care unit where cardiac monitoring and emergency endotracheal intubation can be performed.
4. Epinephrine, 1 mL of 1:1000 solution, must be ready for immediate administration.

B. Desensitization Method

Several methods of desensitization have been described for penicillin, including use of both oral and intravenous preparations. All methods start with very small doses of drug and gradually increase the dose until therapeutic doses are achieved. For penicillin, 1 unit of drug is given intravenously and the patient observed for 15–30 minutes. If there is no reaction, some recommend doubling the dose while others recommend increasing it tenfold every 15–30 minutes until a dosage of 2 million units is reached; then give the remainder of the desired dose.

For recommendations on skin testing and desensitization for other preparations (eg, botulism antitoxin and diphtheria antitoxin), the manufacturer's package inserts should be consulted.

IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION OF INFANTS, CHILDREN, & ADOLESCENTS

The recommended schedules and dosages of vaccination change often, so the manufacturer's package inserts should always be consulted.

The schedule for active immunizations in children can be accessed at www.cdc.gov/travel/destinations/list. All adolescents should see a health care provider to ensure vaccination of those who have not received varicella or hepatitis B vaccine, to make certain that a second dose of MMR has been given, to receive a booster of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap adolescent preparation), to receive meningococcal vaccine conjugate vaccine, to obtain HPV vaccine if not given previously, and to receive immunizations (influenza and pneumococcal vaccines) that may be indicated for certain high-risk individuals.

RECOMMENDED IMMUNIZATION FOR ADULTS

Immunization is one of the most important tools (along with sanitation) used to prevent morbidity and mortality from infectious diseases. In general, the administration of most vaccinations induces a durable antibody response (active immunity). In contrast, passive immunization occurs when preformed antibodies are given (eg, immune globulin from pooled serum), resulting in temporary protection which is a less durable response. The two variants of active immunization are live attenuated vaccines (which are believed to result in an immunologic response more like natural infection), and inactivated or killed vaccines.

The schedule of vaccinations varies based on the risk of the disease being prevented by vaccination, whether a vaccine has been given previously, the immune status of the patient (probability of responding to vaccine) and safety of the vaccine (live versus killed product, as well as implications for the fetus in pregnant women). Recommendations for healthy adults as well as special populations based on medical conditions are summarized in Table 30–7, which can be accessed online at www.cdc.gov/vaccines/schedules.

1. Healthy Adults

Vaccination recommendations are made by the Advisory Committee on Immunization Practices (ACIP) of the US Centers for Disease Control and Prevention (Table 30–7).

2. Pregnant Women

Given the uncertainty of risks to the fetus, vaccination during pregnancy is generally avoided with the following exceptions: tetanus (transfer of maternal antibodies across the placenta important to prevent neonatal tetanus), diphtheria, and influenza. Live vaccines are avoided during pregnancy.

Influenza can be a serious infection if acquired in pregnancy, and all pregnant women should be offered influenza (inactivated) vaccination. The live attenuated (intranasal) influenza vaccine is not recommended during pregnancy.

3. HIV-Infected Adults

HIV-infected patients have impaired cellular and B cell responses. Inactivated or killed vaccinations can generally be given without any consequence, but the recipient may not be able to mount an adequate antibody response. Live or attenuated vaccines are generally avoided with some exceptions (ie, in patients with CD4⁺ T lymphocytes greater than 200 cells/mcL). Guidelines for vaccinating HIV-infected patients have been issued jointly by the Centers for Disease Control and Prevention, the US National Institutes of Health, and the HIV Medical Association of the Infectious Diseases Society of America. Timing of vaccination is important to optimize response. If possible, vaccination should be given early in the course of HIV disease or following immune reconstitution.

4. Hematopoietic Cell Transplant Recipients

Hematopoietic cell transplant (HCT) recipients have varying rates of immune reconstitution following transplantation, depending on (1) the type of chemotherapy or radiotherapy used pretransplant (in autologous HCT), (2) the preparative regimen used for the transplant, (3) whether graft-versus-host disease is present, and (4) the type of immunosuppression used posttransplantation (in allogeneic HCT). Vaccines may not work immediately in the posttransplant period. B cells may take 3–12 months to return to normal posttransplant, and naïve T cells that can respond to new antigens only appear 6–12 months posttransplant. B cells of posttransplant patients treated with rituximab may take up to 6 months to fully recover after the last dose of the drug. Vaccines are therefore administered 6–12 months following transplantation with a minimum of 1 month between doses to maximize the probability of response.

5. Solid Organ Transplant Recipients

Solid organ transplant recipients demonstrate a broad spectrum of immunosuppression, depending on the reason for and type of organ transplantation and the nature of the immunosuppression (including T-cell-depleting agents

Table 30–7. Recommended adult immunization schedule—United States, 2016.

Recommended Adult Immunization Schedule—United States - 2016

Note: These recommendations must be read with the footnotes that follow containing number of doses, intervals between doses, and other important information.

Figure 1. Recommended immunization schedule for adults aged 19 years or older, by vaccine and age group¹

VACCINE ▼	AGE GROUP ►	19-21 years	22-26 years	27-49 years	50-59 years	60-64 years	≥ 65 years
Influenza ^{*,2}		1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap) ^{*,3}		Substitute Tdap for Td once, then Td booster every 10 yrs					
Varicella ^{*,4}		2 doses					
Human papillomavirus (HPV) Female ^{*,5}		3 doses					
Human papillomavirus (HPV) Male ^{*,5}		3 doses					
Zoster ⁶						1 dose	
Measles, mumps, rubella (MMR) ^{*,7}		1 or 2 doses depending on indication					
Pneumococcal 13-valent conjugate (PCV13) ^{*,8}		1 dose					
Pneumococcal 23-valent polysaccharide (PPSV23) ⁸		1 or 2 doses depending on indication					1 dose
Hepatitis A ^{*,9}		2 or 3 doses depending on vaccine					
Hepatitis B ^{*,10}		3 doses					
Meningococcal 4-valent conjugate (MenACWY) or polysaccharide (MPSV4) ^{*,11}		1 or more doses depending on indication					
Meningococcal B (MenB) ¹¹		2 or 3 doses depending on vaccine					
<i>Haemophilus influenzae</i> type b (Hib) ^{*,12}		1 or 3 doses depending on indication					

*Covered by the Vaccine Injury Compensation Program

 Recommended for all persons who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection; zoster vaccine is recommended regardless of past episode of zoster

 Recommended for persons with a risk factor (medical, occupational, lifestyle, or other indication)

 No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, NW, Washington, D.C. 20005; telephone, 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 8:00 a.m. - 8:00 p.m. Eastern Time, Monday - Friday, excluding holidays.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

The recommendations in this schedule were approved by the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), the American College of Obstetricians and Gynecologists (ACOG) and the American College of Nurse-Midwives (ACNM).

Figure 2. Vaccines that might be indicated for adults aged 19 years or older based on medical and other indications¹

VACCINE ▼	INDICATION ►	Pregnancy	Immuno-compromising conditions (excluding HIV infection) ^{4,6,7,8,13}	HIV infection CD4+ count (cells/ μ L) ^{4,6,7,8,13}	Men who have sex with men (MSM)	Kidney failure, end-stage renal disease, on hemodialysis	Heart disease, chronic lung disease, chronic alcoholism	Asplenia and persistent complement component deficiencies ^{8,11,12}	Chronic liver disease	Diabetes	Healthcare personnel
			< 200	\geq 200							
Influenza ^{*2}			1 dose annually								
Tetanus, diphtheria, pertussis (Td/Tdap) ^{*3}		1 dose Tdap each pregnancy	Substitute Tdap for Td once, then Td booster every 10 yrs								
Varicella ^{*4}			Contraindicated		2 doses						
Human papillomavirus (HPV) Female ^{*5}			3 doses through age 26 yrs			3 doses through age 26 yrs					
Human papillomavirus (HPV) Male ^{*5}			3 doses through age 26 yrs			3 doses through age 21 yrs					
Zoster ⁶			Contraindicated		1 dose						
Measles, mumps, rubella (MMR) ^{*7}			Contraindicated		1 or 2 doses depending on indication						
Pneumococcal 13-valent conjugate (PCV13) ^{*8}						1 dose					
Pneumococcal polysaccharide (PPSV23) ⁸						1, 2, or 3 doses depending on indication					
Hepatitis A ^{*9}						2 or 3 doses depending on vaccine					
Hepatitis B ^{*10}						3 doses					
Meningococcal 4-valent conjugate (MenACWY) or polysaccharide (MPSV4) ^{*11}			1 or more doses depending on indication								
Meningococcal B (MenB) ¹¹						2 or 3 doses depending on vaccine					
<i>Haemophilus influenzae</i> type b (Hib) ^{*12}			3 doses post-HSCT recipients only			1 dose					

^{*}Covered by the Vaccine Injury Compensation Program

 Recommended for all persons who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection; zoster vaccine is recommended regardless of past episode of zoster
 Recommended for persons with a risk factor (medical, occupational, lifestyle, or other indication)
 No recommendation
 Contraindicated

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly recommended for adults aged \geq 19 years, as of February 2016. For all vaccines being recommended on the Adult Immunization Schedule: a vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statements from the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/hcp/acip-recs/index.html). Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

U.S. Department of Health and Human Services
Centers for Disease Control and Prevention

(continued)

Table 30–7. Recommended adult immunization schedule—United States, 2016. (continued)**Footnotes****Recommended Immunization Schedule for Adults Aged 19 Years or Older: United States, 2015****1. Additional information**

- Additional guidance for the use of the vaccines described in this supplement is available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- Information on vaccination recommendations when vaccination status is unknown and other general immunization information can be found in the General Recommendations on Immunization at www.cdc.gov/mmwr/preview/mmwrhtml/rr6002a1.htm.
- Information on travel vaccine requirements and recommendations (e.g., for hepatitis A and B, meningococcal, and other vaccines) is available at wwwnc.cdc.gov/travel/destinations/list.
- Additional information and resources regarding vaccination of pregnant women can be found at www.cdc.gov/vaccines/adults/rec-vac/pregnant.html.

2. Influenza vaccination

- Annual vaccination against influenza is recommended for all persons aged ≥ 6 months. A list of currently available influenza vaccines can be found at <http://www.cdc.gov/flu/protect/vaccine/vaccines.htm>.
- Persons aged ≥ 6 months, including pregnant women, can receive the inactivated influenza vaccine (IIV). An age-appropriate IIV formulation should be used.
- Intradermal IIV is an option for persons aged 18 through 64 years.
- High-dose IIV is an option for persons aged ≥ 65 years.
- Live attenuated influenza vaccine (LAIV [FluMist]) is an option for healthy, non-pregnant persons aged 2 through 49 years.
- Recombinant influenza vaccine (RIV [Flublok]) is approved for persons aged ≥ 18 years.
- RIV, which does not contain any egg protein, may be administered to persons aged ≥ 18 years with egg allergy of any severity; IIV may be used with additional safety measures for persons with hives-only allergy to eggs.
- Health care personnel who care for severely immunocompromised persons who require care in a protected environment should receive IIV or RIV; health care personnel who receive LAIV should avoid providing care for severely immunosuppressed persons for 7 days after vaccination.

3. Tetanus, diphtheria, and acellular pertussis (Td/Tdap) vaccination

- Administer 1 dose of Tdap vaccine to pregnant women during each pregnancy (preferably during 27–36 weeks' gestation) regardless of interval since prior Td or Tdap vaccination.
- Persons aged ≥ 11 years who have not received Tdap vaccine or for whom vaccine status is unknown should receive a dose of Tdap followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter. Tdap can be administered regardless of interval since the most recent tetanus or diphtheria-toxoid-containing vaccine.
- Adults with an unknown or incomplete history of completing a 3-dose primary vaccination series with Td-containing vaccines should begin or complete a primary vaccination series including a Tdap dose.
- For unvaccinated adults, administer the first 2 doses at least 4 weeks apart and the third dose 6–12 months after the second.
- For incompletely vaccinated (i.e., less than 3 doses) adults, administer remaining doses.
- Refer to the ACIP statement for recommendations for administering Td/Tdap as prophylaxis in wound management (see footnote 1).

4. Varicella vaccination

- All adults without evidence of immunity to varicella (as defined below) should receive 2 doses of single-antigen varicella vaccine or a second dose if they have received only 1 dose.
- Vaccination should be emphasized for those who have close contact with persons at high risk for severe disease (e.g., health care personnel and family contacts of persons with immunocompromising conditions) or are at high risk for exposure or transmission (e.g., teachers; child care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of childbearing age; and international travelers).
- Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the health care facility. The second dose should be administered 4–8 weeks after the first dose.
- Evidence of immunity to varicella in adults includes any of the following:
 - documentation of 2 doses of varicella vaccine at least 4 weeks apart;
 - U.S.-born before 1980, except health care personnel and pregnant women;
 - history of varicella based on diagnosis or verification of varicella disease by a health care provider;
 - history of herpes zoster based on diagnosis or verification of herpes zoster disease by a health care provider; or
 - laboratory evidence of immunity or laboratory confirmation of disease.

5. Human papillomavirus (HPV) vaccination

- Three HPV vaccines are licensed for use in females (bivalent HPV vaccine [2vHPV], quadrivalent HPV vaccine [4vHPV], and 9-valent HPV vaccine [9vHPV]) and two HPV vaccines are licensed for use in males (4vHPV and 9vHPV).
- For females, 2vHPV, 4vHPV, or 9vHPV is recommended in a 3-dose series for routine vaccination at age 11 or 12 years and for those aged 13 through 26 years, if not previously vaccinated.

- For males, 4vHPV or 9vHPV is recommended in a 3-dose series for routine vaccination at age 11 or 12 years and for those aged 13 through 21 years, if not previously vaccinated. Males aged 22 through 26 years may be vaccinated.
- HPV vaccination is recommended for men who have sex with men through age 26 years who did not get any or all doses when they were younger.
- Vaccination is recommended for immunocompromised persons (including those with HIV infection) through age 26 years who did not get any or all doses when they were younger.
- A complete HPV vaccination series consists of 3 doses. The second dose should be administered 4–8 weeks (minimum interval of 4 weeks) after the first dose; the third dose should be administered 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of 12 weeks).
- HPV vaccines are not recommended for use in pregnant women. However, pregnancy testing is not needed before vaccination. If a woman is found to be pregnant after initiating the vaccination series, no intervention is needed; the remainder of the 3-dose series should be delayed until completion or termination of pregnancy.

6. Zoster vaccination

- A single dose of zoster vaccine is recommended for adults aged ≥ 60 years regardless of whether they report a prior episode of herpes zoster. Although the vaccine is licensed by the U.S. Food and Drug Administration for use among and can be administered to persons aged ≥ 50 years, ACIP recommends that vaccination begin at age 60 years.
- Persons aged ≥ 60 years with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication, such as pregnancy or severe immunodeficiency.

7. Measles, mumps, rubella (MMR) vaccination

- Adults born before 1957 are generally considered immune to measles and mumps. All adults born in 1957 or later should have documentation of 1 or more doses of MMR vaccine unless they have a medical contraindication to the vaccine or laboratory evidence of immunity to each of the three diseases. Documentation of provider-diagnosed disease is not considered acceptable evidence of immunity for measles, mumps, or rubella.

Measles component:

- A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who:
 - are students in postsecondary educational institutions,
 - work in a health care facility, or
 - plan to travel internationally.
- Persons who received inactivated (killed) measles vaccine or measles vaccine of unknown type during 1963–1967 should be revaccinated with 2 doses of MMR vaccine.

Mumps component:

- A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who:
 - are students in a postsecondary educational institution,
 - work in a health care facility, or
 - plan to travel internationally.
- Persons vaccinated before 1979 with either killed mumps vaccine or mumps vaccine of unknown type who are at high risk for mumps infection (e.g., persons who are working in a health care facility) should be considered for revaccination with 2 doses of MMR vaccine.

Rubella component:

- For women of childbearing age, regardless of birth year, rubella immunity should be determined. If there is no evidence of immunity, women who are not pregnant should be vaccinated. Pregnant women who do not have evidence of immunity should receive MMR vaccine upon completion or termination of pregnancy and before discharge from the health care facility.

Health care personnel born before 1957:

- For unvaccinated health care personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, health care facilities should consider vaccinating personnel with 2 doses of MMR vaccine at the appropriate interval for measles and mumps or 1 dose of MMR vaccine for rubella.

8. Pneumococcal vaccination

- General information
 - Adults are recommended to receive 1 dose of 13-valent pneumococcal conjugate vaccine (PCV13) and 1, 2, or 3 doses (depending on indication) of 23-valent pneumococcal polysaccharide vaccine (PPSV23).
 - PCV13 should be administered at least 1 year after PPSV23.
 - PPSV23 should be administered at least 1 year after PCV13, except among adults with immunocompromising conditions, anatomical or functional asplenia, cerebrospinal fluid leak, or cochlear implant, for whom the interval should be at least 8 weeks; the interval between PPSV23 doses should be at least 5 years.
 - No additional dose of PPSV23 is indicated for adults vaccinated with PPSV23 at age ≥ 65 years.
 - When both PCV13 and PPSV23 are indicated, PCV13 should be administered first; PCV13 and PPSV23 should not be administered during the same visit.
 - When indicated, PCV13 and PPSV23 should be administered to adults whose pneumococcal vaccination history is incomplete or unknown.
- Adults aged ≥ 65 years (immunocompetent) who:
 - have not received PCV13 or PPSV23: administer PCV13 followed by PPSV23 at least 1 year after PCV13.
 - have not received PCV13 but have received a dose of PPSV23 at age ≥ 65 years: administer PCV13 at least 1 year after PPSV23.

(continued)

Table 30–7. Recommended adult immunization schedule—United States, 2016. (continued)

- have not received PCV13 but have received 1 or more doses of PPSV23 at age <65 years: administer PCV13 at least 1 year after the most recent dose of PPSV23. Administer a dose of PPSV23 at least 1 year after PCV13 and at least 5 years after the most recent dose of PPSV23.
- have received PCV13 but not PPSV23 at age <65 years: administer PPSV23 at least 1 year after PCV13.
- have received PCV13 and 1 or more doses of PPSV23 at age <65 years: administer PPSV23 at least 1 year after PCV13 and at least 5 years after the most recent dose of PPSV23.
- Adults aged ≥19 years with immunocompromising conditions or anatomical or functional asplenia (defined below) who:
 - have not received PCV13 or PPSV23: administer PCV13 followed by PPSV23 at least 8 weeks after PCV13. Administer a second dose of PPSV23 at least 5 years after the first dose of PPSV23.
 - have not received PCV13 but have received 1 dose of PPSV23: administer PCV13 at least 1 year after the PPSV23. Administer a second dose of PPSV23 at least 8 weeks after PCV13 and at least 5 years after the first dose of PPSV23.
 - have not received PCV13 but have received 2 doses of PPSV23: administer PCV13 at least 1 year after the most recent dose of PPSV23.
 - have received PCV13 but not PPSV23: administer PPSV23 at least 8 weeks after PCV13. Administer a second dose of PPSV23 at least 5 years after the first dose of PPSV23.
 - have received PCV13 and 1 dose of PPSV23: administer a second dose of PPSV23 at least 8 weeks after PCV13 and at least 5 years after the first dose of PPSV23.
 - If the most recent dose of PPSV23 was administered at age <65 years, at age ≥65 years, administer a dose of PPSV23 at least 8 weeks after PCV13 and at least 5 years after the last dose of PPSV23.
 - Immunocompromising conditions that are indications for pneumococcal vaccination are: congenital or acquired immunodeficiency (including B- or T-lymphocyte deficiency, complement deficiencies, and phagocytic disorders excluding chronic granulomatous disease), HIV infection, chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, multiple myeloma, solid organ transplant, and iatrogenic immunosuppression (including long-term systemic corticosteroids and radiation therapy).
 - Anatomical or functional asplenia that are indications for pneumococcal vaccination are: sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, splenic dysfunction, and splenectomy. Administer pneumococcal vaccines at least 2 weeks before immunosuppressive therapy or an elective splenectomy, and as soon as possible to adults who are newly diagnosed with asymptomatic or symptomatic HIV infection.
- Adults aged ≥19 years with cerebrospinal fluid leaks or cochlear implants: administer PCV13 followed by PPSV23 at least 8 weeks after PCV13; no additional dose of PPSV23 is indicated if aged <65 years. If PPSV23 was administered at age <65 years, at age ≥65 years, administer another dose of PPSV23 at least 5 years after the last dose of PPSV23.
- Adults aged 19 through 64 years with chronic heart disease (including congestive heart failure and cardiomyopathies, excluding hypertension), chronic lung disease (including chronic obstructive lung disease, emphysema, and asthma), chronic liver disease (including cirrhosis), alcoholism, or diabetes mellitus, or who smoke cigarettes: administer PPSV23. At age ≥65 years, administer PCV13 at least 1 year after PPSV23, followed by another dose of PPSV23 at least 1 year after PCV13 and at least 5 years after the last dose of PPSV23.
- Routine pneumococcal vaccination is not recommended for American Indian/Alaska Native or other adults unless they have an indication as above; however, public health authorities may consider recommending the use of pneumococcal vaccines for American Indians/Alaska Natives or other adults who live in areas with increased risk for invasive pneumococcal disease.

9. Hepatitis A vaccination

- Vaccinate any person seeking protection from hepatitis A virus (HAV) infection and persons with any of the following indications:
 - men who have sex with men;
 - persons who use injection or noninjection illicit drugs;
 - persons working with HAV-infected primates or with HAV in a research laboratory setting;
 - persons with chronic liver disease and persons who receive clotting factor concentrates;
 - persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A (see footnote 1); and
 - unvaccinated persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity of hepatitis A (see footnote 1). The first dose of the 2-dose hepatitis A vaccine series should be administered as soon as adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.
- Single-antigen vaccine formulations should be administered in a 2-dose schedule at either 0 and 6–12 months (Havrix), or 0 and 6–18 months (Vaqta). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule may be used, administered on days 0, 7, and 21–30 followed by a booster dose at 12 months.

10. Hepatitis B vaccination

- Vaccinate any person seeking protection from hepatitis B virus (HBV) infection and persons with any of the following indications:
 - sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than 1 sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection drug users; and men who have sex with men;
 - health care personnel and public safety workers who are potentially exposed to blood or other infectious body fluids;
 - persons who are aged <60 years with diabetes as soon as feasible after diagnosis; persons with diabetes who are aged ≥60 years at the discretion of the treating clinician based on the likelihood of acquiring HBV infection, including the risk posed by an increased need for assisted blood glucose monitoring in long-term care facilities, the likelihood of experiencing chronic sequelae if infected with HBV, and the likelihood of immune response to vaccination;
 - persons with end-stage renal disease (including patients receiving hemodialysis), persons with HIV infection, and persons with chronic liver disease;

- household contacts and sex partners of hepatitis B surface antigen–positive persons, clients and staff members of institutions for persons with developmental disabilities, and international travelers to regions with high or intermediate levels of endemic HBV infection (see footnote 1); and
- all adults in the following settings: STD treatment facilities, HIV testing and treatment facilities, facilities providing drug abuse treatment and prevention services, health care settings targeting services to injection drug users or men who have sex with men, correctional facilities, end-stage renal disease programs and facilities for chronic hemodialysis patients, and institutions and non-residential day care facilities for persons with developmental disabilities.
- Administer missing doses to complete a 3-dose series of hepatitis B vaccine to those persons not vaccinated or not completely vaccinated. The second dose should be administered at least 1 month after the first dose; the third dose should be administered at least 2 months after the second dose (and at least 4 months after the first dose). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, give 3 doses at 0, 1, and 6 months; alternatively, a 4-dose Twinrix schedule may be used, administered on days 0, 7, and 21–30, followed by a booster dose at 12 months.
- Adult patients receiving hemodialysis or with other immunocompromising conditions should receive 1 dose of 40 mcg/mL (Recombivax HB) administered on a 3-dose schedule at 0, 1, and 6 months or 2 doses of 20 mcg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2, and 6 months.

11. Meningococcal vaccination

- General information
 - Serogroup A, C, W, and Y meningococcal vaccine is available as a conjugate (MenACWY [Menactra, Menveo]) or a polysaccharide (MPSV4 [Menomune]) vaccine.
 - Serogroup B meningococcal (MenB) vaccine is available as a 2-dose series of MenB-4C vaccine (Bexsero) administered at least 1 month apart or a 3-dose series of MenB-FHbp (Trumenba) vaccine administered at 0, 2, and 6 months; the two MenB vaccines are not interchangeable, i.e., the same MenB vaccine product must be used for all doses.
 - MenACWY vaccine is preferred for adults with serogroup A, C, W, and Y meningococcal vaccine indications who are aged ≤55 years, and for adults aged ≥56 years: 1) who were vaccinated previously with MenACWY vaccine and are recommended for revaccination or 2) for whom multiple doses of vaccine are anticipated; MPSV4 vaccine is preferred for adults aged ≥56 years who have not received MenACWY vaccine previously and who require a single dose only (e.g., persons at risk because of an outbreak).
 - Revaccination with MenACWY vaccine every 5 years is recommended for adults previously vaccinated with MenACWY or MPSV4 vaccine who remain at increased risk for infection (e.g., adults with anatomical or functional asplenia or persistent complement component deficiencies, or microbiologists who are routinely exposed to isolates of *Neisseria meningitidis*).
 - MenB vaccine is approved for use in persons aged 10 through 25 years; however, because there is no theoretical difference in safety for persons aged >25 years compared to those aged 10 through 25 years, MenB vaccine is recommended for routine use in persons aged >10 years who are at increased risk for serogroup B meningococcal disease.
 - There is no recommendation for MenB revaccination at this time.
 - MenB vaccine may be administered concomitantly with MenACWY vaccine but at a different anatomic site, if feasible.
 - HIV infection is not an indication for routine vaccination with MenACWY or MenB vaccine; if an HIV-infected person of any age is to be vaccinated, administer 2 doses of MenACWY vaccine at least 2 months apart.
- Adults with anatomical or functional asplenia or persistent complement component deficiencies: administer 2 doses of MenACWY vaccine at least 2 months apart and revaccinate every 5 years. Also administer a series of MenB vaccine.
- Microbiologists who are routinely exposed to isolates of *Neisseria meningitidis*: administer a single dose of MenACWY vaccine; revaccinate with MenACWY vaccine every 5 years if remain at increased risk for infection. Also administer a series of MenB vaccine.
- Persons at risk because of a meningococcal disease outbreak: if the outbreak is attributable to serogroup A, C, W, or Y, administer a single dose of MenACWY vaccine; if the outbreak is attributable to serogroup B, administer a series of MenB vaccine.
- Persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic: administer a single dose of MenACWY vaccine and revaccinate with MenACWY vaccine every 5 years if the increased risk for infection remains (see footnote 1); MenB vaccine is not recommended because meningococcal disease in these countries is generally not caused by serogroup B.
- Military recruits: administer a single dose of MenACWY vaccine.
- First-year college students aged ≤21 years who live in residence halls: administer a single dose of MenACWY vaccine if they have not received a dose on or after their 16th birthday.
- Young adults aged 16 through 23 years (preferred age range is 16 through 18 years): may be vaccinated with a series of MenB vaccine to provide short-term protection against most strains of serogroup B meningococcal disease.

12. *Haemophilus influenzae* type b (Hib) vaccination

- One dose of Hib vaccine should be administered to persons who have anatomical or functional asplenia or sickle cell disease or are undergoing elective splenectomy if they have not previously received Hib vaccine. Hib vaccination 14 or more days before splenectomy is suggested.
- Recipients of a hematopoietic stem cell transplant (HSCT) should be vaccinated with a 3-dose regimen 6–12 months after a successful transplant, regardless of vaccination history; at least 4 weeks should separate doses.
- Hib vaccine is not recommended for adults with HIV infection since their risk for Hib infection is low.

13. Immunocompromising conditions

- Inactivated vaccines (e.g., pneumococcal, meningococcal, and inactivated influenza vaccines) generally are acceptable and live vaccines generally should be avoided in persons with immune deficiencies or immunocompromising conditions. Information on specific conditions is available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.

during treatment of organ rejection). These factors affect the propensity for infection posttransplantation and the ability to develop antibody responses to vaccination. In many cases, the time between placing a patient on a transplant list and undergoing the transplantation takes months or years. Providers should take this opportunity to ensure that indicated vaccines are given during this pretransplant period to optimize antibody responses. If this is not possible, most experts give vaccines 3–6 months following transplantation. Live vaccines are contraindicated in the posttransplant period.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those routinely recommended and may benefit from chemoprophylaxis against various diseases. Vaccinations against yellow fever and meningococcus are the only ones required by certain countries. These and other travel-specific vaccines are listed at <http://wwwnc.cdc.gov/travel/destinations/list>.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 35.

▶ Cholera

Because cholera among travelers is rare and the vaccine marginally effective, the World Health Organization (WHO) does not require immunization for persons traveling to endemic areas or to areas with recent outbreaks (eg, Haiti). No country requires vaccination for entry, but some local authorities may require documentation for entry. In such cases, a medical waiver will suffice or a single dose of the oral vaccine is usually sufficient.

▶ Hepatitis B

The risk of hepatitis B infection for most international travelers is low. Hepatitis B vaccination should be considered for those traveling to areas with high (8% or higher) or intermediate (2–7%) rates of endemic hepatitis B infection if the individual will have contact with blood or secretions, will have unprotected sex, or will be using illicit drugs. Examples of high and intermediate risk areas include all of Africa and most of South Asia and the Middle East. Vaccination should begin at least 6 months before travel to allow for completion of the series.

▶ Hepatitis A

Protection is recommended for susceptible persons traveling to areas where sanitation is poor and the risk of exposure to hepatitis A high because of contaminated food and

water supplies and contact with infected persons (eg, anywhere except Canada, western Europe, Japan, Australia, and New Zealand). Either hepatitis A vaccine or immunoglobulin can be used, although vaccination is preferred. The first dose of vaccine should be given as soon as travel is considered. In healthy individuals, a single dose of vaccine administered any time prior to travel will provide adequate protection. In older patients, those who are immunocompromised, and those with chronic liver disease or other chronic medical problems who are planning to travel in 2 weeks or less should receive hepatitis A vaccine and immunoglobulin 0.02 mL/kg simultaneously at different anatomic sites. Those who choose not to receive vaccine should receive immunoglobulin.

▶ Meningococcal Meningitis

If travel is contemplated to an area where meningococcal meningitis is epidemic (Nepal, sub-Saharan Africa, the “meningitis belt” from Senegal in the west to Ethiopia in the east, northern India) or highly endemic, vaccination with MCV4 is indicated for those 2–55 years of age, otherwise MPSV should be used. (Saudi Arabia requires immunization for pilgrims to Mecca.)

▶ Plague

The risk of plague is so small to travelers that vaccine is no longer commercially available and vaccination is not required for entry into any country. Travelers at unavoidable high risk of exposure to rodents should consider chemoprophylaxis with doxycycline or TMP-SMZ.

▶ Poliomyelitis

Polio remains endemic in three countries (Afghanistan, Pakistan, and Nigeria), and sporadic outbreaks or environmental evidence of infection continues to occur in Cameroon, Ethiopia, Equatorial Guinea, Iraq, Israel, Somalia, and Syria. Adults traveling to endemic or epidemic areas (now termed “polio infected” countries) who have not previously been immunized against poliomyelitis should receive a primary series of three doses of inactivated enhanced-potency poliovaccine (IPV). Travelers who have previously been fully immunized with oral polio vaccine (OPV) or inactivated polio vaccine (IPV) should receive a one-time booster dose with IPV. Travelers departing polio infected countries must now provide evidence of vaccination or booster within the past 1 year. Live attenuated poliovaccine is no longer recommended because of the risk of vaccine-associated disease and is no longer available in the United States, although it continues to be used in many other countries.

▶ Rabies

For travelers to areas where rabies is common in domestic animals (eg, India, Asia, Mexico, Africa, areas of Central and South America), with extensive outdoor activities or certain professional activities (veterinarians, animal handlers, field biologists), preexposure prophylaxis with human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell culture (PCEC) vaccine should be considered. Chloroquine can

blunt the immunologic response to rabies vaccine. If malaria prophylaxis with chloroquine (or mefloquine) is required, vaccination should be given intramuscularly (*not* intradermally) to ensure adequate antibody response.

► Typhoid

Typhoid vaccination is recommended for travelers to developing countries (especially the Indian subcontinent, Asia, Africa, Central and South America, and the Caribbean) who will have prolonged exposure to contaminated food and water. Two preparations of approximately equal efficacy (50–75% effective) are available in the United States: (1) an oral live attenuated Ty21a vaccine supplied as enteric-coated capsules, and (2) a Vi capsular polysaccharide (Vi CPS) vaccine for parenteral use. The Ty21a vaccine is given as one capsule every other day for four doses. The capsules must be refrigerated and taken with cool liquids (37°C or less) at least 1 hour before meals. All four doses must be taken for maximum protection and should be completed 1 week before travel. It is not recommended for infants or children younger than 6 years. The Vi CPS vaccine is given as a single intramuscular injection at least 2 weeks prior to travel. It is not recommended for infants younger than 2 years. If continued or repeated exposures are anticipated, boosters are recommended every 2 years for the Vi CPS and every 5 years for the Ty21a. The live attenuated vaccine should not be used in immunosuppressed patients, including those with HIV infection.

► Yellow Fever

The live attenuated yellow fever virus vaccine is administered once subcutaneously. Although the risk of yellow fever is low for most travelers, a number of countries require vaccination for all visitors and others require it for travelers to or from endemic areas (mainly equatorial Africa and parts of South and Central America). The WHO certificate requires registration of the manufacturer and the batch number of the vaccine. Vaccination is available in the United States only at approved centers; the local health department should be contacted for available resources. Reimmunization is no longer recommended for most travelers.

Because it is a live attenuated vaccine prepared in embryonated eggs, the yellow fever vaccine should not be given to immunosuppressed individuals or those with a history of anaphylaxis to eggs. Pregnancy is a relative contraindication to vaccination.

Two very severe adverse reactions have been associated with yellow fever vaccination. Viscerotropic disease presents with fever, jaundice, and multiple organ system failure within 30 days of yellow fever vaccination. Clinically and histopathologically, the illness is identical to yellow fever and is associated with a high mortality rate. The other adverse reaction is neurotropic disease and presents as encephalitis, encephalomyelitis, or Guillain-Barré syndrome.

► Japanese B Encephalitis

Japanese B encephalitis is a mosquito-borne viral encephalitis that affects primarily children and older adults (65 years and older) and usually occurs from May to September. It is the leading cause of encephalitis in Asia. Because the risk of

infection is low and because adverse effects of the vaccine can be serious, not all travelers to Asia should be vaccinated. Vaccine should be given to travelers to endemic areas who will be staying at least 30 days and who are traveling during the transmission season, particularly if they are visiting rural areas. Travelers who spend less than 30 days in the region should be considered for vaccination if they intend to visit areas of epidemic transmission or if extensive outdoor activities are planned in rural rice-growing areas. Of the two vaccines currently available in the United States, only one (inactivated Vero cell derived vaccine, IXIARO) is for adults aged 17 and older. The schedule is 0.5 mL intramuscularly at 0 and 28 days. Only children are eligible to receive the other vaccine (inactivated mouse brain derived vaccine, JE-VAX) given its limited supply in the United States.

VACCINE SAFETY

Most vaccines are safe to administer. In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade fevers (less than 40.5°C); concurrent antibiotic therapy; soreness or redness at the site; family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 30–8).

Table 30–8. Adverse effects and contraindications to commonly used vaccines in adults.

Vaccine	Adverse Effects	Contraindications ¹
<i>Haemophilus influenzae</i> Type b (Hib)	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis A	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis B	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Human papillomavirus	Minimal Consists mainly of mild to moderate localized pain, erythema, swelling Systemic reactions, mainly fever, seen in 4% of recipients	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Influenza (intramuscular inactivated and intranasal live attenuated vaccines)	Intramuscular, inactivated vaccine: Local reactions (erythema and tenderness) at the site of injection are common, but fevers, chills, and malaise (which last in any case only 2–3 days) are rare. Either inactivated or live attenuated vaccine: A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with intramuscular, inactivated influenza vaccine has been reported (possibly, 1–2 persons per million persons vaccinated), but this rate is lower than the risk of the syndrome developing after influenza itself (given that approximately 750 persons per million adults are hospitalized annually with influenza, and many more cases remain as outpatients). Influenza vaccination may be associated with multiple false-positive serologic tests to HIV, HTLV-1, and hepatitis C, but it is self-limited, lasting 2–5 months.	Contraindication to both inactivated and live attenuated vaccine: History of Guillain-Barré syndrome, especially within 6 weeks of receiving a previous influenza vaccine. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component, including egg protein. ² Intranasal, live attenuated vaccine [FluMist] should not be used in: People 50 years of age and over Immunosuppressed individuals and those on immunosuppressive therapy Household members of immunosuppressed individuals Health care workers, or others with close contact with immunosuppressed persons Presence of reactive airway disease (eg, asthma) or chronic underlying metabolic (eg, kidney), pulmonary, or heart diseases (use intramuscular inactivated vaccine) Pregnancy ³ It is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent Reye syndrome).
Measles, mumps, and rubella (MMR) ⁴	Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limited, lasting only 2–3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine.	Pregnancy ⁵ Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy (eg, > 2 weeks of prednisone 20 mg daily or higher), other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL). Severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component, (eg, neomycin or to related agents such as streptomycin).
Meningococcal oligosaccharide conjugate; (MCV4 or MenACWY [Menactra, Menveo]; meningococcal polysaccharide conjugate MPSV4 [Menomune]); meningococcal group B, recombinant (MenB [Bexsero, Trumenba])	Minor reactions (fever, redness, swelling, erythema, pain) occur slightly more commonly with MCV4. Major reactions are rare. A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with MCV4 has been reported, but current recommendations favor continued use of MCV4, since the benefits of preventing the serious consequences of meningococcal infection outweigh the theoretical risk of Guillain-Barré syndrome.	Any severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component, (eg, persons with history of adverse reaction to diphtheria toxoid should not receive meningococcal oligosaccharide conjugate and polysaccharide conjugate vaccines since the protein conjugate used in them is diphtheria toxoid).

(continued)

Table 30–8. Adverse effects and contraindications to commonly used vaccines in adults. (continued)

Vaccine	Adverse Effects	Contraindications ¹
Pneumococcal conjugate (PCV13 [Pneumovax]); Pneumococcal polysaccharide (PPSV23) [Pneumovax]	Mild local reactions (erythema and tenderness) occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, for PCV13 to any vaccine containing diphtheria toxoid).
Tetanus, diphtheria, and pertussis (DTP, Tdap); tetanus, diphtheria (Td)	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component. For pertussis-containing vaccines: any history of unexplained encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) within 7 days of administration of a previous dose of Tdap or diphtheria and tetanus toxoids and pertussis (DTP) or diphtheria and tetanus toxoids and acellular pertussis (Tdap) vaccine.
Varicella	Can occur as late as 4–6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a diffuse rash, usually with five or fewer vesicular lesions, develops in a smaller percentage. Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small and disease, when it develops, is mild and treatable with acyclovir.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised). Pregnancy. Severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, neomycin). For theoretic reasons, it is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent potential for Reye syndrome).
Zoster	Mild and limited to local reactions Although it is theoretically possible to transmit the virus to susceptible contacts, no such cases have been reported.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy (eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications), other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised). May be used in asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL). Pregnancy. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, gelatin or neomycin).

¹Adapted from CDC, Table 6. Contraindications and precautions to commonly used vaccines. General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices. MMWR. 2011;60(No. RR-2):40-1; and from Hamborsky J et al (editors). Appendix A. Epidemiology and prevention of vaccine preventable diseases. 13th edition. Washington, DC, Public Health Foundation, 2015. Available at www.cdc.gov/vaccines/pubs/pinkbook/index.html.

²The vaccine has typically been prepared using embryonated chicken eggs. However, a new vaccine using mammalian cell culture is now FDA-approved.

³The inactivated influenza vaccine can be given during any trimester.

⁴MMR vaccine can be safely given to patients with a history of egg allergy even when severe.

⁵Although vaccination of pregnant women is *not* recommended, with the currently available RA27/3 vaccine strain the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.

31

HIV Infection & AIDS

Mitchell H. Katz, MD

ESSENTIALS OF DIAGNOSIS

- ▶ Risk factors: sexual contact with an infected person, parenteral exposure to infected blood by transfusion or needle sharing, perinatal exposure.
- ▶ Prominent systemic complaints such as sweats, diarrhea, weight loss, and wasting.
- ▶ Opportunistic infections due to diminished cellular immunity—often life-threatening.
- ▶ Aggressive cancers, particularly non-Hodgkin lymphoma.
- ▶ Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

▶ General Considerations

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31-1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/mL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that **immunodeficiency is the defining characteristic of AIDS**. The choice of a cutoff point at 200 cells/mL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy (ART). The prognosis of persons

with HIV/AIDS has dramatically improved due to the development of effective ART. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of ART. Therefore, **the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defining illness.**

▶ Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, is not known.

A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses, and lack of male circumcision.

Table 31–1. CDC AIDS case definition for surveillance of adults and adolescents.

Definitive AIDS diagnoses (with or without laboratory evidence of HIV infection)
1. Candidiasis of the esophagus, trachea, bronchi, or lungs.
2. Cryptococcosis, extrapulmonary.
3. Cryptosporidiosis with diarrhea persisting longer than 1 month.
4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes.
5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis, or esophagitis of any duration.
6. Kaposi sarcoma in a patient younger than 60 years of age.
7. Lymphoma of the brain (primary) in a patient younger than 60 years of age.
8. <i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. <i>Pneumocystis jirovecii</i> pneumonia
10. Progressive multifocal leukoencephalopathy.
11. Toxoplasmosis of the brain.
Definitive AIDS diagnoses (with laboratory evidence of HIV infection)
1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
2. HIV encephalopathy.
3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
4. Isosporiasis with diarrhea persisting longer than 1 month.
5. Kaposi sarcoma at any age.
6. Lymphoma of the brain (primary) at any age.
7. Other non-Hodgkin lymphoma of B cell or unknown immunologic phenotype.
8. Any mycobacterial disease caused by mycobacteria other than <i>Mycobacterium tuberculosis</i> , disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. Disease caused by extrapulmonary <i>M tuberculosis</i> .
10. <i>Salmonella</i> (nontyphoid) septicemia, recurrent.
11. HIV wasting syndrome.
12. CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14%.
13. Pulmonary tuberculosis.
14. Recurrent pneumonia.
15. Invasive cervical cancer.
Presumptive AIDS diagnoses (with laboratory evidence of HIV infection)
1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis.
2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations.
3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture.
4. Kaposi sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane.
5. <i>Pneumocystis jirovecii</i> pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest film evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) arterial blood gas analysis showing an arterial oxygen partial pressure of less than 70 mm Hg or a low respiratory diffusing capacity of less than 80% of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia.
6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis.
7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's clinician.
8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy.

The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This essentially eliminates donations from persons who are HIV infected but have not yet developed antibodies (ie, persons in the “window” period). HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion in the United States is about 1:1,000,000. Between 13% and 40% of children born to HIV-infected mothers contract HIV infection when the mother has not received treatment or when the child has not received perinatal HIV prophylaxis. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breast-feed their children. The combination of prenatal HIV testing and counseling, antiretroviral treatment for infected mothers during pregnancy and for the infant immediately after birth, scheduled cesarean delivery when the mother has a viral load of greater than 1000 copies/mL, and avoidance of breastfeeding has reduced the rate of perinatal transmission of HIV to less than 2% in the United States and Europe.

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact. Saliva, sweat, stool, and tears are not considered infectious fluids.

There are an estimated 1,218,400 Americans aged 13 years or older living with HIV infection, of whom 156,300 do not know that they are infected. About 50,000 new infections occur each year. There are an estimated 516,401 persons in the United States living with AIDS. Of those, 76% are men, of whom 65% were exposed through male-to-male sexual contact, 14% were exposed through injection drug use, 12% were exposed through heterosexual contact, and 8% were exposed through male-to-male sexual contact and injection drug use. Women account for 24% of living persons with AIDS, of whom 71% were infected through heterosexual contact and 26% were exposed through injection drug use. Children under the age of 13 account for less than 0.1% of living cases. African Americans have been disproportionately hard hit by the epidemic. The estimated rate of new HIV diagnoses in the United States per 100,000 is 49.4 among African Americans, 18.4 among Latinos, 15.4 among persons of multiple races,

10.6 among native Hawaiians and Pacific Islanders, 9.5 among American Indians/Alaskan natives, 6.2 among whites, and 6.1 among Asians.

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women.

Worldwide there are an estimated 37 million persons infected with HIV, with heterosexual spread being the most common mode of transmission for men and women. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes.

▶ Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells as well as the indirect impact of a generalized state of inflammation and immune activation due to chronic viral infection. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in MSM or in bisexual men, and its incidence steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity/Allergic and Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic

interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis (“itchy red bump syndrome”) as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

► Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–1, the CD4 lymphocyte count result enables the clinician to focus on the diagnoses most likely to be seen at each stage of immunodeficiency. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have *Pneumocystis* pneumonia.

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without ART, with a mean time of approximately 10 years between infection and development of

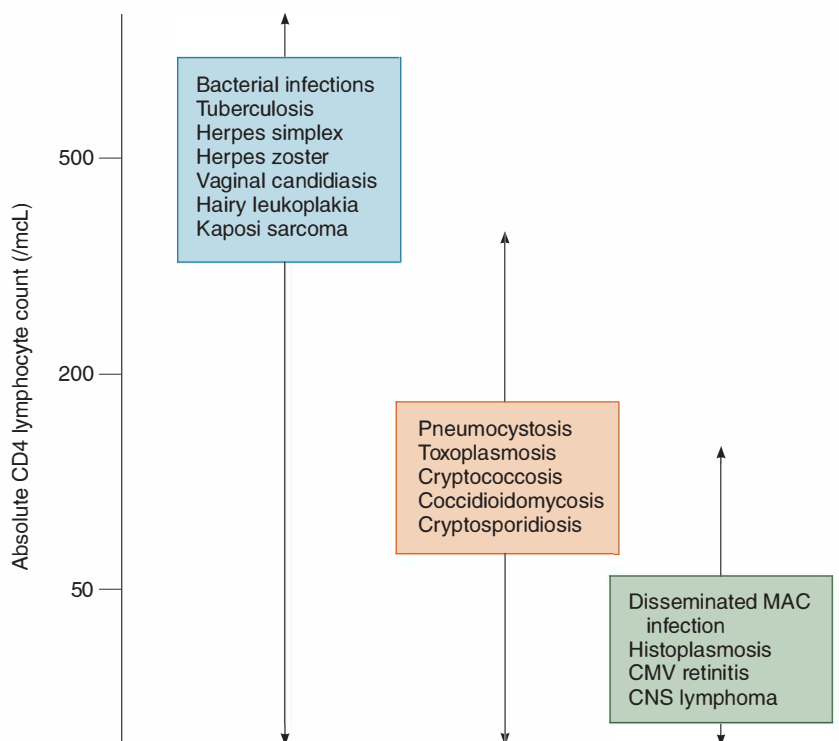

AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

The specific presentations and management of the various complications of HIV infection are discussed under the Complications section below.

B. Laboratory Findings

Specific tests for HIV include antibody and antigen detection (Table 31–2). Conventional HIV antibody testing is done by ELISA. Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is greater than 99.9%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Antibodies will be detectable with current screening serologic tests in 95% of persons within 6 weeks after infection.

▲ **Figure 31–1.** Relationship of CD4 count to development of opportunistic infections. MAC, *Mycobacterium avium* complex; CMV, cytomegalovirus; CNS, central nervous system.

Table 31–2. Laboratory findings with HIV infection.

Test	Significance
HIV enzyme-linked immunosorbent assay (ELISA)	Screening test for HIV infection. Of ELISA tests 50% are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity greater than 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot.
Western blot	Confirmatory test for HIV. Specificity when combined with ELISA greater than 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, influenza vaccine, autoimmune disease, pregnancy, and recent tetanus toxoid administration.
HIV rapid antibody test	Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Positive results must be confirmed with standard HIV tests (ELISA and Western blot).
Complete blood count	Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection.
Absolute CD4 lymphocyte count	Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 less than 200 cells/mcL in the absence of treatment.
CD4 lymphocyte percentage	Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage less than 14% in the absence of treatment.
HIV viral load tests	These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral medications. Best tests available for diagnosis of acute HIV infection (prior to seroconversion); however, caution is warranted when the test result shows low-level viremia (ie, less than 500 copies/mL) as this may represent a false-positive test.

Rapid HIV antibody tests of blood or oral fluid provide results within 10–20 minutes and can be performed in clinician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA)-approved laboratory. Persons who test positive on a rapid test should be told that they may be HIV-infected or their test may be falsely reactive. Standard testing (ELISA with Western blot confirmation) should be performed to distinguish these two possibilities. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV) or when the patient is unlikely to return for a result. Rapid HIV home tests that allow the testers to learn their status privately by simply swabbing along their gum lines are also available (www.oraquick.com).

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous angery is common.

The most widely used marker is the absolute CD4 lymphocyte count to provide prognostic information and guide therapy decisions (Table 31–2). As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1). There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intralaboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient's health status and whether or not they are receiving antiretroviral treatment. **All patients regardless of CD4 count should be offered ART; CD4 counts should be monitored every 3–6 months in patients taking ART**

consistently. Initiation of *Pneumocystis jirovecii* prophylactic therapy is recommended when the CD4 count drops below 200 cells/mcL, and initiation of *Mycobacterium avium* prophylaxis is recommended when the CD4 count drops below 75–100 cells/mcL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. **HIV viral load** tests assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

▶ Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive symptoms must be considered.

► Complications

A. Systemic Complaints

Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (*Pneumocystis* pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5°C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans or sinus radiographs should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

1. Weight loss and wasting syndrome—Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

A. PRESENTATION—AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

B. MANAGEMENT—Several strategies have been developed to slow AIDS wasting. In the long term, nothing is as effective as ART, since it treats the underlying HIV infection. In the short term, effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent **megestrol acetate** (80 mg orally four times a day) and the antiemetic agent **dronabinol** (2.5–5 mg orally three times a day), but neither of these agents increases lean body mass. Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence

and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in marijuana, and many patients report better relief of nausea and improvement of appetite with **medical cannabis** (administered via smoking, vaporization, essential oils or cooked in food). In the United States, at least 23 states and the District of Columbia have legalized medical marijuana. However, the use and sale of marijuana is still illegal under federal law.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. **Growth hormone** at a dose of 0.1 mg/kg/day (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as \$10,000 per month. **Anabolic steroids** also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100–200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

2. Nausea—Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) or medical cannabis can also be used to treat nausea. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

B. Pulmonary Disease

1. Pneumocystis pneumonia—(See also Chapter 36.) *P jirovecii* pneumonia is the most common opportunistic infection associated with AIDS. *Pneumocystis* pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PO₂ less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with *Pneumocystis* pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with *Pneumocystis* pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with *Pneumocystis* pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with *Pneumocystis* pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations in whom *Pneumocystis* pneumonia is still suspected should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of *Pneumocystis* pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of *Pneumocystis* pneumonia, but the specificity of this finding is at best 75%. A serum beta-glucan test is more sensitive and specific test for *Pneumocystis* pneumonia compared with serum lactate dehydrogenase and may avoid more invasive tests when used in the appropriate clinical setting. Either a normal diffusing capacity of carbon monoxide (DL_{CO}) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of *Pneumocystis* pneumonia very unlikely. In addition, a CD4 count greater than 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of *Pneumocystis* pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (Figure 31–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with ART. Pneumothoraces can be seen in HIV-infected patients with a history of *Pneumocystis* pneumonia.

Trimethoprim-sulfamethoxazole is the preferred treatment of *Pneumocystis* pneumonia (Table 31–3). In addition to specific anti-*Pneumocystis* treatment, corticosteroid therapy has been shown to improve the course of patients with moderate to severe *P jirovecii* pneumonia (PaO_2 less than 70 mm Hg on room air or alveolar-arterial O_2 gradient greater or equal to 35 mm Hg) when administered within 72 hours of the start of anti-*Pneumocystis* treatment. It should be started as early as possible after initiation of treatment, using prednisone 40 mg orally twice daily for days 1–5, 40 mg daily for days 6–10, and 20 mg daily for days 11–21 (for patients who cannot take oral medication, intravenous methylprednisolone can be substituted at 75% of the dose). The mechanism of action is presumed to be a decrease in alveolar inflammation.

2. Other infectious pulmonary diseases—

A. PRESENTATION—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. **Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons.** An increased incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia has been reported. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease

and, more rarely, pneumonia from *Rhodococcus equi* infection can occur. The incidence of infection with *Mycobacterium tuberculosis* has markedly increased in metropolitan areas because of HIV infection as well as homelessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Apical infiltrates and disseminated disease occur more commonly than among immunocompetent persons. Although a purified protein derivative (PPD) test should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of anergy. Because “anergy” skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended. **Interferon gamma release assays** (including the QuantiFERON and T-SPOT tests) are likely to be more sensitive than skin testing in HIV-infected patients in whom tuberculosis infection is suspected.

B. MANAGEMENT—Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals. However, rifampin should not be given to patients receiving a boosted protease inhibitor (PI)-regimen. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis has been a major problem in several metropolitan areas of the developed world, and reports from South Africa of “extremely resistant” tuberculosis in AIDS patients is a growing global concern. Noncompliance with prescribed antituberculous medications is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of medication resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Medication therapy should be individualized. Patients with multidrug-resistant *M tuberculosis* infection should receive at least three medications to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between *M tuberculosis* and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. **While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection.** In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mcL—see Figure 31–1), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease as well as more common respiratory viral infections should

Table 31–3. Treatment of AIDS-related opportunistic infections and malignancies.¹

Infection or Malignancy	Treatment	Complications ²
<i>Pneumocystis jirovecii</i> infection ³	<p>Preferred regimen: Trimethoprim-sulfamethoxazole, 15 mg/kg/day (based on trimethoprim component) intravenously or one double-strength tablet orally three times a day for 21 days. Add prednisone when PaO₂ < 70 mm Hg on room air or alveolar-arterial O₂ gradient > 35 mm Hg: 40 mg orally twice a day on days 1–5, 40 mg orally daily on days 6–10, 20 mg orally daily on days 11–21</p> <p>Pentamidine, 3–4 mg/kg/day intravenously for 21 days plus prednisone when indicated as above</p> <p>Primaquine, 30 mg/day orally, and clindamycin, 600 mg every 8 hours orally, for 21 days plus prednisone when indicated as above</p> <p>Not recommended for severe disease: Trimethoprim, 15 mg/kg/day orally in three divided doses, with dapsone, 100 mg/day orally, for 21 days,³ plus prednisone when indicated as above</p> <p>Not recommended for severe disease: Atovaquone, 750 mg orally three times daily with food for 21 days, plus prednisone when indicated as above</p>	<p>Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome</p> <p>Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis</p> <p>Primaquine: hemolytic anemia in G6PD-deficient patients,³ methemoglobinemia, neutropenia, colitis</p> <p>Clindamycin: rash, nausea, abdominal pain, colitis</p> <p>Nausea, rash, hemolytic anemia in G6PD³-deficient patients; methemoglobinemia (weekly levels should be less than 10% of total hemoglobin)</p> <p>Rash, elevated aminotransferases, anemia, neutropenia</p>
<i>Mycobacterium avium</i> complex infection	<p>Clarithromycin, 500 mg orally twice daily with ethambutol, 15 mg/kg/day orally (maximum, 1 g). May also add:</p> <p>Rifabutin, 300 mg orally daily.</p>	<p>Clarithromycin: hepatitis, nausea, diarrhea;</p> <p>ethambutol: hepatitis, optic neuritis</p> <p>Rash, hepatitis, uveitis</p>
Toxoplasmosis	<p>Preferred regimen: Pyrimethamine, 200 mg orally as loading dose, followed by 50 mg daily (weight ≤ 60 kg) or 75 mg daily (weight > 60 kg), combined with sulfadiazine, 1000 mg orally four times daily (weight ≤ 60 kg) or 500 mg orally four times daily (weight > 60 kg) and leucovorin 10–25 mg orally daily for at least 6 weeks. Longer courses are necessary for extensive disease or incomplete clinical or radiographic resolution. Maintenance therapy with pyrimethamine 25–50 mg orally plus sulfadiazine 2000–4000 mg in two to four divided doses plus leucovorin 10–25 mg orally daily. Long-term treatment should be maintained until immune reconstitution with ART occurs.</p> <p>For patients who are intolerant of sulfa who cannot be desensitized: substitute clindamycin 600 mg intravenously or orally every 6 hours for the sulfadiazine in the above regimen</p> <p>If pyrimethamine not available: trimethoprim-sulfamethoxazole, 10 mg/kg/day (based on trimethoprim component)</p>	<p>Pyrimethamine: leukopenia, anorexia, vomiting</p> <p>Sulfadiazine: nausea, vomiting, Stevens-Johnsons syndrome</p> <p>Pyrimethamine: leukopenia, anorexia, vomiting</p> <p>Clindamycin: rash, nausea, abdominal pain, colitis</p> <p>Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome</p>
Non-Hodgkin lymphoma	<p>Combination chemotherapy (eg, EPOCH with rituximab and G-CSF)</p> <p>Central nervous system disease: radiation treatment with dexamethasone for edema</p>	<p>Nausea, vomiting, anemia, neutropenia, thrombocytopenia cardiac toxicity (with doxorubicin)</p>
Cryptococcal meningitis	<p>Preferred regimen: Liposomal amphotericin B, 3–4 mg/kg/day intravenously, with flucytosine, 25 mg/kg/day orally in four divided doses for 2 weeks (adjust dose for renal function), then fluconazole, 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy</p> <p>Amphotericin B, 0.7 mg/kg/day intravenously, with flucytosine, 100 mg/kg/day orally in four divided doses for 2 weeks (adjust dose for renal function), then fluconazole, 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy</p> <p>Fluconazole, 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy</p>	<p>Liposomal amphotericin: fever, chills, hypokalemia, renal failure</p> <p>Flucytosine: bone marrow suppression, renal failure, hepatitis</p> <p>Fluconazole: hepatitis</p> <p>Amphotericin: fever, chills, hypokalemia, renal failure</p> <p>Flucytosine: bone marrow suppression, renal failure, hepatitis</p> <p>Fluconazole: hepatitis</p> <p>Hepatitis</p>

(continued)

Table 31-3. Treatment of AIDS-related opportunistic infections and malignancies.¹ (continued)

Infection or Malignancy	Treatment	Complications ²
Cytomegalovirus retinitis (immediate sight-threatening)	Preferred regimen: Intravitreal ganciclovir (2 mg/injection) or foscarnet (2.4 mg/injection) for 1–4 doses for 7–10 days plus valganciclovir, 900 mg orally twice a day for 14–21 days with food followed by 900 mg daily (maintenance)	Neutropenia, anemia, thrombocytopenia
	Ganciclovir, 10 mg/kg/day intravenously in two divided doses for 14 days, followed by 5 mg/kg daily or valganciclovir 900 mg orally daily (maintenance)	Neutropenia (especially when used concurrently with zidovudine), anemia, thrombocytopenia Adjust ganciclovir dose for renal function
	Foscarnet, 60 mg/kg intravenously every 8 hours or 90 mg/kg intravenously every 12 hours for 14–21 days, followed by 90–120 mg/kg once daily. (Adjust dose for renal function.)	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia
	Cidofovir, 5 mg/kg/week intravenously for 2 weeks then 5 mg/kg every other week with probenecid 2 g orally 3 hours before dose, 1 g orally 2 hours after dose, and 1 g orally 8 hours after dose	Nephrotoxicity (to reduce likelihood, pre and post saline hydration, along with probenecid), neutropenia Avoid in patients with sulfa allergy because of cross hypersensitivity with probenecid
Esophageal candidiasis or recurrent vaginal candidiasis	Fluconazole, 100–200 mg orally daily for 14–21 days for esophageal disease and > 7 days for recurrent vaginal disease	Hepatitis, development of azole resistance
Herpes simplex infection	Acyclovir, 400 mg orally three times daily for 5–10 days; or acyclovir, 5 mg/kg intravenously every 8 hours for severe cases	Resistant herpes simplex with long-term therapy
	Famciclovir, 500 mg orally twice daily for 5–10 days	Nausea
	Valacyclovir, 1 g orally twice daily for 5–10 days	Nausea
	Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases. (Adjust dose for renal function.)	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia
Herpes zoster	Preferred regimen: Valacyclovir, 500 mg orally three times daily for 7–10 days	Resistant herpes simplex with long-term therapy
	Preferred regimen: Famciclovir, 500 mg orally three times daily for 7–10 days	Nausea
	Acyclovir, 800 mg orally four or five times daily for 7–10 days. Intravenous therapy at 10 mg/kg every 8 hours for ocular involvement, visceral disease until clinical improvement then switch to oral therapy to complete a 10- to 14-day course	Nausea
Kaposi sarcoma	Mild to moderate	Initiation or optimization of ART
	Advanced disease	Combination chemotherapy (eg, daunorubicin, bleomycin, vinblastine)

¹ Recommendations drawn from Centers for Disease Control. Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. 2015. http://aidsinfo.nih.gov/contentfiles/lvguidelines/adult_oi.pdf

²List of complications is not exhaustive.

³Prior to use of primaquine or dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in black patients and those of Mediterranean origin.

EPOCH, etoposide, prednisolone, vincristine (Oncovin), cyclophosphamide, doxorubicin (hydroxydaunomycin); G-CSF, granulocyte-colony stimulating factor (filgrastim).

also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

3. Noninfectious pulmonary diseases—

A. PRESENTATION—Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, interstitial pneumonitis, and increasingly, in the current ART

era, lung cancer. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease but more commonly involves other organs as well, especially the brain, liver, and

gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic *Pneumocystis* pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose *Pneumocystis* pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation.

B. MANAGEMENT—Corticosteroids may be helpful in some cases refractory to ART.

4. Sinusitis—

A. PRESENTATION—Chronic sinusitis can be a frustrating problem for HIV-infected patients. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan or sinus x-ray in the absence of significant symptoms.

B. MANAGEMENT—Nonsmoking patients with purulent drainage should be treated with amoxicillin (500 mg orally three times a day). Patients who smoke cigarettes should be treated with amoxicillin-potassium clavulanate (500 mg orally three times a day) to cover *H influenzae*. A 7-day course of pseudoephedrine 60 mg twice daily may be helpful in decreasing congestion. Prolonged treatment (3–6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) is sometimes necessary. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin may be tried (400 mg orally daily). In patients with advanced immunodeficiency, *Pseudomonas* infections should be suspected, especially if there is not a response to first-line antibiotics. Some patients may require referral to an otolaryngologist for sinus drainage.

C. Central Nervous System Disease

Central nervous system disease in HIV-infected patients can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of effective ART. Cognitive declines, however, may be more common in HIV patients especially as they age (older than 50 years), even those who are taking fully suppressive ART.

1. Toxoplasmosis—Toxoplasmosis is the most common space-occupying lesion in HIV-infected patients. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for *Toxoplasma*. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. A positive *Toxoplasma* serologic test does not confirm the diagnosis because many HIV-infected patients have detectable titers without having active disease. Conversely, less than 3% of patients with toxoplasmosis have negative titers. Therefore, negative *Toxoplasma* titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis. The preferred treatment of toxoplasmosis is with pyrimethamine and sulfadiazine (Table 31–3). If pyrimethamine is not available, patients can be treated with trimethoprim-sulfamethoxazole.

2. Central nervous system lymphoma—Primary non-Hodgkin lymphoma is the second most common space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and *Nocardia* lesions.

Stereotactic brain biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). Although a positive polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein–Barr virus DNA is consistent with a diagnosis of lymphoma, the sensitivity and specificity of the test are not high enough to obviate the need for a brain biopsy.

3. HIV-associated dementia—Patients with HIV-associated dementia typically have difficulty with cognitive tasks (eg, memory, attention), exhibit diminished motor function, and have emotional or behavioral problems. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. The diagnosis of HIV-associated dementia is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Many patients improve with effective ART. However, slowly progressive neurocognitive deficits may still develop in patients taking ART as they age.

Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

4. Cryptococcal meningitis—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test of serum that detects cryptococcal antigen (or “CRAG”) or positive culture of spinal fluid for *Cryptococcus*. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection. The preferred treatment is liposomal amphotericin with flucytosine (Table 31–3).

5. HIV myelopathy—Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

6. Progressive multifocal leukoencephalopathy (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of effective ART, and due to wide use of ART, PML is now rarely seen.

D. Peripheral Nervous System

A. PRESENTATION—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An **inflammatory demyelinating polyneuropathy** similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior ART with stavudine or didanosine. Although not used commonly in Western countries, stavudine is still

being used in resource-limited settings through national ART programs. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, medication-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken ART. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B₁₂ deficiency, and syphilis.

B. MANAGEMENT—Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day) or other co-analgesics for neuropathic pain (see Chapter 5). Opioid analgesics should be avoided because the condition tends to be chronic and patients are likely to become dependent on these agents without significant improvement in their well-being.

E. Rheumatologic and Bone Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory medications. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint aspirated, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis, psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 20). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term ART. The etiology is not clear but is probably multifactorial in nature.

Osteoporosis and osteopenia appear to be more common in HIV-infected patients with chronic infection and perhaps associated with long-term use of ART. Vitamin D deficiency appears to be quite common among HIV-infected populations and monitoring vitamin D levels and replacement therapy for detected deficiency are recommended. Bone mineral density scans for postmenopausal women and for men over the age of 50 is also recommended.

F. Myopathy

Myopathies are infrequent in the era of effective ART but can be related to either HIV-infection or ART, particularly with use of zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. Given its long-term toxicities, zidovudine is no longer recommended when alternative treatments are available.

G. Retinitis

Complaints of visual changes must be evaluated immediately in HIV-infected patients by an ophthalmologist familiar with the manifestations of HIV disease. CMV retinitis, characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected people, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. Other rare retinal processes include other herpesvirus infections or toxoplasmosis. Choice of treatment for CMV retinitis (Table 31–3) depends on severity of lesions, their location, as well as the patient's overall condition and circumstances.

H. Oral Lesions

A. PRESENTATION—The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick ("hairy") projections. **Oral candidiasis** can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. The two most common forms of oral candidiasis seen are pseudomembranous (removable white plaques) and erythematous (red friable plaques).

B. MANAGEMENT—Treatment of oral candidiasis is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated with fluconazole (50–100 mg orally once a day for 3–7 days). Angular cheilitis—fissures at the sides of the mouth—is usually due to *Candida* as well and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Apthous ulcers are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10% lidocaine).

Other lesions seen in the mouths of HIV-infected patients include Kaposi sarcoma (usually on the hard palate) and warts.

I. Gastrointestinal Manifestations

1. Candidal esophagitis—(See also Chapter 15.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (100–200 mg orally daily for 14–21 days). Improvement in symptoms should be apparent within 1–2 days of antifungal treatment. If there is no improvement, further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is recommended.

2. Hepatic disease—

A. PRESENTATION—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Mild elevations of alkaline phosphatase and aminotransferases are often noted on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole medications, anti-tuberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. All nucleoside reverse transcriptase inhibitors cause lactic acidosis, which can be fatal. Lactic acidosis, however, occurs most commonly when didanosine is used with stavudine; this combination is no longer recommended in ART regimens. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of ART. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, *M avium* complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site).

B. MANAGEMENT—With patients living longer as a result of advances in ART, advanced liver disease and hepatic failure due to chronic active hepatitis B and/or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfecting with hepatitis B should be treated with antiretroviral regimens that include medications with activity against both viruses (eg, lamivudine [3TC], emtricitabine [FTC], tenofovir [TDF]). It is important to be extremely cautious about discontinuing these medications in coinfecting patients as sudden discontinuation could lead to a fatal flare of hepatitis B infection.

Hepatitis C is more virulent in persons with HIV and should be treated using the new HCV direct-acting antivirals. For treatment-naïve coinfecting patients with genotype 1a (the most common hepatitis C genotype in the United States) the recommended regimens are (1) fixed-dose ledipasvir (90 mg)/sofosbuvir (400 mg) daily for 12 weeks, (2) fixed-dose paritaprevir (150 mg)/ritonavir (100 mg)/ombitasvir (25 mg) plus dasabuvir (250 mg twice daily) and

weight-based ribavirin (1000 mg for patients weighing less than 75 kg and 1200 mg for patients weighing more than 75 kg) for 12 weeks (24 weeks for patients with cirrhosis), (3) sofosbuvir (400 mg) plus simeprevir (150 mg) with or without weight-based ribavirin (see previous regimen) for 12 weeks (24 weeks in patients with cirrhosis). Because there are no data to support one regimen over another, the least expensive regimen may be preferred. At the moment, all are very expensive, but it is hoped that competition between the regimens will ultimately reduce the price. Acid-reducing medicines should be avoided with ledipasvir and paritaprevir/ritonavir/ombitasvir/dasabuvir.

Although the recommended regimens are the same for HIV-infected patients potential drug interactions with ART may complicate treatment. Ledipasvir increases tenofovir levels. These two medications should be avoided in patients with creatinine clearance below 60 mL/min or in those taking these two medications and a ritonavir-boosted PI. Paritaprevir/ritonavir/ombitasvir/dasabuvir can be used safely with raltegravir, enfuvirtide, tenofovir, emtricitabine, lamivudine, and atazanavir. Simeprevir can be used safely with raltegravir, rilpivirine, maraviroc, enfuvirtide, tenofovir, emtricitabine, lamivudine, and abacavir. For hepatitis C treatment recommendations in patients with other scenarios (other medication interactions, genotypes, prior treatment, renal impairment), clinicians should consult the guidelines listed in the references below (see also Table 16–6).

Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts greater than 100 cells/mL and nondetectable viral loads.

3. Biliary disease—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver function tests generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with “pruning” of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen with this syndrome. CMV, *Cryptosporidium*, and microsporidia are thought to play inciting roles in this syndrome but these conditions are rarely seen unless the patient is suffering with very advanced HIV-related immunodeficiency.

4. Enterocolitis—

A. PRESENTATION—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (*Campylobacter*, *Salmonella*, *Shigella*), viruses (CMV, adenovirus), and protozoans (*Cryptosporidium*, *Entamoeba histolytica*, *Giardia*, *Isospora*, microsporidia). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent

persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both *Salmonella* and *Shigella* infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for *Cryptosporidium*) should be performed. Those patients who have *Cryptosporidium* in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as *Cryptosporidium* is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with *Cryptosporidium* infection have persistent enterocolitis with profuse watery diarrhea.

B. MANAGEMENT—To date, no consistently effective treatments have been developed for *Cryptosporidium* infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective ART. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea although the benefit is often short-lived.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective ART. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

5. Other disorders—Two other important gastrointestinal abnormalities in HIV-infected patients are **gastropathy** and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb medications that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to *Campylobacter*, *Salmonella*, and *Shigella*, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in HIV-infected persons.

A **malabsorption** syndrome occurs commonly in AIDS patients. It can be due to infection of the small bowel with *M avium* complex, *Cryptosporidium*, or microsporidia.

J. Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy

include infection (especially with CMV and *M avium* complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg orally daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (T_3), thyroxine (T_4), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT_3). The causes and clinical significance of these abnormalities are unknown.

K. Skin Manifestations

The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

1. Viral dermatitides—

A. HERPES SIMPLEX INFECTIONS—These infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, **all herpes simplex attacks should be treated** for 5–10 days with acyclovir (400 mg orally three times a day), famciclovir (500 mg orally twice daily), or valacyclovir (500 mg orally twice daily) (Table 31–3). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). Long-term suppressive herpes prophylaxis with acyclovir does not reduce HIV transmission between heterosexual men and women from developing countries.

B. HERPES ZOSTER—This is a common manifestation of HIV infection. As with herpes simplex infections, patients with zoster should be treated for 7–10 days with famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day). Acyclovir can also be used, but it requires very frequent dosing (800 mg orally four or five times per day for 7 days). Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir. The **zoster vaccine** appears to be safe and immunogenic in HIV-infected patients over the age of 50 years with CD4 greater than 200/mcL, although the long-term benefit in preventing recurrences has yet to be established.

C. MOLLUSCUM CONTAGIOSUM—This infection is caused by a pox virus and is seen in HIV-infected patients, as in other immunocompromised patients. The characteristic

umbilicated fleshy papular lesions have a propensity for spreading widely over the patient's face and neck and should be treated with topical liquid nitrogen.

2. Bacterial dermatitides

A. STAPHYLOCOCCAL INFECTION—*Staphylococcus* is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **folliculitis**, **superficial abscesses (furuncles)**, or **bullous impetigo**. These lesions should be treated aggressively since sepsis can occur. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need anti-staphylococcal antibiotics as well. Due to high frequency of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Recommendations for empiric treatment are either (1) trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) with or without clindamycin (500 mg orally three times daily); or (2) doxycycline (100 mg orally twice daily) with close follow-up.

B. BACILLARY ANGIOMATOSIS—It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic the lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.

3. Fungal rashes—

A. RASHES DUE TO DERMATOPHYTES AND CANDIDA—The majority of **fungal rashes** afflicting AIDS patients are due to dermatophytes and *Candida*. These are particularly common in the inguinal region but may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% cream twice a day) or ketoconazole (2% cream twice a day).

B. SEBORRHEIC DERMATITIS—This is more common in HIV-infected patients. Scrapings of seborrhea have revealed *Malassezia furfur* (*Pityrosporum ovale*), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

4. Neoplastic dermatitides—See Chapter 6 and the Kaposi sarcoma section below.

5. Nonspecific dermatitides—

A. XEROSIS—This condition presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

B. PSORIASIS—Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–9.75 mg/kg/day orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist.

L. HIV-Related Malignancies

Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987 among single men in San Francisco, the risk of Kaposi sarcoma increased more than 5000-fold and the risk of non-Hodgkin lymphoma more than 10-fold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity. **In the current treatment era, cancers not classified as AIDS-related, such as lung cancer, are being increasingly diagnosed in aging HIV-infected individuals despite optimal ART treatment.** Cohort studies suggest that HIV-infected adults are at increased risk for a variety of cancers compared to age-matched uninfected populations. Mortality secondary to malignancies represents an increasing cause of death in HIV-infected populations.

1. Kaposi sarcoma—

A. PRESENTATION—Lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular. In dark-skinned individuals, the lesions may appear more brown. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. Kaposi sarcoma lesions can occur shortly after initiating ART, especially in patients starting ART who have advanced immunodeficiency. In this situation, Kaposi sarcoma is likely to be an immune reconstitution reaction (see Inflammatory Reactions below). Kaposi sarcoma can also cause visceral disease (eg, gastrointestinal, pulmonary).

B. MANAGEMENT—Patients with mild to moderate forms of Kaposi sarcoma do not require specific treatment as the lesions usually resolve with effective ART. However, it should be noted that the lesions may flare when ART is first initiated—probably as a result of an immune reconstitution process. Advanced disease is treated with combination chemotherapy (Table 31–3).

2. Non-Hodgkin lymphoma—

A. PRESENTATION—Non-Hodgkin lymphoma in HIV-infected persons tends to be very aggressive. The

malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

B. MANAGEMENT—The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of ART, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with combination chemotherapy (eg, EPOCH [etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin]) with rituximab. Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts.

3. Hodgkin disease—Although Hodgkin disease is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

4. Anal dysplasia and squamous cell carcinoma—These lesions have been strongly correlated with previous infection by human papillomavirus (HPV) and have been noted in HIV-infected men and women. Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, **some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons.** An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle. However, there is no evidence that screening for anal cancer with Papanicolaou smears decreases the incidence of invasive cancer.

HPV also appears to play a causative role in **cervical dysplasia and neoplasia**. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

M. Gynecologic Manifestations

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents or a single dose of oral fluconazole (150 mg) (see Chapter 36). Recurrent vaginal candidiasis should be treated with fluconazole (100–200 mg) for at least 7 days.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, recommended screening for **HIV-infected women is more extensive than for uninfected women** (see Chapter 18). For women younger than 30 years, a Papanicolaou smear should be performed within a year of the onset of sexual activity but no later than 21 years of age. If normal, Papanicolaou smears should be performed yearly. After three negative examinations, screening should be done every 3 years. HPV DNA testing of the cervical specimen is not recommended for women younger than 30 years of age.

For women 30 and older, screening should continue beyond age 65 unlike the general population. There are two accepted screening protocols, one using cytology alone, the other using cytology with HPV DNA cotesting. A Papanicolaou smear is done when HIV is diagnosed and every 12 months thereafter and after three negative examinations, ongoing screening should be performed every 3 years. Alternatively, a Papanicolaou smear with cotesting for HPV DNA can be performed when HIV is diagnosed or starting when patients are 30 years old. If Papanicolaou is normal and HPV test is negative, then the next screening would be in 3 years.

The management of abnormal Papanicolaou tests and positive HPV tests is the same in infected women as in uninfected women. Treatment should follow the consensus guidelines in the references below.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see Chapter 18).

N. Coronary Artery Disease

HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and several of the PIs. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because myocardial infarctions tend to present at a younger age in HIV-infected individuals than in HIV-uninfected individuals. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

O. Inflammatory Reactions (Immune Reconstitution Inflammatory Syndromes)

With initiation of ART, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as indicated by a rapid increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or

without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with ART.

M. avium can present as focal even suppurative lymphadenitis or granulomatous masses in patients receiving ART. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated ART in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of immune reconstitution inflammatory syndrome (IRIS) is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that ART be continued unless the reaction is life-threatening.

► Prevention

A. Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend on HIV testing and counseling, including precautions regarding sexual practices and injection drug use, initiation of ART as a prevention tool for transmission to others, preexposure and postexposure use of ART, perinatal management including ART therapy for the mother, screening of blood products, and infection control practices in the health care setting.

1. HIV testing and counseling—Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. Because approximately one-fifth of the HIV-infected persons in the United States do not know they are infected, the **USPSTF recommends that clinicians screen for HIV infection in adolescents and adults ages 15 to 65 years. Younger adolescents and older adults who are at increased risk should also be screened.** Clinicians should review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. Although the CDC recommends “opt-out” testing in medical settings, some states require specific written consent.

For persons whose test results are positive, it is critically important that they be connected to ongoing medical care. Referrals for partner-notification services, social services, mental health services, and HIV-prevention services should also be provided. Prevention interventions focused on the importance of HIV-infected persons not putting others at risk have been successful.

For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

To prevent sexual transmission of HIV, only latex condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men having sex with men should understand how to use condoms to be sure that their partners are using them correctly. Partners of HIV-infected women should use latex barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Several randomized trials in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Persons using injection drugs should be cautioned never to share needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

2. ART for decreasing transmission of HIV to others—Besides preventing progression of HIV disease, effective ART likely decreases the risk of HIV transmission between sexual partners. Among serodiscordant couples, **early ART almost completely eliminates the risk of HIV transmission to the uninfected partner.** Although HIV-negative persons in stable long-term partnerships with HIV-infected persons represent only one group of at risk persons, theoretically increasing the use of ART among the population of HIV-infected persons could decrease community wide transmission of HIV. However, even patients who have been treated with antiretrovirals and have undetectable viral loads must practice safer sex and not share needles so as to avoid the possibility of transmitting HIV.

3. Preexposure ART prophylaxis—Several large randomized double-blind placebo-controlled trials demonstrated that administering emtricitabine/tenofovir (Truvada) can reduce the risk of sexual transmission of HIV among uninfected individuals at high risk for infection; one study was of HIV-negative men and transgender women who have sex with men, two studies were of heterosexual HIV-discordant couples. Preexposure tenofovir has also been shown to reduce HIV infection among injection drug users from Thailand. The combination of emtricitabine/tenofovir is recommended for preexposure prophylaxis (PrEP) by the CDC for use in HIV-negative persons at risk for infection.

4. Postexposure prophylaxis for sexual and drug use exposures to HIV—The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted. Although there is no proof that administration of antiretroviral medications following a sexual or parenteral drug use exposure reduces the likelihood of infection, there is suggestive data from animal models, perinatal experience, and a case-control study of health care workers who experienced a needle stick.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route; the preferred regimen is tenofovir 300 mg with emtricitabine 200 mg daily with raltegravir 400 mg twice a day. Some clinicians prescribe a two-drug regimen of tenofovir 300 mg and emtricitabine 200 mg (Truvada) because it is simpler for patients to take (single pill once a day), and more affordable for individuals and for public entities that provide this service to uninsured persons. In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, **treatment should be provided as soon as possible, and it is not recommended that treatment be offered more than 72 hours after exposure.** In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered with prevention counseling. Counseling should focus on how to prevent future exposures. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinicians' Post-exposure Hotline (1-888-448-4911; <http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/>).

5. Prevention of perinatal transmission of HIV—Prevention of perinatal transmission of HIV begins by offering HIV counseling and testing to all women who are pregnant or considering pregnancy. HIV-infected women who are pregnant should start ART with at least three medications. Recommended regimens are zidovudine and lamivudine with either ritonavir-boosted lopinavir or ritonavir-boosted atazanavir. Cesarean delivery should be planned if HIV viral load is greater than 1000 copies near the time of delivery. Zidovudine should be given to the infant after birth for 6 weeks. When possible, breastfeeding should be avoided.

6. Prevention of HIV transmission in health care settings—In health care settings, universal body fluid precautions should be used, including use of gloves when handling body

fluids and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread, and use of specially designed needles with sheath devices to decrease the risk of needle sticks. Because transmission of tuberculosis may occur in health care settings, all patients with cough should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital housestaff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. **The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300.** The risk is higher with deep punctures, large inoculum, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker's compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months. With the patient's permission, their blood can be tested for HIV antibody and HIV viral load.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, **providers should be offered ART as soon as possible after exposure and continued for 4 weeks.** The preferred regimen is tenofovir 300 mg with emtricitabine 200 mg (Truvada) daily with raltegravir 400 mg twice a day. Providers who have exposures to persons who are likely to have antiretroviral medication resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two medications to which the source is unlikely to be resistant. Because reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine prophylaxis. Counseling of the provider should include "safer sex" guidelines.

7. Prevention of transmission of HIV through blood or blood products—Current efforts in the United States to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000. Use of blood and blood products should be judicious, with patients receiving the least amount necessary, and patients should be encouraged to donate their own blood prior to elective procedures.

8. HIV vaccine—Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans have been disappointing. Only one vaccine trial has shown any degree of efficacy. In this

randomized, double-blind, placebo-controlled trial, a recombinant canarypox vector vaccine plus two booster injections of a recombinant gp120 vaccine was moderately efficacious (26–31%) in reducing the risk of HIV among a primarily heterosexual population in Thailand. Vaccine development efforts are aimed at identifying broadly neutralizing antibodies to the highly conserved regions of the HIV envelope.

B. Secondary Prevention

In the era prior to the development of effective ART, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS developed within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–4.

1. Tuberculosis—Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo **annual PPD testing.** Although anergy is common among AIDS patients, the likelihood of a false-negative result is much lower when the test is done early in infection. Those with positive tests (defined for HIV-infected patients as greater than 5 mm of induration) need a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by

Table 31–4. Health care maintenance and monitoring of HIV-infected individuals.

For all HIV-infected individuals:

- CD4 counts every 3–6 months (Can decrease to every 12 months if viral load suppressed on ART for 2 years and CD4 count greater than 300 cells/mL)
- Viral load tests every 3–6 months and 1 month following a change in therapy
- Genotypic resistance testing at baseline and if viral load not fully suppressed and patient taking ART
- Complete blood count, chemistry profile, transaminases and total bilirubin, at baseline and every 3–6 months
- Urinalysis at baseline and annually during ART (every 6 months if ART regimen includes TDF)
- Fasting glucose or hemoglobin A_{1c} at baseline and annually during ART
- Fasting lipid panel at baseline, 4–8 weeks after starting or changing an ART regimen that affects lipids, and annually for everyone over 40 years of age
- PPD annually
- INH for those with positive PPD and normal chest radiograph
- RPR or VDRL at entry and periodically based on sexual activity
- Toxoplasma IgG serology at baseline
- Hepatitis serologies: hepatitis A antibody, hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody
- Pneumococcal vaccine
- Inactivated influenza vaccine annually in season
- Hepatitis A vaccine for those without immunity to hepatitis A
- Hepatitis B vaccine for those who are hepatitis B surface antigen and antibody negative. (Use 40 mcg formulation at 0, 1, and 6 months; repeat if no immunity 1 month after three-vaccine series.)
- Combined tetanus, diphtheria, pertussis vaccine
- Human papillomavirus vaccine for HIV-infected women age 26 years or less
- Haemophilus influenzae* type b vaccination
- Bone mineral density monitoring for postmenopausal women and men 50 years of age or older
- Papanicolaou smears annually; if three smears are negative, can switch to longer intervals (see Complications, Section M)
- Consider anal swabs for cytologic evaluation
- For HIV-infected individuals with CD4 less than 200 cells/mL:**
- Pneumocystis jirovecii* prophylaxis (see Prophylactic Treatment of Complications of HIV Infection section under Treatment and Table 31–5)
- For HIV-infected individuals with CD4 less than 75 cells/mL:**
- Mycobacterium avium* complex prophylaxis (see Prophylaxis of Opportunistic Infections section under Treatment)
- For HIV-infected individuals with CD4 less than 50 cells/mL:**
- Consider CMV prophylaxis

ART, antiretroviral therapy; BUN, blood urea nitrogen; CMV, cytomegalovirus; IgG, immunoglobulin G; INH, isoniazid; PPD, purified protein derivative; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories.

mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with a positive PPD but negative evaluations for active disease should receive isoniazid (300 mg orally daily) with pyridoxine (50 mg orally daily) for 9 months to a year. Blood tests can also be used to assess prior tuberculosis exposure. Blood samples are

mixed with synthetic antigens representing *M tuberculosis*. Patients infected with *M tuberculosis* produce interferon-gamma in response to contact with the antigens. Unlike the PPD, the patient does not have to return for a second visit. The test is less likely to result in false-positive results than a PPD. HIV-infected persons with a CD4 count less than 100 cells may not respond to the Mitogen positive control; their results will be reported as indeterminate by QuantiFERON.

2. Syphilis—Because of the increased number of cases of syphilis among MSM, including those who are HIV infected, **all such men should be screened for syphilis by rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months.** Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, **the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of longer than 1 year or unknown duration.** All such patients should have a lumbar puncture with cerebrospinal fluid cell count and cerebrospinal fluid VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive cerebrospinal fluid-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2–4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days) followed by weekly benzathine penicillin G 2.4 million units intramuscularly for 3 weeks. Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see Chapter 34.

3. Immunizations—HIV-infected individuals should receive immunizations as outlined in Table 31–4. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40 mcg formulation; the higher dose is to increase the chance of developing protective immunity. If the patient does not have immunity 1 month after the three-shot

series, then the series should be repeated. HIV-infected persons should also receive the standard inactivated vaccines such as tetanus and diphtheria boosters that would be given to uninfected persons. **Most live vaccines, such as yellow fever vaccine, should be avoided.** Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated. The herpes zoster vaccine, two doses 6 weeks apart, has been found to be reasonably safe for HIV-infected persons with CD4 counts greater than 200 cells/mL and undetectable viral loads even though it is a live vaccine. However, it is not known if it is efficacious in preventing herpes zoster in this population.

4. Other measures—A randomized study found that multivitamin supplementation decreased HIV disease progression and mortality in HIV-infected women in Africa. However, supplementation is unlikely to be as effective in well-nourished populations.

HIV-infected individuals should be counseled with regard to the importance of practicing safer sex even with other HIV-infected persons because of the possibility of contracting a sexually transmitted disease, such as gonorrhea or syphilis. There is also the possibility of transmission of a particularly virulent or a drug-resistant strain between HIV-infected persons. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat, eggs, or shellfish to avoid infections with *Toxoplasma*, *Campylobacter*, and *Salmonella*. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with *Bartonella* species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

▶ Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination ART.

A. Prophylactic Treatment of Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, recent HIV viral load, and a history of having had the infection in the past. In the era prior to ART, patients who started taking prophylactic regimens were maintained on them indefinitely. However, **studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.**

Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable.

1. Prophylaxis against *Pneumocystis pneumonia*—Patients with CD4 counts below 200 cells/mL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for *Pneumocystis pneumonia*. Patients with a history of *Pneumocystis pneumonia* should receive secondary prophylaxis until their viral load is undetectable and they have maintained a CD4 count of 200 cells/mL or more while receiving ART for longer than 3 months. Regimens for *Pneumocystis* prophylaxis are given in Table 31–5.

Table 31–5. *Pneumocystis jirovecii* prophylaxis, in order of preference.

Medication	Dose	Side Effects	Limitations
Trimethoprim-sulfamethoxazole	One double-strength tablet three times a week to one tablet daily	Rash, neutropenia, hepatitis, Stevens-Johnson syndrome	Hypersensitivity reaction is common but, if mild, it may be possible to treat through.
Dapsone	50–100 mg orally daily or 100 mg two or three times per week	Anemia, nausea, methemoglobinemia, hemolytic anemia	Less effective than above. Glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to therapy. Check methemoglobin level after 1 month of treatment.
Atovaquone	1500 mg orally daily with a meal	Rash, diarrhea, nausea	Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to dapsone, but more expensive.
Aerosolized pentamidine	300 mg monthly	Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis	Apical <i>P jirovecii</i> pneumonia, extrapulmonary <i>P jirovecii</i> infections, pneumothorax.

2. Prophylaxis against *M avium* complex infection—

Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against *M avium* complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated *M avium* complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Prophylaxis against *M avium* complex infection may be discontinued in patients whose CD4 counts rise above 100 cells/mcL in response to ART for longer than 3 months.

3. Prophylaxis against *M tuberculosis* infection—

Isoniazid, 300 mg orally daily, plus pyridoxine, 50 mg orally daily, for 9–12 months should be given to all HIV-infected patients with positive PPD reactions (defined as greater than 5 mm of induration for HIV-infected patients) without evidence of active disease.

4. Prophylaxis against toxoplasmosis—

Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month. Prophylaxis can be discontinued when the CD4 cells have increased to greater than 200 cells/mcL for more than 3 months.

B. Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed above and in Table 31–3. In the era prior to the use of ART, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, **among patients who have a good response to ART, maintenance therapy for some opportunistic infections can be terminated.** For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving ART have had a sustained increase in CD4 count to greater than 100 cells/mcL for at least 3–6 months. Similar results have been observed in patients with *M avium* complex bacteremia, who have completed a year or more of therapy for *M avium* complex and have an increase in their CD4 count for greater than 6 months while receiving ART. Cessation of secondary prophylaxis for *Pneumocystis pneumonia* is described above.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of *Pneumocystis pneumonia* may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of *Pneumocystis* infection. Trimethoprim with dapsone and primaquine with clindamycin are two

combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. Patients in whom second episodes of *Pneumocystis pneumonia* develop while taking prophylaxis tend to have milder courses.

Adjunctive Treatments—Epoetin alfa (erythropoietin) is

approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. As zidovudine is rarely used now, especially at high doses, the use of epoetin alfa has also decreased. An erythropoietin level greater than 500 milli-units/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the medication is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week subcutaneously are usually sufficient.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–6) has had a profound impact on the natural history of HIV infection. Indeed, **with the advent of effective ART, the life expectancy of HIV-infected persons approaches that of uninfected persons when treatment is initiated early in the course of the disease.**

The recognition that HIV damages the immune system from the beginning of infection, even when the damage is not easily measured by conventional tests, combined with the greater potency, the improved side effect profile, and the decreased pill burden of modern HIV regimens, have led to the recommendation to **start treatment for all HIV-infected persons regardless of CD4 count**, which is supported by the World Health Organization. The START trial demonstrated that immediate treatment is associated with a greater than 50% reduction in risk for serious illness or death, compared to delaying treatment until the CD4 count falls below 350 cells/mcL. Because 5–20% of patients in developed countries who are treatment-naïve have a virus that is resistant to some medications, **resistance testing is recommended for all patients prior to initiating ART.**

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because medication resistance to antiretroviral agents develops in HIV-infected patients, **a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load.** Therapy that achieves undetectable viral load has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, **combination therapy with at least three medications from at least two different classes is necessary**, and partially suppressive combinations such as dual nucleoside therapy should be

Table 31–6. Antiretroviral therapy.

Medication	Dose	Common Side Effects	Special Monitoring ¹	Cost ²	Cost/Month
Nucleoside reverse transcriptase inhibitors					
Abacavir (Ziagen)	300 mg orally twice daily	Rash, fever—if occur, rechallenge may be fatal	No special monitoring	\$10.04/300 mg	\$602.40
Didanosine (ddl) (Videx)	400 mg orally daily (enteric-coated capsule) for persons greater or equal to 60 kg 250 mg orally daily (enteric-coated capsule) for persons 30–59 kg	Peripheral neuropathy, pancreatitis, dry mouth, hepatitis	Bimonthly neurologic questionnaire for neuropathy, potassium, amylase, bilirubin, triglycerides	\$12.29/400 mg	\$368.72
Emtricitabine (Emtriva)	200 mg orally once daily	Skin discoloration palms/soles (mild)	No special monitoring	\$21.46/200 mg	\$643.82
Lamivudine (3TC) (Epivir)	150 mg orally twice daily or 300 mg daily	Rash, peripheral neuropathy	No special monitoring	\$7.16/150 mg	\$429.60
Stavudine (d4T) (Zerit)	40 mg orally twice daily for persons ≥ 60 kg 30 mg orally twice daily for persons < 60 kg	Peripheral neuropathy, hepatitis, pancreatitis	Monthly neurologic questionnaire for neuropathy, amylase	\$6.85/40 mg	\$410.70
Zidovudine (AZT) (Retrovir)	600 mg orally daily in two divided doses	Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy	CBC with differential 4–8 weeks after starting AZT	\$6.02/300 mg	\$360.97
Nucleotide reverse transcriptase inhibitors					
Tenofovir TDF (Viread)	300 mg orally once daily	Renal failure, bone resorption, gastrointestinal distress	Creatinine every 3–4 months, urine analysis every 6 months	\$39.91/300 mg	\$1197.32
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)					
Delavirdine (Rescriptor)	400 mg orally three times daily	Rash	No special monitoring	\$2.75/200 mg	\$494.62
Efavirenz (Sustiva)	600 mg orally daily	Neurologic disturbances, rash	No special monitoring	\$37.00/600 mg	\$1110.13
Etravirine (Intelence)	200 mg orally twice daily	Rash, peripheral neuropathy	No special monitoring	\$10.90/100 mg	\$1308.06
Nevirapine (Viramune)	200 mg orally daily for 2 weeks, then 200 mg orally twice daily	Rash	No special monitoring	\$10.83/200 mg	\$649.80
Rilpivirine (Edurant)	25 mg daily	Depression, rash	No special monitoring	\$35.84/25 mg	\$1075.15
Protease inhibitors (PIs)					
Fosamprenavir (Lexiva)	For PI-experienced patients: 700 mg orally twice daily and 100 mg of ritonavir orally twice daily For PI-naïve patients: 1400 mg orally twice daily or 1400 mg orally once daily and 200 mg of ritonavir orally once daily	Gastrointestinal, rash	No special monitoring	\$21.47/700 mg	\$1288.02–2576.04 (plus cost of ritonavir for lower dose)
Indinavir (Crixivan)	800 mg orally three times daily	Renal calculi	Bilirubin level every 3–4 months	\$3.05/400 mg	\$548.12

(continued)

Table 31–6. Antiretroviral therapy. (continued)

Medication	Dose	Common Side Effects	Special Monitoring ¹	Cost ²	Cost/Month
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg orally twice daily	Diarrhea	No special monitoring	\$9.22/200 mg (lopinavir)	\$1106.29
Nelfinavir (Viracept)	750 mg orally three times daily or 1250 mg twice daily	Diarrhea	No special monitoring	\$4.16/250 mg \$10.42/625 mg	\$1250.36 \$1250.36
Ritonavir (Norvir)	600 mg orally twice daily or in lower doses (eg, 100 mg orally once or twice daily) for boosting other PIs	Gastrointestinal distress, peripheral paresthesias	No special monitoring	\$10.29/100 mg	\$3703.20 (\$617.20 in lower doses)
Saquinavir hard gel (Invirase)	1000 mg orally twice daily with 100 mg ritonavir orally twice daily	Gastrointestinal distress	No special monitoring	\$11.45/500 mg	\$1373.41 (plus cost of ritonavir)
Atazanavir (Reyataz)	400 mg orally once daily or 300 mg atazanavir with 100 mg ritonavir daily	Hyperbilirubinemia	Bilirubin level every 3–4 months	\$27.61/200 mg	\$1656.52 (plus cost of ritonavir)
Atazanavir/cobicistat (Evotaz)	300 mg of atazanavir with 150 mg cobicistat orally once daily	Hyperbilirubinemia	Bilirubin level every 3–4 months.	60.58/tablet	\$1817.51
Darunavir/ritonavir (Prezista/Norvir)	For PI-experienced patients: 600 mg of darunavir and 100 mg of ritonavir orally twice daily For PI-naïve patients: 800 mg of darunavir and 100 mg of ritonavir orally daily	Rash	No special monitoring	\$27.15/600 mg (darunavir) \$10.29/100 mg (ritonavir) \$25.16/400 mg (darunavir)	\$2246.26 (for combination) \$1818.40 (for combination)
Darunavir/cobicistat (Prezcobix)	800 mg of darunavir and 150 mg of cobicistat orally once daily	Rash	No special monitoring	\$62.07/tablet	\$1862.12
Tipranavir/ritonavir (Aptivus/Norvir)	500 mg of tipranavir and 200 mg of ritonavir orally twice daily	Gastrointestinal, rash	No special monitoring	\$14.04/250 mg (tipranavir) \$10.29/100 mg (ritonavir)	\$2920.00 (for combination)
Entry inhibitors					
Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Injection site pain and allergic reaction	No special monitoring	\$68.30/90 mg	\$4097.78
Maraviroc (Selzentry)	150–300 mg orally daily	Cough, fever, rash	No special monitoring	\$25.94/150 mg or 300 mg	\$1556.12
Integrase inhibitors					
Raltegravir (Isentress)	400 mg orally twice daily	Diarrhea, nausea, headache	No special monitoring	\$25.75/400 mg	\$1545.07
Elvitegravir (Vitekta)	Elvitegravir 85 or 150 mg once daily depending on combination regimen used OR 85 mg once daily when administered with atazanavir and ritonavir, or lopinavir and ritonavir 150 mg once daily when administered with darunavir and ritonavir, or fosamprenavir and ritonavir or tipranavir and ritonavir	Diarrhea, rash		\$48.18/Tablet	\$1445.34

(continued)

Table 31–6. Antiretroviral therapy. (continued)

Medication	Dose	Common Side Effects	Special Monitoring ¹	Cost ²	Cost/Month
Dolutegravir (Tivicay)	Treatment-naïve or integrase-naïve patients: 50 mg daily. When administered with efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin: 50 mg twice daily. When administered to integrase-experienced patients with suspected integrase resistance: 50 mg twice daily.	Hypersensitivity, rash	No special monitoring	\$56.91/50 mg	\$1707.26

¹Standard monitoring is complete blood count (CBC) and differential, basic chemistries, serum aminotransferases and total bilirubin every 3–6 months, urinalysis at baseline and annually during ART, fasting glucose or hemoglobin A_{1c} at baseline and annually during ART, fasting lipid profile at baseline, 4–8 weeks after starting an ART regimen that affects lipids, and annually for everyone over 40 years of age.

²Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book* (electronic version), Truven Health Analytics Information, <http://www.micromedexsolutions.com/> accessed April 8, 2016. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

avoided. Similarly, if toxicity develops, it is preferable to change the offending medication rather than reduce individual doses.

The presence of an acute opportunistic infection in most cases does not preclude the initiation of ART. Randomized trials compared early initiation of ART (within 2 weeks of starting treatment for an opportunistic infection or tuberculosis) with ART that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early ART arm.

Several randomized studies have also demonstrated improved clinical outcomes in HIV/tuberculosis coinfecting patients who initiate ART early in the setting of active treatment for tuberculosis and whose CD4 counts are less than 50 cells/mL. The exception to early ART in the setting of active infections may be in patients with a CNS-associated infection, such as cryptococcal or tuberculosis meningitis. Several studies from low-income countries have shown high mortality rates with early ART initiation in this setting.

For hospitalized patients, initiating treatment in patients with opportunistic infections requires close coordination between inpatient and outpatient clinicians to ensure that treatment is continued once patients are discharged.

D. Choosing an ART Regimen

Although the ideal combination of medications has not yet been defined for all possible clinical situations, possible regimens can be better understood after a review of the available agents. These medications can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTI); nonnucleoside reverse transcriptase inhibitors (NNRTI); PIs; entry inhibitors,

which include a fusion inhibitor and CCR5 antagonists; and integrase inhibitors.

1. Nucleoside and nucleotide reverse transcriptase inhibitors (NRTI)

—There are currently seven NRTI agents available and approved for use. The choice of which agent to use depends primarily on the patient's prior treatment experience, results of resistance testing, medication side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations (see Table 31–7) of either tenofovir/emtricitabine (TDF/FTC) or abacavir/lamivudine (ABC/3TC), both of which can be given once a day. Abacavir should only be given to HLA-B*5701-negative persons. In patients with viral loads greater than 100,000 copies/mL, ABC/3TC was less effective than tenofovir/emtricitabine when combined with efavirenz or ritonavir-boosted atazanavir. However, ABC/3TC appears to be equally efficacious as tenofovir/emtricitabine in patients with viral loads greater than 100,000 copies/mL when combined with dolutegravir or raltegravir. In some studies, abacavir increased risks of myocardial infarction, and therefore should be avoided in patients at high risk for cardiovascular disease. Zidovudine/lamivudine (AZT/3TC) is usually reserved for second- or third-line regimens because of toxicity and dosing schedule. Of the available agents, zidovudine is the most likely to cause anemia. Zidovudine and didanosine are the most likely to cause neutropenia. Stavudine is the most likely to cause lipodystrophy (loss of fat in the face, extremities, and buttocks) followed by zidovudine. Didanosine is the most likely to cause peripheral neuropathy. Lamivudine, emtricitabine, and tenofovir have activity against hepatitis B. Didanosine, lamivudine, emtricitabine, and tenofovir can be administered daily. Information specific to each medication is given below.

A. ZIDOVUDINE—Zidovudine was the first approved antiviral medication for HIV infection. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir;

Table 31–7. Fixed dose antiretroviral combinations.

Name	Components	Dosing and Special Considerations	Cost per month
Truvada	TDF 300 mg Emtricitabine 200 mg	One pill daily with a NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor). Most commonly used nucleoside/nucleotide reverse transcriptase inhibitor backbone.	\$1759.73
Epzicom	Abacavir 600 mg Lamivudine 300 mg	One pill daily with a NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor).	\$1550.05
Trizivir	Abacavir 300 mg Lamivudine 150 mg Zidovudine 300 mg	One tablet twice daily with a NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor). Although it contains three medications it <i>does not</i> constitute a complete treatment.	\$1931.64
Atripla	TDF 300 mg Emtricitabine 200 mg Efavirenz 600 mg	One pill daily constitutes a complete regimen.	\$2869.86
Stribild	TDF 300 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete regimen. Although it contains four medications, one component (Cobicistat) is a medication booster only.	\$3244.76
Genvoya	TAF 10 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete regimen. Although it contains four medications, one component (cobicistat) is a medication booster only. The only difference between Stribild and Genvoya is that Genvoya has a different form of tenofovir (TAF) that appears to be safer than tenofovir (TDF) with less effect on renal function and bone mineral density.	\$3093.19
Triumeq	Abacavir 600 mg Lamivudine 300 mg Dolutegravir 50 mg	One pill constitutes a complete regimen.	\$2889.22
Complera	TDF 300 mg Emtricitabine 200 mg Ralpivirine 25 mg	One pill daily constitutes complete regimen. Only for patients with HIV viral load less than 100,000/mL.	\$2815.04

TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate. Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: Red Book (electronic version), Truven Health Analytics Information, <http://www.micromedexsolutions.com/> accessed April 8, 2016. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

see Table 31–7) is available. Side effects seen with zidovudine are listed in Table 31–6. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipotrophy.

B. LAMIVUDINE—Lamivudine (3TC) is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced with chronic kidney disease. There are no significant side effects with lamivudine, and it has activity also against hepatitis B.

C. EMTRICITABINE—Emtricitabine is a nucleoside analog that is dosed at 200 mg orally. It was developed primarily as a once a day alternative to lamivudine. However, lamivudine can be dosed daily, eliminating the special indication for emtricitabine. As is true of lamivudine, emtricitabine has activity against hepatitis B and its dosage should be reduced in patients with chronic kidney disease.

D. ABACAVIR—A daily dose of 300 mg orally twice daily results in potent antiretroviral activity. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity

reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops *should not* be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir has also been associated with an increased risk of myocardial infarction in some cohort studies. This increased risk is generally seen in patients who have underlying risks of cardiovascular disease. Consequently, abacavir should not be used in such patients if effective alternative nucleoside or nucleotide analog agents exist. Abacavir is usually prescribed as a fixed-dose combination pill with lamivudine for use as a once daily pill (Epzicom; Table 31–7).

Abacavir is also formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily; Table 31–7). Trizivir is not recommended as solo treatment for HIV because it is not as efficacious as combining two nucleoside/nucleotide analogs with a ritonavir-boosted PI, an NNRTI, or an integrase inhibitor.

E. TENOFOVIR—Tenofovir is the only licensed nucleotide analog. It comes in two forms: tenofovir disoproxil

fumarate (TDF) and tenofovir alafenamide (TAF). TDF is the older form and is available both as a single medication with a daily oral dose of 300 mg and as a fixed-dose combination pill with emtricitabine (Truvada; Table 31–7) for daily dosing. Several single-tablet once-a-day complete regimens that include TDF (Atripla, Complera, Stribild) are available (Table 31–7). Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine. TDF is associated with a clinically modest loss of kidney function, a small increased risk of acute renal injury, and increased rate of bone resorption.

TAF is the newer form of the medication; it attains higher levels in cells with a much lower plasma level. For this reason, it appears to cause less harm to kidneys, less bone resorption, and appears to have stronger antiviral properties than TDF. It is available in a combination tablet with elvitegravir, cobicistat, and emtricitabine (Genvoya, Table 31–7). It is likely that the FDA will approve combinations containing TAF with emtricitabine, and TAF with rilpivirine and emtricitabine.

F. DIDANOSINE—The most convenient formulation of didanosine (ddI) is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine has been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine. Because of the side-effect profile, didanosine is rarely used today.

G. STAVUDINE—Because of its side effects including lipodystrophy, lipodystrophy, peripheral neuropathy and, rarely, lactic acidosis and hepatitis, stavudine (d4T) should no longer be used except when there is no alternative.

2. Nonnucleoside reverse transcriptase inhibitors—

NNRTI inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. All five NNRTI have shown antiviral activity as measured by HIV viral load and CD4 responses. The major advantage of the NNRTI is that three of them (efavirenz, rilpivirine, and nevirapine) have potencies comparable to that of PI (next section), at least for patients with viral loads under 100,000 copies/mL—with lower pill burden and fewer side effects. In particular, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of the NNRTI are distinct from those of the PI, so their use still leaves open the option for future PI use.

The NNRTI can be used with PI in patients who are difficult to suppress on simpler regimens or when it is difficult to identify at least two NRTI agents to which the patient is not resistant. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance among the “first-generation” NNRTIs, such that resistance to one medication in this class uniformly predicts resistance to other medications. However, the “second-generation” NNRTI etravirine appears to have consistent antiviral activity in patients with prior exposure and resistance to nevirapine, efavirenz, or delavirdine. In particular, the K103N mutation does not appear to have an impact on etravirine (or rilpivirine). There is no therapeutic reason for using more than one NNRTI at the same time.

A. EFAVIRENZ—The major advantages of efavirenz is that it can be given once daily in a single dose (600 mg orally), and it is available in a once-daily fixed-dose combination with tenofovir and emtricitabine in a single pill (Atripla; Table 31–7). The major side effects are rash and psychiatric/neurologic complaints, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. These side effects tend to wane over time, usually within a month or so; however, there are some patients who cannot tolerate these effects, especially if they persist longer than a month. Participant level data from four randomized trials of efavirenz regimens versus non-efavirenz containing regimens found increased suicidality (hazard ratio of 2.6) among those taking efavirenz. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Therefore, it should be taken on an empty stomach; taking before bedtime may also reduce patients’ experience of neuropsychiatric symptoms.

B. RILPIVIRINE—This medication, dosed at 25 mg once daily, is equal in efficacy to efavirenz in patients with HIV viral loads below 100,000 copies/mL. Rilpivirine should not be used in patients with baseline viral loads of 100,000 copies/mL or greater or those with CD4 counts below 200 cells/mL because of greater risk of viral failure. As is true of efavirenz, rilpivirine is available in a once-daily fixed-dose combination with tenofovir and emtricitabine (Complera; Table 31–7) to be taken with a fatty meal (at least 290 calories). Proton pump inhibitors should not be given with rilpivirine. Rilpivirine has fewer neurologic side effects than efavirenz.

C. NEVIRAPINE—The dose of nevirapine is 400 mg orally daily (extended release) but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg daily, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with CD4 counts greater than 250 cells/mL or in males with CD4 counts greater than 400 cells/mL because they have greater risk of hepatotoxicity.

In general, because of the risk of fatal hepatotoxicity, nevirapine should be used only when there is not a better alternative.

D. DELAVIRDINE—Of the available NNRTIs, delavirdine is used the least largely because of its inconvenient dosing and pill burden compared with the other available NNRTIs. Unlike nevirapine and efavirenz, delavirdine inhibits P450 cytochromes rather than inducing these enzymes. This means that delavirdine can act like ritonavir and boost other antiretrovirals, although delavirdine is not as potent as ritonavir in this capacity. The dosage is 400 mg orally three times a day. The major side effect is rash.

E. ETRAVIRINE—Etravirine is an NNRTI approved for the treatment of patients with prior NNRTI intolerance or resistance. Etravirine has been shown to be effective even when some degree of NNRTI-resistance is present, making it a true “second generation” medication in this class. Etravirine dosage is one 200-mg tablet twice daily. It should be used with a PI and an NRTI and not just with two NRTI. The most common side effects are nausea and rash; rarely, the rash can be severe (toxic epidermal necrolysis). Patients with signs of severe rash or hypersensitivity reactions should immediately discontinue the medication. Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine. Etravirine should not be taken by people with severe liver disease or administered with tipranavir/ritonavir, fosamprenavir/ritonavir, atazanavir/ritonavir, full-dose ritonavir, or PI without low-dose ritonavir.

3. Protease inhibitors—Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir (in combination with ritonavir), atazanavir, darunavir, and tipranavir are available. PIs are potent suppressors of HIV replication and are administered as part of a combination regimen.

All the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, medication interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Medications such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the medication levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. A second boosting agent, cobicistat, is coformulated with the PI atazanavir (Evotaz) and darunavir (Prescobix). Similar to ritonavir, cobicistat also inhibits liver enzymes that metabolize other HIV medications.

In fact, **guidelines recommend that all PI-containing regimens except nelfinavir use boosting if possible.**

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority

of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as **lipodystrophy**. Although lipodystrophy is commonly associated with PIs, it has been seen also in HIV-infected persons who have never been treated with these agents. In particular, the lipodystrophy effects seen in patients receiving ART appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs (stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. **All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 12 months.** Clinicians should assess for coronary heart disease risk (see Chapter 28) and consider initiating dietary changes or medication therapy (or both). PIs inhibit statin metabolism. Lovastatin and simvastatin should be avoided. In general, the least interaction is with pravastatin (20 mg daily orally). Atorvastatin (10 mg daily orally) or rosuvastatin (5 mg/day orally initially; maximum 10 mg/day) may also be used cautiously. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglyceride levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals). PIs are associated with abnormalities in cardiac conduction, especially prolongation of the PR interval.

A. INDINAVIR—Indinavir is usually dosed at 800 mg twice daily in combination with 100 mg of ritonavir twice daily. Nausea and headache are common complaints with this medication. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this medication should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the medication.

B. SAQUINAVIR—Saquinavir is formulated only as a hard-gel capsule (Invirase). It should only be used with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

C. RITONAVIR—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the

cytochrome P450 pathway causing a large number of drug–drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

D. NELFINAVIR—Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is generally not as potent as a boosted PI regimen (eg, lopinavir plus ritonavir). The dose of nelfinavir is 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, but this symptom may be controlled with over-the-counter antidiarrheal agents in most patients.

E. AMPRENAVIR—Amprenavir has efficacy and side effects similar to those of other PIs. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. The concentration of amprenavir decreases when coadministered with ethinyl estradiol; therefore, amprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

F. FOSAMPRENAVIR—Fosamprenavir is a prodrug of amprenavir. Its major advantage over using amprenavir is a much lower pill burden. For PI-naïve patients, it can be dosed at 1400 mg orally twice daily (four capsules a day) or at 1400 mg orally daily (two capsules) with ritonavir 200 mg orally daily (two capsules) or at 700 mg orally with ritonavir 100 mg orally twice daily. Patients previously treated with a PI should receive 700 mg orally with ritonavir 100 mg orally twice daily. Side effects are similar to those with amprenavir—most commonly gastrointestinal distress and hyperlipidemia. As with amprenavir, the concentration of fosamprenavir decreases when coadministered with ethinyl estradiol; therefore, fosamprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

G. LOPINAVIR/R—Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. It has been shown to be more effective than nelfinavir when used in combination with stavudine and lamivudine. The usual dose is 400 mg lopinavir with 100 mg of ritonavir (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent. Because of these side effects, lopinavir/r has fallen off the list of medications recommended as part of first-line treatment regimens.

H. ATAZANAVIR—Atazanavir is available alone and coformulated with cobicistat (Evotaz). Atazanavir can be dosed as 400 mg (two 200-mg capsules) daily with food or it can be dosed as 300 mg in combination with 100 mg of ritonavir once daily with food. When coformulated with cobicistat, it is dosed at 300 mg atazanavir and 150 mg cobicistat. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the medication. Nephrolithiasis and cholelithiasis have also been reported with this PI. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of

these two medications is used with atazanavir, it should be boosted by administering ritonavir or given coformulated with cobicistat. Proton pump inhibitors are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

I. TIPRANAVIR—Tipranavir is the only nonpeptidic PI approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250 mg capsules of tipranavir with two 100 mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfa-containing medication, its use should be closely monitored in patients with sulfa allergy.

J. DARUNAVIR—Darunavir has impressive antiviral activity in the setting of significant PI resistance and in treatment-naïve patients. It is formulated by itself and coformulated with cobicistat (Prezcobix). When formulated without cobicistat it requires boosting with ritonavir. For initial treatment of HIV or for treatment-experienced patients without darunavir-related resistance mutations, daily dosing is 800 mg of darunavir with 100 mg of ritonavir or with 150 mg of cobicistat. For patients with prior PI treatment experience or PI resistance (with mutations known to impact darunavir), darunavir should be dosed at 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily. Darunavir has a safety profile similar to other PIs, such as ritonavir-boosted lopinavir, but is generally better tolerated. Like tipranavir, darunavir is a sulfa-containing medication, and its use should be closely monitored in patients with sulfa allergy.

4. Entry inhibitors—

A. ENFUVIRTIDE—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients, which makes long-term use problematic.

B. MARAVIROC—Maraviroc is a CCR5 co-receptor antagonist. Medications in this class prevent the virus from entering uninfected cells by blocking the CCR5 co-receptor. Before starting therapy, a viral tropism assay should be performed because this class of entry inhibitors is only active against “CCR5-tropic virus.” This form of the HIV-1 virus tends to predominate early in infection, while so-called “dual/mixed tropic virus” (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection

progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The medication has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. The dose of maraviroc is 150–300 mg orally twice daily, based on the other medications the patient is taking at the time—in combination with a ritonavir boosted PI, 150 mg daily of maraviroc has been used successfully. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness; however, maraviroc is generally well tolerated with limited impact on serum lipids.

5. Integrase inhibitors—Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. Three integrase inhibitors are available: raltegravir, elvitegravir, and dolutegravir. Clinical trials of all integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. The clinical significance of this observation is unclear. Integrase inhibitors are effective (when combined with other active medications) in the treatment of HIV-infected patients with documented resistance to each of the three main classes of antiretroviral medications (nucleoside analogs, PIs, NNRTIs). Avoid administering with antacids or other medications with divalent cations (Ca^{2+} , Mg^{2+} , Al^{2+} , Fe^{2+}) because chelation of the integrase inhibitor by the cation reduces absorption. When these medications must be taken with integrase inhibitors, consult a pharmacist to determine the best separation of times of administration.

A. RALTEGRAVIR—The dose of raltegravir is 400 mg orally twice daily. It has been found to be superior to efavirenz and ritonavir-boosted darunavir and ritonavir-boosted atazanavir. Common side effects are diarrhea, nausea, and headache, but overall it is well tolerated and has the additional advantage over PI-based regimens and efavirenz-based regimens in that it appears to have little impact on lipid profiles or glucose metabolism.

B. ELVITEGRAVIR—Elvitegravir has been studied only in treatment naïve patients. It has the advantage of being available in a combination pill (Stribild) (Table 31–7) that contains 125 mg of elvitegravir and 150 mg of cobicistat, a boosting agent, along with standard doses of TDF and emtricitabine. Stribild has been shown to be noninferior to two preferred first-line regimens: Atripla and boosted atazanavir with tenofovir/emtricitabine. The main side effects include increases in serum creatinine levels which has been shown to be related to the cobicistat inhibition of tubular secretion of creatinine by the kidney and is thought to be nonpathologic and reversible. However, because of this effect, Stribild is recommended in treatment-naïve patients with estimated creatinine clearance greater than 70 mL/min. A urine analysis should be done at baseline and at initial follow-up to look for proteinuria and glycosuria, which are signs of tubulopathy. Diarrhea and rash may also occur, although overall the medication is well tolerated. Elvitegravir is also coformulated with TAF along with emtricitabine and cobicistat boosting in a single once a day

pill (Genvoya). Since TAF appears to have greater activity and fewer side effects than TDF, this is likely to become the preferred elvitegravir regimen.

C. DOLUTEGRAVIR—Dolutegravir shows excellent potency and tolerability and is dosed once-a-day in most circumstances. Unlike elvitegravir, dolutegravir does not require a boosting agent. Similar to cobicistat, it inhibits tubular secretion of creatinine by the kidney, resulting in small increases in serum creatinine levels. The standard dosage used in treatment-naïve, integrase-naïve patients is 50 mg/day. It is available combined with abacavir and lamivudine in a single once a day tablet (Triumeq, Table 31–7). In patients receiving efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin, the dose should be increased to 50 mg twice daily. It should also be dosed at 50 mg twice daily in integrase-experienced patients in whom integrase resistance is suspected. Indeed, when combined with other active medications, it has been shown to provide some activity in patients with integrase resistance who have not responded to prior raltegravir- or elvitegravir-containing regimens. Dolutegravir has demonstrated impressive results from clinical trials of treatment-naïve patients when compared with the more standard NNRTI, boosted PI, and raltegravir-containing regimens.

6. Constructing regimens—Only combinations of three or more medications from two or more classes have been able to decrease HIV viral load by 2–3 logs and provide durable suppression of HIV RNA to below the threshold of detection.

Six antiretroviral regimes are recommended for initiating treatment (Table 31–8). These regimens are recommended because of their combination of antiviral potency and tolerability as well as dosing convenience. Of note, five out of the six regimens use integrase inhibitors, indicating the greater efficacy and tolerability of this class compared to other classes that can be combined with NRTI backbones. Studies have shown dolutegravir/abacavir/lamivudine to be superior to efavirenz/TDF/emtricitabine and have shown dolutegravir to be superior to ritonavir-boosted darunavir (both combined with either abacavir/lamivudine or TDF/emtricitabine). A network meta-analysis adjusting for NRTI backbone found that dolutegravir had superior efficacy in suppressing viral load compared with regimens containing ritonavir-boosted atazanavir, ritonavir-boosted darunavir, efavirenz, or ritonavir-boosted lopinavir. Discontinuation due to adverse events was also statistically lower in the dolutegravir regimens.

The integrase inhibitor raltegravir has done well in comparative studies. Among treatment-naïve patients, raltegravir in combination with TDF/emtricitabine is as effective as efavirenz/TDF/emtricitabine for daily treatment and has fewer side effects. In a 5-year follow-up to the double-blind trial, the raltegravir arm out-performed the efavirenz combination regimen largely due to better long-term tolerability. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination.

Three of the recommended integrase inhibitor/NRTI regimens are available in a single pill that can be dosed just

Table 31–8. Recommended and alternative initial antiretroviral regimens.¹ (continued)

Regimen	Advantages	Disadvantages
Recommended		
Dolutegravir + abacavir + lamivudine ² (Triumeq)	Single pill once-a-day regimen Has activity in some patients with integrase resistance Superior to Atripla Dolutegravir plus either abacavir/lamivudine or emtricitabine/TDF superior to darunavir/ritonavir plus either of the NRTI backbones	Abacavir should be used only in HLA-B*5701-negative persons When used in patients with integrase resistance or combined with certain other medications, requires twice a day dosing Avoid antacids and other medications with divalent cations (Ca ²⁺ , Mg ²⁺ , Al ²⁺ , Fe ²⁺)
Dolutegravir (50 mg daily) + emtricitabine/TDF (Truvada)	Has activity in some patients with integrase resistance Once-a-day regimen	No single tablet available When used in patients with integrase resistance or combined with certain other medications, requires twice a day dosing Avoid antacids and other medications with divalent cations (Ca ²⁺ , Mg ²⁺ , Al ²⁺ , Fe ²⁺)
Emtricitabine/TAF/elvitegravir with cobicistat boosting (Genvoya)	Single tablet once-a-day regimen Excellent response across broad range of CD4 and viral loads Contains TAF instead of TDF and is therefore less nephrotoxic and less likely to lead to bone resorption when compared with Stribild	Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic) No dosage adjustment with estimated creatinine clearance > 30 mL/min Avoid antacids and other medications with divalent cations (Ca ²⁺ , Mg ²⁺ , Al ²⁺ , Fe ²⁺)
Emtricitabine/TDF/elvitegravir with cobicistat boosting (Stribild)	Single tablet once-a-day regimen Excellent response across broad range of CD4 and viral loads	Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic) Requires estimated creatinine clearance ≥ 70 mL/min Avoid antacids and other medications with divalent cations (Ca ²⁺ , Mg ²⁺ , Al ²⁺ , Fe ²⁺)
Raltegravir (400 mg twice daily) + emtricitabine/TDF (Truvada)	Superior to Atripla over 5 years of follow-up	Requires twice a day dosing No single tablet available Avoid antacids and other medications with divalent cations (Ca ²⁺ , Mg ²⁺ , Al ²⁺ , Fe ²⁺)
Darunavir (800 mg daily) with ritonavir (100 mg daily) boosting + emtricitabine/TDF (Truvada)	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet. May cause rash in patients with sulfa allergy. Ritonavir boosting required. Has metabolic side effects.
Alternative regimens		
TDF/emtricitabine/efavirenz (Atripla)	Single tablet once-a-day regimen Longest term clinical experience Highly effective across broad range of initial CD4 counts and viral loads	Avoid in patients with transmitted K103N Neuropsychiatric symptoms common and can be persistent
TDF/emtricitabine/rilpivirine (Complera)	Single tablet once-a-day regimen Noninferior to Atripla in patients with baseline viral load < 100,000/mcL Limited metabolic side-effects	Requires taking with a meal Cannot be used with proton pump inhibitors Use only in patients with viral loads < 100,000/mcL and CD4 counts > 200 cells/mcL
Atazanavir (300 mg daily) coformulated with 150 mg cobicistat + emtricitabine/TDF (Truvada)	Once-a-day regimen. Limited risk of resistance with poor adherence Resistance to atazanavir generally does not confer resistance to other PI	Not available as a single tablet Increases in bilirubin (nonpathologic) Increased risk of cholelithiasis, nephrolithiasis, and chronic kidney injury Has metabolic side effects Should be taken with food and H ₂ -blockers and proton pump inhibitors should be avoided Requires estimated creatinine clearance > 70 mL/min
Atazanavir (300 mg daily) with ritonavir (100 mg daily) boosting + emtricitabine/TDF (Truvada)	Once-a-day regimen Limited risk of resistance with poor adherence Resistance to atazanavir generally does not confer resistance to other PI	Not available as a single tablet Increases in bilirubin (nonpathologic) Increased risk of cholelithiasis, nephrolithiasis, and chronic kidney injury Has metabolic side effects Should be taken with food and H ₂ -blockers and proton pump inhibitors should be avoided

(continued)

Table 31–8. Recommended and alternative initial antiretroviral regimens.¹ (continued)

Regimen	Advantages	Disadvantages
Darunavir (800 mg daily) coformulated with cobicistat (150 mg daily) + abacavir/lamivudine (Epzicom)	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet May cause rash in patients with sulfa allergy Has metabolic side effects
Darunavir (800 mg daily) with ritonavir (100 mg daily) boosting + abacavir/lamivudine (Epzicom)	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet May cause rash in patients with sulfa allergy Has metabolic side effects
Darunavir (800 mg daily) coformulated with cobicistat (150 mg daily) + emtricitabine/TDF (Truvada)	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet Requires creatinine clearance >70 mL/min May cause rash in patients with sulfa allergy Has metabolic side effects

²Usual medication doses are supplied when not part of a fixed-dose preparation.

TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

once a day (Triumeq, Genvoya, and Stribild). Seven alternative regimens that are generally not as good but may be indicated in certain populations are also listed in Table 31–8. **Resistance testing should be performed prior to starting ART.** Of newly infected persons in some urban areas of the United States, 8–10% have NNRTI resistance (primarily K103N). Patients with NNRTI resistance would not be expected to respond fully to an efavirenz-based regimen. The boosted PI regimens require more pills, have many drug-drug interactions and may have additional undesirable metabolic impacts. In patients with increased risk of metabolic abnormalities or comorbidities, the dolutegravir or raltegravir integrase regimens should be considered preferred choices.

In constructing regimens, toxicities should be nonoverlapping and agents that are either virologically antagonistic or incompatible in terms of drug-drug interactions should be avoided. For example, the combination of stavudine plus didanosine should be avoided, since there is increased risk of toxicities, in particular in pregnant women because of the increased risk of lactic acidosis, which can be fatal. Moreover, the nucleoside pair of zidovudine and stavudine should be avoided because of increased toxicity and the potential for antagonism that results from intracellular competition for phosphorylation. The combination of didanosine with tenofovir should be avoided because of observed declines in CD4 counts. Etravirine should not be used with boosted tipranavir because of drug-drug interactions. Lamivudine and emtricitabine are essentially the same medication and so are not used together.

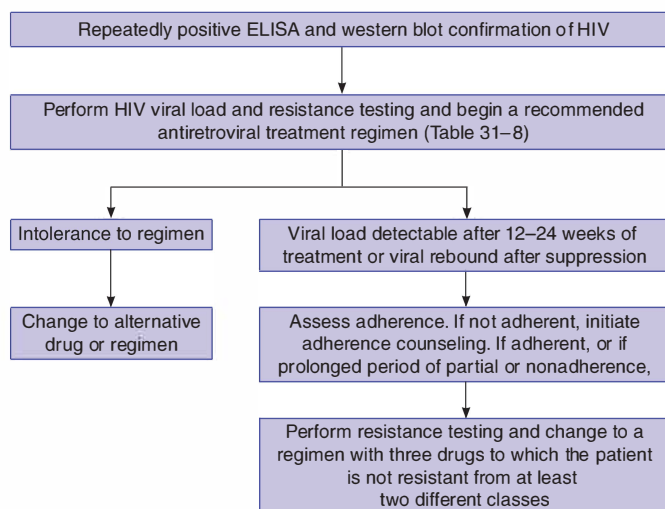

The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere (Figure 31–2). In general, patients are more compliant with medication regimens (Table 31–8) that offer a complete regimen in one pill that needs to be

taken only once or twice a day, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. Given the high level of effectiveness of recommended regimens, patients for whom the viral load does not fully suppress are likely noncompliant. Pharmacists and other specially trained clinicians can be very effective in helping patients improve their adherence by taking the time to understand why patients miss their medications and problem solve (eg, take medicine at same time every day, keep a supply in the car or at work in case you forget.) For certain populations (eg, unstably housed individuals), specially tailored programs that include medication dispensing are needed.

E. Monitoring ART

1. Goals of monitoring ART—Monitoring of ART has two goals: evaluate for toxicity and measure efficacy using objective markers. Laboratory evaluation for toxicity depends on the specific medications in the combination but generally should be done approximately every 3–4 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen (eg, patients who cannot tolerate the neurologic side effects of efavirenz) should be changed to an alternative medication or regimen. The second aspect of monitoring is to regularly measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 3–6 months thereafter in clinically stable patients. (Patients receiving ART with undetectable viral load for 2 years and CD4 counts 300 cells/mL or more may have CD4 testing only every 12 months.)

2. The challenge of compliance—In a patient who is adherent to an effective regimen, viral loads should be

▲ **Figure 31-2.** Approach to initial and subsequent antiretroviral therapy.

undetectable within 12–24 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is **whether the patient is nonadherent or has resistance to the regimen, or both**. The issue is complicated because many patients report being more compliant than they really are. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply with their treatment. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing should be performed. Based on the results of resistance testing, and assessment of the patient's ability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance.

Once ART has been initiated, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called “drug holidays” or “structured treatment interruptions” have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non-AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

3. The challenge of medication resistance—HIV-1 medication resistance limits the ability to fully control HIV replication and remains an important cause for antiretroviral regimen failure. **Resistance has been documented for all currently available antiretrovirals including the newer classes of fusion inhibitor, CCR5 inhibitors, and integrase inhibitors.** The problem of medication resistance is widespread in HIV-infected patients undergoing treatment in countries where ART is widely available. However, reports suggest that the degree of high level resistance is declining in the past few years, which is likely related to better tolerated, easier to use, and more efficacious antiretroviral agents. Resistance also occurs in patients who are ART-naïve, but who have been infected

with a medication resistant strain—primary resistance or transmitted medication resistance. Cohort studies of ART-naïve patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a medication-resistant strain of HIV-1.

In addition to being performed as part of a standard baseline, resistance testing is also recommended for patients who are receiving ART and have suboptimal viral suppression (ie, viral loads greater than 200 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during ART are medication-specific or contribute to broad cross-resistance to multiple medications within a therapeutic class. An example of a medication-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two medications. Conversely, the thymidine analog mutations (“TAMs”) of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the medications in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one medication can actually make the virus that contains this mutation more sensitive to

another medication. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with medication resistance and cross-resistance patterns for NRTIs, NNRTIs, PIs, and integrase inhibitors can be found at <http://hivdb.stanford.edu>. Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available medications.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing because the dominant virus is likely the wild-type, even if there are resistant viruses in the body that can become dominant with the selective pressure of antivirals. Thus, resistance results do not replace a careful history of what medications a patient has taken in the past and for how long. Also, the results of resistance testing should be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three medications from at least two different classes to which the virus is not resistant. Even without resistance testing certain forms of cross-resistance between medications within a class can be assumed. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping—as are the resistance patterns between raltegravir and elvitegravir.

Given the availability of new class medications and new generation medications, **a combination of ART can successfully treat virtually all patients—no matter how much resistance is present.**

Course & Prognosis

With improvements in therapy, patients who are compliant with treatment should have near normal life spans. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy similar to that of an uninfected 25-year-old. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

When to Refer

- HIV-infected patients should be referred to specialists, given the increasing number of treatment regimens available.

- Extra efforts should be made to obtain specialty consultation for those patients with detectable viral loads on ART; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

When to Admit

Patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

VIRAL DISEASES

HUMAN HERPESVIRUSES

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- ▶ Spectrum of illness from stomatitis and urogenital lesions to facial nerve paralysis (Bell palsy) and encephalitis.
- ▶ Variable intervals between exposure and clinical disease, since HSV causes both primary (often subclinical) and reactivation disease.

General Considerations

Herpes simplex viruses 1 and 2 affect primarily the oral and genital areas, respectively. Asymptomatic shedding of either virus is common and may be responsible for transmission. Asymptomatic HSV-2-infected individuals shed the virus less frequently than those with symptomatic infection. Disease typically indicates reactivation. Total and subclinical shedding of HSV-2 virus decreases after the first year of initial infection, although viral shedding continues for years thereafter.

Although HSV-2 is the most common cause of genital ulcers in the developed world, epidemiologic studies show that HSV-1 is a more common cause of both genital and oral lesions than HSV-2 in young women in the United States. Most HSV-2 infected persons in the United States are unaware that they are infected.

HSV-2 seropositivity increases the risk of HIV acquisition (it is threefold higher among persons who are HSV-2 seropositive than among those who are HSV-2 seronegative), and reactivates more often in advanced HIV infection. HIV replication is increased by interaction with HSV proteins. Suppression of HSV-2 decreases HIV-1 plasma levels and genital tract shedding of HIV, which can contribute to a reduction in the sexual transmission of HIV-1.

Clinical Findings

A. Symptoms and Signs

1. Mucocutaneous disease—See Chapter 6 for **HSV-1 mucocutaneous disease** involving the mouth and oral cavity (“herpes labialis” or “gingivostomatitis;” the latter largely in children). Digital lesions (**whitlows**) (Figure 32–1) are an occupational hazard in medicine and dentistry. Contact sports (eg, wrestling) are associated with outbreaks of skin infections (“herpes gladiatorum”). Asymptomatic shedding of HSV-1 is frequent, with most infected individuals shedding virus at least once a month.

Vesicles form moist ulcers after several days and epithelialize over 1–2 weeks if untreated. Primary infection is usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine, azathioprine) or other undetermined factors.

HSV-2 lesions largely involve the genital tract, with the virus remaining latent in the presacral ganglia (see Chapter 6). Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women. Proctitis and extensive, ulcerating, weeping sacral lesions may be presenting symptoms in HIV-infected persons with CD4 cytopenia. Large ulcerations and atypical lesions suggest drug-resistant isolates.

2. Ocular disease—HSV can cause keratitis, blepharitis, and keratoconjunctivitis. Keratitis is usually unilateral and is often associated with impaired visual acuity. Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. Recurrences of ocular disease are frequent. HSV is the second most common cause, after VZV, of acute retinal necrosis.

3. Neonatal and congenital infection—Both herpesviruses rarely infect the fetus and induce congenital malformations (organomegaly, bleeding, and central nervous system [CNS] abnormalities). Maternal infection during the third trimester is associated with the highest risk of neonatal transmission, but about 70% of these infections are asymptomatic or

▲ **Figure 32-1.** Herpetic whitlow. (Reproduced, with permission, from Richard P. Usatine, MD.)

unrecognized. Neonatal transmission during delivery, however, is more common than intrauterine infection. Invasive fetal monitoring and vacuum or forceps delivery increase the risk of herpesvirus transmission.

4. CNS disease—Traditionally, herpes simplex encephalitis is associated with HSV-1 infection and aseptic meningitis with HSV-2. However, both viruses can cause encephalitis. Encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality rate. Many survivors suffer neurologic sequelae, which are observed more frequently among patients with HSV-1. Both HSV-1 and HSV-2 are increasingly recognized as causes of mild, nonspecific neurologic symptoms and are also associated with benign recurrent lymphocytic (Mollaret) meningitis.

5. Disseminated infection—Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns. Pneumonia can occur regardless of immune status.

6. Bell palsy—HSV-1 is a cause of Bell palsy.

7. Esophagitis and proctitis—HSV-1 can cause esophagitis in immunocompromised patients, particularly those with AIDS. The lesions are smaller and deeper than those observed in patients with cytomegalovirus (CMV) esophagitis or with other herpesviruses known to cause esophagitis in immunocompromised persons. Proctitis occurs mainly in men who have sex with men.

8. Erythema multiforme—Herpes simplex viruses remain, along with certain drugs, a leading cause of erythema multiforme minor (“herpes-associated erythema multiforme”) and of the more severe condition Stevens-Johnson syndrome/toxic epidermal necrolysis (see also Chapter 6).

9. Other—HSV is the cause of approximately 1% of cases of acute liver failure, particularly in pregnant women and immunosuppressed patients. The mortality of such rare fulminant hepatitis is nearly 75%. An HSV lower respiratory tract infection of unknown clinical significance is common in mechanically ventilated patients. Evidence suggests that this finding is usually an indicator rather than the cause of a poor clinical condition. HSV-1 pneumonia is associated with high morbidity in patients with solid tumors. HSV-1 is reported to be a cause of perinephric abscess, febrile neutropenia, chronic urticaria, and esophagitis and enteritis in systemic lupus erythematosus. HSV is also associated with *Helicobacter pylori*-negative upper gastrointestinal tract ulcers.

B. Laboratory Findings

1. Mucocutaneous disease—See Chapter 6.

2. Ocular disease—Herpes keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein. The extent of epithelial injury in herpes keratitis correlates well with polymerase chain reaction (PCR) positivity.

3. Encephalitis and recurrent meningitis—Cerebrospinal fluid pleocytosis is common, with a similar increase in the number of red cells although cerebrospinal fluid findings may be atypical in immunosuppressed patients. HSV DNA PCR of the cerebrospinal fluid is a rapid, sensitive, and specific tool for early diagnosis and can be included in a multiple rapid array panel. Viral detection by this method can be delayed and should be repeated if the clinical picture is consistent. Antibodies to HSV in cerebrospinal fluid can confirm the diagnosis but appear late in disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be shown on electroencephalograms (EEGs).

4. Esophagitis and proctitis—Esophagitis is diagnosed by endoscopic biopsy with real-time PCR and cultures. Proctitis may be diagnosed by rectal swab for PCR, culture, or both. Complicated cases may require biopsy.

5. Pneumonia—Pneumonia is diagnosed by clinical, pathologic, and radiographic findings. The CT findings include diffuse or multifocal areas of ground-glass attenuation or consolidative changes or both and are best confirmed by using high-resolution CT techniques.

▶ Treatment & Prophylaxis

Medications that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32-1).

A. Mucocutaneous Disease

See Chapter 6.

B. Keratitis

For the treatment of acute epithelial keratitis, oral antiviral agents such as valacyclovir or famciclovir are first-line therapies. Alternatives include topical antiviral agents (ophthalmic

Table 32–1. Agents for viral infections.¹

Drug	Dosing	Spectrum	Toxicities
Acyclovir	200–800 mg orally five times daily; 250–500 mg/m ² intravenously every 8 hours for 7 days	HSV, VZV	Neurotoxic reactions, reversible renal dysfunction, local reactions
Amantadine	200 mg daily orally, once daily in the elderly	Influenza A (not H1N1)	Confusion
Cidofovir	5 mg/kg intravenously weekly for 2 weeks, then every other week	CMV	Neutropenia, renal failure, ocular hypotonia
Famciclovir	500 mg orally three times daily for 7 days for acute VZV; 250 mg three times daily for 7–10 days for genital or cutaneous HSV-1/HSV-2 infection; 125 mg twice daily for 5 days for recurrences (500 mg twice daily for 7 days if HIV-infected)	HSV, VZV	Early angioedema; later rarely, gastrointestinal symptoms, headaches, rashes
Fomivirsen	165 mcg by intravitreal injection once weekly for 3 weeks, then every other week	CMV	Ocular inflammation, retinal detachment
Foscarnet	20 mg/kg intravenous bolus, then 120 mg/kg intravenously every 8 hours for 2 weeks; maintain with 60 mg/kg/day intravenously for 5 days each week	CMV, HSV resistant to acyclovir, VZV, HIV-1	Nephrotoxicity, genital ulcerations, calcium disturbances
Ganciclovir	5 mg/kg intravenous bolus every 12 hours for 14–21 days; maintain with 3.75 mg/kg/day intravenously for 5 days each week	CMV	Neutropenia, thrombocytopenia, CNS side effects
Idoxuridine	Topical, 0.1% every 1–2 hours for 3–5 days	HSV keratitis	Local reactions
Interferon alpha-2b	3–5 million international units subcutaneously three times weekly to daily. Intralesionally: 1 million international units per 0.1 mL in up to five warts three times weekly for 3 weeks	HBV, HCV, HPV	Influenza-like syndrome, myelosuppression, neurotoxicity
Interferon alpha-n3	0.05 mL/wart biweekly up to 8 weeks 3 milli-units intravenously three times per week	HPV HCV	Local reactions Influenza-like syndrome, myelosuppression, neurotoxicity
Laninamivir (CS-8958)	40 mg single inhaled dose	Influenza A and B	Under study (medication is marketed in Japan)
Oseltamivir	75 mg orally twice daily for 5 days beginning 48 hours after onset of symptoms	Influenza A and B	Few
Palivizumab	15 mg/kg intramuscularly every month in RSV season	RSV	Upper respiratory infection symptoms
Penciclovir	Topical 1% cream every 2 hours for 4 days	HSV	Local reactions
Peramivir	Intravenous, 600 mg single dose	Influenza (H1N1)	Nausea, vomiting, diarrhea, neutropenia
Ribavirin	Aerosol: 1.1 g/day as 20 mg/mL dilution over 12–18 hours for 3–7 days (See text for Lassa fever doses.)	RSV, severe influenza A or B, Lassa fever	Wheezing
Rimantadine	100 mg twice daily orally, once daily in the elderly	Influenza A (not H1N1)	Confusion
Trifluridine	Topical, 1% drops every 2 hours to 9 drops/day	HSV keratitis	Local reactions
Valacyclovir	1 g orally three times daily for 7 days for acute VZV; 1 g twice daily for primary genital HSV-1/HSV-2 infection with 500 mg three times daily for recurrences	VZV, HSV	Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome in AIDS
Valganciclovir	900 mg orally twice daily for 3 weeks; 900 mg daily as maintenance	CMV	See ganciclovir
Vidarabine	15 mg/kg/day intravenously for 10 days	HSV, VZV	Teratogenic, megaloblastosis, neurotoxicity
Zanamivir	2–5 mg inhalations twice daily for 5 days	Influenza A and B	Few

¹Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31. Agents used in the management of HBV and HCV infections are found in Chapter 16.

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

trifluridine, vidarabine, acyclovir, and ganciclovir), which are all nearly equivalent in efficacy. Intravenous acyclovir is used for acute retinal necrosis. The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (more than 1 year) with acyclovir at a dosage of 800 mg/day orally decreases recurrence rates of keratitis, conjunctivitis or blepharitis due to HSV.

C. Neonatal Disease

Intravenous acyclovir (20 mg/kg every 8 hours for 14–21 days) is effective for the treatment of disseminated lesions in neonatal disease. Counseling with serologic screening should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg three times daily) beginning at 36 weeks gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean delivery. Cesarean delivery is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

D. Encephalitis and CNS Meningitis

Because of the need for rapid treatment to decrease mortality and neurologic sequelae, intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney dysfunction) should be started in those patients with suspected HSV encephalitis, stopping only if another diagnosis is established. If the PCR of cerebrospinal fluid is negative but clinical suspicion remains high, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. HSV viral load does not appear to correlate with outcome of meningitis, and it is not recommended to follow viral load over time.

Long-term neurologic sequelae of HSV encephalitis are common and late pediatric relapse is recognized. Acyclovir resistance in a case of herpes simplex encephalitis is reported. Aseptic meningitis may also require a course of intravenous acyclovir or valacyclovir. Long-term oral prophylaxis with valacyclovir, however, does not appear to prevent recurrences of aseptic meningitis with HSV-2.

E. Disseminated Disease

Disseminated disease responds best to parenteral acyclovir when treatment is initiated early.

F. Bell Palsy

Prednisolone, 25 mg orally twice daily for 10 days started within 72 h of onset, significantly increases the rate of recovery. Data on antiherpes antiviral agents are equivocal; according to one study, valacyclovir (but not acyclovir), 1 g orally daily for 5 days, plus corticosteroid therapy may be beneficial if started within 7 days of symptom onset. In patients with severe or complete facial paralysis, such antiviral therapy is often administered but without proof of efficacy.

G. Esophagitis and Proctitis

Patients with esophagitis should receive either intravenous acyclovir (5–10 mg/kg every 8 hours) or oral acyclovir

(400 mg five times daily) through resolution of symptoms, typically 3–5 days; however, longer treatment may be necessary for immunosuppressed patients. Maintenance therapy for AIDS patients is also with acyclovir (400 mg three to five times daily). Proctitis is treated with similar dosages and usually responds within 5 days.

H. Erythema Multiforme

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg twice a day) may be effective in cases unresponsive to acyclovir.

Prevention

Besides antiviral suppressive therapy (see above and Chapter 6), prevention also requires counseling and the use of condom barrier precautions during sexual activity. Disclosure to sexual partners of HSV-seropositive status is associated with about a 50% reduction in HSV-2 acquisition. Male circumcision is associated with a lower incidence of acquiring HSV-2 infection.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and the usage of handwashing and gloving–gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. There is no approved herpes vaccine.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

ESSENTIALS OF DIAGNOSIS

- ▶ **Varicella rash:** pruritic, centrifugal, papular changing to vesicular (“dewdrops on a rose petal”), pustular, and finally crusting.
- ▶ **Zoster rash:** tingling, pain, eruption of vesicles in a dermatomal distribution, evolving to pustules and then crusting.

▶ General Considerations

Varicella zoster virus (VZV), or HHV-3, disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox generally presents during childhood; has an incubation period of 10–20 days (average 2 weeks); and is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster (“shingles”), which affects up to 25% of persons during their lifetime, increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years, and the incidence of herpes zoster reaches 10 cases per 1000 patient-years by age 80 (by which time 50% are infected with VZV). The annual incidence in the United States of 1 million cases is

increasing as the population ages. Populations at increased risk for varicella-zoster–related diseases include immunosuppressed persons and persons receiving biologic agents (eg, tumor necrosis factor [TNF] inhibitors).

▶ Clinical Findings

A. Varicella

1. Symptoms and signs—Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities (Table 32–2). Maculopapules change in a few hours to vesicles that become pustular and eventually form crusts (Figures 32–2 and 32–3). New lesions may erupt for 1–5 days, so that different stages of

Table 32–2. Diagnostic features of some acute exanthems.

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Atypical measles	Same as measles.	Maculopapular centripetal rash, becoming confluent.	History of measles vaccination.	Measles antibody present in past, with titer rise during illness.
Chikungunya fever	2–4 (sometimes 1–12) days, fever, headaches, abdominal complaints, myalgias, arthralgias.	Maculopapular, centrally distributed, pruritus, can be bullous with sloughing in children, occasional facial edema and petechiae.	History of mosquito bites, epidemiologic factors.	ELISA-based IgM or IgG (four-fold increase in titers); PCR and cultures are infrequently available.
Eczema herpeticum	None.	Vesiculopustular lesions in area of eczema.		Herpes simplex virus isolated in cell culture. Multinucleate giant cells in smear of lesion.
Ehrlichiosis	Headache, malaise.	Rash in one-third, similar to Rocky Mountain spotted fever.	Pancytopenia, elevated liver function tests.	Polymerase chain reaction, immunofluorescent antibody.
Enterovirus infections	1–2 days of fever, malaise.	Maculopapular rash resembling rubella, rarely papulovesicular or petechial.	Aseptic meningitis.	Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise.
Erythema infectiosum (parvovirus B19)	None. Usually in epidemics.	Red, flushed cheeks; circumoral pallor; maculopapules on extremities.	“Slapped face” appearance.	White blood count normal.
Exanthema subitum (HHV-6, 7; roseola)	3–4 days of high fever.	As fever falls, pink maculopapules appear on chest and trunk; fade in 1–3 days.		White blood count low.
Infectious mononucleosis (EBV)	Fever, adenopathy, sore throat.	Maculopapular rash resembling rubella, rarely papulovesicular.	Splenomegaly, tonsillar exudate.	Atypical lymphocytes in blood smears; heterophile agglutination (Monospot test).
Kawasaki disease	Fever, adenopathy, conjunctivitis.	Cracked lips, strawberry tongue, maculopapular polymorphous rash, peeling skin on fingers and toes.	Edema of extremities. Angiitis of coronary arteries.	Thrombocytosis, electrocardiographic changes.
Measles (rubeola)	3–4 days of fever, coryza, conjunctivitis, and cough.	Maculopapular, brick red; begins on head and neck; spreads downward and outward, in 5–6 days rash brownish, desquamating. See Atypical Measles, above.	Koplik spots on buccal mucosa.	White blood count low. Virus isolation in cell culture. Antibody tests by hemagglutination inhibition or neutralization.

(continued)

Table 32–2. Diagnostic features of some acute exanthems. (continued)

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Meningococemia	Hours of fever, vomiting.	Maculopapules, petechiae, purpura.	Meningeal signs, toxicity, shock.	Cultures of blood, cerebrospinal fluid. White blood count high.
Rocky Mountain spotted fever	3–4 days of fever, vomiting.	Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms).	History of tick bite.	Indirect fluorescent antibody; complement fixation.
Rubella	Little or no prodrome.	Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days. No desquamation.	Lymphadenopathy, postauricular or occipital.	White blood count normal or low. Serologic tests for immunity and definitive diagnosis (hemagglutination inhibition).
Scarlet fever	One-half to 2 days of malaise, sore throat, fever, vomiting.	Generalized, punctate, red; prominent on neck, in axillae, groin, skin folds; circumoral pallor; fine desquamation involves hands and feet.	Strawberry tongue, exudative tonsillitis.	Group A beta-hemolytic streptococci in cultures from throat; antistreptolysin O titer rise.
Smallpox	Fever, malaise, prostration.	Maculopapules to vesicles to pustules to scars (lesions develop at the same pace).	Centrifugal rash; fulminant sepsis in small percentage of patients, gastrointestinal and skin hemorrhages.	Contact CDC ¹ for suspicious rash; EM and gel diffusion assays.
Typhus	3–4 days of fever, chills, severe headaches.	Maculopapules, petechiae, initial distribution centrifugal (trunk to extremities).	Endemic area, lice.	Complement fixation.
Varicella (chickenpox)	0–1 day of fever, anorexia, headache.	Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal.	Lesions on scalp and mucous membranes.	Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions.

¹<http://www.bt.cdc.gov/agent/smallpox/response-plan/>.

EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; HHV, human herpesvirus; Ig, immunoglobulin; PCR, polymerase chain reaction.

the eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Pitted scars are frequent. Although the disease is often mild, complications (such as secondary bacterial infection, pneumonitis, and encephalitis) occur in about 1% of cases and often lead to hospitalization.

After the primary infection, the virus remains dormant in cranial nerve sensory ganglia and spinal dorsal root ganglia. Latent VZV will reactivate as herpes zoster in about 10–30% of persons (see below). Varicella is more severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described.

There is a small increased risk of Guillain-Barré syndrome for at least 2 months after an acute herpes zoster attack.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody staining or PCR of scrapings from lesions. Multinucleated giant cells are usually apparent on a Tzanck smear of material from the vesicle base. Leukopenia and subclinical transaminase elevation are often present and thrombocytopenia occasionally occurs. A varicella skin test and interferon-gamma enzyme-linked immunospot (ELISPOT) can screen for VZV susceptibility.

B. Herpes Zoster

Herpes zoster (“shingles”) usually occurs among adults, but cases are reported among infants and children. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single

▲ **Figure 32-2.** Primary varicella (chickenpox) skin lesions. (Public Health Image Library, CDC.)

unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (**Hutchinson sign**) indicate involvement of the

▲ **Figure 32-3.** Chickenpox (varicella) with classic "dew drop on rose petal" appearance. (Reproduced, with permission, from Richard P. Usatine, MD.)

trigeminal nerve (**herpes zoster ophthalmicus**). Facial palsy, lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, or deafness signify geniculate ganglion involvement (**Ramsay Hunt syndrome** or **herpes zoster oticus**). Shingles is a particularly common and serious complication among immunosuppressed patients. Other rare risk factors include statin therapy and possibly anti-TNF therapy. Contact with patients who have varicella does not appear to be a risk factor for zoster.

► Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A streptococcus and *Staphylococcus aureus*, are the most common complications. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, pancreatitis, and purpura fulminans. Toxic shock syndrome can also develop.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.

Historically, neurologic complications developed in about 1 in 2000 children. Cerebellar ataxia occurs at a frequency of 1:4000 in the young. A limited course and complete recovery are the rule. Encephalitis is similarly infrequent, occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. The rates for both mortality and long-term neurologic sequelae are about 10%. Ischemic strokes in the wake of acute VZV infection present at a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myeloradiculitis, arterial aneurysm formation, and arteritis are also described in immunosuppressed, especially HIV-infected, patients.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. Reye syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B virus), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

B. Herpes Zoster

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for

postherpetic neuralgia include advanced age, female sex, the presence of a prodrome, and severity of rash or pain but not family history.

Other complications include the following: (1) bacterial skin superinfections; (2) herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve and is a sight-threatening complication (especially when it involves the iris), and is a marker for stroke over the ensuing year (Hutchinson sign is a marker of ocular involvement in the HIV-positive population); (3) rarely, unilateral ophthalmoplegia; (4) involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; (5) aseptic meningitis; (6) peripheral motor neuropathy; (7) transverse myelitis; (8) encephalitis; (9) acute cerebellitis; (10) stroke; (11) vasculopathy; (12) acute retinal necrosis; (13) progressive outer retinal necrosis (largely among HIV infected persons); (14) temporal arteritis; and (15) sacral meningoradiculitis (Elsberg syndrome). VZV is a major cause of Bell palsy in patients who are HSV seronegative.

Diagnosis of neurologic complications requires the detection of VZV DNA in cerebrospinal fluid or the detection of VZV DNA in tissue. Diagnosis by examination of saliva may be possible. *Zoster sine herpete* (pain without rash) can also be associated with most of the above complications.

▶ Treatment

A. General Measures

In general, patients with varicella should be isolated until primary lesions have crusted. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. Fever can be treated with acetaminophen (not aspirin). Fingernails can be closely cropped to avoid skin excoriation and infection.

B. Antiviral Therapy

1. Varicella—Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 5 days, should be given within the first 24 hours after the onset of varicella rash and should be considered for patients older than 12 years, secondary household contacts (disease tends to be more severe in secondary cases), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Acyclovir hastens defervescence and healing of lesions but does not impact complication rates. Experience with valacyclovir and famciclovir in these settings is scant and while these agents are often used, their use is not FDA-approved in the United States.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/day in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia. Prolonged prophylactic acyclovir is important to prevent VZV reactivation in profoundly immunosuppressed patients.

2. Herpes zoster—For uncomplicated herpes zoster, valacyclovir or famciclovir is preferable to acyclovir due to dosing convenience and higher drug levels in the body. Therapy should start within the first 72 hours of the onset of the lesions and be continued for 7 days or until the lesions crust over. Antiviral therapy reduces the duration of herpetic lesions and associated episodes of acute pain but does not in all studies decrease the risk of postherpetic neuralgia. Corticosteroids (a tapering course starting at 60 mg/day, for 2–3 weeks) are safe in immunocompetent patients and may be useful in the acute management of disease to hasten the resolution of acute lesions. Corticosteroids do not prevent the development of postherpetic neuralgia.

Intravenous acyclovir is used for extradermatomal complications of zoster. Adjunctive therapy may be considered in retinal disease (foscarnet) and acute herpes zoster (sorivudine, a topical antiviral). In cases of prolonged or repeated acyclovir use, immunosuppressed patients may require a switch to foscarnet due to the development of acyclovir-resistant VZV infections. The Ramsay Hunt syndrome is more resistant to antiviral therapy.

C. Treatment of Postherpetic Neuralgia

Once established, postherpetic neuralgia may respond to neuropathic pain agents such as gabapentin or lidocaine patches. Tricyclic antidepressants, opioids, and capsaicin cream are also widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but, as with oral corticosteroids, is not effective for prevention of long-term postherpetic neuralgia. There is reported success using transcutaneous electrical nerve stimulation.

▶ Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

▶ Prevention

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For patients with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work between days 10 and 21 after exposure. Health care workers with zoster should receive antiviral agents during the first 72 hours of disease and withdraw from work until lesions are crusted. Postexposure prophylaxis should be evaluated (see below).

A. Varicella

1. Vaccination—Universal childhood vaccination against varicella is effective. The varicella vaccine (Varilrix) is live and attenuated, safe, and over 98.1% effective when given after 13 months of age. A single antigen live attenuated vaccine (VARIVAX) or a quadrivalent measles, mumps, rubella, and varicella vaccine (ProQuad) are available. The first dose should be administered at 12–15 months of age and the second at 4–6 years. Aspirin should be avoided for at least 6 weeks because of the risk of Reye syndrome. This vaccine is safe, well tolerated, but the quadrivalent vaccine is associated with a small risk of febrile seizures 5–12 days after vaccination among infants aged 12–23 months. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4–8 weeks apart are recommended. For those who received a single dose in the past, a catch-up second dose is advised, especially in the epidemic setting (where it is effective when it can be given during the first 5 days postexposure). Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women (who should not be vaccinated with live varicella-zoster vaccines during pregnancy) need to receive the first dose of vaccine before discharge after delivery and the second dose 4–8 weeks later. The quadrivalent vaccine MMRV can be used for the second doses of MMR and varicella in patients aged 15 months to 12 years and for the first dose in patients aged 48 months or older. The vaccine, administered as two doses 3 months apart, should also be considered for HIV-infected adolescents and adults with CD4 T lymphocyte counts 200 cells/mcL or more. The vaccine may also be given to patients with impaired humoral immunity, to patients receiving corticosteroids, and to patients with juvenile rheumatoid arthritis who receive methotrexate. Patients receiving high doses of corticosteroids for over 2 weeks may be vaccinated a month after discontinuation of the therapy. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated. Kidney and liver transplant patients should be vaccinated if they are susceptible to varicella.

The incidence of varicella in the United States is significantly reduced with the varicella vaccine. Meanwhile, the varicella vaccine is associated with a small increase in the incidence of herpes zoster, with the latter occurring more often in warm months. It is thought that vaccination against varicella provides less protection against future zoster than does natural varicella.

The FDA no longer maintains a registry for exposed pregnant women because of the low rate of such incidents and the general safety of varicella vaccines. Incidents can be reported to Merck (877-888-4231) or through the Vaccine Adverse Events Registry System Vaccine (<https://vaers.hhs.gov/index>).

2. Postexposure—Postexposure vaccination is recommended for unvaccinated persons without other evidence

of immunity. Varicella-zoster immune globulin available in the United States only as VariZIG should be considered for susceptible exposed patients (for up to 10 days after exposure but as soon as feasible) who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at greater than 28 weeks of gestation, neonates born at less than 28 weeks of gestation regardless of maternal serostatus, and pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VariZIG is given by intramuscular injection in a dosage of 125 international units/10 kg, to a maximum of 625 international units with a weight-based (2 kg cutoff) minimum dose of 62.5 or 125 international units, with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VariZIG has no place in therapy of established disease; however, it reduces severity of varicella in high-risk children or adults (ie, those with impaired immunity, pregnant women, and infants exposed peripartum) if given within 4 days of exposure. Varicella vaccination should be delayed at least 5 months after VariZIG administration.

Further information may be obtained by calling the Centers for Disease Control and Prevention's Immunization Information Hotline (800-232-2522).

B. Herpes Zoster

A live attenuated VZV vaccine (ZOSTAVAX, 19,400 plaque forming units [pfu] of Oka/Merck strain) contains at least 14 times the concentration of varicella virus found in VARIVAX. It is recommended for persons 60 years and older because it reduces the incidence of herpes zoster and postherpetic neuralgia by 51% and 67%, respectively. **Even if the person has had a prior episode of herpes zoster, the vaccine has efficacy and can be administered.** No specific recommendations exist regarding how long to wait between a zoster outbreak and administering the vaccine; the CDC recommends waiting at least until the outbreak has resolved. An adjuvanted recombinant subunit vaccine (HZ/su, GlaxoSmithKline Biologicals) is in trials. Two doses of this vaccine given 2 months apart had 97% efficacy with no significant decrease with age.

Concurrent administration of the live attenuated VZV vaccine with pneumococcal vaccine is safe. If a varicella vaccine is mistakenly administered to an adult instead of a live attenuated zoster vaccine, the dose should be considered invalid and the patient should be administered a dose of zoster vaccine at the same visit. On the other hand, the zoster vaccine cannot be used in children in place of varicella vaccine; if the vaccine is accidentally given to a child, the event should be reported to the CDC.

3. Epstein-Barr Virus & Infectious Mononucleosis

ESSENTIALS OF DIAGNOSIS

- ▶ Malaise, fever, and sore throat, sometimes with exudates.
- ▶ Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- ▶ Positive heterophile agglutination test (Monospot).
- ▶ Atypical large lymphocytes in blood smear; lymphocytosis.
- ▶ Complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction secondary to lymph node enlargement, hemolytic anemia, thrombocytopenia.

General Considerations

Epstein-Barr virus (EBV, or human herpes virus-4 [HHV-4]) is one of the most ubiquitous human viruses, infecting more than 95% of the adult population worldwide and persisting for the lifetime of the host. Infectious mononucleosis is a common manifestation of EBV and may occur at any age. In the United States the incidence of EBV infection is declining although prevalence of EBV remains high for those aged 12–19 years. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in the elderly occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence, for 6 months or longer after symptom onset. The incubation period lasts several weeks (30–50 days).

Clinical Findings

A. Symptoms and Signs

The protean manifestations of infectious mononucleosis reflect the dissemination of the virus in the oral cavity and through peripheral blood lymphocytes and cell-free plasma. Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness.

▲ **Figure 32–4.** Conjunctival hemorrhage of the eye due to infectious mononucleosis. (From Dr. Thomas F. Sellers, Emory University, Public Health Image Library, CDC.)

Physical findings include lymphadenopathy (discrete, non-suppurative, slightly painful, especially along the posterior cervical chain), transient bilateral upper lid edema (Hoagland sign), and splenomegaly (in up to 50% of patients). A maculopapular or occasionally petechial rash occurs in less than 15% of patients unless ampicillin is given (in which case rash is seen in more than 90%). Conjunctival hemorrhage (Figure 32–4), exudative pharyngitis, uvular edema, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted.

Other manifestations include hepatitis, interstitial pneumonitis, cholestasis, gastritis, acute interstitial nephritis, nervous system involvement in 1–5% (mononeuropathies and occasionally aseptic meningitis, encephalitis, cerebellitis, peripheral and optic neuritis, transverse myelitis, or Guillain-Barré syndrome), kidney disease (mostly interstitial nephritis), pneumonia, pleural involvement, and myocarditis. Vaginal ulcers are rare but may be present. Airway obstruction from lymph node enlargement, pericarditis, life-threatening thrombocytopenia, severe CNS complications, and massive splenomegaly are all considered indications for hospitalization or close observation.

B. Laboratory Findings

An initial phase of granulocytopenia is followed within 1 week by lymphocytic leukocytosis (greater than 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising more than 10% of the leukocyte count. Hemolytic anemia, with anti-i antibodies, occurs occasionally as does thrombocytopenia (at times marked).

Diagnosis is made on the basis of characteristic manifestations and serologic evidence of infection (the heterophile sheep cell agglutination [HA] antibody tests or the correlated mononucleosis spot test [Monospot]). These tests usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. Heterophile antibodies may be absent in young children and in as many as 20% of adults. During acute illness,

there is a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in IgG antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection.

PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in cerebrospinal fluid shows a sensitivity of 90% and specificity of nearly 100% for the diagnosis of primary CNS lymphoma in patients with AIDS.

► Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophile antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophile-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. CMV, toxoplasmosis and, on occasion, EBV can cause heterophile-negative infectious mononucleosis with atypical lymphocytosis. Mycoplasma infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

► Complications

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture (0.5–1%) is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications. Neurologic involvement—including transverse myelitis, encephalitis, and Guillain-Barré syndrome—is infrequent.

► Treatment

A. General Measures

Over 95% of patients with acute EBV-associated infectious mononucleosis recover without specific antiviral therapy. Treatment is symptomatic with acetaminophen or other nonsteroidal anti-inflammatory drugs and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but shows no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved

for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well established. If a throat culture grows beta-hemolytic streptococci, a 10-day course of penicillin or azithromycin is indicated. **Ampicillin and amoxicillin are avoided because of the frequent association with rash.**

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most of ten caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination, which can be insensitive).

► Prognosis & Prevention

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

A glycoprotein vaccine and a protein vaccine are under development with the former reducing the rate of infectious mononucleosis in EBV seronegative recipients. Neither vaccine is currently commercially available. Handwashing after contact and avoidance of close personal contact with active cases is prudent.

4. Other EBV-Associated Syndromes

EBV viral antigens are found in more than 90% of patients with endemic (African) Burkitt lymphoma and nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). Risk factors for Burkitt lymphoma include a history of malaria (which may decrease resistance to EBV infection) while risk factors for nasopharyngeal carcinoma include long-term heavy cigarette smoking and seropositive EBV serologies (VCA and deoxyribonuclease [DNase]). VCA-IgA in peripheral blood is a sensitive and specific predictor for nasopharyngeal carcinoma in endemic areas.

Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific CD8⁺ T cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T cell lymphoproliferative disorder in children.

EBV is an important trigger for hemophagocytic lymphohistiocytosis among immunodeficient patients and causes B-cell lymphomas (such as primary CNS lymphoma in HIV-infected individuals), natural killer/T cell lymphoma, and posttransplant lymphoproliferative disorders. Posttransplant lymphoproliferative states are commonly associated with EBV, especially in children. EBV-naïve patients who receive a donor organ from an EBV-infected donor are at the highest risk for the development of

posttransplant lymphoproliferative disorder. Decreasing the iatrogenic immunosuppression given to prevent graft rejection is the initial step in managing such patients, while rituximab (CD20 monoclonal antibody) is effective in treating more than two-thirds of cases. The efficacy of rituximab or traditional chemotherapy often can be assessed by monitoring levels of EBV DNA load in the blood and, if indicated, CNS. Infusion of EBV-specific cytotoxic T cell lymphocytes (adoptive cell therapy) is also used but with a less established role.

Age is a major determinant of the type of tumor associated with EBV. T and NK cell lymphoma caused by chronic active EBV infections are more frequent in childhood while peripheral T cell lymphomas and diffuse large B cell lymphomas are more common in the elderly due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T cell lymphomas.

▶ When to Admit

Severe complications of EBV disease, including the following conditions:

- Acute meningitis, encephalitis, or acute Guillain-Barré syndrome.
- Severe thrombocytopenia; significant hemolysis.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

5. Cytomegalovirus Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Mononucleosis-like syndrome.
- ▶ Frequent pathogen seen in transplant populations.
- ▶ Diverse clinical syndromes in HIV (retinitis, esophagitis, pneumonia, encephalitis).
- ▶ Major pathogen to consider in neonates in the differential of maternally transmitted agents.

▶ General Considerations

Most cytomegalovirus (CMV) infections are asymptomatic. After primary infection, the virus remains latent in most body cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. CMV seroprevalence increases with age and lower socioeconomic status and is higher among persons employed in child-care centers. Seroprevalence further increases with the number of sexual partners and a history of prior sexually transmitted infections. The virus can be isolated from a variety of tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease; (2) diseases in immunocompetent persons; and (3) diseases in immunocompromised persons. **Congenital CMV infection** is the most common congenital infection in developed countries (about 0.6% of live births, with higher rates in underdeveloped areas and among lower socioeconomic groups). Transmission is much higher from mothers with primary disease than those with reactivation (40% vs 0.2–1.8%). About 10% of infected newborns will be symptomatic with CMV inclusion disease.

In **immunocompetent persons**, acute CMV infection is the most common cause of the mononucleosis-like syndrome with negative heterophile antibodies. In critically ill immunocompetent adults, CMV reactivation is associated with prolonged hospitalization and death.

In **immunocompromised persons**, solid organ and bone marrow transplant patients are at highest risk for a year after allograft transplantation (but especially during the first 100 days afterward) and in particular when graft-versus-host disease is present or when the donor is CMV seropositive and the recipient is seronegative. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the degree of immunosuppression and manifestations may differ by the cause. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection. CMV retinitis may develop after solid organ or bone marrow transplantation. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is less than 50 cells/mcL and can be a marker for increased mortality. Antiretroviral therapy (ART) reduces the frequency of retinitis and may reverse active disease. Patients with immune recovery with CD4 cell count greater than 100 cells/mcL show decreased mortality. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-TNF antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV may exist alongside other pathogens, such as *Cryptosporidium*, in up to 15% of patients

with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less often in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV in patients with advanced AIDS is usually associated with disseminated CMV infection.

▶ Clinical Findings

A. Symptoms and Signs

1. Perinatal disease and CMV inclusion disease—CMV inclusion disease in infected newborns is characterized by jaundice, hepatosplenomegaly, thrombocytopenia, purpura, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in more than 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life, including hearing loss in 15% and mental retardation in 10–20%. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

2. Disease in immunocompetent persons—Acute acquired CMV infection is characterized by fever, malaise, myalgias, arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, thrombocytopenia (on occasion, refractory), the Guillain-Barré syndrome, pericarditis, and myocarditis. A mononucleosis-like syndrome due to CMV can also occur postsplenectomy, often years later and associated with a protracted fever, marked lymphocytosis, and impaired anti-CMV IgM response.

3. Disease in immunocompromised persons—Distinguishing between CMV infection (with evidence of CMV replication) and CMV disease (evidence for systemic symptoms or organ invasion by pathologic diagnosis) is important. In addition to patients infected with HIV, those who have undergone transplantation (solid organ or hematopoietic stem cell) show a wide spectrum of disease including gastrointestinal (eg, acute cholecystitis), renal, and CNS disease, as outlined above. CMV viral loads serve as an important predictor of disease presence.

A. CMV RETINITIS—A funduscopic examination reveals neovascular, proliferative lesions (“pizza-pie” retinopathy). Immune restoration with ART is associated with CMV vitritis and cystoid macular edema. Infants with CMV retinitis tend to have more macular than peripheral disease.

B. GASTROINTESTINAL AND HEPATOBILIARY CMV—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss and may mimic inflammatory bowel disease. CMV

hepatitis commonly complicates liver transplantation and appears to be increased in those with hepatitis B or hepatitis C viral infection.

C. RESPIRATORY CMV—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production.

D. NEUROLOGIC CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

B. Laboratory Findings

1. Mothers and newborns—Pregnant women should be tested for CMV viremia every 3 months if an assay during the first trimester is seropositive. Congenital CMV disease is confirmed by presence of the virus in amniotic fluid or an IgM assay from fetal blood. Amniocentesis is less reliable before 21 weeks of gestation (due to inadequate fetal urinary development and release into the amniotic fluid), but amniocentesis is attendant with greater risk when performed after 21 weeks of gestation. PCR assays of dried blood samples from newborns, micro-enzyme-linked immunosorbent assay (ELISA), shell-vial culture, or culture of urine, saliva, or blood specimens obtained during the first 3 weeks of life are used to diagnose congenital CMV infection.

2. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver function tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of CMV DNA, specific IgM, or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

3. Immunocompromised persons—CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. PCR analysis should be used to diagnose CNS infection since cultures are not specific for disease.

Detection of CMV by quantitative DNA PCR is used in posttransplant patients for guidance on both treatment and prevention and should be interpreted in the context of clinical and pathologic findings. CMV viral loads are internationally standardized and have replaced conventional CMV antigenemia tests in many settings. The PCR is sensitive in predicting clinical disease. Serial PCR should be performed and compared using the same specimen type (ie, whole blood or plasma).

Rapid shell-vial cultures detect early CMV antigens with fluorescent antibodies in 24–48 hours. Shell-vial cultures are more useful on bronchoalveolar lavage fluid than in routine blood monitoring. CMV colitis can occur in the absence of a detectable viremia.

C. Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear (“owl’s eye”) and intracytoplasmic inclusions. In situations where histopathologic or immunohistochemical findings are not seen but CMV colitis is suspected, CMV DNA PCR can be used to identify additional cases.

▶ Treatment

In congenital CMV infection, treatment with ganciclovir or valganciclovir for 6 months (or as little as 6 weeks in one study) is associated with improved hearing and with some improvement in developmental outcomes up to 24 months of age.

Sight-threatening CMV retinitis (lesions close to the fovea or optic nerve head) is treated with ganciclovir induction therapy (5 mg/kg intravenously every 12 hours for 14–21 days) followed by maintenance therapy at lower doses (5 mg/kg intravenously daily) (Table 32–1). Intravitreal injections of ganciclovir or foscarnet may be used as adjunct therapy. Treatment is effective in improving survival and preventing dissemination. In less severe retinal disease, valganciclovir (900 mg orally twice daily for 14–21 days followed by 900 mg/day maintenance) is preferred. Due to potential toxicities, foscarnet and cidofovir are usually reserved for CMV infections resistant to ganciclovir. Combinations of ganciclovir and foscarnet are shown to be safe and effective in treating clinically resistant CMV retinitis. The role of ART in reducing the need for CMV antiviral agents is essential. Because recurrence occurs even at high CD4 cell counts, ongoing ophthalmologic surveillance is necessary. Other forms of CMV disease in AIDS are managed initially with intravenous ganciclovir and subsequently with oral valganciclovir; alternative agents (listed above) are used when resistance evolves.

The treatment of other systemic CMV infection (colitis, encephalitis, pneumonia) involves valganciclovir, ganciclovir with foscarnet, and cidofovir reserved for treatment of resistant infections; the efficacy of ganciclovir is established in childhood pneumonia. The length of therapy depends on the state of immunosuppression, and secondary prophylaxis is typically maintained until immune restoration with two CD4 T-cell counts greater than 100 cells/mL is present for at least 6 months in the setting of HIV infection. Prolonged prophylaxis may be necessary in other immunosuppressed patients, such as those receiving TNF inhibitors.

For non-severe, posttransplant CMV disease, oral valganciclovir (900 mg twice daily) or intravenous ganciclovir (5 mg/kg every 12 hours) are the recommended first-line agents. Valganciclovir has been shown to be non-inferior to intravenous ganciclovir-based therapy in solid organ transplant patients and is associated with less clinical

resistance than ganciclovir. **For severe CMV disease,** intravenous ganciclovir remains the treatment of choice. Dose adjustments of all medications are needed for kidney dysfunction. Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). Treatment should be continued for at least 2 weeks until viral clearance is achieved. Two consecutive negative results from CMV DNA PCR or antigenemia-based assay ensure viral clearance. Other agents that may be useful in resistant CMV infections include leflunomide, sirolimus-based therapy, artesunate and adoptive immunotherapy.

▶ Prevention

A multitude of humoral and cellular immunity vaccines against CMV are under study and development. An experimental CMV glycoprotein B with MF59 adjuvant vaccine shows efficacy of 50% in preventing primary infection in pregnant women and in reducing viremia in kidney transplant recipients.

A major source of CMV for pregnant women is their own young children, particularly those in childcare. These women can decrease their risk of contracting primary CMV just before pregnancy or during pregnancy by practicing hand hygiene after changing diapers and after contact with respiratory secretions; avoiding kissing young children on the face; and avoiding sharing utensils, food, and cleansing objects that have been in contact with children’s secretions.

ART is effective in preventing CMV infections in HIV-infected patients. Primary prevention is best accomplished by good hand hygiene and use of barrier methods during sexual contacts with persons who are members of high prevalence groups (ie, men who have sex with men, injection drug users, and those who have exposure to children in child care).

The use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antiviral agents only when antigen detection or PCR assays show evidence of active CMV replication) appear equally effective in preventing invasive disease and mortality after hematopoietic stem cell transplant. The appropriate management of transplant patients is based on the serostatus of the donor and the recipient. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants. Acyclovir may also be used. The dose for valganciclovir prophylaxis is 450 mg orally twice daily. Brincidofovir (CMX001, Chimerix of Durham NC), under study, appears to be effective when given 100 mg twice a week in preventing CMV infections among hematopoietic stem cell transplant recipients.

CMV immune globulin may also be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients. CMV immune globulin as prophylaxis is not recommended in hematopoietic stem cell transplant recipients.

▶ When to Refer

- Neonatal infections consistent with CMV inclusion disease.
- AIDS patients with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Organ and hematopoietic stem cell transplants with suspected reactivation CMV.

▶ When to Admit

- Escalating CMV viral load at the onset of illness.
- Risk of colonic perforation.
- Evaluation of unexplained, advancing encephalopathy.
- Initiation of treatment with intravenous anti-CMV agents.

6. Human Herpesviruses 6, 7, & 8

HHV-6 is a B cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures. HHV-6 is also associated with encephalitis (symptoms may include insomnia, seizures, and hallucinations) and with acute liver failure. Primary infection in immunocompetent adults is rare and can produce a mononucleosis-like illness. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Imaging studies in HHV-6 encephalitis typically show lesions in the hippocampus, amygdala, and limbic structures.

Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation, however, occur in immunocompromised persons. Reactivation is

associated with graft rejection, graft-versus-host disease, and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients. In recipients of hematopoietic stem cell transplants, HHV-6–induced encephalitis is associated strongly with umbilical cord hematopoietic cell transplants (in the absence of an HHV-6 association with survival in such patients surveillance for the virus may not be needed).

HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes. HHV-6 may cause fulminant hepatic failure and acute decompensation of chronic liver disease in children. Purpura fulminans and corneal inflammation are reported with HHV-6 infection. Two variants (A and B) of HHV-6 have been identified. HHV-6B is the predominant strain found in both normal and immunocompromised persons. Ganciclovir, cidofovir, and foscarnet (but not acyclovir) appear to be clinically active against HHV-6.

HHV-7 is a T cell lymphotropic virus that is associated with roseola (serologically), seizures and, rarely, encephalitis. Pregnant women are often infected. Infection with HHV-7 is synergistic with CMV in kidney transplant recipients.

HHV-8 (see also Chapter 31) is associated with Kaposi sarcoma, multicentric Castleman disease, and primary effusion (body cavity) lymphoma. HHV-8 infection is endemic in Africa; transmission seems to be primarily horizontal in childhood from intrafamilial contacts and continues through adulthood possibly by nonsexual routes.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS¹

1. Measles

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 10–14 days before onset in an unvaccinated patient.¹
- ▶ Prodrome of fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- ▶ Rash: brick red, irregular, maculopapular; onset 3–4 days after onset of prodrome; begins on the face and proceeds “downward and outward,” affecting the palms and soles last.
- ▶ Leukopenia.

¹A general guide for vaccine preventable diseases is available at <http://www.who.int/influenza/vaccines/en/>.

▶ General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by inhalation of infective droplets. It is a major worldwide cause of pediatric morbidity and mortality, although vaccination programs successfully reduced this number. Despite encouraging vaccination reports in 2013 with 91.9% of children aged 19–35 months in the United States having received one or more doses of measles, mumps, and rubella vaccine (MMR) between January 1 and September 18, 2015, 189 cases of measles were reported to the CDC from 24 states and the District of Columbia in at least 5 outbreaks with 113 (60%) part of a multi-state outbreak associated with an amusement park in Southern California. Low vaccine uptake in children aged 10–19 years drives these outbreaks and is rooted in unfounded concerns over the potential link between MMR and autism.

The 668 confirmed measles cases reported to CDC in 2014 was the highest number reported since the United States declared elimination of measles in 2000. Many countries struggle with measles, including the United Kingdom, France, Bosnia, and the Philippines (the likely source of the Southern California outbreak) with all reporting recent outbreaks. Reassuringly, however, the caseloads appear to be decreasing in four of six World Health Organization (WHO) areas, and the WHO anticipates elimination of measles globally by 2020.

Illness confers permanent immunity. It is highly contagious and communicability is greatest during the preeruptive and catarrhal stages but continues as long as the rash remains. Despite high community vaccination coverage, rising rates of intentional undervaccination lead to sporadic outbreaks among clusters of intentionally undervaccinated children and can undermine measles elimination programs. Therefore, laboratory testing and confirmation of suspected measles infection is especially important in countries that report the elimination of measles. Sporadic outbreaks of the disease in adults, adolescents, and unvaccinated preschool children in dense urban areas, and sporting event participants emphasize the need for specific recommendations concerning prevention.

▶ Clinical Findings

A. Symptoms and Signs

Fever is often as high as 40–40.6°C. It persists through the prodrome and early rash (about 5–7 days) (Table 32–2). Malaise may be marked. Coryza (nasal obstruction, sneezing, and sore throat) resembles that seen with upper respiratory infections. Cough is persistent and nonproductive. Conjunctivitis manifests as redness, swelling, photophobia, and discharge. These symptoms intensify over 2–4 days before onset of the rash and peak on the first day of the rash.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles. They appear about 2 days before the rash and last 1–4 days as tiny “table salt crystals” on the buccal mucosa opposite the molars and vaginal membranes. The rash lasts for 3–7 days and fades in the same manner it appeared.

Hyperpigmentation remains in fair-skinned individuals and severe cases. Slight desquamation may follow.

Other findings in measles include pharyngeal erythema, tonsillar yellowish exudate, coating of the tongue in the center with a red tip and margins, moderate generalized lymphadenopathy and, at times, splenomegaly.

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed. Although technically difficult, virus can be cultured from nasopharyngeal washings and from blood. Detection of IgM measles antibodies with ELISA or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. Fluorescent antibody staining of respiratory or urinary epithelial cells can also confirm the diagnosis.

IgM assays can be falsely negative the first few days of infection and falsely positive in the presence of rheumatoid factor or with acute rubella, erythrovirus (parvovirus) B19, or HHV-6 infection. Reverse transcriptase-PCR (RT-PCR) techniques, typically available in research settings, can help establish a diagnosis. The virologic clearance of measles can take months, leading to false-positive results.

▶ Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for other exanthematous infections (Table 32–2). Frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent than is recognized.

▶ Complications

A. Central Nervous System

Postinfectious encephalomyelitis occurs in about 0.05–0.1% of cases. Higher rates of encephalitis occur in adolescents and adults than in school-aged children. Its onset is usually 3–7 days after the rash. Vomiting, convulsions, coma, and diverse, severe neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus is usually not found in the CNS, though demyelination is prominent. There is an appreciable mortality (10–20%) and morbidity (33% of survivors are left with neurologic deficit).

A similar form, “inclusion body encephalitis,” occurs months after exposure. This complication is reported to occur after measles vaccination in patients with inadequate cellular immunity but is associated with isolation of the measles virus.

Subacute sclerosing panencephalitis (SSPE) is a very rare, late CNS complication (5–15 years after infection); the measles virus acts as a “slow virus” to produce degenerative CNS disease years after the initial infection.

Measles virus can opportunistically invade the CNS. An acute progressive encephalitis (subacute measles encephalitis), characterized by seizures, neurologic deficits, and stupor progressing to death, can occur among immunosuppressed patients. Treatment is supportive, withholding

immunosuppressive chemotherapy when feasible. Interferon and ribavirin are variably successful.

B. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties. Bronchiectasis may occur in up to a quarter of nonvaccinated children.

C. Secondary Bacterial Infections

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients.

D. Immune Reactivity

Measles produces temporary anergy to cell-mediated skin tests.

E. Gastroenteritis

Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may be seen) are significant complications among malnourished children.

F. Other Complications

Other complications include conjunctivitis, keratitis, and otosclerosis.

▶ Treatment

A. General Measures

The patient should be isolated for the week following onset of rash and kept at bed rest until afebrile. Treatment is symptomatic including antipyretics and fluids as needed. Vitamin A, 200,000 units/day orally for 2 days (the benefit being maintenance of gastrointestinal and respiratory epithelial mucosa) reduces pediatric morbidity (diarrhea, night blindness, xerophthalmia) and measles-associated mortality for infants between 6 months and 5 years of age, although high-dose vitamin A exposure increases the severity and risk of antibiotic failure in non-measles pneumonia. Measles virus is susceptible to ribavirin *in vitro* and has been used in selected severe cases of pneumonitis (35 mg/kg/day intravenously in three divided doses for 2 days, followed by 20 mg/kg/day intravenously in three divided doses for 5 days).

B. Treatment of Complications

Secondary bacterial infections, including pneumonia, are treated with appropriate antibacterial antibiotics. Post-measles encephalitis, including SSPE, can only be managed symptomatically.

Repeated studies fail to show an association between vaccination and autism. The prevalence of asthma-like diseases in childhood appears to be reduced among vaccinated children. Some data implicate the measles virus in the pathogenesis of rheumatoid arthritis.

▶ Prognosis

Between 2000 and 2008, the measles mortality rate declined by 78%. In the last decade, the case-fatality rate in the United States stayed around 3 per 1000 reported cases, with deaths principally due to encephalitis (15% mortality rate) and secondary bacterial pneumonia. Deaths in the developing world are mainly related to diarrhea and protein-losing enteropathy.

▶ Prevention

In the United States, children receive their first vaccine dose at 12–15 months and a second at age 4–6 years, prior to entry into school. Combination measles-mumps-rubella-varicella vaccines (MMRV) can be used in place of the traditional measles, mumps, and rubella (MMR) vaccine. The median coverage with at least one dose of MMR vaccine nationally in 2013 was 91.9% among children 19–35 months of age; however, there is considerable geographic disparity in this value (in the US Virgin Islands the coverage is only 59% and in Ohio and West Virginia it is 86%). The clustering of unvaccinated individuals also increases the likelihood of an outbreak. Susceptibility to measles is 2.4-fold higher if the vaccine is given prior to 15 months, suggesting that administration before that age may not be optimal for measles eradication. The evidence is not convincing that routine anthelmintic treatment affects the immune response to childhood vaccination.

American students beyond high school and medical staff starting employment require documentation of the above vaccination schedule or must show serologic evidence of immunity if they were born after 1956. For individuals born before 1957, herd immunity is assumed. Health care workers, immigrants, and refugees should be screened and vaccinated if necessary regardless of date of birth. International travelers (if immunocompetent and born after 1956) to the developing world and teachers should receive booster doses of vaccination.

At 6 months of age, more than 99% of infants of vaccinated women and 95% of infants of naturally immune women lose maternal antibodies. Therefore, in outbreaks that include infants less than 1 year of age, initial vaccination may be given at 6 months, with repeat at 15 months. When outbreaks take place in day care centers, K–12 institutions, or colleges and universities, revaccination is probably indicated for all, in particular for students and their siblings born after 1956 who do not have documentation of immunity as defined above. Susceptible personnel who were exposed should be isolated from patient contact between the fifth and the twenty-first day after exposure regardless of whether they were vaccinated or given immune globulin. If measles develops in these persons, they should be isolated from patient contact until 7 days after the rash develops.

When susceptible individuals are exposed to measles, live virus vaccine can prevent disease if given within 5 days of exposure. In addition, immune globulin (0.25 mL/kg [0.11 mL/lb] body weight) can be injected intramuscularly for prevention or modification of clinical illness if given within 6 days after exposure. This must be followed by

active immunization with live measles vaccine 3 months later. In the developing world, the use of a second vaccine dose is an important aspect of achieving control of measles. Health care settings can be a source of continuing exposure in measles outbreaks, particularly in the developing world, and the mandatory two-dose immunization of health care workers is a means of control recommended in South Asia, with other means of control being postexposure prophylaxis of the immunocompromised, and strict triage of admissions.

Pregnant women and immunosuppressed persons should *not* receive this vaccine. Exception to this contraindication is asymptomatic HIV-infected patients (with normal CD4 counts), including children, who have not shown adverse effects from measles vaccination. In asymptomatic HIV-infected children, vaccination improves survival after measles, and ART is associated with an improved vaccine response. Repeat vaccination may be necessary in HIV-infected children after immune restoration. Immune globulin should be administered within 6 days of exposure for postexposure prophylaxis in any high-risk person exposed to measles. Such high-risk persons include children with malignancy and patients with AIDS who are at risk for developing severe or fatal disease.

Severe allergic reactions including anaphylaxis to the MMR vaccine are rare, though fever and rash appear to occur slightly more often among female recipients. Quadrivalent MMRV vaccine is associated with an increased risk of seizures that appears to be age-related; the risk is highest when MMRV is given to infants under 15 months of age.

▶ When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

▶ When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

2. Mumps

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 14–21 days before onset.
- ▶ Painful, swollen salivary glands, usually parotid.
- ▶ Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.
- ▶ Mumps occurs in appropriately vaccinated persons in the majority of cases in highly vaccinated communities.

▶ General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets. Children are the age group most affected, although in some outbreaks, patients are in the late second or early third decades of life. Mumps can spread rapidly in congregate settings, such as colleges and schools. The incidence is highest in spring. The incubation period is 14–21 days (average, 18 days). Infectivity occurs via saliva and urine and precedes the symptoms by about 1 day and is maximal for 3 days, although it may last a week. Up to one-third of affected individuals have subclinical infection. Despite high vaccination rates in America, Europe, and other regions, several mumps outbreaks were reported in these places over the past few years. More than half of these mumps cases reported appropriate MMR vaccination histories.

▶ Clinical Findings

A. Symptoms and Signs

Mumps is more serious in adults than in children. Parotid tenderness and overlying facial edema (Figure 32–5) are the most common physical findings and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis alone occurs in 25% of patients. The orifice of Stensen duct may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within a week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases.

Fever and malaise are variable but often minimal in young children. High fever accompanies meningitis or orchitis. Neck stiffness, headache, and lethargy suggest meningitis. Testicular swelling and tenderness (unilateral in 75% of cases) denote orchitis; the testes are the most common extrasalivary disease site in adults. Orchitis develops 7–10 days after the onset of parotitis in about 25–40% of postpubertal men but occurred in only 7% of males

▲ **Figure 32–5.** Mumps. (Public Health Image Library, CDC.)

above age 12 in the Orthodox Jewish outbreaks in New York. Sterility is rare. Acute hormonal disturbances are prevalent, including decreased levels of testosterone and inhibin B with low or normal levels of gonadotropins in up to 35% cases with mumps orchitis. Upper abdominal pain, nausea, and vomiting suggest pancreatitis. Mumps is the leading cause of pancreatitis in children. Lower abdominal pain and ovarian enlargement suggest oophoritis (which occurs in 5% of postpubertal women, usually unilateral); it is a difficult diagnosis to establish.

B. Laboratory Findings

Mild leukopenia with relative lymphocytosis may be present. Serum amylasemia usually reflects salivary gland involvement rather than pancreatitis. Lymphocytic pleocytosis and hypoglycorrhachia of the cerebrospinal fluid in meningitis may be asymptomatic. Mild kidney function abnormalities are found in up to 60% of patients.

Characteristic clinical picture is usually sufficient for diagnosis. An elevated serum IgM is considered diagnostic and a repeat test 2–3 weeks after the onset of symptoms is recommended if the first assay is negative due to a delay in IgM rise, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection. Confirmatory diagnosis of mumps is also made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from cerebrospinal fluid early in the course of aseptic meningitis. Isolation from urine is no longer advised. Nucleic acid amplification techniques are more sensitive than viral cultures but their availability is limited.

▶ Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts, or to a reaction to iodides.

Other causes include starch ingestion, sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (eg, *S aureus*, gram-negative organisms [particularly in debilitated individuals with poor oral intake]), drug reaction (phenothiazines, propylthiouracil), and other viruses (influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

▶ Complications

Other manifestations of the disease are less common and usually follow parotitis but may precede it or occur without salivary gland involvement. Such manifestations include meningitis (30%), priapism or testicular infarction from orchitis, thyroiditis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias (infrequently among adults and even rarer in children), and nephritis. Mumps has also been associated with cases of endocardial fibroelastosis and a hemophagocytosis syndrome. Rare neurologic complications include encephalitis, Guillain-Barré syndrome, cerebellar ataxia, facial palsy, and transverse myelitis. Encephalitis is associated with cerebral edema, serious neurologic manifestations, and sometimes death. Deafness from eighth nerve neuritis develops in about 0.1%; it is typically unilateral, severe, and permanent.

▶ Treatment

The patient should be isolated until swelling subsides (about 9 days from onset) and kept on bed rest while febrile. Treatment is symptomatic. Topical compresses may relieve parotid discomfort. Some clinicians advocate intravenous immunoglobulin (IVIG) for complicated disease (eg, thrombocytopenia) although its definitive role is unproven.

▶ Prognosis

The entire course of mumps rarely exceeds 2 weeks. Rare fatalities are usually due to encephalitis.

▶ Prevention

Mumps live virus vaccine is safe and effective (there is some variability among vaccines, the Jeryl Lynn strain being highly effective, the Urabe intermediate, the Rubini less so) with long lasting immunity. It is recommended for routine immunization for children older than 12 months, either alone or in combination with other virus vaccines (eg, in the MMR vaccine or as a quadrivalent vaccine with varicella). A second dose is recommended for children (ages 4–6 years) before starting school. Two doses of the vaccine should also be considered for high-risk adults (eg, health care workers) born before 1957 and without evidence of immunity. In a recent summer camp outbreak, a single, third dose of the mumps vaccine has shown efficacy.

There are no known cases of long-term sequelae associated with mumps vaccination and the currently used

mumps strain (Jeryl Lynn) shows the lowest associated incidence of post vaccine aseptic meningitis (from 1 in 150,000 to 1 in 1.8 million). This vaccine is less effective in epidemic settings. Reactions are reviewed in the measles section. It should not be given to pregnant women or to immunocompromised individuals. The vaccine can be given to HIV-infected persons who show immune restoration with ART.

▶ When to Refer

Any suspect cases should be reported to public health authorities.

▶ When to Admit

- Trismus; meningitis, encephalitis; myocarditis; pancreatitis.
- Severe testicular pain; priapism.
- Severe thrombocytopenia.

3. Poliomyelitis

ESSENTIALS OF DIAGNOSIS

- ▶ Incubation period 9–12 days from exposure.
- ▶ Muscle weakness, headache, stiff neck, fever, nausea and vomiting, sore throat.
- ▶ Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.
- ▶ Cerebrospinal fluid shows lymphocytic pleocytosis but rarely greater than 500/mcL.

▶ General Considerations

Poliomyelitis virus, an enterovirus, is present in throat washings and stools (excretion may last for weeks after infection). It is highly contagious through fecal-oral route, especially during the first week of infection. By 2013, all but two countries (Afghanistan, Pakistan with Africa considered now poliomyelitis-free) had eliminated indigenous transmission of wild poliovirus (WPV) type 1. Only type 1 remains endemic currently and 359 cases were reported in 2014. As of October 20, 2015, there were 51 cases of poliomyelitis in the two endemic countries, and 14 circulating vaccine-derived type 1 cases, 9 of which were in Madagascar. The last type 2 case of poliomyelitis

occurred in 1999 in India and the last type 3 in 2012 in Nigeria. At least 80% of the world now lives in polio-free regions, which include the Americas (since 1994), the Western Pacific (since 2000), Europe (since 2002), Southeast Asia (since 2014), and possibly Africa (since 2015).

▶ Clinical Findings

A. Symptoms and Signs

At least 95% of infections are asymptomatic, but in those who become ill, manifestations include abortive poliomyelitis (minor illness), nonparalytic poliomyelitis, and paralytic poliomyelitis.

1. Abortive poliomyelitis (minor illness)—Such minor illness occurs in 4–8% of infections and the symptoms are fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days. This entity is suspected clinically only during an epidemic.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis. This disease is indistinguishable from aseptic meningitis caused by other viruses.

3. Paralytic poliomyelitis—Paralytic poliomyelitis represents 0.1% of all poliomyelitis cases (the incidence is higher when infections are acquired later in life). Paralysis may occur at any time during the febrile period. Tremors, muscle weakness, constipation, and ileus may appear. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) **spinal poliomyelitis**, with involvement of the muscles innervated by the spinal nerves, and (2) **bulbar poliomyelitis**, with weakness of the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers.

In spinal poliomyelitis, paralysis of the shoulder girdle often precedes intercostal and diaphragmatic paralysis, which leads to diminished chest expansion and decreased vital capacity. The paralysis occurs over 2–3 days, is flaccid, has an asymmetric distribution, and affects the proximal muscles of the lower extremities more frequently. Sensory loss is very rare.

In bulbar poliomyelitis, symptoms include diplopia (uncommonly), facial weakness, dysphagia, dysphonia, nasal voice, weakness of the sternocleidomastoid and trapezius muscles, difficulty in chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. Lethargy or coma may be due to hypoxia, most often from hypoventilation. Vasomotor disturbances in blood pressure and heart rate may occur. Convulsions are rare. Bulbar poliomyelitis is more common in adults. Bulbar and spinal disease can coexist (bulbospinal poliomyelitis).

B. Laboratory Findings

The virus may be recovered from throat washings (early) and stools (early and late) and PCR of washings, stool, or cerebrospinal fluid can also facilitate diagnosis. Cerebrospinal fluid findings include the following: (1) normal or

slightly increased pressure and protein, (2) glucose is not decreased, and (3) white blood cells usually number less than 500/mcL and are principally lymphocytes after the first 24 hours. Cerebrospinal fluid is normal in 5% of patients. Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild type and vaccine-related virus infections.

► Differential Diagnosis

Nonparalytic poliomyelitis is similar to other forms of enteroviral meningitis; the distinction is made serologically. **Acute flaccid paralysis** is the term used in the developing world for the variety of neurologic illnesses that both include and mimic poliomyelitis. Acute flaccid paralysis due to poliomyelitis is distinguished by the greater frequency of fever and asymmetric neurologic signs. Acute inflammatory polyneuritis (Guillain-Barré syndrome), Japanese virus encephalitis, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain-Barré syndrome (see Chapter 24), the weakness is more symmetric and ascending in most cases, but the Miller Fisher variant is quite similar to bulbar polio. Paresthesias are uncommon in poliomyelitis but common in Guillain-Barré syndrome. The cerebrospinal fluid usually has high protein content but normal cell count in Guillain-Barré syndrome.

► Complications

Urinary tract infection, atelectasis, pneumonia, myocarditis, paralytic ileus, gastric dilation, and pulmonary edema may occur. Respiratory failure may be a result of paralysis of respiratory muscles, airway obstruction from involvement of cranial nerve nuclei, or lesions of the respiratory center.

► Treatment

In the acute phase of paralytic poliomyelitis patients should be hospitalized. Strict bed rest in the first few days of illness reduces the rate of paralysis. Comfortable but rotating positions should be maintained. In cases of respiratory weakness or paralysis, intensive care is needed. Intensive physiotherapy may help recover some motor function with paralysis. Attention to psychological disorders in long-standing disease is also important. Physical therapy is essential.

► Prognosis

During the febrile period, paralysis may develop or progress. Mild weakness of small muscles is more likely to regress than severe weakness of large muscles. Bulbar poliomyelitis carries a mortality rate of up to 50%. Long-term sequelae include pain, weakness, fatigue, and obesity, factors often worsened by age and comorbidities. When new muscle weakness and pain develop and progress slowly years after recovery from acute paralytic poliomyelitis, the entity is called **postpoliomyelitis syndrome**. Risk factors for the syndrome include female gender, respiratory symptoms during the acute polio syndrome, and the need for orthoses and aids during the rehabilitation phase. The syndrome presents with signs of chronic and new

denervation, is associated with increasing dysfunction of surviving motor neurons, and is not infectious in origin; patients do not shed the virus. Immune modulators, such as prednisone, interferon, and IVIG, do not show any clear benefit in the treatment of postpoliomyelitis syndrome.

► Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease (estimated in 1:750,000 recipients) with the trivalent oral live poliovirus vaccine (OPV), the inactivated (Salk) parenteral vaccination is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, 6–18 months, and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world where one dose is often administered although immunogenicity is improved with additional doses. Oral vaccines have been limited to usage for outbreak control, for travel to endemic areas within the ensuing month, and for protection of children whose parents do not comply with the recommended number of immunizations. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity. They are known to attenuate the response to BCG vaccination. Because of the risks with oral vaccination of vaccine-derived poliomyelitis, there is currently a global movement toward the total elimination of oral vaccines by the end of this decade.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Exceptions include adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas (currently only Afghanistan and Pakistan). Vaccination should also be considered for adults engaged in high-risk activities (eg, laboratory workers handling stools). Such adults should be given inactivated poliomyelitis vaccine (Salk) as should immunodeficient or immunosuppressed individuals and members of their households. Ancillary useful control measures (“supplementary immunization activities”) in polio-endemic countries include national immunization days (mass campaigns in which all children are vaccinated twice, 4–6 weeks apart, regardless of vaccine history); cross-border vaccination activities; surveillance for acute flaccid paralysis, an indicator for poliomyelitis; and aggressive outbreak responses as well as intensified immunization activities in countries impacted by armed conflicts.

4. Rubella

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 14–21 days before onset.
- ▶ Arthralgia, particularly in young women.
- ▶ No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coinciding with eruption.
- ▶ Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- ▶ Fine maculopapular rash of 3 days duration; face to trunk to extremities.
- ▶ Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is moderately communicable. One attack usually confers permanent immunity but reinfection is possible, albeit rarely. The incubation period is 14–21 days (average, 16 days). The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The clinical picture of rubella is difficult to distinguish from other viral illnesses such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections; however, arthritis is more prominent in rubella. The principal importance of rubella lies in its devastating effects on the fetus in utero, producing teratogenic effects and a continuing congenital infection (**congenital rubella syndrome**). The burden of congenital rubella continues to drop, with fewer than 100 cases reported in 2014 compared with 103,000 cases reported in 2010 and 121,344 cases in 2009. This precipitous drop is due to widespread implementation of rubella-containing vaccines, currently used in 68% of countries as of 2013, with 58% of countries showing over 90% of the population showing immunization coverage. The United States reported elimination of rubella in 2004, although a median of 11 cases of rubella occurred annually through 2011. As of April 25, 2015, PAHO declared that the Americas are free of congenital rubella syndrome. The six US cases of congenital rubella syndrome between 2004 and 2012 were associated with overseas maternal acquisition of rubella. Globally, the remaining

cases of congenital rubella syndrome were reported from Bangladesh (66), Romania (26), Nepal (16), Zambia (10), Japan (9), Sri Lanka (4), Cambodia and Zimbabwe (2 each), with one each from Jordan, Mauritius, the Republic of South Africa, Sweden, Tunisia, and Vietnam. The large unknown is sub-Saharan Africa where rates of immunization coverage are known in only a few countries. The WHO currently anticipates global elimination of rubella along with measles by 2020.

Clinical Findings

A. Symptoms and Signs

While fetal rubella can be devastating, postnatally acquired rubella is usually innocuous and asymptomatic in up to 50% of cases. In the postnatally acquired infection, fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Mild coryza may be present. Polyarticular arthritis occurs in about 25% of adult cases and involves the fingers, wrists, and knees. Rarely does chronic arthritis develop. The polyarthritis usually subsides within 7 days but may persist for weeks. Early posterior cervical and postauricular lymphadenopathy is very common. Erythema of the palate and throat, sometimes patchy, may be noted.

A fine, pink maculopapular rash appears on the face, trunk, and extremities in rapid progression (2–3 days) and fades quickly, usually lasting 1 day in each area (Table 32–2). Rubella without rash may be at least as common as the exanthematous disease. When rubella is suspected because of disease in the community, the diagnosis requires serologic confirmation.

B. Laboratory Findings

Leukopenia may be present early and may be followed by an increase in plasma cells. The definitive diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. False-positive IgM antibodies, however, are associated with EBV, CMV, erythrovirus (parvovirus), and rheumatoid factor. Detection of antibodies against rubella in other body fluids, such as urine and saliva, are promising diagnostic aids. An interferon-gamma-ELISPOT can provide valuable additional information in seronegative individuals. PCR techniques are also available.

Complications

A. Exposure During Pregnancy

When a pregnant woman is exposed to a possible case of rubella, an immediate hemagglutination-inhibiting rubella antibody level should be obtained to document immunity, since fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses.

Positive tests for IgG antibodies alone indicate past infection or vaccination. High-avidity anti-rubella IgG assays may distinguish past infection from vaccination. If no antibodies are found, clinical observation and serologic follow-up are essential. An isolated IgM-positive test

needs to be interpreted with caution, because it does not necessarily imply acute infection. Confirmation of rubella in the expectant mother raises the question of therapeutic abortion, an alternative to be considered in light of personal, religious, legal, and other factors.

The immune status of the mother needs to be evaluated because titers fall to seronegativity in about 10% by 12 years after vaccination.

B. Congenital Rubella

An infant acquiring the infection in utero may be normal at birth but probably—50% in a series of nearly 70 pregnant women with rubella in Mexico—will have a wide variety of manifestations, including early-onset cataracts and glaucoma, microphthalmia, hearing deficits, psychomotor retardation, congenital heart defects (patent ductus arteriosus, branch pulmonary artery stenosis), organomegaly, and maculopapular rash. In general, the younger the fetus when infected, the more severe the illness. Deafness is the primary complication in the second trimester. Viral excretion in the throat and urine persists for many months despite high antibody levels. A specific test for IgM rubella antibody is useful for diagnosis in the newborn. A confirmatory diagnosis is made by isolation of the virus or PCR detection of viral RNA in tissues. Treatment is directed toward the many anomalies.

C. Postinfectious Encephalopathy

In 1:6000 cases, postinfectious encephalopathy develops 1–6 days after the rash; the virus cannot always be isolated. The mortality rate is 20%, but residual deficits are rare among the recovered. The mechanism is unknown.

Other unusual complications of rubella include hemorrhagic manifestations due to thrombocytopenia and vascular damage, duodenal stenosis, and mild hepatitis.

▶ Treatment

Rubella and its complications should be treated symptomatically.

▶ Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella, on the other hand, has a high mortality rate, and the associated congenital defects are largely permanent.

▶ Prevention

Live attenuated rubella virus vaccine should be given to all infants and a second dose should be given to children of school age. It is important that girls in particular are immune to rubella prior to the menarche. When women are immunized, they should not be pregnant, and the absence of antibodies should be established. (In the United States, about 80% of 20-year-old women are immune to rubella.) Postpartum administration to susceptible female hospital employees is recommended. It is recommended that women not become pregnant for at least 3 months

after vaccine administration. Nonetheless, there are no reports of congenital rubella syndrome after rubella immunization, and inadvertent immunization of a pregnant woman is not considered an indication for therapeutic abortion. Arthritis is more marked after rubella vaccination than in native disease and appears to be immunologically mediated. A flare of juvenile rheumatoid arthritis after rubella vaccination is reported. The association between chronic arthropathies and rubella vaccination is controversial. Anaphylactoid reactions following vaccination are rare, and a self-limited thrombotic thrombocytopenic purpura is a reported but very rare (2.6 per 100,000 doses) complication.

MMR may be given in conjunction with DPT or varicella boosters as adequate serologic responses are documented. The administration of two or more doses appears to overcome an immunogenetic risk for vaccine failure in some vaccinees. Immunogenicity is similar with intramuscular and intracutaneous infection, for MMR and varicella vaccinations. Children with biliary atresia in particular show impaired responses to MMR and varicella vaccinations, although children with juvenile rheumatoid arthritis show intact responses to MMR boosters. Preliminary data suggests that vaccination may be safe for patients receiving immunosuppressive therapy in the setting of solid organ, bone marrow, or stem cell transplantation. Immigrants, especially the HIV-positive, should be vaccinated if CD4 counts show immune restoration.

Geographic areas with high birth rates and transmission rates of rubella may require baseline societal coverage rates for rubella higher than the conventional 80% often used.

▶ When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Significant vaccination reactions.
- Any suspect cases should be reported to public health authorities.

OTHER NEUROTROPIC VIRUSES

1. Rabies

ESSENTIALS OF DIAGNOSIS

- ▶ History of animal bite.
- ▶ Paresthesias, hydrophobia, rage alternating with calm.
- ▶ Convulsions, paralysis, thick tenacious saliva.

▶ General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that gains entry into the body by an animal bite or an open wound. Worldwide, 17.4 million cases of animal bites are reported every year, and it is estimated that between 26,400 and 61,000 deaths annually are attributable to rabies. Most of these cases occur in rural areas of Africa and Asia. India has the highest incidence, accounting for 36% of global deaths. In developing countries, more than 90% of human cases and 99% of human deaths from rabies are secondary to bites from infected dogs. Many victims are children. Rabies among travelers to rabies-endemic areas is usually associated with animal injuries (including dogs in North Africa and India, cats in the Middle East, and non-human primates in sub-Saharan Africa and Asia), with most travel-associated cases occurring within 10 days of arrival. Rare but related viruses are the Australian lyssavirus, transmitted by bats including one referred to as the black flying fox, and which has caused 3 deaths over the last 20 years, and the European lyssavirus, with cases from Germany and the United Kingdom.

In the United States, domestically acquired rabies cases are rare (approximately 92% of cases are associated with wildlife) but probably underreported. Reports largely from the East Coast show an increase in rabies among cats, with about 1% of tested cats showing rabies seropositivity. In 2013, 3 cases of rabies were reported among United States citizens, one in Maryland transmitted by organ transplantation, a second in North Carolina identified retrospectively in the organ donor, and the third a Guatemalan refugee under detention in Texas. Surveillance for animal rabies showed 5865 cases occurring in 39 states and Puerto Rico. Wildlife reservoirs, with each species having its own rabies variant(s), follow a unique geographic distribution in the United States: raccoons on the East Coast; skunks in the Midwest, Southwest, and California; and foxes in the Southwest and in Alaska. Hawaii is the only rabies-free state to date. Most of Western Europe and much of Oceania is rabies-free.

Raccoons and bats were the most commonly reported rabid animals during 2013. Raccoons, bats, and skunks account for 84% of the rabid animals found in the United States; other rabid animals include foxes, cats, cattle, and dogs. Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it (woodchucks and groundhogs are exceptions). Wildlife epizootics present a constant public

health threat in addition to the danger of reintroducing rabies to domestic animals. Vaccination is the key to controlling rabies in small animals and preventing rabies transmission to human beings.

The virus gains entry into the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported. A number of transplantation-associated cases are reported, including two clusters in the United States. Postexposure prophylaxis can be administered in these patients and may prevent development of disease.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands. Rabies virus infection forms cytoplasmic inclusion bodies similar to Negri bodies. These Negri body-like structures are thought to be the sites of viral transcription and replication.

▶ Clinical Findings

A. Symptoms and Signs

While there is usually a history of animal bite, bat bites may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodrome and may be either encephalitic (“furious”) or paralytic (“dumb”). The encephalitic form (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Quantitative RT-PCR, nucleic acid sequence-based amplification, direct rapid immunohistochemical test and viral isolation from the cerebrospinal fluid or saliva are

advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the cerebrospinal fluid. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

▶ Treatment & Prognosis

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. Corticosteroids are of no use.

If postexposure prophylaxis (discussed below) is given expediently, before clinical signs develop, it is nearly 100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis. The very rare cases in which patients recover without intensive care are referred to as “abortive rabies.”

▶ Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites. Animals that are frequent sources of infection to travelers are dogs, cats, and non-human primates.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs (at recurrent intervals) are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife. Human contact with animal vaccine baits is a recent public health concern although no new cases of rabies from such contact have been reported.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. **Any contact or suspect contact with a bat, skunk, or raccoon is usually deemed a sufficient indication to warrant prophylaxis.** Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

The optimal form of passive immunization is human rabies immune globulin (HRIG; 20 international units/kg),

administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available and appropriate tests for horse serum sensitivity are done, equine rabies antiserum (40 international units/kg) can be used. As much as possible of the rabies immune globulin should be injected at the wound site and the remainder injected intramuscularly at a site distant from vaccine administration.

Two vaccines are licensed and available for use in humans in the United States: a human diploid cell vaccine and a purified chick embryo cell vaccine. The current vaccines may be given as four injections of 1 mL intramuscularly in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, and 14 after exposure. (The fifth dose at 28 days after exposure is no longer recommended except among immunosuppressed patients.) The vaccine should not be given in the gluteal area due to suboptimal response. An alternative vaccination strategy that only takes 1 week, with injections on days 0, 3, and 7 after exposure with a verocell vaccine is reportedly successful in achieving adequate neutralizing titers at days 14 and 28 in a study from Thailand.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccine is commercially available or can be obtained through health departments.

Globally, diverse anti-rabies vaccines are used. In some countries, the full spectrum of vaccines, from human diploid rabies to chromatographically purified rabies vaccine are available, whereas in others, the gamut is smaller and intradermal application of smaller vaccine doses at multiple sites and at different times is commonly practiced in an attempt to lower costs, and is deemed safe and effective by the WHO.

In patients with history of past vaccination, the need for HRIG is eliminated (RIG is in short supply worldwide), but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination.

C. Preexposure Immunization

Preexposure prophylaxis with three injections of human diploid cell vaccine intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly); animal handlers; laboratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also

available (0.1 mL on days 0, 7, and 21 over the deltoid) but not in the United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response. A single dose booster at 10 years after initial immunization increases the level of antibody titers. Unfortunately, data from travel services indicate that only a small proportion of travelers with anticipated lengthy stays in rabies-impacted areas receive the vaccine as recommended.

▶ When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

▶ When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

2. Arbovirus Encephalitides

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, malaise, stiff neck, sore throat, and vomiting, progressing to stupor, coma, and convulsions.
- ▶ Upper motor neuron lesion signs: exaggerated deep tendon reflexes, absent superficial reflexes, and spastic paralysis.
- ▶ Cerebrospinal fluid opening pressure and protein are often increased, with lymphocytic pleocytosis.

▶ General Considerations

The arboviruses are arthropod-borne pathogens that produce clinical manifestations in humans. The **mosquito-borne pathogens** that cause encephalitis include three togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), six flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese encephalitis, dengue (see below under Hemorrhagic Viruses), Murray Valley encephalitis, and Zika virus (see below under Other Systemic Viruses) and bunyaviruses (the California serogroup of viruses, including the La Crosse agent of California encephalitis). The **tick-borne** causes of encephalitis include the flavivirus of the Powassan encephalitis (northeastern United States and Canada), tick-borne encephalitis virus of Europe, and the Colorado tick fever reovirus. Tick-borne encephalitis virus, Colorado tick fever, and the arboviruses associated with viral hemorrhagic fever (including dengue) are discussed below, and only those viruses causing primarily encephalitis in the United States will be discussed here, although West Nile agent is being reported in many other areas, including Italy, Greece, Portugal, and Hungary as well as in Africa (Madagascar and South Africa), Canada, the Middle East, and West Asia.

West Nile virus is the leading cause of domestically acquired arboviral disease in the United States. Infection with West Nile virus was first identified in the United States in the New York City area in 1999. The virus spread rapidly, and current cases are reported throughout the continental United States. As of October 13, 2015 CDC surveillance data identified 1332 cases of West Nile virus infection in 48 states (all but Alaska and Hawaii) and the District of Columbia. The total caseload from 1999 through 2014 includes 41,762 cases; of these, neuroinvasive disease was present in 18,810. The mortality of the collected cases through the end of 2014 was 4.2% but 8.7% among neuroinvasive cases. In the United States, the highest incidence of neuroinvasive disease is among the Rocky Mountain states, the upper Midwest and the lower Mississippi River valley, while the largest numbers of cases occur in Texas, Colorado, and California. Outbreaks with West Nile infection tend to occur between mid-July and early September. Climatic factors, including elevated mean temperatures and rainfall, correlate with increased West Nile infection.

La Crosse virus was the second most commonly reported cause of arboviral disease in 2013 with 77 reported cases of neuroinvasive disease and the highest caseloads between 2004 and 2013 occurring in North Carolina, Ohio, and Tennessee. Other recognized and reported arbovirus infections in 2013 include Jamestown Canyon virus (22 cases, 7 in Wisconsin), Powassan virus (15 cases, 4 in New York), and eastern equine encephalitis virus (8 cases, 3 in Florida), and St. Louis encephalitis (1 case in Texas). These arboviruses can also cause sporadic cases, neuroinvasive disease, and seasonal outbreaks.

Pathogen-specific reservoirs (typically small mammals or birds) are responsible for maintaining the encephalitis-producing viruses in nature. For the eastern equine encephalitis virus, cotton rats and house sparrows serve as amplifying reservoirs. Birds are the main reservoir for West Nile virus and substantial avian mortality accompanies

West Nile fever outbreaks (monitoring chickens is recommended and a possible mode of disease surveillance). The mosquito species associated with transmission is different in the Western vs Eastern United States (*Culex tarsalis* vs *Culex pipiens*) and consequently the terrain associated with high prevalence areas differs (open grasslands vs urban areas).

Only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks between humans and vectors (mosquitoes of distinct species). Human to human transmission of the other arboviruses is usually related to blood (including granulocyte) transfusion or organ transplantation (although most infected donors give a history of clinically significant disease). Perinatal, transplacental, breastfeeding (rarely), laboratory, solid organ transplant, and possibly aerosol transmission of West Nile virus can also occur. St. Louis encephalitis and Powassan encephalitis occur among adults; western equine encephalitis, Venezuelan equine encephalitis, La Crosse and California encephalitis occur primarily among children. West Nile fever and eastern equine encephalitis are diseases of both children and adults.

► Clinical Findings

A. Symptoms and Signs

The human incubation period for arboviral encephalitides is 2–14 days. Symptoms include fever, malaise, sore throat, headache, gastrointestinal upset, lethargy, and stupor progressing to coma. Using blood donor surveys, it is estimated that only about 26% of infections are symptomatic (women and the highly viremic are more symptomatic). A nonpruritic maculopapular rash is variably present. Stiff neck and mental status changes are the most common neurologic signs. It is estimated that West Nile fever develops in 20–25% of those infected with West Nile virus, while neuroinvasive disease occurs in less than 1%, but has a mortality rate of at least 10%. About 50% of hospitalized patients with West Nile virus infection in the United States have significant muscle weakness that may be initially confused with the Guillain-Barré syndrome. Acute flaccid (poliomyelitis-like) paralysis is seen in 10% of West Nile virus neuroinvasive disease and less commonly with the other arboviruses. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Myocarditis, pancreatitis, and hearing loss are also reported. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms (but on occasion meningitis) are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in the middle aged, and frank encephalopathy is seen more often in the elderly. All forms of disease tend to be severe in immunocompromised persons in whom neuroinvasive manifestations and associated high mortality are more apt to develop.

Host genetic variation in the interferon response pathway is associated with both risk for symptomatic West Nile virus infection and West Nile virus disease progression.

B. Laboratory Findings

The peripheral white blood cell count is variable. Cerebrospinal fluid protein is elevated; cerebrospinal fluid glucose is normal; there is usually a lymphocytic pleocytosis; and polymorphonuclear cells may predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. Antibodies to arboviruses persist for life and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Individuals with chronic symptoms after West Nile virus infection may show persistent renal infection for up to 6 years with West Nile virus RNA present in urine. Documentation of a fourfold increase in acute/convalescence titers IgG or the presence of IgM antibodies is confirmatory. For West Nile virus, an IgM capture ELISA in serum or cerebrospinal fluid is almost always positive by the time the disease is clinically evident, and the presence of IgM in cerebrospinal fluid indicates neuroinvasive disease. These tests are available commercially but also through local or state health departments. Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever and St. Louis encephalitis (with possible seroreactivity now in the United States against dengue as well). PCR assays (also available through the CDC) are less sensitive than serologic tests for the diagnosis of acute infections but are the preferred method for screening blood products and may be particularly useful in immunocompromised patients with abnormal antibody responses. CT scans of the brain usually show no acute disease, but MRI may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

► Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis.

Severe forms of arbovirus encephalitides are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination (a demyelinating type following rabies, measles, pertussis), toxic encephalitis (from drugs, poisons, or bacterial toxins such as *Shigella dysenteriae* type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, anti-N-methyl-D-aspartate receptor (anti-NMDAR) encephalitis is a more common cause of encephalitis than viral diseases especially in the young, with 65% of encephalitis due to anti-NMDAR occurring among patients 18 or younger.

► Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and decubitus ulcers may occur. A chronic syndrome consisting of myalgias, arthralgias, and difficulty with concentration and memory is reported in over half the symptomatic cases.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Such measures include reduction of intracranial pressure (mannitol) and monitoring of intraventricular pressure. The efficacy of corticosteroids in these infections is not established. Ribavirin is commonly used to treat some tick-borne viral hemorrhagic diseases such as Crimean-Congo hemorrhagic fever, although the effectiveness of ribavirin is unclear. Other potentially beneficial therapeutic options include IVIG, interferon-alpha, and hyperimmune plasma and gamma globulin. Poor therapeutic options propel the search for an effective vaccine.

Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Most fatalities occur with neuroinvasive disease. In 2014, one of the largest prospective clinical investigations of West Nile virus neuroinvasive disease in the United States revealed that 7 (12%) of 55 patients died. Most presented in a coma. Otherwise, age older than 50 years is an important risk factor for severe disease and death. Other risk factors for mortality include black race, chronic kidney disease, hepatitis C virus infection, and immunosuppression. Recovery of persons with severe neurologic compromise may take months; in a cohort of 157 persons infected with West Nile virus, 40% continued to experience symptoms related to their infection up to 8 years later. Sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery.

The long-term prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

Prevention

No human vaccine is currently available for the arboviruses prevalent in North America, although phase I studies of a peroxide inactivated vaccine for West Nile are currently under way. Mosquito control (repellents, protective clothing, and insecticide spraying) is effective in prevention. Since 2003, all blood donations in the United States are screened with nucleic acid amplification tests for West Nile virus. Laboratory precautions are indicated for handling all these pathogens, in particular the West Nile virus. Because of reports of poor pregnancy outcomes possibly associated with Zika virus infection, pregnant women are advised to postpone travel to areas where Zika virus is circulating if possible. If they must travel, pregnant women are advised to follow recommendations to avoid mosquito bites while traveling.

3. Japanese Encephalitis

ESSENTIALS OF DIAGNOSIS

- ▶ Major cause of summertime encephalitis in East Asia.
- ▶ Vector-borne, with *Aedes* mosquito the carrier.
- ▶ Wide spectrum of symptoms with many asymptomatic infections.
- ▶ Vaccine available but no effective antiviral therapy.

General Considerations

The Japanese encephalitis virus is a flavivirus akin to those causing West Nile infection and St. Louis encephalitis. It is the most common cause of encephalitis in East Asia with over 68,000 estimated annual cases. It is geographically contained to East Asia but the area of distribution includes 24 countries, extending from Pakistan to Japan and from Northern China to Indonesia, Malaysia, and Northern Australia. Most cases occur in the summer and late fall, although in tropical and subtropical areas transmission occurs throughout the year. Major outbreaks every 2–15 years often correlate with patterns of agricultural development. The vector is the *Culex* species of mosquito, especially *Culex tritaeniorhynchus*. Wading birds and pigs more commonly sustain the infection as reservoirs in nature, since the viremia in man is transient and not usually high enough to sustain transmission.

Clinical Findings

Most persons asymptotically seroconvert. The 1% of patients in whom meningitis develops report the usual symptoms of headaches, nausea, mental status changes, movement disorders, and in a smaller percentage, seizures, typically in children. Infections that most clinically mimic Japanese encephalitis are St. Louis encephalitis and West Nile encephalitis, although epidemiologic data readily distinguishes these infections in most instances. Cases among travelers to the Orient are rare.

Suspicion of disease is based on epidemiologic data, with laboratory confirmation of cases based on serum or cerebrospinal fluid examination of antibodies at reference laboratories.

► Complications

A variety of cognitive, neurologic, and psychiatric complications are recognized to occur in as many as 50% of survivors. The mortality is reportedly as high as 30%.

► Treatment

Treatment is only supportive, including antipyretics, analgesics, bedrest, and fluids.

► Prevention

Four effective types of vaccine against Japanese encephalitis are available. A live attenuated vaccine made in China (referred to as SA14-14-2) is the most common. Other vaccine types include inactivated mouse brain-derived vaccines, live recombinant vaccines, and inactivated Vero cell–derived vaccines. In the United States, a vaccine licensed as inactivated Vero-cell culture–derived Japanese encephalitis vaccine (IXIARO, also based on the SA14-14-2 vaccine) has been available for those age 17 years and older since 2009 and a pediatric vaccine for those age 7–16 years since 2013. Travelers who plan to spend time (typically at least 1 month) in rural East Asia during the summer or fall should receive the two-course vaccine, given at a 1-month interval. The risk of serious reactions, including potential encephalitis, with live vaccines is very low (1:1,000,000 or less), with the newer vaccines being safer. Booster doses can be given for anticipated near future exposures.

Use of mosquito repellents, wearing long sleeves, long pants, and socks, and use of air conditioned facilities and bed nets are essential means of protection.

World Health Organization. Japanese encephalitis: fact sheet No. 386. December 2015. <http://www.who.int/mediacentre/factsheets/fs386/en/>

4. Tick-Borne Encephalitis

ESSENTIALS OF DIAGNOSIS

- ▶ Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.
- ▶ Transmitted via ticks or ingestion of unpasteurized milk.
- ▶ Long-term neurologic sequelae occur in 2–25% of cases.
- ▶ Therapy is largely supportive.
- ▶ Prevention is based on avoiding tick exposure, pasteurization of milk, and vaccination.

► General Considerations

Tick-borne encephalitis (TBE), a flaviviral infection caused by TBE virus, is the most common arbovirus infection transmitted by ticks in Europe. An estimated 10,000 to 12,000 cases occur each year in parts of Eurasia (from eastern France to northern Japan, from northern Siberia to Albania), with annual increases thought to be a function of increased recognition, climatic changes, and personal or social habits. TBE is endemic in Japan and parts of China as well. TBE occurs predominantly in the late spring through fall. It is usually a consequence of exposure to infected ticks, although unpasteurized milk from viremic livestock is also a recognized form of transmission. Surges in cases over the last 20 years are thought to be a consequence of agricultural policies that alter land cover, host prevalence, climatic factors, and human behavior (including pesticide usage and travel to endemic areas). The maximum altitude for occurrence of cases has increased to 5000 feet (about 1500 meters). The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion. The principal reservoirs for TBE virus are small rodents; humans are an accidental host. The vectors for most cases are *Ixodes ricinus* (most of Europe, including Turkey, Iran, and the Caucasus) and *Ixodes persulcatus* (in the belt from Eastern Europe to China and Japan).

Related viruses found in Eastern and mid-Western North America are the Powassan agent and the deer tick virus. In Germany during 2015, an unrelated bornavirus, variegated squirrel bornavirus-1, was thought to have caused fatal encephalitis in three breeders of variegated squirrels.

► Clinical Findings

A. Symptoms and Signs

Most cases are subclinical and many resemble a flu-like syndrome. There are two variants of clinical presentation: the Western subtype occurs mainly in the fall (but as early as April) and is most severe among the elderly, and the Eastern subtype is more severe among children.

Western subtype disease is biphasic in which after 2–10 days of fever (usually with malaise, headache, and myalgias), a 1–21 day symptom-free interval leads to a second phase with resumed fevers followed by neurologic symptoms. **Eastern subtype disease** is progressive without an asymptomatic interval. The neurologic manifestations range from febrile headache (accounting for up to 50% of Eastern subtype cases) to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Peripheral facial palsies, sometimes bilaterally, tend to occur infrequently, late in the course of infection, usually after encephalitis, and usually are associated with a favorable outcome within 30–90 days. Double infection with *Borrelia burgdorferi* (the agent of Lyme disease; transmitted by the same tick vector) may result in a more severe disease. Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

B. Diagnosis

Leukocytosis and neutrophilia are common. Abnormal cerebrospinal fluid findings include an inconsistent pleocytosis that may persist for up to 4 months. Neuroimaging shows hyperintense lesions in the thalamus, brainstem, and basal ganglia. TBE virus IgM and IgG are detected by ELISA techniques when neurologic symptoms occur. Cross-reactivity with other flaviviruses or a vaccinated state may require confirmation by detection of TBE virus-specific antibodies in cerebrospinal fluid. RT-PCR of blood (at earlier stages of the disease) or cerebrospinal fluid can sometimes, if available, assist with the diagnosis. Viral detection in the urine has been reported in a small group of cases. TBE virus can be differentiated from serologically indistinguishable viruses (Powassan agent and deer tick virus) by plaque-reduction neutralization tests.

► Complications

The main sequela of disease is paresis, which occurs in up to 10% of Western and up to 25% of Eastern subtype disease. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The **postencephalitic syndrome**, characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue, occurs with both subtypes. A progressive motor neuron disease and partial continuous epilepsy are complications seen with the Eastern subtype. Cognitive impairments may develop in children after infection. Long-standing psychiatric complications are reported and these include attention deficits, slowness of thought and learning impairment, depression, lability, and mutism.

► Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis such as enteroviral infections, herpes simplex encephalitis, and a variety of tick-borne pathogens including tularemia, the rickettsial diseases, babesiosis, Lyme disease, poliomyelitis (no longer reported from Eastern Europe), and other flaviviral infections. Coinfections are documented with *Anaplasma*, *Babesia*, and *Borrelia* infections.

► Treatment

Therapy is largely supportive. Some clinicians believe corticosteroids may be useful, although no controlled clinical trials exist.

► Prognosis

TBE usually has a good prognosis. In Switzerland, the mortality rate was of 0.7% between 2005 and 2011. A 1–2% mortality rate was reported from Croatia in 2015. Worse outcomes are associated with older age.

► Prevention

There are two inactivated TBE virus vaccines for adults and two vaccines for children licensed in Europe. Their

effectiveness is about 99%. They were developed in Austria and Germany and in Russia, and there appears to be cross-reactivity against isolates from diverse geographic areas although concomitant administration of the two different vaccines may result in immune interference. The initial vaccination schedule requires three doses given over 1 year with boosters every 3–5 years. There are decreased antibody titers (quantity not quality) and booster response in recipients of TBE vaccines who are over 50 years of age, indicating the need for a modified immunization strategy in older patients.

Poor uptake of the vaccine in endemic countries is responsible for limited abilities to control the disease. Other prevention recommendations include avoidance of tick exposure and pasteurization of cow and goat milk.

5. Lymphocytic Choriomeningitis

ESSENTIALS OF DIAGNOSIS

- “Influenza-like” prodrome of fever, chills, and cough, followed by a meningeal phase.
- Aseptic meningitis with stiff neck, headache, nausea, vomiting, and lethargy.
- Cerebrospinal fluid: slight increase of protein, lymphocytic pleocytosis (500–3000/mcL); low glucose in 25% of patients.
- Complement-fixing antibodies within 2 weeks.

► General Considerations

The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that primarily infects the CNS. Its main reservoir is the house mouse (*Mus musculus*). Other rodents (such as rats, guinea pigs, and even pet hamsters), monkeys, dogs, and swine are also potential reservoirs. The infected animal sheds lymphocytic choriomeningitis virus in nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles and mucosal exposure, direct contact, or animal bites. The disease in humans is underdiagnosed and occurs most often in autumn. The lymphocytic choriomeningitis virus is typically not spread person to person, although vertical transmission is reported, and it is considered as an underrecognized teratogen. Rare cases related to solid organ transplantation and autopsies of infected individuals are also reported. All

reported cases were donor derived. Outbreaks are uncommon, and usually occur in laboratory settings among those workers with significant rodent exposure.

The ubiquitous nature of its reservoir and the wide distribution of the reported cases suggest a widespread geographic risk for lymphocytic choriomeningitis virus infection. Serologic surveys in the southern and eastern United States suggest past infection in approximately 3–5% of those tested, although more recent data from upstate New York showed less than 1% seroprevalence. The risk of infection can be reduced by limiting contact with pet rodents and rodent trappings.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms. Symptoms are biphasic, with a prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days the fever subsides only to return after 2–4 days alongside the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Arthralgias can develop late in the course. Transverse myelitis, deafness, Guillain-Barré syndrome, and transient and permanent hydrocephalus are reported. Lymphocytic choriomeningitis virus is a well-known, albeit underrecognized, cause of congenital infection frequently complicated with obstructive hydrocephalus and chorioretinitis. In fetuses and newborns with ventriculomegaly or other abnormal neuroimaging findings, screening for congenital lymphocytic choriomeningitis may be considered; mothers are asymptomatic half the time. In over one-third of cases, rodent exposure is reported retrospectively. Occasionally, a syndrome resembling the viral hemorrhagic fevers is described in transplant recipients of infected organs and in patients with lymphoma.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be initially present. During the meningeal phase, cerebrospinal fluid analysis frequently shows lymphocytic pleocytosis (total count is often 500–3000/mcL) alongside a slight increase in protein, while a low to normal glucose is seen in at least 25%. The virus may be recovered from the blood and cerebrospinal fluid by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

► Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

► Treatment

Treatment is supportive. In the survivor of a transplant-associated outbreak, ribavirin (which is effective against other arenaviruses) was used successfully along with decreasing immunosuppression.

► Prognosis

Complications and fatalities are rare in the general population. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Congenital infection is more severe with about 30% mortality rate among infected infants, and more than 90% of survivors suffering long-term neurologic abnormalities. Lymphocytic choriomeningitis in solid organ transplant recipients is associated with a poor prognosis; of reported cases, the mortality rate is more than 80%.

► Prevention

Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

6. Prion Diseases

ESSENTIALS OF DIAGNOSIS

- ▶ Rare in humans.
- ▶ Cognitive decline.
- ▶ Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- ▶ Variant form presents in younger persons with prominent psychiatric or sensory symptoms.
- ▶ Specific EEG patterns.

► General Considerations

The transmissible spongiform encephalopathies are a group of fatal neurodegenerative diseases affecting humans and animals. They are caused by **proteinaceous infectious particles** or **prions**. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change of a normal brain protein (prion protein; PrP[C]) into an abnormal isoform (PrP[Sc]) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia and, in some cases, the deposition of beta-amyloid oligomeric plaques.

Prion disease can be hereditary, sporadic, or transmissible in humans. Hereditary disorders are caused by germ line mutations in the PrP[C] gene causing **familial**

Creutzfeldt–Jakob disease (fCJD), Gerstmann–Sträussler–Scheinker syndrome (GSS), and fatal familial insomnia. Another uncommon hereditary disorder is PrP systemic amyloidosis.

Sporadic Creutzfeldt–Jakob disease (sCJD) is the most common of the human prion diseases, accounting for approximately 85% of cases; it has no known cause. Transmissible prion disease is only described for kuru and Creutzfeldt–Jakob disease in its **iatrogenic (iCJD)** and **variant (vCJD)** form. Iatrogenic transmission of CJD is associated with prion contaminated human corneas, dura mater grafts, growth hormone, gonadotropins, stereotactic electroencephalography, electrodes, and neurosurgical instruments.

Kuru, once prevalent in central New Guinea, is now rare, a decline in prevalence that started after the abandonment of cannibalism in the late 1950s (a protective allele of the PrP gene is now identified at codon 127).

More than 200 cases of vCJD (**bovine spongiform encephalopathy [BSE]** or “**mad cow disease**”) were reported in the United Kingdom since the first documented cases there in the mid-1990s. It is far less common in North America, with only four cases reported in the United States (the last one in 2014) and two deaths in Canada from definite or probably vCJD. Of the US-reported cases, none are confirmed to have acquired the disease locally (two of them acquired the infection in the United Kingdom, one in Saudi Arabia, one possibly in a Middle Eastern or Eastern European country). This disease is characterized by its bovine-to-human transmission through ingestion of meat from cattle infected with BSE. There is no animal-to-animal spread of BSE, and milk and its derived products are not considered infectious. Reports of secondary transmission of vCJD due to blood transfusions from asymptomatic donors are reported in the United Kingdom. Although iCJD and vCJD are not associated with a known PrP gene mutation, a polymorphism in codon 129 is prevalent and seems to determine susceptibility and expression of clinical disease.

The overall annual incidence of prion disease worldwide is approximately 1–2 in 1 million persons per year. In the United States, among the 3285 cases reported through August 25, 2015 to the US National Prion Disease Pathology Surveillance Center, 2929 (89.2%) were sporadic, 333 (10.1%) familial, 7 (0.2%) iatrogenic, and 4 (0.1%) vCJD.

▶ Clinical Findings

A. Symptoms and Signs

Both sCJD and fCJD usually present in the sixth or seventh decade of life, whereas the iCJD form tends to occur in a much younger population. Clinical features of these three forms of disease usually involve mental deterioration (dementia, behavioral changes, loss of cortical function) progressive over several months, as well as myoclonus, extrapyramidal (hypokinesia) and cerebellar manifestations (ataxia, dysarthria). Finally, coma ensues, usually associated with an akinetic state and less commonly decerebrate/decorticate posturing. Like iCJD, vCJD usually affects younger patients (averaging ~28 years), but the

duration of disease is longer (about 1 year). The degree of organ involvement is often extensive, and the clinical symptoms are unique, mainly characterized by prominent psychiatric and sensory symptoms.

B. Laboratory Findings

CJD should be considered as a diagnosis in the proper clinical scenario, in the absence of alternative diagnoses after routine investigations. Abnormalities in cerebrospinal fluid are subtle and rarely helpful. The detection of 14-3-3 protein in the cerebrospinal fluid is helpful for the diagnosis of sCJD but not in vCJD and fCJD. Its sensitivity and specificity are widely variable among different studies. Cerebrospinal fluid detection of total PrP can differentiate CJD from atypical Alzheimer disease with 82.1% sensitivity and 91.3% specificity.

A blood-based assay and PCR in cerebrospinal fluid show promising results in the diagnosis of vCJD with high specificity but 71% sensitivity. The assay is available through academic specialty prion clinics in the United Kingdom. It is also recognized that a variant with low titers (“very low peripheral prion colonization”) in peripheral tissue, including frequently biopsied tonsillar tissue, may lead to underrecognition of vCJD.

In sCJD, EEG typically shows a pattern of paroxysms with high voltages and slow waves, while MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. MRI has great potential for improving early diagnosis of sCJD because clinical findings are often missed. When an experienced neuroradiologist or a prion disease expert reviews the MRI, diagnostic sensitivity of MRI for sCJD increases to 91%. Cortical findings associated with sCJD often are not documented by referring centers. In contrast, vCJD shows a diffusely abnormal but nondiagnostic EEG. MRI characteristically reveals hyperintensity of the posterior thalamus (“pulvinar sign”). Positron emission tomography can help distinguish GSS disease. The differentiation and definitive diagnosis of these neurodegenerative diseases are established by neuropathologic confirmation.

▶ Differential Diagnosis

Autoimmune encephalitis can have a similar clinical picture. The presence of high titer autoantibodies (eg, to the NMDA receptor) in the cerebrospinal fluid is consistent with autoimmune encephalitis.

▶ Treatment & Prevention

There is no specific treatment for CJD. Once symptoms appear, the infection invariably leads to death. Flupirtine (an analgesic drug) is sometimes useful in slowing the associated cognitive decline but does not affect survival. Studies are in progress to identify vaccines, but no promising candidates exist to date.

Iatrogenic CJD can be prevented by limiting patient exposure to potentially infectious sources as mentioned above. Prevention of vCJD relies on monitoring livestock for possible infection. The American Red Cross does not

accept blood donations from persons with a family history of CJD or with a history of dural grafts or pituitary-derived growth hormone injections.

An international referral and database for CJD is available at: <http://www.cjdsurveillance.com>.

Reference centers are available at Case Western Reserve University in the United States and the University College London Hospitals in the United Kingdom.

7. Progressive Multifocal Leukoencephalopathy (PML)

PML is a rare demyelinating CNS disorder caused by the reactivation of the JC virus (John Cunningham virus or JCV). This polyomavirus usually causes its primary infection during childhood with about 80% of adults typically being seropositive. The virus remains latent in the kidneys, lymphoid tissues, epithelial cells, peripheral blood leukocytes, bone marrow, and possibly brain until reactivation occurs and symptoms become evident. This reactivation is usually seen in adults with impaired cell-mediated immunity, especially AIDS patients (5–10% of whom develop PML), as well as those with idiopathic CD4 lymphopenia syndrome. It is also reported among those with lymphoproliferative and myeloproliferative disorders; granulomatous, inflammatory, and rheumatic diseases (systemic lupus erythematosus and rheumatoid arthritis in particular); as well as in those who have undergone solid and hematopoietic cell transplantation; and occasionally in those who have other medical states, including cirrhosis and kidney disease.

Diagnostic criteria that use clinical, imaging, pathologic, and virologic manifestations of JCV are available from the American Academy of Neurology.

Medication-associated PML is described with the use of natalizumab, rituximab, infliximab (one case), azathioprine with corticosteroids (one case), and mycophenolate mofetil. Natalizumab, a monoclonal antibody used in the treatment of multiple sclerosis, is associated with the risk of PML developing in 1.35 cases per 1000 patients treated for more than a year and 1.78 per 1000 for patients treated for longer than 2 years. The risk of clinical PML appears to increase up to 36 months of therapy and levels off thereafter. The virus is detected in the cerebrospinal fluid of up to one-half all patients treated with natalizumab although the exact relationship between latent JCV and frank PML remains unclear, with higher JC viral loads detected among patients who are immunosuppressed and among those who have HIV with lower CD4 counts.

Although an immune reconstitution inflammatory state may follow cessation of monoclonal antibody therapy, the JCV presence and the residual neurologic deficits may not clear for years after therapy is stopped. The risk of developing PML associated with rituximab is at least 1 in 25,000 exposed patients with cases reported in various autoimmune conditions (systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis). The mean interval between use of the drug to the diagnosis of PML is 5.5 months. Smoking is reportedly associated with an increased risk of PML.

Clinical Findings

A. Symptoms and Signs

JCV causes lytic infection of oligodendrocytes in the white matter and symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and the cervical spine is rare.

B. Laboratory Findings

PCR for JCV in cerebrospinal fluid is used for diagnosis in patients with compatible clinical and radiologic findings. A quantitative PCR is more sensitive. Persistent JC viremia and increasing urinary JCV DNA may be predictive of PML. An anti-JCV immunoglobulin G (IgG) was higher 6 months before diagnosis but was not predictive of PML in a cohort of HIV-infected persons.

MRI of the brain shows multifocal areas of white matter demyelination without mass effect or, usually, contrast enhancement. These findings may not be distinguishable from immune reconstitution inflammatory syndrome. Increased uptake of methionine with concomitant decreased uptake of fluorodeoxyglucose in positron emission tomography may be helpful for diagnosis. In HIV-infected patients, a syndrome of cerebellar degeneration is described.

Treatment & Prevention

Limiting the immunosuppressed state represents the mainstay of therapy for PML. Treatment of HIV with ART reduces the incidence of PML, improves the clinical symptoms, reverses some of the radiographic abnormalities, and improves the 1-year mortality rate, regardless of baseline CD4 count. Immune restoration can induce worsening of the clinical picture in a small number of cases. Immune reconstitution syndromes do not alter mortality but are associated with a form of PML called non-determined leukoencephalopathy associated with a distinct chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule. Deficits associated with PML, including monoclonal associated forms, may persist for years.

Decreasing immunosuppression in non-AIDS patients with PML (eg, transplant patients) is also typically beneficial. Cidofovir may be beneficial in non-AIDS related cases while corticosteroids may be useful with immune reconstitution. Because the JCV infects cells through

serotonin receptors, some clinicians recommend the use of risperidone and mirtazapine. Plasma exchange, which theoretically reduces the plasma level of agents associated with PML, may be useful in natalizumab-associated PML.

8. Human T Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses that infect CD4 and CD8 T cells respectively, where they persist as a lifelong latent infection. HTLV-1 currently infects approximately 20 million individuals worldwide. It is endemic to many regions in the world including southern Japan, the Caribbean, much of sub-Saharan Africa, South America, Eastern Europe, and Oceania. The Caribbean basin and southwestern Japan show the highest prevalence of infection (4–37%). Conversely, HTLV-2 is mainly found in native populations of South (1–58%), Central (8–10%), and North America (2–13%) as well as African pygmy tribes.

In the United States, studies done in blood donors show a seroprevalence of HTLV-1 of 0.005% and HTLV-2 of 0.014%, a decline since the early 1990s. Over 85% of cases found in the United States are located in the West or Southwest. The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and breast feeding), and parenterally (injection drug use and blood transfusion). Hence, a higher prevalence is seen among injection drug users. Coinfection with HIV-1 occurs but is often underrecognized. Transmission via organ transplant has been reported.

► Clinical Findings

A. Symptoms and Signs

HTLV-1 infection is associated with **HTLV-1 adult T cell lymphoma/leukemia (ATL)** and **HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP)**. In contrast, HTLV-2 is significantly less pathogenic, with few reported cases of HAM/TSP as well as other neurologic manifestations. The causative association of HTLV-1 with ATL, attributed to the virally encoded oncoprotein *tax*, is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age of diagnosis of ATL is 40–50 years in Central and South America and 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. A primary cutaneous tumor is also described and shows a worse prognosis compared with the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma,

organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as *Pneumocystis jirovecii* pneumonia and cryptococcal meningitis, are common.

HAM/TSP, associated with both HTLV-1 and HTLV-2, develops in 0.3–4% of seropositive individuals and is more common in women. A chronic inflammation of the spinal cord leads to progressive motor weakness and symmetric spastic paraparesis, nociceptive low back pain, and paraplegia with hyperreflexia. Bladder and sexual disorders (eg, dyspareunia, erectile dysfunction), sensory disturbances, and constipation are also common. A progressive cognitive impairment is seen with HAM/TSP in children. Both viruses can also induce motor abnormalities, such as leg weakness, impaired tandem walk, and vibration sense, without overt HTLV-associated myelopathy.

An HTLV-1 provirus load in peripheral blood mononuclear cells and cerebrospinal fluid cells, and an HTLV-1 mRNA load are proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis, lymphocytosis (HTLV-2) and with thrombocytosis (HTLV-1).

HTLV-1 seropositivity is associated with an increased risk of tuberculosis, *Strongyloides stercoralis* hyperinfection, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, polymyositis, uveitis, Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis. Bronchioloalveolar carcinoma is increased in frequency in the presence of HTLV-1.

HTLV-2 appears to cause a myelopathy that is milder and slower to progress than HAM. All-cause and cancer mortality is higher among HTLV-2 seropositive patients.

HTLV-1/HIV coinfection is associated both with higher CD4 counts and a higher risk of HAM.

B. Laboratory Findings

The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. The identification of HTLV-1 antibodies supports the diagnosis.

► Treatment, Prevention, & Prognosis

Management of ATL consists mainly of chemotherapy, with allogeneic stem cell transplantation and the use of monoclonal antibodies (anti-CCR4 and anti-CD25). A chemotherapy regimen in Japan using eight different agents shows a higher response rate than traditional biweekly CHOP (40% vs 25%). Combination therapy with interferon-alpha has been used with success. A therapeutic vaccine is in early clinical trials. Prophylaxis against infections is needed in ATL because patients show a profound immunodeficiency.

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination therapy with antiretrovirals does not show benefit. Interferon-alpha may be of some efficacy. Small, uncontrolled studies suggest plasmapheresis results in improvement in gait and sensory disturbance among

some patients. Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two. Improved assays to screen organ donors for HTLV-1 and -2 infections are needed although such screening is not currently required.

Patients who are coinfecting with HIV-1 and HTLV require underlying management of each individually because HTLV does not respond to ART.

VIRAL HEMORRHAGIC FEVERS

1. Ebola Viral Disease (EVD)

ESSENTIALS OF DIAGNOSIS

- ▶ Early stage EVD presents as a nonspecific febrile illness.
- ▶ Later stage EVD typically includes severe gastrointestinal symptoms, followed by neurologic symptoms and hypovolemic shock.
- ▶ Hemorrhagic manifestations are rare.
- ▶ Travel and contact history from an Ebola-affected country raise suspicion.
- ▶ Diagnosis is confirmed by detection of virus with a real-time RT-PCR.

General Considerations

Genus *Ebolavirus* is a single-stranded RNA virus in the Filoviridae family. Five species of *Ebolavirus* have been identified, and each species has an associated virus:

1. Species, *Tai Forest ebolavirus*; virus, Tai Forest (TAFV).
2. Species, *Reston ebolavirus*; virus, Reston virus (RESTV).
3. Species, *Sudan ebolavirus*; virus, Sudan virus (SUDV).
4. Species, *Zaire ebolavirus*; virus, Ebola virus (EBOV or ZEBOV).
5. Species, *Bundibugyo ebolavirus*; virus, Bundibugyo virus (BDBV).

Only three viruses are clinically relevant in humans (EBOV, SUDV, and TAFV). “Ebola” as discussed in this section refers to the clinically relevant viruses.

While the zoonotic reservoir is unknown, evidence from Marburg suggests fruit bats as a possible vector. After

a zoonotic transmission to a human occurs, Ebola can continue to be transmitted among humans who directly contact infected body fluids (droplet and contact precautions advised). There is no evidence supporting airborne transmission; however, the virus aerosolizes, meaning that certain settings such as health care facilities carry additional risk.

To acquire EVD, the virus must enter the body via mucous membranes, nonintact skin, sexual intercourse, breastfeeding, or needlestick. Ebola has a 2–21 day incubation period, and over 95% of cases present with symptoms during the first 14 days. **Prior to manifestation of symptoms, Ebola is not transmissible.** Even at symptom onset, the risk of transmission is extremely low but increases over time. Traditional burial practices (which entail considerable contact with the corpse) and unprotected direct care of persons with EVD are associated with highest transmission risk.

The first Ebola outbreak occurred in 1976 as a simultaneous epidemic in Congo and Sudan. The first cases were identified along the Ebola River, in Congo but near the Sudanese border, resulting in naming of the disease. This was the second largest Ebola outbreak in history. Subsequent outbreaks had been confined to Congo, Uganda, and Sudan until March 2014 when the first Ebola case in West Africa was identified in Gueckedou, Guinea, near the borders of Sierra Leone and Liberia. *Zaire ebolavirus* was the species identified, more specifically referred to as a novel variant of Ebola virus (EBOV) called “Makona.” Subsequently, this Ebola outbreak grew to be larger than all prior Ebola outbreaks.

As of October 18, 2015, there were 28,476 reported EVD cases in eight affected countries, with 11,298 reported deaths. The number of EVD cases in the highly affected countries during this outbreak is as follows: 3803 persons in Guinea, 10,666 persons in Liberia, and 14,001 persons in Sierra Leone. There were 881 cases with 531 deaths in these three countries among health care workers. Other EVD cases were reported from Italy, Mali, Nigeria, Senegal, Spain, the United Kingdom, and the United States. Significant underreporting of cases, estimated at 2.5-fold, is noted across the highly affected countries.

Several factors led to the unprecedented magnitude of the 2014–2015 Ebola epidemic. Although Côte d’Ivoire did have one EVD case (TAFV) in 1994, the 2014–2015 epidemic was the first significant outbreak in West Africa. These countries with fragile health systems were recovering from civil wars and a coup d’état and had no Ebola surveillance systems. Another compounding factor was the size of the epidemic at the time it was uncovered, with the epidemic already having reached Conakry, the capital of Guinea, and having progressed into Sierra Leone and Liberia. Aside from the earlier Kikwit outbreak in Congo, which occurred in an isolated, quarantined city, this epidemic has been recognized as the first truly urbanized outbreak, making traditional public health measure such as contact tracing more difficult. Liberia was declared free of EVD on September 15, 2015. As of October 18, 2015, Sierra Leone reported no new cases for 5 weeks. Cases continue at 1–3 per week in Guinea. Besides Liberia, the following countries as of October 20, 2015, with prior cases are free

of EVD (42 days without evidence for an infection): Italy, Mali, Nigeria, Spain, the United Kingdom, and the United States.

▶ Clinical Findings

A. Symptoms and Signs

At symptom onset, early stage EVD most typically presents as a nonspecific febrile illness. Along with fevers, patients tend to experience malaise, fatigue, myalgia, and arthralgia. After 3–5 days, later stage EVD may develop with nausea, vomiting, abdominal pain, diarrhea, and other gastrointestinal symptoms accompanying the febrile illness. Nausea and vomiting continue to worsen until the patient can no longer tolerate oral intake, and diarrhea becomes large volume (5 or more liters per day). This stage of the illness may continue for a week during which time neurologic symptoms gain prominence. Encephalitis is commonly observed and includes the symptoms of confusion, slowed cognition, agitation, and occasional seizures. Shock develops in most patients, but hemorrhagic manifestations develop in only 1–5% of patients. Respiratory symptoms (ie, cough) are not typical for EVD.

B. Laboratory Findings

Although several novel point-of-care diagnostic technologies are available, EBOV continues to be diagnosed with RT-PCR. Blood samples obtained within the first 3 days of illness should be repeated if the results are negative and clinical symptoms and signs persist. After about 10 days, IgM antibodies begin to develop and, after approximately 2 weeks, an IgG antibody response develops.

Given that filoviruses infect dendritic cells and then hepatocytes and renal cortical cells, laboratory findings typically include a low platelet count, leukopenia, transaminitis (aspartate aminotransferase [AST] greater than alanine aminotransferase [ALT]), and increased serum creatinine level. The nature of this illness and its significant fluid loss tend to cause electrolyte abnormalities and accelerate acute kidney injury. For many patients in highly affected countries, non-Ebola diagnostic testing is inaccessible.

C. Imaging

Radiographic findings can be used to suggest alternative diagnoses.

▶ Differential Diagnosis

The differential diagnosis varies with the stage of illness. Early stage EVD is commonly mistaken for malaria, typhoid, and other viral illnesses. Myriad illnesses, though, could present as a nonspecific febrile illness. As gastrointestinal symptoms develop, health providers should also consider viral hepatitis, toxins, leptospirosis, and rickettsial diseases. In later stage EVD, health providers need to consider bacterial, viral, and parasitic illnesses, including cholera and, in children, rotavirus infection, which can present with severe gastroenteritis and shock. Encephalitis

must be differentiated from the confusion associated with acute kidney injury and other neurologic manifestations. Hemorrhagic manifestations raise suspicion for EVD but could be due to leukemia, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or disseminated intravascular coagulation. Travel and contact history are crucial when considering the differential diagnosis in areas where Ebola is not endemic. If such histories are present, patients need to be asked if they had unprotected exposures to persons with Ebola.

▶ Complications

Hypovolemic shock and multiorgan failure are the most common complications of EVD. Coinfections with malaria or bacteria (or both) are important considerations and can occur before presentation and during treatment of EVD.

▶ Treatment

Treatment is supportive. In the presence of oral rehydration salts, mortality rates are approximately 70%. Several studies have shown that intravenous fluids can reduce the mortality rates to less than 50%. In these studies, the amount of intravenous fluid replacement was relatively less than what would be used in countries with developed health systems. According to the CDC and other agencies, as of October 20, 2015, 10 persons have been treated for Ebola in the United States. Most were healthcare workers who were evacuated to biocontainment units in the United States and received intensive care and experimental therapies. All but two patients survived.

In addition to supportive care, two particular antivirals used in the EVD outbreak are the monoclonal antibody combination referred to as **ZMapp** (the supply of which is easily exhausted) and an RNA inference agent referred to as **TKM-Ebola**, which appears ineffective in phase II trials. Other antiviral agents under study include brincidofovir (whose trial was discontinued because of low caseload in Liberia) and favipiravir, an RNA-dependent RNA polymerase inhibitor, which showed preliminary encouraging antiviral activity among patients with low viremia in Guinea; it cannot be given during pregnancy.

Aside from Ebola treatment and experimental therapies, patients typically receive empiric antimalarial agents and broad-spectrum antibiotics. Empiric therapies are important at presentation because the risk associated with non-Ebola diagnostics prevents studies from being conducted until results are obtained.

▶ Prognosis

The prognosis depends greatly on patient, exposure, and clinical characteristics. Children under the age of 5 and adults older than 40 years have a high risk of death from EVD. In prior Ebola outbreaks, pregnant women all died. In the 2014–2015 epidemic, a small but significant percentage of pregnant women survived. Immunosuppressed patients show a poor prognosis. All persons who had a needlestick of a confirmed Ebola case died. Clinical characteristics indicating a poor prognosis include a short

incubation time, rapid progression of symptoms, hepatic dysfunction, and hemorrhagic manifestations. In general, poor overall medical care confers a poor prognosis.

► Prevention

Disinfection, hygiene, and sanitation are the cornerstones to infection prevention and control measures.

At least nine vaccines are under clinical development. A summary of these vaccines is available at http://www.who.int/medicines/emp Ebola_q_as/en/.

► When to Admit

- Persons living in or returning from a country with high rates of Ebola transmission should be monitored for 21 days and admitted to a healthcare facility when symptoms meeting the WHO case definition of a suspected EVD case develop, in accordance with the screening protocol designated by the respective country's governmental health decision-making body. For example, the screening protocol from the Ministry of Health and Sanitation in Sierra Leone includes:
 - Any person suffering from a fever (or history of fever) and having had contact with suspected, probable, or confirmed Ebola case; **or**
 - Any person with a fever (or history of fever) and at least three of the following symptoms: headaches, vomiting, anorexia/loss of appetite, diarrhea, lethargy, stomach pain, aching muscles or joints, difficulty swallowing, breathing difficulties, or hiccups; **or**
 - Any person with inexplicable bleeding.

2. Other Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever (both with occasional hemorrhagic complications), and Filoviridae, causing Ebola and Marburg, are discussed in separate sections.

Lassa fever (an Old World arenavirus) is rodent associated and transmission usually occurs through aerosolized particles (from rodents or infected individuals). Transmission through direct contact with infected biologic fluids or tissues is also documented and food-borne transmission, while considered, is not definitively proven. Similar modes of transmission are assumed for **Junin virus** and other members of the New World Arenaviridae (Machupo virus, Sabia virus, Guanarito virus, Whitewater Arroyo virus).

The bunyaviruses include the **Crimean-Congo hemorrhagic fever** (transmitted by infected animal exposure or tick bite), the **Rift Valley fever** (transmitted by exposure to infected animal products or bite of an infected mosquito or flea), and the **hantaviruses** (associated with rodent exposure and discussed separately below). The geographic distribution of Crimean-Congo hemorrhagic fever, like that of its tick vector, is widespread with cases reported in Asia, the Middle East, and Eastern Europe. In 2002, Turkey experienced the largest reported outbreak with over 2500 cases. An outbreak occurred with 22 cases in the country of Georgia. Rift Valley fever causes outbreaks in sub-Saharan and Northern Africa. The last reported outbreak was in 2010 in Sudan. Rift Valley cases have also been confirmed outside the African continent, in Saudi Arabia and Yemen.

A new bunyavirus, a phlebovirus, associated with fever and thrombocytopenia, was identified in 2010 in Central and Northeastern China and is named for its symptoms: the **severe fever with thrombocytopenia syndrome (SFTS) virus**. Its differential diagnosis includes anaplasmosis, hemorrhagic fever with renal syndrome, or leptospirosis. The current candidate vector is a tick of the Ixodidae family. A mortality of 12% was noted among the first 171 patients. A new pathogenic virus (**Heartland virus**) similar to the SFTS virus was isolated in Missouri in 2009 from two farmers who had fever, diarrhea, and fatigue. The virus appears to be amplified in deer and raccoons. Transmission occurs via the Lone Star tick (*Amblyomma americanum*). There is no evidence for the transmission of viral hemorrhagic fever through air travel.

► Clinical Findings

A. Symptoms and Signs

The incubation period can be as short as 2 days for the Rift Valley fever or as long as 21 days for Lassa fever. The clinical symptoms in the early phase of a viral hemorrhagic fever are very similar, irrespective of the causative virus, and resemble a flu-like illness or gastroenteritis. Hepatitis is common.

The late phase is more specific and is characterized by organ failure, persistent leukopenia, altered mental status,

and hemorrhage. Exanthemas and mucosal lesions can occur. The range of pathology described with Crimean-Congo hemorrhagic fever continues to grow and includes cardiac failure, bilateral alveolar hemorrhages, and retinal hemorrhages. Rift Valley fever is reportedly associated with encephalitis and also retinitis. Adrenal dysfunction is a common sequela of this class of infections and a cause for the development of the late-stage shock associated with these infections. The case-fatality rate ranges from 5% to 30%. The convalescence period can be long and complicated. There is no evidence of chronic infection among survivors. Risk factors for complications in patients with Crimean-Congo hemorrhagic fever include advanced age, thrombocytopenia, prolonged clotting factor parameters, and hepatitis while risk factors for mortality include altered sensorium and prolonged international normalized ratio. Risk factors for acquiring Rift Valley fever include male sex; working with abortive animal tissue; slaughtering, skinning, or sheltering animals; and drinking raw milk; complications of Rift Valley fever are more common among older men and among persons with a history of herding or slaughtering livestock and having poor visual acuity.

B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia, (although with Lassa fever leukocytosis is noted), anemia, increased hematocrit, elevated liver function tests, and findings consistent with disseminated intravascular coagulation (although less prominently in Lassa fever). Urinalysis can reveal proteinuria and hematuria.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion and the CDC must be contacted for guidance (Special Pathogens Branch, 404-639-1115). Diagnosis may be made by antigen detection (by ELISA), nucleic acid amplification (PCR techniques), or by demonstration of a significant specific fourfold or greater rise in antibody titer. Crimean-Congo hemorrhagic fever is best diagnosed with an IgM serology, although IgG ELISA or immunofluorescence and quantitative reverse transcription PCR are nearly as effective. These viruses can be isolated in culture, but this testing should be done at a biosafety level 4 laboratory facility.

▶ Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. The likelihood of acquiring hemorrhagic fevers among travelers is low.

▶ Treatment

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne

precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Certain arenaviruses (the Lassa pathogen, Junin virus in its viscerotropic phase, Machupo virus) and bunyaviruses (the Congo-Crimean hemorrhagic fever and Rift Valley fever pathogens) respond to oral ribavirin if it is started promptly. Patients rarely survive without ribavirin therapy. The efficacy for postexposure ribavirin in the management of Lassa fever, other arenaviruses, or hospital-associated Crimean-Congo hemorrhagic fever remains anecdotal; its successful use in a German hospital on a soldier infected in Afghanistan is encouraging. If ribavirin is used, expert experience suggests a high loading dose (35 mg/kg orally followed by 15 mg/kg three times daily for 10 days) and only for high-risk settings (eg, needlestick injury, mucous membrane contamination, emergency resuscitative contact, or prolonged intimate exposure during transport). The anti-trypanosomal agent suramin may be effective against the Rift Valley fever virus.

The flaviviruses do not respond to ribavirin. Live attenuated vaccines are available for Junin hemorrhagic fever and the Rift Valley fever, and they are under study for Crimean-Congo hemorrhagic fever. In addition, recombinant and virus-like particle vaccines are under development for most of these pathogens (including the Lassa fever virus but not the Junin hemorrhagic fever virus). Therapeutic interventions that target the hematologic system are at most only marginally effective.

▶ When to Admit

- Persons with symptoms compatible with those of any hemorrhagic fever and who have travelled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Lassa virus, are highly transmissible to healthcare workers.

3. Dengue

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure 7–10 days before onset.
- ▶ Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, sore throat, and depression.
- ▶ Biphasic fever curve: initial phase, 3–7 days; remission, few hours to 2 days; second phase, 1–2 days.
- ▶ Biphasic rash: evanescent, then maculopapular, scarlatiniform, morbilliform, or petechial changes from extremities to torso.
- ▶ Leukopenia and thrombocytopenia in the hemorrhagic form.

▶ General Considerations

Dengue is due to a flavivirus transmitted by the bite of the *Aedes* mosquito. It may be caused by one of four, possibly five, distinct serotypes widely distributed globally between the tropics of Capricorn and Cancer. An estimated 70–500 million cases of dengue fever and several hundred thousand cases of dengue hemorrhagic fever occur each year with numbers growing in both dengue fever and dengue hemorrhagic fever as a consequence of climatic factors, travel, and urbanization. **It is thus along with malaria one of the two most common and important vector-borne diseases of humans**, with 2.5 billion persons living in dengue-infected regions and regions of major intermittent outbreaks. In the Philippines, for example, there are over 117,000 cases annually. The incubation period is 3–15 days (usually 7–10 days). When the virus is introduced into susceptible populations, usually by viremic travelers, epidemic attack rates range from 50% to 70%.

Dengue is endemic in the lower Rio Grande Valley and adjacent border towns, with 40% of Brownsville, Texas residents showing serologic evidence of past infection and the virus being detected in mosquito larvae among 30% of households. In other areas of the world, the seroprevalence of southern Indians is 21%, of Haitians by age 3 is over 53%, and of residents of the French West Indies islands of Guadeloupe and Martinique, 93.5%. In some areas of endemicity there is cyclicity (in China, cases surge every 4–7 years). Surveillance systems for dengue are relatively undeveloped in much of sub-Saharan Africa.

Severe epidemics of dengue hemorrhagic fever (serotype 3) occurred over the past 20 years in East Africa, Sri Lanka, and Latin America. In 2014, an unexpected large outbreak of more than 40,000 dengue virus serotype 2 infections occurred in Guangdong province, China. Other significant regional outbreaks include the Portuguese archipelago of Madeira (Europe) in 2012 with over 2000 persons infected.

Dengue is the second overall cause of a febrile illness (after malaria) in travelers returning from developing countries. The high transmission rates of malaria

compared to dengue and high numbers of travelers with a febrile illness returning from sub-Saharan Africa drive the global statistic. Yet on other continents (and regions), dengue is more common than malaria, except for Central America where slightly more malaria transmission is reported. In one US series based on CDC reports, the highest proportion of laboratory-confirmed and probable cases were among travelers returning from the Dominican Republic (121 cases, 20% of total), Mexico (55 cases, 9% of total) and India (43 cases, 7% of total). Since the 1980s, domestically acquired cases of dengue are reported from Guam, Puerto Rico, Samoa, the US Virgin Islands, and in the continental United States at the Texas-Mexico border, and Key West, Florida. Health care-associated transmission (needlestick, mucocutaneous exposure or transplant related) and vertical transmission occur rarely. Cases among returning missionaries from Jamaica emphasize that even short trips (in this case, 1 week) to endemic areas are sufficient intervals of exposure for acquiring dengue.

▶ Clinical Findings

A. Symptoms and Signs

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis of dengue. Dengue infection may range from asymptomatic to severe hemorrhagic fever to fatal shock (**dengue shock syndrome**). Dengue fever is usually a nonspecific, self-limited biphasic febrile illness. More than half of infected children are asymptomatic. The illness is more severe and begins more suddenly in adults. After an incubation period of 4–5 days, there is a sudden onset of high fever, chills, and “break bone” aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. The fever is usually cleared by day 8. There may be conjunctival redness, particularly with serotype 1. Initially, the skin appears flushed or blotched, but 3–4 days after the lysis of the fever, a maculopapular rash, which spares palms and soles, appears in over 50% of cases. As the rash fades, localized clusters of petechiae on the extensor surface of the limbs become apparent. Up to 25% may manifest signs of cardiac involvement. Arthralgias are commonly seen among serotype 2 cases. Hepatitis frequently complicates dengue fever with acute fulminant hepatitis in up to 5%.

Severe dengue, often with hemorrhage, usually affects children living in endemic areas and is most likely to occur in secondary infections and in infections with serotype 2. A few days into the illness, signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Symptoms found more often among the dengue hemorrhagic fever subset of patients include restlessness, epistaxis, and abdominal pain. Gastroenterologic complications, including hemorrhage, tenderness, and ascites, are more common with dengue hemorrhagic fever and often require intensive care observation. Severe dengue occurs more commonly among HIV-infected persons, although initial presentations do not differ by HIV status.

A subset of patients (more often girls than boys) often with secondary infection, may progress to severe dengue, which is defined by the presence of serum leakage,

hemorrhage, or organ involvement (typically liver, heart, CNS). Acute fever, hemorrhagic manifestations, and marked capillary leak may be prominent, with the latter manifesting as pleural effusions and ascites, and there is a tendency for shock to develop. In infants, even primary infection can lead to dengue shock syndrome. While the infection is difficult to distinguish from malaria, yellow fever, or influenza, the rash makes dengue far more likely. Continuous abdominal pain with vomiting, bleeding, a decrease in the level of consciousness, rash, conjunctival congestion, and hypothermia should raise concern about dengue shock syndrome. Acute kidney injury in dengue largely occurs with dengue shock syndrome and shows a high mortality. While acute severe hepatitis can occur with dengue, concomitant other hepatotropic agents are usually responsible.

B. Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia (seen more often with serotype 2 and more severe among diabetic patients in whom dengue develops), increased fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. Liver biochemical test abnormalities are nearly universal. Thrombocytopenia, plasma leakage, and acute hepatitis are identified as predictors of severe manifestations of dengue and higher mortality. The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus may be recovered from the blood during the acute phase. PCR or detection of the specific viral protein NS1 by ELISA may be diagnostic during the first few days of infection and may be appropriate for febrile travelers. Immunohistochemistry for antigen detection in tissue samples and dried blood spots can also be used. Because the erythrocyte sedimentation rate is normal in most cases, elevation may suggest an alternative diagnosis. Chest radiographs in dengue hemorrhagic fever show infiltrates and effusions, which follow the course of laboratory abnormalities.

Differential Diagnosis

Distinguishing between dengue and other causes of febrile illness in endemic areas is difficult. Fevers due to dengue are more often associated with neutropenia and thrombocytopenia and with myalgias, arthralgias/arthritis, and lethargy among adults. Chikungunya is more apt to develop a chronic arthritis and the arboviral forms of encephalitis require assistance with epidemiologic information and serologic data. Influenza and malaria are easily confused early in disease although the rhinitis and malaise should help distinguish influenza, and the cyclicity of fevers and presence of splenomegaly should suggest malaria.

Complications

Usual complications include pneumonia, bone marrow failure, hepatitis, iritis, retinal hemorrhages and maculopathy, orchitis, and oophoritis. Depression and chronic fatigue, occurring more often in older women, are also

reported. Neurologic complications (such as encephalitis, Guillain-Barré syndrome, phrenic neuropathy, subdural hematoma, and transverse myelitis) are less common, although encephalitic complications are increasingly recognized. Aplastic anemia and hemophagocytosis syndrome are very rare complications. Dengue is rarely associated with stroke in patients with focal neurologic deficit and encephalopathy. Maternal infection poses a risk for premature birth and hemorrhage in both the mother and the infant if infection occurs near term. While placental transmission is not usually considered detrimental, vertical transmission is documented.

Bacterial superinfection occurs more commonly with advanced age, higher fever, gastrointestinal bleeding, kidney disease, and altered consciousness.

Treatment

Treatment entails the appropriate use of volume support, blood products, and pressor agents, and acetaminophen rather than nonsteroidal anti-inflammatory drugs for analgesia. Activities are gradually restored during prolonged convalescences. Endoscopic therapy is useful in evaluating and managing gastrointestinal hemorrhage, although injection therapy with sclerosing agents is not beneficial in most dengue hemorrhagic states. Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions, however, should be considered for severe thrombocytopenia (less than 10,000/mcL) or when there is evidence of bleeding. Monitoring vital signs and blood volume may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

There are no specific therapeutic options for the clinical management of dengue, besides supportive care. Statins show a strong therapeutic potential because lovastatin has *in vitro* evidence of antiviral effects in dengue and may provide protective anti-inflammatory benefits in the disease pathophysiology.

Prognosis

Fatalities are rare but do occur (and more often among girls and the very young), especially during epidemic outbreaks, with occasional patients dying of fulminant hepatitis. Acute kidney injury in dengue shock syndrome portends an especially poor prognosis. Convalescence for most patients is slow. Factors associated with development of severe disease in Sri Lanka included elevated AST, lymphopenia, and thrombocytopenia, while factors associated with mortality in Brazil included age 50 years or older, limited education, need for hospitalization, rural residence, male gender, and elevated hematocrit (but not moderate thrombocytopenia). In general, the more advanced forms of disease (hemorrhagic fever and shock) occur less often in the Americas than in Asia.

Prevention

A recombinant, live, attenuated, tetravalent dengue vaccine (CYD-TDV) showed 64.7% efficacy with a reduction in hospitalization in healthy children between the ages of 9 and 16 years which were conducted in five Latin American

countries and later in Southeast Asia. A follow-up study showed an anomalous increase in hospitalization among recipients younger than age 9 when they were infected 2–5 years after vaccination. There was no difference in safety profiles of the vaccine and placebo. The dengue vaccine Dengvaxia, made by Sanofi Pasteur, was approved for use in Mexico in December 2015 for persons aged 9–45 years.

Preventive measures should be encouraged such as control of mosquitoes by screening and insect repellents including long-lasting insecticides, particularly during early morning and late afternoon exposures. Screening blood transfusions for dengue is of increasing importance, especially in endemic areas. Stochastic models using rainfall and temperature are useful in predicting geographic areas at increased risk for dengue.

clinical features, a specific strain is not associated with a specific syndrome and overlap is seen between the syndromes. Usually seen in the southwestern United States, **Sin Nombre virus** (Muerto Canyon, Four Corners) is the most common hantavirus infection in the United States and is the main North American virus responsible for HPS. The presence of antibodies in Mexican rodents suggests HPS is probably unrecognized in Mexico. While retrospective diagnostics show that the disease occurred decades earlier in the United States, it was not until 1993 when the first outbreak was recognized. Through December 31, 2013, 637 cases were reported in 34 states; 95% of the cases were reported from states west of the Mississippi River, including all continental states west of the Mississippi River except Missouri, with over one-half the cases from the Four Corners area and another focus recognized in Yosemite National Park, California. Other strains native to North America known to cause HPS include Bayou, Black Creek Canal, New York, and Monongahela viruses. Outbreaks of HPS associated with other hantavirus types are also reported in Central and South America, and nearly two-thirds of cases from a series in Panama experienced little or no pulmonary disease.

Hantaviruses are ubiquitous, with infections described in North and South America (New World hantaviruses) as well as Europe, Africa, and Asia (Old World hantaviruses). The Hantaan viruses cause severe hemorrhagic fever with renal syndrome and are found primarily in Korea, China, and eastern Russia. The Seoul viruses produce a less severe form of disease and are found primarily in Korea and China. Cases of autochthonous Seoul hantavirus infections are described in the United States. The Puumala and Dobrava-Belgrade viruses are found in Scandinavia and Europe and are associated with a mild form of the syndrome termed “nephropathia epidemica,” which presents with fever, headache, gastrointestinal symptoms, and impaired kidney function. Between 16% and 48% of Dobrova-Belgrade virus cases, however, may require dialysis.

Aerosols of virus-contaminated rodent urine and feces are thought to be the main vehicle for transmission to humans. Person-to-person transmission is observed only with the Andes virus. Occupation is the main risk factor for transmission of all hantaviruses: animal trappers, forestry workers, laboratory personnel, farmers, and military personnel are considered to be at highest risk. Climate change appears to be impacting the incidence of hantavirus infection mainly through effects on reservoir ecology.

4. Hantaviruses

ESSENTIALS OF DIAGNOSIS

- ▶ Transmitted by rodents and cause two clinical syndromes.
- ▶ Hantavirus pulmonary syndrome (HPS): 40% mortality rate.
- ▶ Hemorrhagic fever with renal syndrome (HFRS): mild to severe illness.
- ▶ Ribavirin is used with some success in HFRS.

▶ General Considerations

Hantaviruses are enveloped RNA bunyaviruses naturally hosted in rodents, moles, and shrews. Over 21 hantavirus strains are known to cause human disease. These differ in rodent hosts, geographic distribution, and degree of pathogenicity. Two major clinical syndromes are described: **hemorrhagic fever with renal syndrome (HFRS)** and **hantavirus pulmonary syndrome (HPS)**. Each year, over 150,000 cases of these two syndromes occur globally, with HPS being far less common. While they share many

▶ Clinical Findings

A. Symptoms and Signs

Vascular leakage is the hallmark of the disease for both syndromes, with lungs being the main target of HPS and the kidneys on HFRS.

HPS is a more severe disease than HFRS, with a mortality rate of about 40%. The clinical course of HPS is divided into a febrile prodrome, a cardiopulmonary stage, oliguric and diuretic phase followed by convalescence. A 14- to 17-day incubation period is followed by a prodromal phase, typically lasting 3–6 days, that is associated with myalgia,

malaise, gastrointestinal disturbance, headache, chills, and fever of abrupt onset. An ensuing cardiopulmonary phase is characterized by the acute onset of pulmonary edema. In this stage, cough is generally present, gastrointestinal manifestations may dominate the clinical presentation, and in severe cases, significant myocardial depression occurs. Acute kidney injury and myositis may occur. Sequelae include neuropsychological impairments in some HPS survivors.

HFRS manifests as mild, moderate, or severe illness depending on the causative strain, with a mortality rate of up to 12%. A 2- to 3-week incubation period is followed by a protracted clinical course, typically consisting of five distinct phases: febrile period, hypotension, oliguria, diuresis, and convalescence phase. Various degrees of renal involvement are usually seen, occasionally with frank hemorrhage. Pulmonary edema is not typically seen but when present usually occurs in the final stages of disease (oliguric and diuretic phase). Encephalitis and pituitary involvement are rare findings with hantavirus infection, although a few cases are reported with Puumala virus. Patients may have persistent hematuria, proteinuria, or hypertension up to 35 months after infection.

B. Laboratory Findings

Laboratory features include hemoconcentration and elevation in lactate dehydrogenase, serum lactate, and hepatocellular enzymes. Early thrombocytopenia and leukocytosis (as high as 90,000 cells/mcL in HPS) are seen in both HFRS and HPS. In HPS, immunoblasts (activated lymphocytes with plasmacytoid features) can be seen in blood, lungs, kidneys, bone marrow, liver, and spleen. The severity of “nephropathia epidemica” correlates with plasma interleukin-6 levels.

The viremia of human hantavirus infections is short-term, and therefore, viral RNA cannot be readily detected in the blood or urine of patients. An indirect fluorescent assay and enzyme immunoassay are available for detection of specific IgM or low-avidity IgG virus-specific antibodies. Seroconversion in the absence of pulmonary symptoms probably occurs often and is documented to be common in Panama.

A plaque reduction neutralization test is considered the gold standard serologic assay and distinguishes between the different hantavirus species, although cross reaction between Old and New World viruses exist. This test needs to be performed in a laboratory with appropriate biosafety (level 3).

▶ Differential Diagnosis

The differential diagnosis of the acute febrile syndrome seen with HFRS or early HPS includes scrub typhus, leptospirosis, and dengue. HPS requires differentiation from other respiratory infections caused by such pathogens as *Legionella*, *Chlamydia*, and *Mycoplasma*. Coxsackievirus infections should also be considered in the differential diagnosis.

▶ Treatment

Treatment is mainly supportive. Cardiorespiratory support with vasopressors is frequently needed; extracorporeal membrane oxygenation may be required in severe cases of

HPS. Intravenous ribavirin is used in HFRS (Hantaan virus) with some success in decreasing the severity of the kidney injury. Its effectiveness in HPS, however, is not established. The bradykinin receptor antagonist icatibant was used successfully in two cases of Puumala virus infection in Germany.

▶ Prognosis

The outcome is highly variable depending on severity of disease. In Sin Nombre virus infections, the persistence of elevated IgG titers correlates with a favorable outcome.

▶ Prevention

Because infection is thought to occur by inhalation of rodent waste, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta, including forest service facilities. Multiple vaccines, inactivated, virus-like particles, and recombinant remain under development.

5. Yellow Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Endemic area exposure (tropical South and Central America, Africa, but not Asia).
- ▶ Sudden onset of severe headache, aching in legs, and tachycardia.
- ▶ Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- ▶ Proteinuria, leukopenia, bilirubinemia, bilirubinuria.
- ▶ Rare and potentially fatal reactions to vaccination.

▶ General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by *Aedes* mosquitoes. It occurs in urban, intermediate (involving small outbreaks in villages in humid savannahs), and sylvatic cycles in Africa, while in South America only the urban and sylvatic cycles are recognized. Genetic studies suggest it arose in South America through the slave

trade 300–400 years ago. Epidemics have extended into unvaccinated populations. There are only seven countries in Latin America that struggle with endemic disease and a partially unvaccinated population. Yellow fever outbreaks continue to occur in Africa and South America, although the 21 recognized cases in 2014 among 3 outbreaks (Peru (1), the Democratic Republic of Congo [2]) suggest an encouraging decrease in total global caseload.

Infection is transmitted by an infected mosquito bite. The incubation period in humans is 3–6 days. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Between 5% and 50% of infections are asymptomatic.

► Clinical Findings

A. Symptoms and Signs

1. Mild form—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

2. Severe form—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but a brief fever remission lasting hours to a few days is followed by a “period of intoxication” manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

B. Laboratory Findings

Leukopenia occurs, although it may not be present at the onset. Kidney disease with proteinuria is present, sometimes as high as 5–6 g/L, and usually disappears completely with recovery. Levels of liver enzymes and bilirubin can be remarkably abnormal with the levels of AST usually doubling those of ALT. Prothrombin time may be elevated as well. Serologic diagnosis is made by using capture ELISA to measure IgM during the acute and convalescent phases. Viral culture is used in epidemic settings. Rapid test involving PCR and monoclonal antibody assays against circulating viral antigens are available through reference laboratories. The plaque reduction neutralization assay is the most frequently used. IgM antibodies are shown to persist in up to 73% of recipients 3–4 years after vaccination.

► Differential Diagnosis

It may be difficult to distinguish yellow fever from hepatitis, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. **Albuminuria is a constant feature in yellow fever patients** and its presence helps differentiate yellow fever from other viral hepatitis. Serologic confirmation is often needed.

► Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications.

► Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. In survivors, the temperature returns to normal by the seventh or eighth day. The prognosis in any individual case is guarded at the onset, since sudden changes for the worse are common. Intractable hiccups, copious black vomitus, melena, anuria, jaundice, and elevated AST are unfavorable signs. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

► Prevention

The yellow fever vaccine, which is derived from the live attenuated 17D strain, and currently given as a single dose for a lifetime, is the most effective way to prevent and control disease. A single dose of vaccine provides life-long immunity. WHO recommends that all endemic countries should include yellow fever vaccine in their national immunization programs. Yellow fever vaccines can be given to immunocompetent persons over 9 months of age living in or traveling to endemic areas. In one study of US travelers visiting a yellow fever endemic country to provide humanitarian service, over 90% were vaccinated at their pretravel health consultation or reported a yellow fever vaccination within the past 10 years.

The vaccine is contraindicated in severely immunocompromised populations and persons with severe egg allergies. HIV-infected persons with CD4 cell counts at least 200 cells/mL can safely receive the vaccine, while pregnant women should receive the vaccine only if they cannot defer travel to endemic areas (Chapter 30). Clinicians should be aware of rare but frequently fatal vaccine-induced reactions, including neurotropic (encephalitis-like syndrome) and viscerotropic (yellow fever-like) diseases; persons at risk include older men, women 19–34, patients who have undergone thymectomy, infants and children 11 years or younger (especially at risk for the neurologic complications), and immunocompromised patients (including those with autoimmune diseases).

The best personal protective measures are to avoid mosquito bites. Eradication of mosquitoes is difficult because of the sylvatic cycle (mainly maintained by nonhuman primates). If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

OTHER SYSTEMIC VIRAL DISEASES

1. Zika Virus

ESSENTIALS OF DIAGNOSIS

- ▶ Most infected persons asymptotically seroconvert.
- ▶ Clinical symptoms are akin to those of chikungunya virus infection.
- ▶ Complications include Guillain-Barré and possibly microcephaly, the latter among infants born to mothers infected during pregnancy.
- ▶ There is no effective antiviral or vaccine.

General Considerations

Zika virus is a flavivirus, akin to the viruses that cause dengue fever, Japanese encephalitis, and West Nile infection. It was originally isolated from macaques in 1947, in the Zika forest near the Entebbe airport of Uganda. The virus was named Zika in 1952, and the first human cases were noted in Nigeria in 1968 although earlier cases probably occurred in Uganda and Tanzania.

The virus was noted in Africa and Asia during the 1950s–1980s but first spread beyond those two continents during 2007 when an outbreak occurred in Yap State, Federated States of Micronesia. A large outbreak occurred in French Polynesia in 2013. A smaller outbreak occurred on Easter Island during 2014. The virus then spread to the Western hemisphere and was first noted in northeastern Brazil in 2015. Up to 1.3 million cases occurred in Brazil during that year. Zika virus then spread rapidly throughout South America, Central America, the Caribbean, and Mexico. An area of particular concern is northeastern Brazil where it is associated with microcephaly among infants born to women infected during the first trimester.

Aedes species mosquitoes, particularly *Aedes aegypti*, are responsible for transmission of Zika virus. The biodistribution of the species largely determines the area of prevalence for Zika virus. *Aedes* species mosquitoes are found primarily in the southeastern United States, but one species *Aedes albopictus* (the Asian tiger mosquito known to sequester in tires) may be seen as far north as Pennsylvania. As of May 4, 2016, there were reported in the fifty US states no locally-acquired vector borne Zika cases, but there were 472 imported, travel-associated Zika cases, among whom 44 were pregnant. Sexual transmission was deemed to have occurred among 10 cases and 1 had the Guillain Barré syndrome. In the US territories (largely Puerto Rico but also American Samoa and the US Virgin Islands) there were only 3 travel-associated cases reported, but there were 658 locally

acquired cases, among whom 59 were pregnant and 5 had developed the Guillain-Barré syndrome.

Clinical Findings

A. Symptoms and Signs

The incubation period is about 10 days. Symptoms include acute onset fever, maculopapular rash, nonpurulent conjunctivitis, and arthralgias, the latter mimicking the symptoms of the chikungunya virus. Rash may outlast the fever but is not always present. Symptoms last up to 7 days. Most infections are asymptomatic. Viral infections most often confused with Zika include dengue and chikungunya virus infections.

B. Laboratory Findings and Diagnostic Studies

The CDC recommends that everyone with symptoms of Zika infection be tested if they have traveled to an endemic area in the past two weeks, as well as all pregnant women who have lived or visited affected regions. Men should be tested if they have lived in, or visited, an affected region, in case of sexual transmission of the virus. Infants born to mothers who while pregnant lived or traveled to transmission areas should also be tested.

Diagnosis is made with RT-PCR or neutralizing antibody, IgM early in infection, IgG after 4 days of symptoms. A commercially available RT-PCR test of blood samples for the Zika virus provides results in one to two days. This molecular testing detects the virus when it is in blood. A negative test does not exclude the presence of the virus in other tissues. Other diagnostic modalities are available from the CDC and at some state health department laboratories. Zika virus RNA can be detected in urine for at least 2 weeks after onset of symptoms. A CDC Triplex rRT-PCR assay is the only diagnostic tool authorized by the FDA for Zika virus testing of urine. The CDC recommends Zika virus rRT-PCR be performed on urine collected <14 days after onset of symptoms in patients with suspected Zika virus disease. Tests of amniotic fluid are of indeterminate accuracy but may be very suggestive of active infection. Amniocentesis is attendant with the small risk of fetal loss, especially early in pregnancy. Infants in whom infection is suspected should have umbilical cord blood or blood from the infant within 2 days of birth collected and serum tested by RT-PCR for the virus and by neutralizing antibody assay. Neutralizing antibodies can cross-react with dengue and other flaviviruses, so public health laboratories may perform specialized testing to definitively make the diagnosis. Cerebrospinal fluid and placental tissue may also be tested by RT-PCR. Ophthalmologic evaluation is recommended in infants in whom congenital Zika virus infection is diagnosed. Pregnant women with suspected Zika virus infection can be monitored by serial ultrasounds at 3–4 week intervals, assessing the fetus for intracranial calcifications and head size.

Complications

Two neurologic complications are of particular concern: (1) Guillain-Barré syndrome, first noted during the outbreak in French Polynesia where 73 cases were reported; and (2) microcephaly, an association noted in Brazil but without firmly documented data regarding pathogenicity.

Macular atrophy, diffuse brain calcifications, and other abnormalities in brain development are reported to accompany microcephaly. A possible contributory role of pesticides or other teratogenic viruses is under investigation, in part because the selective geographic distribution of microcephalic cases in northeastern Brazil is not fully explained. Nonetheless, the isolation of the viral tissue from the brain of infected fetal material supports the role of Zika virus in the pathogenesis of microcephalic infants.

► Treatment

There are no effective antivirals against Zika virus. Aspirin is not used for another flavivirus, dengue, because of its propensity toward hemorrhage on reinfection. Zika virus infections, however, do not appear to be associated with major hemorrhagic complications.

► Prevention

The most effective means is environmental control of mosquitoes and removal of areas where water is stagnant or builds up. Such measures include screens on houses; removal of old tires and debris from endemic areas of infection; and movement toward better living conditions, including air conditioning in impoverished areas. Because of the association between microcephaly and Zika virus infection during pregnancy, pregnant women are advised to avoid travel to areas where Zika virus is circulating. Guidelines for testing of pregnant women potentially exposed are available through CDC. Infected individuals should refrain from blood donations for several months.

There is no current vaccine against Zika virus, although there is hope that one will become available because other flavivirus vaccines exist, including the effective Japanese encephalitis vaccine and dengue virus vaccines which are both commercially available (for those aged 9–45 years in Mexico) and under considerable study.

2. Chikungunya Fever

Chikungunya (“that which bends up” in the Bantu language Makonde) fever is an alphavirus infection transmitted to

humans by *A aegypti* and *A albopictus* and is considered a classic “arthritogenic” virus. The virus is indigenous to tropical Africa and Asia. Outbreaks originated in Kenya in 2004 and subsequently were reported from areas that adjoin the Indian Ocean, Southeast Asia and its neighboring islands (2005–2007), South India (2005), the island of La Réunion (2005–2006), with subsequent spread with autochthonous cases in Italy and France (2007). In 2013, the first autochthonous case of chikungunya occurred on Saint Martin in the Caribbean. As of October 23, 2015, a total of 1,118,578 suspected and 25,627 laboratory-confirmed autochthonous cases have been reported in the Americas, including 12 confirmed cases in Florida during 2014. The incidence rate in the Caribbean decreased during 2015—the highest incidence rate was reported in Central America 400/100,000 population. Travel-associated cases are reported widely with 2799 cases from 46 states (all but Alaska, Nebraska, North Dakota, and Wyoming). The US Caribbean territories reported 4622 locally acquired cases. Among naïve populations, attack rates are often as high as 50%. Vertical transmission is documented if the mother is viremic during parturition. Endemicity of *A aegypti* in the Americas and the introduction of *A albopictus* into Europe and the New World raise concern for global extension of the epidemic. There are reports of cases of chikungunya coinfection with yellow fever, malaria, and dengue fever. Statistics on chikungunya virus infection in the Western hemisphere may be found at http://www.paho.org/hq/index.php?option=com_topics&view=readall&cid=5927&Itemid=40931&lang=en. Statistics for the United States may be found at: <http://www.cdc.gov/chikungunya/geo/united-states-2014.html>.

► Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–12 days (average 2–4), there is an abrupt onset of fever; headache; intestinal complaints; myalgias; and arthralgias/arthritis affecting small, large, and axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pigmented or pruritic maculopapular rash is reported in 10–40% of patients; it can be bullous with sloughing in children. Mucosal disease occurs in about 15%. Facial edema and localized petechiae are reported. Neurologic complications, including encephalitis, myelopathy, peripheral neuropathy, myeloneuropathy, and myopathy, are usually associated with a good outcome. In infants, primary manifestations of disease include fever, lethargy, acrocyanosis, and erythema evolving into vesiculobullous lesions. Hemorrhagic fever-like presentations are exceptional. Coinfection with other respiratory viruses and with dengue is common. Death is rare and usually related to underlying comorbidities.

B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate

well with the severity of arthritis. Radiographs of affected joints are normal during the acute phase. Bone lesions are visible in some patients with chronic symptoms.

Serologic confirmation requires elevated IgM titers or fourfold increase in convalescent IgG levels using an ELISA. RT-PCR and ELISA are commercially available; no ELISA kit is FDA-cleared. Culture techniques (viral isolation in insect or mammalian cell lines or by inoculation of mosquitoes or mice) require BSL-3 containment. Suspected cases in the United States should be promptly reported to public health authorities including the CDC Arboviral Diseases Branch, 970-221-6400. The differential includes other tropical febrile diseases, such as malaria, leishmaniasis, or dengue.

► Complications & Prognosis

A major complication of chikungunya fever is long-term weakness, asthenia, and arthritis, noted to occur in up to 66.5% of cases at 1-year in a series from Italy but in between 4% and 25% in series from India. Risk factors for long-term arthralgias include the presence of such symptoms at 4 months after onset of disease and age over 35 years. Persons with preexisting arthritis are also at increased risk for prolonged symptoms after chikungunya infection. Children with symptomatic congenital chikungunya infection may have adverse neurocognitive outcomes.

► Treatment & Prevention

Treatment is supportive with nonsteroidal anti-inflammatory drugs. Chloroquine may be useful for managing refractory arthritis. In a retrospective study on La Réunion, methotrexate was associated with a positive response. No licensed vaccine exists. However, a live recombinant measles virus–based vaccine and a virus-like particle vaccine are in early clinical trials. At this time, prevention relies on avoidance of the mosquito vectors.

3. Colorado Tick Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Onset 1–19 days (average, 4 days) following tick bite.
- ▶ Fever, chills, myalgia, headache, prostration.
- ▶ Leukopenia, thrombocytopenia.
- ▶ Second attack of fever after remission lasting 2–3 days.

► General Considerations

Colorado tick fever is a reportable biphasic, febrile illness caused by a reovirus infection transmitted by *Dermacentor andersoni* tick bite. About five cases occur annually, largely among men over age 40. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors. Despite frequent exposure among national park and forest employees to ticks and reported bites, Colorado tick fever rarely develops in these persons. Most cases occur in late spring and early summer.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 3–6 days, rarely as long as 19 days. The onset is usually abrupt with a high fever. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. Remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case, there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia (2000–3000/mcL) with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. Viremia may be demonstrated by inoculation of blood into mice or by fluorescent antibody staining of the patient's red cells (with adsorbed virus). An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

► Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very uncommon. Rarely, spontaneous abortion or multiple congenital anomalies may complicate Colorado tick fever infection acquired during pregnancy.

▶ Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although salicylates should be avoided due to potential bleeding with the thrombocytopenia seen in patients with Colorado tick fever.

▶ Prognosis

The disease is usually self-limited and benign.

▶ Prevention

Tick avoidance is the best prevention. The tick season is primarily from March to November, and the ticks mostly live at high altitudes (over 7000 feet) in sagebrush.

COMMON VIRAL RESPIRATORY INFECTIONS

1. Respiratory Syncytial Virus (RSV) & Other Paramyxoviruses

ESSENTIALS OF DIAGNOSIS

- ▶ RSV is a major cause of morbidity and mortality at the extremes of age.
- ▶ Care for patients with RSV infections is largely supportive.
- ▶ A monoclonal antibody against RSV, palivizumab, is good but expensive prophylaxis among patients with certain at-risk cardiopulmonary conditions.
- ▶ No active vaccination for RSV is available.

▶ General Considerations

Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks during the wintertime with usual onset of pulmonary symptoms between mid-October and early January in the continental United States (excluding Florida). Outside the United States, RSV usually peaks during wet months in areas with high annual precipitation and during cooler months in hot and dry areas. There are two major subtypes, A and B, and it appears that the A genotype is associated with disease severity. **RSV is the leading cause of hospitalization in US children**, with annual hospitalization rates of 6 per 1000 children under 5 years of age. Risk factors for infection in children include prematurity, low birth weight, younger age (especially younger than 6 months), bronchopulmonary dysplasia, congenital heart disease, later birth order, and day care exposure. HIV-infected children are at higher risk for hospitalization and

poorer outcomes than uninfected children. RSV infection in children is associated with persistence of airway reactivity later in life.

RSV also causes upper and lower respiratory tract infection in adults with increasingly recognized severity in those with comorbid conditions, the elderly (accounting for a rate of 4 per 1000 hospitalizations and 14,000 deaths annually), persons with severe combined immunodeficiency, and following lung or bone marrow transplantation (because CD8 T cells are not available for viral clearance). Recurrent infections occur throughout life. The virus enters through contact with mucosal surfaces. The average incubation period is 5 days. Up to 10% of disease classified as invasive pneumococcal disease is thought to be RSV or influenza (above).

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur, and outbreaks with a high mortality rate (greater than 70%) are reported.

Other paramyxoviruses important in human disease include human metapneumovirus, parainfluenza virus, and Nipah virus.

Human metapneumovirus is a seasonal virus circulating during late winter to early spring. It is divided into subgroups A and B. Clinical presentations range from mild upper respiratory tract infections to severe lower respiratory tract infections (eg, bronchiolitis, croup, and pneumonia). Lower respiratory tract (sometimes severe) infections have been observed among immunocompromised and elderly adults. In lung transplant recipients, human metapneumovirus is a common cause of respiratory illness and is thought to increase the risk of acute and chronic graft rejection.

Human parainfluenza viruses (HPIVs) are commonly seen in children and are the most common cause of laryngotracheitis (croup). Four different serotypes are described, and they differ in their clinical presentations as well as epidemiology. HPIV-1 and HPIV-2 are responsible for croup. HPIV-3 is associated with bronchiolitis and pneumonia. HPIV-4 is a less frequently reported pathogen. Reinfections are common throughout life. HPIVs can also cause severe disease in the elderly, immunocompromised persons, and those with chronic illnesses.

Nipah virus, is a highly virulent paramyxovirus first described in 1999. Cases are concentrated mainly in Southeast Asia (Malaysia, Singapore, Bangladesh and India). Fruit bats are identified as the natural host of the virus. Direct pig-human, cow-human, human-human, and nosocomial transmission are reported. Nipah virus causes acute encephalitis with a high fatality rate (67–92%), although respiratory symptoms are also described. Cranial nerve palsies, encephalopathy, and dystonia are among neurologic sequelae (15–32%) seen in infected individuals. Relapses occurring weeks and months after initial infection are described (3.4–7.5%).

Bocavirus infections are discussed under Erythrovirus (parvovirus) infections below.

▶ Clinical Findings

A. Symptoms and Signs

In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from

sloughed epithelium and increased mucus secretion. An interleukin-1 receptor polymorphism is shown to be associated with more severe bronchiolitis. Signs of infection include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. In children, RSV is globally the most common cause of acute lower respiratory infection and also a common cause of acute and recurrent otitis media. In patients with Down syndrome, RSV develops at a later age and is associated with more protracted hospitalizations.

B. Laboratory Findings

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay. PCR is increasingly used. RSV viral load assay values at day 3 of infection may correlate with requirement of intensive care and respiratory failure in children.

Human metapneumovirus is best diagnosed by PCR. Tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also widely available for detection of HPIV. Culture may also be used. ELISA (serum and cerebrospinal fluid) and PCR (urine, respiratory secretions but not blood) are both used for Nipah virus infection diagnosis.

▶ Treatment & Prevention

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them. Oral antiviral agents are being studied through healthy adult challenge experiments.

The use of aerosolized ribavirin can be considered in high-risk patients, such as those with a history of bone marrow transplantation, and appears to lessen mortality. Pregnant women, including hospital staff, should avoid ribavirin exposure. Prophylactic administration of palivizumab, an anti-RSV monoclonal antibody, (15 mg/kg intramuscularly monthly during the season of high transmission) is recommended for infants at high-risk for complication, including those with chronic lung disease of prematurity and hemodynamically significant congenital heart disease. Data support the use of palivizumab in upper airway anomalies, other pulmonary diseases, and cystic fibrosis as well as in children with Down syndrome.

No RSV vaccine is available but a promising live attenuated intranasal vaccine candidate is under study. It was associated with decreased shedding of the vaccine virus, increasing titers of neutralizing antibodies, and antibody responses in previously seronegative individuals. Vaccines for use in pregnant women designed to protect infants during their period of highest vulnerability are in early clinical trials.

Prevention in hospitals entails rapid diagnosis, handwashing, contact isolation, and perhaps passive immunization. The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries.

Therapeutic modalities for human metapneumovirus and parainfluenza virus infections under investigation include intravenous ribavirin administration.

2. Seasonal Influenza

ESSENTIALS OF DIAGNOSIS

- ▶ Cases usually in epidemic pattern.
- ▶ Onset with fever, chills, malaise, cough, coryza, and myalgias.
- ▶ Aching, fever, and prostration out of proportion to catarrhal symptoms.
- ▶ Leukopenia.

▶ General Considerations

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route in humans. Transmission occurs primarily by droplet nuclei rather than fomites or direct contact. There are three types of influenza viruses. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed on their surface. There are 18 subtypes of hemagglutinin and 11 subtypes of neuraminidase.

Annual epidemics usually appear in the fall or winter in temperate climatic areas (although sporadic cases occur as summer outbreaks in northern areas such as Alaska or the southern hemisphere). Up to 5 million cases of severe influenza are estimated by the WHO to occur annually, with up to 0.5 million annual deaths. Influenza epidemics affect 10–20% of the global population on average each year and are typically the result of frequent minor antigenic variations of the virus, or antigenic drift, which are more common in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer and varying intervals (decades) as a consequence of a major genetic reassortment of the virus (antigenic shift) or the mutation of an avian virus that adapts to the human (as with the pandemic virus of 1918 with H1N1 properties).

The highly pathogenic avian (H5N1) and the H7N9 subtypes are discussed in the next section. The novel swine-origin influenza A (pandemic H1N1) virus emerged in Mexico in March 2009 and quickly spread throughout North America. This virus originated from triple-reassortment of North American swine, human and avian virus lineages and Eurasian swine virus lineages and has now replaced the previous H1N1 seasonal strain and is subsequently referred to here as seasonal H1N1. This virus, as with other pathogenic influenza viruses, is of particular concern for pregnant women and immunosuppressed persons.

▶ Clinical Findings

A. Symptoms and Signs

Seasonal influenza viruses of types A and B produce clinically indistinguishable infections, whereas type C usually causes a minor illness. The incubation period is 1–4 days. In unvaccinated persons, uncomplicated influenza often begins abruptly. Symptoms range widely from a nearly asymptomatic state to a constellation of symptoms including fever, chills, malaise, myalgias, substernal soreness, headache, nasal stuffiness, and occasionally nausea. Fever lasts 1–7 days (usually 3–5). Coryza, nonproductive cough, and sore throat are present. Elderly patients especially may present with only lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes may be observed. The presence of fever (higher than 38.2°C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years of age.

Other symptoms particularly noted during the 2009 H1N1 pandemic included gastrointestinal (especially diarrhea) and respiratory (pneumonia) manifestations. Hospitalization or ICU admission for influenza is often a consequence of diffuse viral pneumonitis with severe hypoxemia and sometimes shock. Neurologic complications, including seizures and encephalopathy, and cardiac dysfunction, including myocarditis and pulmonary thromboemboli, may occur. Asthmatic patients with pneumonia are at higher risk for ICU admission and death. H1N1-associated hemophagocytic syndromes are reported. Most patients with mild disease recover fully, but 9–31% of hospitalized cases require ICU admission, where the mortality was as high as 46% during the 2009 pandemic.

Attack rates for influenza are highest in children and young adults of certain ethnic backgrounds, particularly Hispanics, blacks, and Native Americans, with relative sparing of adults older than 60 years of age presumably due to previous exposure with related strains (conferring some degree of cross-protection). High-risk groups include patients with severe obesity, asthma, immunosuppression, or neurologic disorders, and pregnant and postpartum women. Infection during pregnancy increases the risk for hospitalization and may be associated with severe illness, sepsis, pneumothorax and respiratory failure, spontaneous abortion, preterm labor, and fetal distress. Overall case fatality rate is < 0.5% with 90% of deaths in those under 65 years of age and higher mortality recognized among men and patients with liver disease or a cancer diagnosis within the last year.

B. Laboratory Findings

Leukopenia is common, but leukocytosis can occur. Proteinuria may be present. The virus may be isolated from throat swabs or nasal washings by inoculation of embryonated eggs or cell cultures. Rapid immunofluorescence assays and enzyme immunoassays for detection of influenza antigens from nasal or throat swabs are widely available. The sensitivity of such assays is suboptimal (at most 60–80%), especially among adults, and with very significant intertest variability, only a few can distinguish between influenza A and B. More sensitive nucleic acid amplification (PCR) techniques are increasingly accessible although their sensitivity is compromised early in the season during low prevalence periods. Complement-fixing and hemagglutination-inhibiting antibodies (for which fourfold or greater rises in levels are needed to establish diagnosis) appear during the second week. A nasopharyngeal swab, nasal aspirate, combined nasopharyngeal swab with oropharyngeal swab, or material from a bronchoalveolar lavage can be tested for any influenza strain.

Local laboratories can perform rapid influenza antigen enzyme or direct immunofluorescent assays to distinguish influenza viruses types A and B, but the results of these assays should be interpreted with caution due to a limited sensitivity (11–70%). Test material can be kept at 4°C up to 4 days (not frozen) and shipped with an ice pack. The CDC or many state public health laboratories can then perform a real-time PCR or viral culture, when needed, such as during a pandemic. Chest radiographic findings rarely show lobular infiltrates and pathologic findings show similar particular propensities toward diffuse alveolar damage.

▶ Differential Diagnosis

The differential diagnoses for influenza-like infections include a variety of viral infections (parainfluenza infections, RSV infections, dengue, adenovirus, echoviruses, CMV, EBV infection, acute HIV infection, as well as bacterial infections such as mycobacterial infection (atypical pneumonia), pertussis, and Legionnaire disease. Epidemiologic factors can suggest Legionnaire (elderly smokers), chronicity of cough may support adenovirus, mycobacterial and pertussis infections, leukocytosis initially supports CMV, and lymphadenopathy is more common with EBV or CMV infection. Distinguishing influenza from dengue requires attention to rhinitis (influenza) and thrombocytopenia (dengue).

▶ Complications

Influenza causes necrosis of the respiratory epithelium, which predisposes to secondary bacterial infections. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, and streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Children under 5 years of age, pregnant women, residents of nursing homes and long-term-care facilities, the elderly (aged 65 years or older), children and teens under 19 years of age who are receiving long-term aspirin therapy, and persons with

underlying medical conditions (pulmonary, renal, cardiovascular, hepatic, hematologic, neurologic and neurodevelopmental conditions and immune-deficient conditions such as HIV) are at high risk for complications. Persons who are morbidly obese (body mass index greater than 40), American Indians, and Alaskan natives are also at high risk for complications.

Cardiovascular diseases are a particular complication of influenza infection, in particular among the elderly, and influenza is postulated to be a significant trigger for myocardial infarction, cerebrovascular diseases, and sudden death.

Primary influenza pneumonia may occur, particularly in young children with cardiovascular disease and pregnant women, and is associated with high mortality. Secondary bacterial pneumonia due to pneumococci, staphylococci, or *Haemophilus* spp is not uncommon. Pericarditis and myocarditis occur rarely. There is an association of acute myocardial infarction with preceding respiratory infection, including influenza; a UK study showed that influenza vaccination is associated with a lower rate of acute myocardial infarction. Rhabdomyolysis and leukocytoclastic vasculitis are rare complications of influenza.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (especially varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in the management of viral infections.

Encephalopathic complications of influenza are uncommon and include an acute necrotizing encephalopathy associated with disseminated intravascular coagulation and cytokine storm, with worsening when treated with certain nonsteroidal anti-inflammatory medications (diclofenac and mefenamic acid), and an acute encephalopathy associated with febrile seizures and the use of theophylline. An analysis of Medicare utilization data shows no increase in the Guillain-Barré syndrome following influenza vaccination.

▶ Treatment

Many patients with influenza prefer to rest in bed. Analgesics and a cough mixture may be used. Treatment should be considered for all persons with acute illness, in particular those with a suggestive clinical presentation or with laboratory confirmed influenza and at high risk for developing complications (nursing home residents; patients with chronic pulmonary, cardiovascular, kidney, or liver disease; those with diabetes mellitus, active malignancy, immunosuppression, or impairment for managing respiratory secretions), or living with persons at significant risk for them. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is reduced, it should be considered if the patient is hospitalized. There is no benefit to double-dose oseltamivir in severe influenza infections although some

influenza experts continue to recommend double-dose therapy among immunocompromised patients.

The neuraminidase inhibitors, inhaled **zanamivir**, 10 mg (2 inhalations) twice daily for 5 days, oral **oseltamivir**, 75 mg twice daily for 5 days, or intravenous **peramivir**, 600 mg single dose, are equally effective in the treatment of susceptible strains of influenza. Clinical trials show a reduction in the duration of symptoms as well as secondary complications, such as otitis, sinusitis, or pneumonia, but not in the rate of hospitalizations or mortality when using these agents. When administered early (within the first 2 days of illness), antiviral medications (neuraminidase inhibitors) are most effective. Patients with asthma who are hospitalized with pneumonia should be treated early with antivirals.

Since high levels of resistance to the adamantanes (amantadine and rimantadine) persist among seasonal H1N1 and H3N2 influenza A viruses and these agents are not effective against influenza B viruses, adamantanes are generally not recommended for treatment.

Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur with prolonged use in immunocompromised patients. With the previous seasonal H1N1 strain, oseltamivir resistance was reported at rates as high as 25% in Europe and Africa due to a genetic mutation (H275Y). With the current seasonal H1N1 strain, rates of oseltamivir resistance have been low (~1%) but are associated with the same H275Y mutation, and person-to-person transmission is documented. An outbreak with a resistant strain may have occurred in Australia in 2011. Increasing rates of oseltamivir resistance should be expected over time.

Zanamivir is relatively contraindicated among persons with asthma because of the risk of bronchospasm and is not formulated for use in mechanically ventilated patients. Transient neuropsychiatric events, occasionally resulting in self-injury and death, have been reported post marketing for both neuraminidase inhibitors. Patients receiving these medications should be closely monitored for any unusual behavior, and healthcare professionals should be notified immediately if such signs occur. Laninamivir is a long-acting inhaled neuraminidase inhibitor used for the treatment of seasonal influenza, including infection caused by oseltamivir-resistant virus. It is licensed in Japan (RAPIACTA) and South Korea (PERAMIFLU) and was used in the past for severe H1N1 influenza during the 2009 pandemic under an Emergency Authorization Use but remains under clinical study. The license for its clinical use in the United States expired in 2010. Antibacterial antibiotics should be reserved for treatment of bacterial complications. Acetaminophen or ibuprofen rather than aspirin should be used for fever in children to avoid Reye syndrome.

Oseltamivir-resistant virus usually remains sensitive to zanamivir. Intravenous zanamivir is available for patients unable to take medication by mouth through compassionate use programs available through GlaxoSmithKline at 877-626-8019 or 866-341-9160 or gskclinicalsupportHD@gsk.com (<http://www.clinicalsupporthd.gsk.com/>) (<http://www.flu.nc.gov/providers/documents/IVzanamivirRequestInformation.pdf>).

Peramivir is FDA approved for intravenous therapy of influenza infections. It does not have activity against oseltamivir-resistant virus.

For oseltamivir-resistant seasonal H1N1 viral infection, intravenous zanamivir is preferred. While a case of multi-drug-resistant seasonal H1N1 virus with resistance to oseltamivir, zanamivir, and peramivir is reported, this particular isolate is less pathogenic in animal studies than susceptible H1N1 strains.

The use of high frequency oscillatory ventilation and extracorporeal membrane oxygenation can improve oxygenation but the impact on mortality is unknown. Corticosteroids for an associated ARDS are not useful and may increase the mortality except that the use of corticosteroids is associated with a lower rate of mechanical ventilation if used in high doses (1 mg/kg prednisone equivalence orally at the time of diagnosis) in patients with a history of hematopoietic stem cell transplantation.

Updated advice is available at <http://www.cdc.gov/flu/index.htm>.

► Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Hospitalization typically occurs in those with underlying medical disease, at the extremes of age and in pregnant woman. Young adults and obese individuals were also at increased risk for hospitalization during the 2009 pandemic. With the current H1N1 strain, elevated alkaline phosphatase, creatine kinase, creatinine, thrombocytopenia and metabolic acidosis suggest a poor prognosis. Purulent bronchitis and bronchiectasis may result in chronic pulmonary disease and fibrosis that persist throughout life. Most fatalities are due to bacterial pneumonia although exacerbations of other disease processes, in particular cardiac diseases, occur which contributed to the overall increase in fatalities. Pneumonia resulting from influenza has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. Mortality among adults hospitalized with influenza ranges from 4% to 8%, although higher mortality (greater than 10–15%) may be seen during pandemics and among immunocompromised individuals. An increase in mortality among the elderly in Europe from influenza was attributed to the return to pandemic status of H3N2 strains.

If the fever recurs or persists for more than 4 days with productive cough and white cell count over 10,000/mcL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common secondary infection, and staphylococcal pneumonia is the most serious.

► Prevention

Annual administration of influenza vaccine is the most effective measure for preventing influenza and its complications (Table 30–7). The main circulating seasonal influenza viruses that are the target of 2015–16 vaccines are an A/California/7/2009 (H1N1)pdm09-like virus, an A/Switzerland/9715293/2013 (H3N2)-like virus, and a B/Phuket/3073/2013-like virus (a B/Yamagata lineage virus),

with quadrivalent preparations also including a B/Brisbane/60/2008-like virus. For the Southern Hemisphere, recommendations include two differences: replacing the second A influenza strain and inverting the order of the B strains: an A/California/7/2009 (H1N1)pdm09-like virus, an A/Hong Kong/4801/2014 (H3N2)-like virus, and the B/Brisbane/60/2008-like virus (a B/Victoria-lineage virus), with use in the quadrivalent vaccines of a B/Phuket/3073/2013-like virus (a B/Yamagata-lineage virus).

Currently 12 vaccines are available for use in the United States. These include seven trivalent inactivated influenza vaccines (including one cell-culture based, one recombinant, one high-dose recommended for those 65 and older, and one adjuvanted vaccine also recommended for those 65 and older) and five quadrivalent influenza vaccines (four inactivated, one of which is given intradermally, and one live attenuated vaccine [LAIV] given intranasally) (Table 32–3). All vaccines contain antigens from one strain each of influenza A (H1N1), influenza A (H3N2), and influenza B. Persons with a history of egg allergy with hives only may receive inactivated influenza vaccine under close observation for adverse effects or trivalent recombinant influenza vaccine (RIV3 or FluBlok) for those 18 or older. For those with severe egg allergies, RIV3 can be administered in those age 18 or over. Administration in the deltoid is recommended for older children and adults, in the anterolateral thigh for children. Influenza vaccine recommendations can be found at <http://www.cdc.gov/flu/professionals/vaccination/index.htm>.

Chemotherapeutic regimens containing rituximab show persistent perturbations of B cell and Ig synthesis, and these modifications decrease humoral responses to the influenza vaccine.

The Advisory Committee on Immunization Practices (ACIP) and the American College of Obstetricians and Gynecologists' Committee recommend annual influenza vaccination for all persons over 6 months of age. In particular, vaccination is emphasized for women who will be pregnant through the influenza season (October through May with peak activity during December to March in the United States) with vaccination early in the season regardless of gestational age. No study to date has shown any major adverse consequence of inactivated influenza vaccine in pregnant women or their offspring.

Fluzone High-Dose is an FDA-approved trivalent influenza vaccine (TIV) containing four times more hemagglutinin than standard TIV and is recommended for persons age 65 or older. Fluzone intradermal trivalent vaccine (15 mcg hemagglutinin per strain given to those aged 18–64, with current data suggesting 60 mg is the appropriate dose) is an intradermal vaccine that is equally immunogenic and safe but more expensive than the traditional intramuscular vaccine (given to those over age 2 years). Fluvad is the first seasonal influenza vaccine containing an adjuvant approved in the United States. It contains MF59[®], an oil-in-water squalene oil emulsion, as an adjuvant and is recommended for persons 65 years and older.

The LAIV is available for use in healthy individuals between 2 and 49 years of age; it should not be given to asthmatic patients, pregnant women, or those who have

Table 32–3. Current influenza vaccination preparations available in the United States.

Trade name	Manufacturer	Presentation	Mercury (from thimerosal) mcg/0.5 mL	Ovalbumin mcg/0.5 mL	Age Indications	Latex	Route
Inactivated influenza vaccine, quadrivalent (IIV4), standard dose							
<i>Contraindications*:</i> Severe allergic reaction to any vaccine component, including egg protein, or after previous dose of any influenza vaccine.

(continued)

Table 32–3. Current influenza vaccination preparations available in the United States.(continued)

Trade name	Manufacturer	Presentation	Mercury (from thimerosal) mcg/0.5 mL	Ovalbumin mcg/0.5 mL	Age Indications	Latex	Route
Recombinant influenza vaccine, trivalent (RIV3), standard dose							
<i>Contraindications*:</i> Severe allergic reaction to any vaccine component.							
<i>Precautions*:</i> Moderate to severe acute illness with or without fever; history of Guillain-Barré syndrome within 6 weeks of receipt of influenza vaccine.							
Flublok	Protein Sciences	0.5 mL single-dose vial	—	0	≥ 18 yrs	No	IM†
Live attenuated influenza vaccine, quadrivalent (LAIV4)							
<i>Contraindications*:</i> Severe allergic reaction to any vaccine component, including egg protein, or after previous dose of any influenza vaccine. Concomitant use of aspirin or aspirin-containing medications in children and adolescents.							
<i>In addition, ACIP recommends LAIV4 not be used for pregnant women, immunosuppressed persons, persons with egg allergy, and children aged 2 through 4 years who have asthma or who have had a wheezing episode noted in the medical record within the past 12 months, or for whom parents report that a health care provider stated that they had wheezing or asthma within the last 12 months. LAIV4 should not be administered to persons who have taken influenza antiviral medications within the previous 48 hours. Persons who care for severely immunosuppressed persons who require a protective environment should not receive LAIV4, or should avoid contact with such persons for 7 days after receipt.</i>							
<i>Precautions*:</i> Moderate to severe acute illness with or without fever; history of Guillain-Barré syndrome within 6 weeks of receipt of influenza vaccine; asthma in persons aged 5 years and older; medical conditions that might predispose to higher risk for complications attributable to influenza.							
FluMist Quadrivalent†††	MedImmune	0.2 mL single-dose prefilled intranasal sprayer	—	< 0.24 (per 0.2 mL)	2 through 49 yrs	No	IN

ACIP, Advisory Committee on Immunization Practices; ID, intradermal; IM, intramuscular; IN, intranasal.

* Immunization providers should check Food and Drug Administration-approved prescribing information for 2015–16 influenza vaccines for the most complete and updated information, including (but not limited to) indications, contraindications, warnings, and precautions. Package inserts for U.S.-licensed vaccines are available at www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm.

† For adults and older children, the recommended site for intramuscular influenza vaccination is the deltoid muscle. The preferred site for infants and young children is the anterolateral aspect of the thigh. Specific guidance regarding site and needle length for intramuscular administration may be found in the ACIP General Recommendations on Immunization, available at www.cdc.gov/mmwr/preview/mmwrhtml/rr6002a1.htm.

‡ Available upon request from Sanofi Pasteur (1–800–822–2463 or MIS.Emails@sanofipasteur.com).

¶ Quadrivalent inactivated influenza vaccine, intradermal: a 0.1-mL dose contains 9 mcg of each vaccine antigen (36 mcg total).

** The preferred injection site is over the deltoid muscle. Fluzone Intradermal Quadrivalent is administered using the delivery system included with the vaccine.

†† Age indication per package insert is ≥5 years; however, ACIP recommends Afluria not be used in children aged 6 months through 8 years because of increased risk of febrile reactions noted in this age group with bioCSL's 2010 Southern Hemisphere IIV3. If no other age-appropriate, licensed inactivated seasonal influenza vaccine is available for a child aged 5 through 8 years who has a medical condition that increases the child's risk for influenza complications, Afluria can be used; however, providers should discuss with the parents or caregivers the benefits and risks of influenza vaccination with Afluria before administering this vaccine. Afluria may be used in persons aged ≥9 years.

‡‡ Syringe tip cap may contain natural rubber latex.

¶¶ Information not included in package insert. Estimated to contain <50 femtograms (5x10⁻⁸ mcg) of total egg protein (of which ovalbumin is a fraction) per 0.5 mL dose of Flucelvax.

*** Trivalent inactivated influenza vaccine, high-dose: a 0.5-mL dose contains 60 mcg of each vaccine antigen (180 mcg total).

††† FluMist is shipped refrigerated and stored in the refrigerator at 35°F–46°F (2°C–8°C) after arrival in the vaccination clinic. The dose is 0.2 mL divided equally between each nostril. Health care providers should consult the medical record, when available, to identify children aged 2 through 4 years with asthma or recurrent wheezing that might indicate asthma. In addition, to identify children who might be at greater risk for asthma and possibly at increased risk for wheezing after receiving LAIV, parents or caregivers of children aged 2 through 4 years should be asked: "In the past 12 months, has a health care provider ever told you that your child had wheezing or asthma?" Children whose parents or caregivers answer "yes" to this question and children who have asthma or who had a wheezing episode noted in the medical record within the past 12 months should not receive FluMist.

Reproduced with permission from Grohskopf LA et al. Prevention and control of influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices, United States, 2015–16 Influenza Season. *MMWR Morb Mortal Wkly Rep.* 2015 Aug 7;64(30):818–25. [PMID: 26247435]

taken neuraminidase inhibitors within the prior 48 hours. For children, the CDC no longer preferentially recommends the LAIV.

Among the HIV-infected and the elderly, preliminary data suggest that a quadruple-dose influenza vaccine is associated with higher seroconversion rates. Data are limited supporting particular protective efficacy in vaccinating those with end-stage renal disease, although annual vaccination continues to be recommended, with benefits present even with low rates of efficacy considering the high risks of influenza in this population.

The seasonal influenza vaccines can reduce influenza hospitalizations by an estimated 61%. Vaccine efficacy is greater by serologic indices of infection rather than clinical disease or days of work lost. New recombinant and cell culture vaccines are available for those with a hypersensitivity to chicken eggs or other components of the vaccine, although inactivated vaccines can safely be given to most patients with suspected egg allergies. Determination of the degree of egg allergy (only skin reactions or frank angioedema) as well as consultation with CDC sources and infectious disease physicians and allergists may be prudent in cases of severe egg allergy. Patients with significant egg allergies should be vaccinated only in physicians' (or for severe cases, allergists') offices.

Vaccination remains contraindicated for persons with a history of vaccine-associated Guillain-Barré syndrome, or in persons with an acute febrile illness until symptomatic improvement. Concomitant warfarin or corticosteroid therapy is not a contraindication to influenza vaccination. Statin therapy at the time of influenza vaccination may adversely affect vaccine effectiveness in the elderly. Side effects are infrequent and include tenderness, redness, or induration at the intramuscular site of the TIV and mild upper respiratory symptoms for the LAIV. There is great inequity globally in the distribution of influenza vaccine with only 3.7% of the vaccine available to the 47% of the population living in Africa, Eastern Europe, and Southeast Asia.

Chemoprophylaxis is considered for individuals who are unvaccinated, for those in whom vaccination is contraindicated, and in those exposed to an infected patient within 2 weeks after vaccination with TIV. Chemoprophylaxis is not necessary and is contraindicated for those vaccinated with the LAIV, since this vaccine confers more rapid protection. Other circumstances that warrant consideration of chemoprophylaxis include outbreaks in long-term-care facilities, persons living with or in close contact with high-risk individuals, persons with immune deficiencies who might not respond to vaccination, unvaccinated staff during response to an outbreak in a closed institutional setting with residents at high risk, and first responders to epidemic situations.

Winter school breaks during periods of high influenza transmission appear to decrease rates of visits to primary care practitioners for influenza illness among children and adults.

Chemoprophylaxis against influenza A and B is accomplished with a single daily dose of the neuraminidase inhibitors oseltamivir (75 mg/day, oral) or zanamivir (10 mg/day, inhaled). These agents reduce the attack rate

among unvaccinated individuals if begun within 48 hours after exposure. The CDC recommends chemoprophylaxis for up to 10 days after exposure. For outbreak control in long-term-care facilities and hospitals, a minimum of 2 weeks is recommended, including in vaccinated persons, and until 1 week after identification of the last known case. Zanamivir should not be given as chemoprophylaxis to asthmatic persons, nursing home residents, or children under 5 years of age. A Cochrane review on the effects of usage and stockpiling of neuraminidase inhibitors showed that adverse effects of the agents might limit the cost-benefit balance of their usage. Attendant recommendations that question the use of these agents in both prophylaxis and treatment of influenza have been met with controversy.

Breakthrough infections with influenza occur with neuraminidase inhibitors (in a study with zanamivir) with vaccination. The efficacy of chemoprophylaxis is proven for individual and household but not community settings.

Hand hygiene and surgical facemasks appear to prevent household transmission of influenza virus isolates when implemented within 36 hours of recognition of symptoms in an index patient. Such nonpharmaceutical interventions assist in mitigating the spread of pandemic and inter-pandemic influenza to nonvaccinated persons. Patients with seasonal H1N1 influenza infection should be considered potentially infectious from 1 day before to about 7 days following illness onset. Children and immunosuppressed persons exhibit prolonged viral shedding and may be infectious longer.

Any hospital patient in whom the infection is suspected should be isolated in individual rooms with standard and droplet precautions. CDC guidelines recommend the equivalent of N95 masks for aerosol generating procedures (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications). For such procedures, an airborne infection isolation room can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. Precautions should be maintained until 7 days from symptom onset or until symptom resolution, whichever is longer. Postexposure prophylaxis should be considered for close contacts of patients (confirmed, probable, or suspected) who are at high risk for complications of influenza as well as for healthcare personnel, public health workers, or first responders who experienced a recognized, unprotected close contact exposure to a person with influenza virus infection (confirmed, probable, or suspected) during that person's infectious period. The CDC continues to recommend considering postexposure prophylaxis with neuraminidase inhibitors to contacts of the infected person.

▶ When to Admit

- Limited availability of supporting services.
- Pneumonia or decreased oxygen saturation.
- Changes in mental status.
- Consider with pregnancy.

3. Avian Influenza (H5N1 & Analogs)

ESSENTIALS OF DIAGNOSIS

- ▶ Cases to date in humans, mostly from Southeast Asia and Egypt.
- ▶ Clinically indistinguishable from seasonal influenza.
- ▶ Epidemiologic factors assist in diagnosis.
- ▶ Rapid antigen assays confirm diagnosis but do not distinguish avian from seasonal influenza.

▶ General Considerations

The normal hosts for avian influenza viruses are aquatic waterfowl. Although avian influenza was first recognized in Italy in 1878, the current outbreak of highly pathogenic influenza A subtype (H5N1) in poultry was recognized in 1997 in Hong Kong and was followed by the first documented human cases. A massive slaughter of poultry contained the disease. Outbreaks of H5N1 influenza in poultry reemerged in 2003 and now involve more than 65 countries of East and Southeast Asia, Eurasia, Western and Eastern Europe, Northern Africa, and Haiti. The 884 confirmed human cases as of October 15, 2015 include 449 deaths (51% of cases and 94% of deaths are reported from China, Cambodia, Egypt, Indonesia, Turkey, and Vietnam) (the details are maintained and updated by the Global Outbreak Alert and Response Network, WHO: http://www.who.int/influenza/human_animal_interface/EN_GIP_20151015cumulativeNumberH5N1cases.pdf?ua=1)

Although highly contagious among birds, the transmission of this H5N1 strain from human-to-human is inefficient and not sustained although studies documented transmissibility of laboratory mutated virus via aerosols between ferrets. Evidence from cluster outbreaks suggests that host genetic susceptibility limits human-to-human transmission. The result is only rare cases of person-to-person infection. Occasional transmission to other mammals, including domestic cats and dogs, is also documented. Most human cases of H5N1 and analogous viruses occur after exposure to infected poultry or surfaces contaminated with poultry droppings. Because infection in humans is associated with a mortality rate greater than 50% and the avian H5N1 subtype continues to spread among birds (with many parts of Southeast Asia now considered endemic for the virus), there is worldwide concern that the virus may undergo genetic reassortment or mutation (as with the 1918 strain) and develop greater human-to-human transmissibility with the potential to produce a global pandemic.

Cases of H7 influenza viruses are sporadic and global and usually occur among poultry handlers. Infections with several of these H7 avian influenza viruses (H7N2, H7N3, and H7N7) have occurred in Australia, Canada, Italy, Mexico, the Netherlands, the United Kingdom, and the United States (New York). Cases of H7N9 are significantly reported from Canada, Taiwan, and Malaysia, with 571 to date, and associated with 212 deaths (a mortality of 37%). Unique characteristics were bilateral ground-glass opacities, lymphocytopenia, and thrombocytopenia. ARDS developed in patients who had underlying coexisting medical conditions. Person-to-person transmission was also documented. Rare cases of influenza H9N2, another poultry pathogen, are reported from Bangladesh, and human-to-human transmission of this pathogen is not documented. Poultry infected with H5N2 have been detected in 13 American states and with H5N8 in 2 states with most leading poultry-importing foreign countries having banned at least partially the importation of American poultry. Rates of bird-to-human transmission are low, although serologic data for H5 and H7 infection are high among poultry and slaughterhouse workers.

▶ Clinical Findings

A. Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill poultry in the prior 10 days, recent travel to Southeast Asia or Egypt, or contact with known cases should be investigated. The symptoms and signs include fever and predominantly respiratory symptoms (cough and dyspnea), but a variety of other systems may be involved, producing headaches and gastrointestinal complaints in particular. Subclinical disease is relatively rare. With cytokines responsible for much of the pathology, prolonged febrile states and generalized malaise are common. Children are preferentially impacted. Respiratory failure is the usual cause of death.

B. Laboratory Findings

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza but are still first-line diagnostic tests because of their widespread availability. Diagnostic yield can be improved by early collection of samples. More sensitive RT-PCR assays are available through many hospitals and state health departments. An initial negative result in the right clinical setting warrants retesting. Throat or lower respiratory swabs may provide higher yield of detection than nasal swabs. When highly pathogenic strains (eg, H5N1) are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigations (eg, culture) in laboratories with the adequate level of biosafety (level 3).

► Treatment

Resistance of avian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas. Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur in avian (H5N1)-infected patients. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg orally twice daily for 5 days administered within 48 hours from onset of illness. Overall oseltamivir, by modeling, is associated with a 49% reduction in mortality from H5N1 infections. A higher dose (150 mg twice daily), longer duration (7–10 days), and possible combination therapy with amantadine or rimantadine (in countries where A [H5N1] viruses are likely to be susceptible to adamantanes) may be considered in patients with pneumonia or progressive disease, although in general the adamantanes are no longer recommended for influenza infections. Twice daily oseltamivir is also recommended for H7N9 influenza infections. Evidence of resistance to oseltamivir is reported. Although inhaled zanamivir is proven effective in treating seasonal influenza, no data of its efficacy against H5N1 strains are available. Zanamivir is recommended, intravenously, for patients not improving with oseltamivir after 2 days of treatment. Peramivir was used through an Emergency Use Act with the FDA during the 2009–2010 outbreak. It is now approved for treatment of seasonal influenza.

► Prevention

Postexposure prophylaxis with 75 mg of oseltamivir orally once daily for 7–10 days should be given to close contacts and considered for moderate contacts of documented cases of H5N1 and H7N9 influenza infections although human-to-human transmission appears to be limited. Personnel exposed to patients should be monitored for symptoms. Careful surveillance for human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of

control include masks, social distancing, quarantine, travel limitations, and infrastructure development, particularly for emergency departments.

An adjuvanted human vaccine against H5N1 influenza is licensed by Sanofi Pasteur (but not marketed) in the United States with the government stockpiling supplies in the event of need. It appears to be only moderately immunogenic. Other vaccines are licensed by Glaxo-SmithKline in Europe and CS Limited in Australia. Vaccine candidates include one made with an oil-in-water emulsion-based adjuvant that is highly immunogenic and well tolerated. A major concern with H5N1 vaccinology is the evolution of the virus in vaccinated poultry, especially in the endemic nations of Egypt and Indonesia, and the need to maintain current surveillance and update vaccine development should avian influenza become more pathogenic in humans. Seasonal and H5N1 vaccines in phase II studies can be given either combined or in sequence safely and without affecting immunogenicity. An intranasal H5N1 vaccine trial is under development. Prevention of exposure to avian influenza strains also includes hygienic practices during handling of poultry products, including hand washing and prevention of cross-contamination, as well as thorough cooking of poultry products (to 70°C). There is no risk of acquiring avian influenza through the consumption of cooked poultry products, although there is a risk associated with handling feathers or birds from endemic areas, and the US government bans the importation of poultry from infected areas. Culling of infected H7 poultry is difficult because most animals are asymptomatic.

Because the potential for pandemic influenza for many of the new reassortment viruses is not fully known, continued surveillance is essential, and stockpiling of vaccines, adjuvant, and medications (oseltamivir and zanamivir) is warranted at the public health level.

4. Middle East Respiratory Syndrome–Coronavirus (MERS-CoV)

ESSENTIALS OF DIAGNOSIS

- ▶ Mild, moderate, or severe respiratory illness.
- ▶ Travel to endemic area, including Saudi Arabia, United Arab Emirates, Qatar, and Jordan, within 14 days before symptom onset.
- ▶ Contact with camels reported in many cases.
- ▶ Fever, cough, and dyspnea are most common symptoms.
- ▶ CDC can assist with real time-PCR using serum and lower and upper respiratory samples, or serology.
- ▶ No specific treatment available; mortality as high as 45%.

▶ General Considerations

Middle East respiratory syndrome (MERS) is a syndrome associated with a coronavirus similar to the cause of severe acute respiratory syndrome (SARS). Patients with MERS have had a history of residence or travel in the Middle East, in particular Saudi Arabia, or contact with such patients. The virus is probably transmitted through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stool, but the role of fecal–oral transmission is unknown. The earliest cases were identified in 2012 in the Kingdom of Saudi Arabia, and 75% of all cases have occurred there. Additional cases from the Middle East have occurred in Iran, Jordan, Kuwait, Lebanon, Oman, Qatar, United Arab Emirates (UAE), and Yemen; in Africa, cases are reported from Algeria, Egypt, and Tunisia; from Europe, in Austria, France, Germany, Greece, Italy, the Netherlands, and the United Kingdom; from Asia in China, Malaysia, South Korea, Philippines, Thailand, and Turkey; and from North America in the United States. During 2015, a large outbreak began in South Korea from a single patient with travel history to multiple countries in the Middle East. As of October 25, 2015, this outbreak included 186 cases, including 36 deaths. As of October 25, 2015, 1599 laboratory-confirmed cases have been recognized worldwide with at least 574 deaths (36%). Among 163 laboratory-associated cases, as of May 2014, 138 (84%) were reported from the Kingdom of Saudi Arabia, although laboratory-associated cases also occurred in the UAE, Iran, Jordan, Lebanon, the Netherlands, and the United States.

Person-to-person transmission can occur within families; hospital-associated cases comprise 25% of cases. The median incubation period is 5.2 days (range, 2–13) with the mean age of 50 (range 9 months to 99 years) and 65% occurring among men. Over 90% of patients have an underlying medical condition, including diabetes mellitus (68%), hypertension (34%), or chronic heart or kidney

disease. Those with diabetes, renal failure, chronic lung disease, or other immunocompromising conditions are considered to be at highest risk for severe disease.

Camels appear to be the principal reservoir, and several studies show that contact with dromedary herds of camels is greater among cases than controls. Raw camel milk is considered a potential source. Persons who work with camels are more likely to have antibody evidence of past infection.

▶ Clinical Findings

A. Symptoms and Signs

MERS is an acute respiratory syndrome, with the most common symptoms being fever (98%), cough (83%), and dyspnea (72%). Chills and rigors are common (87%). Gastrointestinal symptoms may occur with diarrhea being most common (26%), followed by nausea and abdominal pain, and may precede respiratory symptoms. Mild and asymptomatic cases have been reported.

B. Laboratory Findings and Imaging

Hematologic findings in the largest series to date include thrombocytopenia (36%), lymphopenia (34%), and lymphocytosis (11%). Moderate elevations in lactate dehydrogenase (49%), AST (15%), and ALT (11%) are recognized. Chest radiograph abnormalities are nearly universal and include increased bronchovascular markings, patchy infiltrates or consolidations, interstitial changes, opacities (reticular and nodular) as well as pleural effusions and total lung opacification. Ground-glass opacities and consolidation are most commonly seen. The findings mimic those of many other causes of pneumonia.

Serum serologies and RT-PCR are available through CDC (contact information below, on MMWR reference site). Highest viral loads are found in lower respiratory tract specimens, including bronchoalveolar lavage fluid, sputum, and tracheal aspirates. These samples are preferred for diagnosis. The CDC recommends sending lower respiratory tract specimens, nasopharyngeal and oropharyngeal swabs, and serum for testing. In confirmed cases, serial sample collection (perhaps every 2–4 days) from multiple sites is recommended to increase understanding of virus shedding kinetics. In cases in which symptom onset occurred more than 14 days prior and symptoms are ongoing, serum should be sent to the CDC for serologic testing and the above specimens should be sent for RT-PCR.

C. Case Definition

A patient with **severe illness** shows the following characteristics: fever (38°C, 100.4°F or higher) and pneumonia or ARDS (based on clinical or radiologic evidence); and **either** history of travel in or near the Arabian Peninsula (Bahrain, Iraq, Iran, Israel, Jordan, Kuwait, Lebanon, Oman, Palestinian territories, Qatar, Saudi Arabia, Syria, the United Arab Emirates (UAE), and Yemen) within 14 days before symptom onset; **or** close contact with a

symptomatic traveler in whom fever and acute respiratory illness (not necessarily pneumonia) developed within 14 days after travelling in or near the Arabian Peninsula (above); **or** is a member of a cluster of patients with severe acute respiratory illness (eg, fever and pneumonia requiring hospitalization) of unknown etiology in which MERS-CoV is being evaluated, in consultation with state and local health departments.

In milder illness, patients have fever and symptoms of respiratory illness (not necessarily pneumonia; eg, cough, shortness of breath) and history of having close contact with a confirmed MERS case as well as a history of being in a healthcare facility (as a patient, worker, or visitor) within 14 days of symptom onset in a country or territory within the Arabian Peninsula in which recent healthcare-associated cases of MERS have been identified.

Of note, fever may not be present in certain patients, including the very young, elderly, immunosuppressed, or those taking certain medications.

► Complications

Respiratory failure is such a common complication that in a series from Saudi Arabia, 89% of patients required intensive care and mechanical ventilation. Patients with MERS-CoV appear to advance faster to respiratory failure than do those with SARS.

► Treatment

Respiratory support is essential. A small retrospective study found improved survival at 14 days with ribavirin and interferon-alpha but not at 28 days.

► Prognosis

The overall mortality rate of identified cases is about 45%. Advanced age is associated with a poor prognosis.

► Prevention

Isolation and quarantine of cases is authorized by CDC. Strict infection control measures are essential as well as care and management of household contacts and hospital workers engaged in the care of patients. Travelers to Saudi Arabia (including the many pilgrims to the holy sites) should practice frequent hand washing and avoid contact with those who have respiratory symptoms. Evaluation of patients with suspect symptoms within 14 days of return from Saudi Arabia is essential. Because health care workers engaged in procedures that involve contact with respiratory droplets are at risk, isolation of high-risk patients is essential, as are simple hygienic measures. Control measures, including quarantining in the home for high-risk exposed persons and the use of facemasks for preventing hospital-acquired infections, are important. Assisting public health authorities with case reporting and surveillance is essential.

Camel workers including slaughterhouse and market workers, veterinarians, and racing personnel should wear facial protection and protective clothing and practice good personal hygiene, including frequent hand washing after touching animals. Family members of such personnel

should not be exposed to work paraphernalia including clothing and shoes and workers should shower at the site of employment rather than the home. Avoid direct contact with camels (who may be asymptomatic but who can transmit the virus through nasal or ocular discharge, milk, urine, and feces). All infected animals should be kept off the market, including their meat products, and buried or destroyed.

MMWR and the WHO periodically update the infection control recommendations and the status of ongoing outbreaks.

ADENOVIRUS INFECTIONS

► General Considerations

At least 56 serotypes of adenovirus are described to date and divided into 7 subgroups A–G. About half of these subgroups produce a variety of clinical syndromes. Adenoviruses show a worldwide distribution and occur throughout the year. These infections are usually self-limited or clinically inapparent and occur most commonly among infants, young children, and military recruits. However, these infections may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and COPD patients, as well as in patients who have undergone solid organ and hematopoietic stem cell transplantation or cardiac surgery or in those who have received cancer chemotherapy. A few cases of donor-transmitted adenoviral infection have been reported in past years. Adenoviruses, although a common cause of human disease, also receive particular recognition through their role as vectors in gene therapy.

► Clinical Findings

A. Symptoms and Signs

The incubation period is 4–9 days. Clinical syndromes of adenovirus infection, often overlapping, include the following. The **common cold** (Chapter 8) is characterized

by rhinitis, pharyngitis, and mild malaise without fever. Conjunctivitis is often present. **Nonstreptococcal exudative pharyngitis** is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. **Lower respiratory tract infection** may occur, including bronchiolitis, suggested by cough and rales, or pneumonia. (Types 1, 2, 3, 4, and 7 commonly cause acute respiratory disease and atypical pneumonia; coinfections or serial infections are documented to occur.) Infections are especially severe in Native American children. Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease but is also seen in healthy young adults and military recruit outbreaks. Viral or bacterial coinfections occur with adenovirus in 15–20% of cases. **Pharyngoconjunctival fever** is manifested by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. **Epidemic keratoconjunctivitis** (transmissible person-to-person, most often types 8 [and showing considerable variation by season], 19, and 37) occurs in adults and is manifested by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Various outbreaks (types 3, 8, 19) were reported from four US states in 2008–2010. Keratitis may lead to subepithelial opacities (especially with the above types). **Acute hemorrhagic cystitis** is a disorder of children often associated with adenovirus type 11 and 21. **Sexually transmitted genitourinary ulcers and urethritis** may be caused by types 2, 8, and 37 in particular. Adenoviruses also cause **acute gastroenteritis** (types 40 and 41), **mesenteric adenitis, acute appendicitis, and intussusception**. Rarely, they are associated with encephalitis, meningitis, acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with **myocarditis** and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), **pneumonia, and hemorrhagic cystitis** (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Syndromes that may develop in hematopoietic stem cell transplant patients include hepatitis, pneumonia, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

B. Laboratory Findings and Imaging

Antigen detection assays including direct fluorescence assay or enzyme immunoassay are rapid and show sensitivity of 40–60% compared with viral culture (considered the standard). Samples with negative rapid assays require PCR assays or viral cultures for diagnosis. Quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematopoietic stem cell transplant patients. Multiplex nucleic acid amplification assays are increasingly used to test for multiple respiratory viruses simultaneously with increased sensitivity. Adenovirus differs from other viral and bacterial respiratory infections seen on chest CT imaging, appearing as a multifocal consolidation or ground-glass opacity without airway inflammatory findings.

▶ Treatment & Prognosis

Treatment is symptomatic. Ribavirin or cidofovir is used in immunocompromised individuals with occasional success, although cidofovir is attendant with significant renal toxicity. IVIG is also used in immunocompromised patients and can be used in combination with other therapies, but data are still limited. Reduced immunosuppression is often required. Adoptive immunotherapy with transfusion of adenovirus-specific T cells is being investigated and has been associated with improved mortality. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Topical steroids or tacrolimus may be used to treat adenoviral keratoconjunctivitis. Complications of adenovirus pneumonia in children include bronchiolitis obliterans. Deaths are reported on occasion (eight in one season among the American military).

The control of epidemic adenoviral conjunctivitis is often difficult and requires meticulous attention to hand hygiene, use of disposable gloves, sterilization of equipment (isopropyl alcohol is insufficient, recommendations of manufacturers are preferred), cohorting of cases, and furloughing of employees.

Vaccines are not available for general use. Use of live oral vaccines containing attenuated type 4 and type 7 was reinstated in military personnel in 2013 and has been associated with significant decrease in adenoviral disease.

OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Erythrovirus (Parvovirus) Infections

Erythrovirus, formerly parvovirus B19, infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG), and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission with 30–50% of pregnant women nonimmune), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. Bocavirus, another erythrovirus (parvovirus), is a cause of winter acute respiratory disease in children and adults.

Clinical Findings

A. Symptoms and Signs

Erythrovirus (parvovirus B19) causes several syndromes and manifests differently in various populations.

1. Children—In children, an exanthematous illness (“fifth disease,” erythema infectiosum) is characterized by a fiery red “slapped cheek” appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Malaise, headache, pruritus (especially on the palms and soles), and diarrhea (rarely) occur. Systemic symptoms and fever are mostly abated by the time of rash appearance. Eosinophilic cellulitis (Well syndrome) is also reported with parvovirus. Parvovirus is also one of the most common causes of myocarditis in childhood.

2. Immunocompromised patients—A transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts. The parvovirus B19 gene is detected in 16–19% of acute leukemia and chronic myeloid leukemia patients.

3. Adults—A limited nonerosive symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, which may in some cases be a type II mixed cryoglobulinemia, can develop in middle-aged persons (especially women) but can also occur in children. Rashes, especially facial, are less common in adults.

Chloroquine and its derivatives exacerbate erythrovirus (parvovirus)-associated anemia and are linked with significantly lower hematocrit in hospital admissions in malaria endemic areas. Rare reported presentations include myocarditis with infarction, constrictive pericarditis, chronic dilated cardiomyopathy, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulopathy, CNS vasculitis, papular-purpuric “gloves and socks” syndrome, and a chronic fatigue syndrome. A subclinical infection is documented among patients with sickle cell disease. Other CNS manifestations of erythrovirus (parvovirus) include encephalitis, meningitis, stroke (usually in sickle cell anemia patients with aplastic crises), and peripheral neuropathy (brachial plexitis and carpal tunnel syndrome) with occasional chronic residua.

The symptoms of erythrovirus (parvovirus) infection can mimic those of autoimmune states such as lupus, systemic sclerosis, antiphospholipid syndrome, or vasculitis. The molecular mimicry of erythrovirus (parvovirus) to human cytokeratin and transcription factors engaged in hematopoiesis is the basis for theories that implicate erythrovirus (parvovirus) in the pathogenesis of these autoimmune states.

In pregnancy, premature labor, hydrops fetalis, and fetal loss are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

B. Laboratory Findings

The diagnosis is clinical (Table 32–2) but may be confirmed by either an elevated titer of IgM anti-erythrovirus

(parvovirus) antibodies in serum or with PCR in serum or bone marrow. By the time common presenting symptoms manifest, in particular a rash or polyarthropathy in an immunocompetent patient, the viremia may have cleared but IgM antibodies are likely present. In immunocompromised patients, RT-PCR is the optimal test. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry. False-positive serologies also occur in the presence of recent IVIG and anti-B cell therapy. Assays on marrow tissue are indicated only if a marrow is deemed necessary for other hematologic reasons.

Complications

Uncommon complications include the CNS diseases listed above, chronic hemolytic anemia, thrombotic thrombocytopenic purpuric syndrome, acute postinfectious glomerulonephritis, and hepatitis.

Treatment

Treatment in healthy persons is symptomatic (nonsteroidal anti-inflammatory drugs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients including those infected with HIV, IVIG is very effective in the short-term reduction of anemia. Relapses tend to occur about 4 months after administration of IVIG. There is no reduction in encephalitic complications with IVIG. Intrauterine blood transfusion can be considered in severe fetal anemia, although such transfusions have been linked to impaired neurologic development.

Prevention & Prognosis

Several nosocomial outbreaks are documented. In these cases, standard containment guidelines, including handwashing after patient exposure and avoiding contact with pregnant women are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of erythrovirus (parvovirus) infection in AIDS patients may occur with ART, though the immune restoration syndrome is also reported.

2. Poxvirus Infections

Among the nine poxviruses causing disease in humans, the following are the most clinically important: variola/vaccinia, molluscum contagiosum, orf and paravaccinia, and monkeypox.

1. Variola/vaccinia—Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations include severe headache, acute onset of fever, prostration and a rash characterized by the uniform progression from macules to papules to firm, deep-seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6).

Complications of smallpox include bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations (risk factor for blindness). **Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985.** Despite the recommendation of destroying remaining samples of this virus, significant concern exists for the potential misuse of these repositories in military or terrorist activities.

Smallpox should be considered, in concordance with the CDC's Smallpox Response Plan (www.bt.cdc.gov/agent/smallpox/response-plan/index.asp), in any patient with fever and a characteristic rash (see above) for which other etiologies—such as herpes infections, erythema multiforme, drug reactions (eczema herpeticum may be differentiated from suspect smallpox by appropriate serologic stains), or other infections—are unlikely. One hundred and fifteen cases of vaccine-related disease from contact with a smallpox vaccinee in the United States between 2003 and 2011 (including sexual transmission) were reported. Two cases of vaccinia infection after contact with oral rabies animal baits (which uses the vaccinia vector) are reported. Patients with suspected infection should be placed in airborne and contact isolation and the official agency contacted (CDC Emergency Preparedness and Response Branch; 770-488-7100).

Cidofovir may be considered for treatment of poxviral conditions and intravenous human vaccinia immunoglobulin may be useful for vaccinia. In the event of accidental smallpox exposure, a guideline for the use of the three vaccinia-based smallpox vaccinations and their contraindications in immunosuppressive states, including HIV and atopic eczema, is available at <http://www.cdc.gov/ncidod/monkeypox/treatmentguidelines.htm>.

2. Molluscum contagiosum—Molluscum contagiosum may be transmitted sexually or by other close contact. It

may occur also in an extensive form in children with genetic defects in dendritic and T cell migration (the DOCK8 [dedicator of cytokinesis] deficiency). The disease is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. There may be an association with atopic dermatitis or eczema. Marked and persistent lesions in AIDS patients respond readily to combination ART. Treatment options include destructive therapies (curettage, cryotherapy, cantharidin, and keratolytics, among others), immunomodulators (imiquimod, cimetidine, and *Candida* antigen), and antiviral agents (topical cidofovir is effective anecdotally in refractory cases and there is some efficacy suggested for a new lipid acyclic nucleoside phosphonate called CMX001, an agent used for other viral infections, including in particular CMV). No treatment is uniformly effective and multiple courses of therapy are often needed. There is anecdotal evidence that intralesional MMR vaccination may expedite resolution. Cryptococcal skin lesions can mimic molluscum contagiosum.

3. Orf and paravaccinia—Orf (contagious pustular dermatitis, or ecthyma contagiosa) and paravaccinia (milker's nodules) are occupational diseases acquired by contact with sheep and cattle, respectively. Household meat processing and animal slaughter have been implicated as non-traditional risk factors. A new poxvirus akin to parapoxviruses was reported in 2015 in two patients, from rural Tennessee and Missouri (the latter had also traveled to Tanzania). The use of nonporous gloves for persons with animal handling is recommended, especially if the persons are immunosuppressed.

4. Monkeypox—First identified in 1970, monkeypox is enzootic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 12 days, and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending on the immune status of the patient. Secondary attack rates appear to be about 10%. The first community-acquired outbreak in the United States of monkeypox occurred in 2003 in Wisconsin and other states of the upper Midwest. African outbreaks have been reported from the Sudan and the Democratic Republic of Congo. The source appeared to be imported Gambian giant rats via consequent exposure of prairie dogs. Other susceptible animals include nonhuman primates, rabbits, and rodents. Confusion with smallpox and varicella occurs; however, both lymphadenopathy (seen in up to 90% of unvaccinated persons) and a febrile prodrome are prominent features in monkeypox infection. Distinguishing characteristics of the monkeypox rash are its deep seated and well-circumscribed nature, it appears at the same stage of development (unlike varicella but like smallpox), and is centrifugal (including the palms and soles). Suspected cases should be placed on standard, contact and droplet precautions; and local and state public health officials and the CDC should be notified for assistance with confirmation of the diagnosis (electron microscopy, viral culture, ELISA, PCR). Cidofovir is effective against monkeypox, and IVIG can be used in selected cases.

Other general precautions that should be taken are avoidance of contact with prairie dogs and Gambian giant rats (whose illness is manifested by alopecia, rash, and ocular or nasal discharge), appropriate care and isolation of those exposed within 3 prior weeks to such animals, and veterinary examination and investigation of suspect animals through health departments. Vaccinia immunization is effective against monkeypox and is recommended, if no contraindication exists (outlined above), for those involved in the investigation of the outbreak and for healthcare workers caring for those infected with monkeypox. Post exposure vaccination is also advised for documented contacts of infected persons or animals. US federal agencies currently prohibit the importation of African rodents.

5. A new orthopox virus—Two cases in the country of Georgia with a novel orthopox virus occurred in 2013 with a third diagnosed serologically from 2010. All cases had animal contact, cattle for two, and serologic data showed possible associations with rodents and shrews as well as cattle. None had been vaccinated for smallpox (routine smallpox vaccinations ceased before their births).

estimated 20,000 to 35,000 pediatric hospitalizations annually from rotavirus infection, a fall from 70,000 annually in 2006). Each year, about 400,000 children die of rotavirus infection worldwide. Children aged 6 months to 2 years are the most affected, although adults are affected occasionally as well. By age 5, virtually every child has been infected with this pathogen. The diverse set of rotaviruses (classified by glycoproteins and protease-sensitive proteins [G-type and P-type antigens] which segregate independently) results in a constellation of phenotypes although only about four of these are responsible for over 90% of disease. Rotavirus infections follow an endemic pattern, especially in the tropics and low-income countries, although they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, daycare centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). Nosocomial outbreaks are reported.

The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by non-bloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. It is thought that rarely systemic disease occurs and rare reported presentations include cerebellitis and pancreatitis. Children with gastroenteritis are not routinely tested for rotavirus because the results do not alter treatment. If confirmatory testing is required, stool PCR is the most sensitive tool for diagnosing rotavirus. Antigen detection by enzyme immunoassay is another option. Oral and intravenous rehydration solutions are the primary treatment options, but effective adjunctive therapies include specific probiotics (eg, *Lactobacillus* GG or *Saccharomyces boulardii*), nitazoxanide, diosmectite, or racecadotril. Adjunctive therapies shorten the median duration of diarrhea and hospitalization. Local intestinal immunity gives protection against successive infection.

Two oral rotavirus vaccines are available in the United States: a live, oral, pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and a live, oral attenuated monovalent human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). The vaccines showed 85–98% efficacy against severe rotavirus gastroenteritis in trials based in the Americas and Europe. Reduced efficacy (50–64%) has been noted in studies conducted in Asia and Africa. One advantage of these vaccines is the evidence of heterotypic immunity (prevention against rotavirus strains not included in the vaccine). RotaTeq showed efficacy even with incomplete two-dose regimens. Contraindications include allergy to any of the vaccine ingredients, previous allergic reaction to the vaccine, and immunodeficiency. The risk of intussusception, which is far lower with this than earlier rotavirus preparations, is small (1:51,000 to 1:68,000 vaccinated infants) and is considered significantly lower than the risk associated with untreated rotavirus gastroenteritis. Vaccine coverage is inadequate in the United States for rotavirus (68% in the 2012 National Immunization Study), particularly among the poor. As of October 2015, national immunization programs of 79 countries include rotavirus vaccine.

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses (including the Aichi virus), and pestiviruses. Rotaviruses and noroviruses are responsible for most nonbacterial cases of gastroenteritis.

Rotaviruses are reoviruses with eight species and significant animal reservoirs. They are the leading worldwide cause of dehydrating gastroenteritis in young children and are associated with significant morbidity and mortality (an

Several other rotavirus vaccines are available throughout the world. Examples include live, oral vaccines such as Rotavin-M1 (approved in Vietnam in 2012) and RotaVac or the new Indian vaccine, 116E, which was approved in 2014.

Noroviruses, such as Norwalk virus (one of a variety of small round viruses divided into 5 genogroups and at least 34 genotypes), are major causes of severe diarrhea in adults and are recognized as the major cause of epidemic gastroenteritis (with food handlers largely responsible and associated foods most often leafy vegetables, fruits/nuts, and molluscs). They are responsible for a significant percentage of childhood hospitalizations for gastroenteritis in the developing world (15% in surveys from India, 31% from Peru) and about 13% of gastroenteritis-associated ambulatory visits in the United States. In the United States, noroviruses are responsible for over 90% of reported nonbacterial gastroenteritis outbreaks during cold weather intervals (hence the colloquial name “gastric flu”).

Norovirus gastroenteritis is responsible for an estimated 800 deaths annually in the United States and 200,000 deaths globally. The efficacy of the rotavirus vaccination is increasing the percentage of gastroenteritis caused by norovirus. The noroviruses appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting protective immunity develops and reinfections are common.

Outbreak environments include long-term-care facilities (nursing homes in particular), restaurants, hospitals, schools, daycare centers, vacation destinations (including cruise ships), and military bases. Persons at particular risk are the young, the elderly, the institutionalized, and the immunosuppressed. A strain that began in Australia (GII.4 Sydney) is responsible for increasing proportions of US cases and is transmitted most often in long-term-care facilities. Although transmission is usually fecal-oral, airborne, person-to-person, and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours, but up to 5 days in hospital-associated cases and in children younger than 11 years), a high frequency (greater than 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis.

RT-PCR of stool samples is used for diagnostic and epidemiologic purposes. Several licensed multiple pathogen platform assays are available, but they are expensive and interpretation of the cause of illness in a given patient may be difficult. Treatment options are similar to rotavirus (see above) and rely mostly on oral and intravenous rehydration. Deaths are rare in the developed world, and the more common associated diseases are aspiration pneumonia, septicemia, and necrotizing enterocolitis.

A number of vaccines for norovirus are under development and all entail the use of Norwalk viral-like proteins (VLP).

Outbreak control for both **rotavirus and norovirus infections** include strict adherence to general hygienic measures. Despite the promise of alcohol-based sanitizers for the control of pathogen transmission, such cleansers

may be relatively ineffective against the noroviruses compared with antibacterial soap and water, reinforcing the need for new hygienic agents against this prevalent group of viruses. Cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 h after this for norovirus disease), and proper decontamination procedures are crucial.

ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES

The most famous enterovirus, the poliomyelitis virus, is discussed above under Major Vaccine-Preventable Viral Infections. Other clinically relevant enteroviral infections are discussed in this section.

1. Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

► Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection are summer grippé; herpangina; epidemic pleurodynia; aseptic meningitis and other neurologic syndromes; acute nonspecific pericarditis; myocarditis; hand, foot, and mouth disease; epidemic conjunctivitis; and other syndromes.

1. Summer gripe (A and B)—A febrile illness, principally of children, summer gripe usually lasts 1–4 days. Minor symptoms of upper respiratory tract infection are often present.

2. Herpangina (A2–6, 10; B3)—There is sudden onset of fever, which may be as high as 40.6°C, sometimes with febrile convulsions. Other symptoms are headache, myalgia, and vomiting. The sore throat is characterized early by petechiae or papules on the soft palate that ulcerate in about 3 days and then heal. An outbreak in Taiwan with A2 was associated with herpangina and coincided with an enterovirus 71 (below) outbreak, characterized by hand, foot, and mouth disease. Dual A6/A10 outbreaks are reported from Europe. Treatment is symptomatic.

3. Epidemic pleurodynia (Bornholm disease) (B1–5)—Pleuritic pain is prominent. Tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in less than 10% of patients. Most patients are ill for 4–6 days.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and cerebrospinal fluid lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A. Disseminated encephalitis occurs after group B infection, and acute flaccid paralysis is reported with both coxsackievirus groups A and B. An outbreak of aseptic meningitis occurred in central China (Gansu Province) in 2008, with 85 cases reported of coxsackie A9 disease. Severe neonatal illnesses are reported with B1 infections, including encephalomyocarditis and neonatal deaths due to multiorgan failure.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1–5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 6, 10, 12, and 16, B5)—This disease is sometimes epidemic and is characterized by stomatitis, a vesicular rash on hands and feet, nail dystrophies and onychomadesis (nail shedding). Enterovirus 71 is also a causative agent.

8. Epidemic conjunctivitis—As with enterovirus 70, the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with outbreaks reported in the last few years in southern China,

Pakistan, southern Sudan, the Comoros, Uganda, Cuba, and Thailand. It is also reported as a cause of corneal endo-
thelitis after cataract surgery.

9. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), pancreatitis with concomitant hepatitis and myocarditis (A4), infant sepsis (A10), glomerulopathy (group B infections), onychomadesis (B1), neonatal hemophagocytic lymphohistocytosis (B1), types 1 and 2 diabetes mellitus (mainly group B infections), and thyroid disease (group B4), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections. A report of confirmed infective endocarditis due to coxsackievirus B2 in a patient with a prosthetic cardiac device suggests that viral etiologies of culture-negative infective endocarditis should be considered.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor intensive, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, appears to be useful, particularly in cases of meningitis.

► Treatment & Prognosis

Treatment is symptomatic. With the exception of meningitis, myocarditis, pericarditis, diabetes, and rare illnesses such as pancreatitis or poliomyelitis-like states, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this medication has stopped. There are anecdotal reports of success with IVIG in severe disease. Coxsackie A16 and enterovirus 71 in outbreaks of hand, foot, and mouth disease can be controlled with 5 minutes of exposure to 3120 ppm sodium hypochlorite. Vaccine development for Coxsackie-associated hand, foot, and mouth disease is underway in China.

2. Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death

ensues in about 3%. Males younger than 20 years are more commonly infected than other persons.

Over 30 serotypes of echoviruses are recognized and the most common serotypes for disease are types 6, 9, 11, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Transmission is primarily fecal–oral. Handwashing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported in the past.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases (bronchiolitis occurs often in children) and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, severe hepatitis with coagulopathy, leukocytoclastic vasculitis, and neonatal as well as adult cases of encephalitis and sepsis, interstitial pneumonitis, pleurodynia, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, acute flaccid paralysis (a current leading cause in India), optic neuritis, uveitis, and septic shock. Echoviruses and enteroviruses are also a common cause of nonspecific exanthems.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the cerebrospinal fluid can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. *In vitro* data suggest some role for amantadine or ribavirin but clinical studies supporting these findings are not available.

From a public health standpoint, clustered illnesses such as swimming in sewage-infested seawater in travelers suggest point-source exposure. Prevention of fecal–oral contamination and maintenance of pool hygiene through chlorination and pH control are important public health control measures.

3. Enteroviruses 68, 70, 71, & Related Agents

Several distinct clinical syndromes are being described in association with enteroviruses.

Enterovirus 68 (EV-D68) is a unique enterovirus that shares epidemiologic characteristics with human rhinovirus and is typically associated with respiratory illness. Several clusters are reported from the Netherlands, Japan, the Philippines, the United States, and Thailand. An

outbreak was reported during August 2014–January 2015, with 1153 cases reported from 49 states. Respiratory illness was caused by EV-D68. The outbreak was also associated with cases of acute flaccid myelitis but not definitively linked thus far. The agent is implicated also in aseptic meningitis, and encephalitis.

Enterovirus 70 (EV-70), a ubiquitous agent first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with **acute hemorrhagic conjunctivitis**. Enterovirus infection of the pancreas can trigger cell-mediated autoimmune destruction of beta cells resulting in diabetes. Enterovirus myocarditis can be a serious infection in neonates, complicated by cardiac dysfunction and arrhythmias.

Enterovirus 71 (EV-71) almost always occurs in the Asia-Pacific region and is associated with **hand, foot, and mouth disease (HFMD)**, which can be severe or even fatal, herpangina as well as a form of **epidemic encephalitis** associated on occasion with pulmonary edema, and **acute flaccid paralysis** often mimicking poliomyelitis. A recombinant virus (between EV-71 and coxsackievirus A16) caused an outbreak of HFMD in Fuyang China in 2008. In Taiwan, 29% of EV-71 in children is asymptomatic. There is an association reported between gastrointestinal enterovirus infection and type 1 diabetes.

Human enteroviruses are neurotropic. They may have a role in amyotrophic lateral sclerosis. EV-68 has been reported in a case of fatal meningitis/encephalitis.

Mortality is especially high in enterovirus 71-associated brainstem encephalitis, which is often complicated by pulmonary edema, particularly when it occurs in children younger than 5 years. A complication is autonomic nervous system dysregulation, which may develop prior to the pulmonary edema. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Disease is usually more severe and sequelae more common than with other enteroviruses. Some children with enterovirus-associated cardiopulmonary failure require the usage of extracorporeal life support, which can improve the outcome. Recognized sequelae include central hypoventilation, dysphagia, and limb weakness.

Clinical and epidemiologic findings aided by isolation of the suspect agent from conjunctival scraping for enterovirus 70; vesicle swabs, body secretions, or cerebrospinal fluid for enterovirus 71; and respiratory secretions for D68 facilitate diagnosis of these enteroviral entities. Enzyme immunoassays and complement fixation tests show good specificity but poor sensitivity (less than 80%). RT-PCR may increase the detection rate in enterovirus infections and is useful in the analysis of cerebrospinal fluid samples among patients with meningitis and of blood samples among infants with a sepsis-like illness.

Treatment of these entities remains largely symptomatic. There is anecdotal success in managing myocarditis with immunoglobulins. The major complication associated with enterovirus 70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Attention-deficit with hyperactivity occurs in about

20% with confirmed infection. Treatment of acute flaccid paralysis related to enterovirus 71 with IVIG does not appear to improve neurologic outcomes.

EV-D68 requires supportive care with particular attention to respiratory support. The CDC's National Enterovirus Surveillance System should receive reports of disease at wnix@cdc.gov.

Household contacts, especially children under 6 months of age, are at particular risk for enterovirus 71 acquisition. A commercial disinfectant, Virkon S, at 1–2% application, appears to reduce infectivity titers. A stage-based supportive treatment for enterovirus 71 infections, recognizing the potential for late onset CNS disease and cardiopulmonary failure is important. There is no commercial EV-71 vaccine in the United States although vaccines produced in China appear to be successful against EV-71-associated hand, foot, and mouth disease and herpangina. Decreases in antibody titers suggest booster doses of these vaccines may be needed.

Enterovirus 72 (EV-72) is another term for hepatitis A virus (see Chapter 16). Enterovirus EV-104A is related to rhinoviruses and associated with respiratory illness in reports from Italy and Switzerland.

4. Human Parechovirus Infection (HPeV)

HPeV is one of six members of the Picornaviridae family that cause disease in humans. The pathogen mainly affects small children during the summer and early fall, although disease can also occur in older adults. Cases are reported worldwide, and 16 genotypes are recognized. During 2009–2013, HPeV3 was most commonly reported among isolates in the United States. Clinical presentation is mainly driven by gastrointestinal and respiratory illness, although otitis, neonatal sepsis, flaccid paralysis, myalgias, diffuse maculopapular and palmar-plantar rashes, aseptic meningitis, and encephalitis are described in the literature.

Screening with a human parechovirus-specific PCR provides a significant increase in determining the viral cause of neonatal sepsis or CNS symptoms in children younger than 5 years but is not widely performed. Human parechoviruses are one of the leading causes of viral sepsis and meningitis in young children. HPeV1 is the most

prevalent genotype found among stool and nasopharyngeal samples in children (under 2 years old) but may particularly cause severe disease among neonates. HPeV6 affects individuals older than 20 years. HPeV3 is responsible for meningitis/encephalitis, neonatal sepsis, and was reported in association with necrotizing enterocolitis and hepatitis. It is the most prevalent picornavirus type found in cerebrospinal fluid samples of CNS-related infections in very young children. Cerebrospinal fluid parameters may be normal. CNS infection may be seen with HPeV4 as well. Respiratory and gastrointestinal illnesses are seen with types HPeV4–HPeV6, HPeV10, HPeV13–HPeV15. Neonatal deaths are reported with HPeV3 and HPeV6.

Treatment is largely supportive and rapid identification of the viral antigen by PCR in stools, respiratory samples, and cerebrospinal fluid may decrease use of unnecessary antibiotics and shorten hospital stay, although current PCR assays are not always sufficiently sensitive to exclude parechoviruses. Intravenous immunoglobulin was anecdotally successful in one case of parechovirus dilated cardiomyopathy. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy.

RICKETTSIAL DISEASES

TYPHUS GROUP

1. Epidemic Louse-Borne Typhus

ESSENTIALS OF DIAGNOSIS

- ▶ Prodrome of headache, then chills and fever.
- ▶ Severe, intractable headaches, prostration, persisting high fever.
- ▶ Macular rash appearing on the fourth to seventh days on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.
- ▶ Diagnosis confirmed by specific antibodies using complement fixation, microagglutination, or immunofluorescence.

▶ General Considerations

Epidemic louse-borne typhus is caused by *Rickettsia prowazekii*, an obligate parasite of the body louse *Pediculus humanus corporis* (Table 32–4). Transmission is favored by

Table 32–4. Rickettsial diseases.

Disease	Rickettsial Pathogen	Geographic Areas of Prevalence	Insect Vector	Mammalian Reservoir	Travel Association
Typhus group					
Epidemic (louse-borne) typhus	<i>Rickettsia prowazekii</i>	South America, Northeastern and Central Africa	Louse	Humans, flying squirrels	Rare
Endemic (murine) typhus	<i>Rickettsia typhi</i>	Worldwide; small foci (United States: southeastern Gulf coast)	Flea	Rodents, opossums	Often
Scrub typhus group					
Scrub typhus	<i>Orientia tsutsugamushi</i>	Southeast Asia, Japan, Australia, Western Siberia	Mite ¹	Rodents	Often
Spotted fever group					
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Western Hemisphere; United States (especially mid-Atlantic coast region)	Tick ¹	Rodents, dogs, porcupines	Rare
California flea rickettsiosis	<i>Rickettsia felis</i>	Worldwide	Flea	Cats, opossums	
Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian tick typhus	<i>Rickettsia conorii</i>	Africa, India, Mediterranean regions	Tick ¹	Rodents, dogs	Often
Queensland tick typhus	<i>Rickettsia australis</i>	Eastern Australia	Tick ¹	Rodents, marsupials	Rare
Siberian Asian tick typhus	<i>Rickettsia sibirica</i>	Siberia, Mongolia	Tick ¹	Rodents	Rare
African tick bite fever	<i>Rickettsia africae</i>	Rural sub-Saharan Africa, Eastern Caribbean	Tick ¹	Cattle	Often
Lymphangitis associated rickettsiosis	<i>R sibirica mongolitimonae</i>	Europe, Africa, Mongolia	Tick ¹	Unknown	Unknown
Tick-borne lymphadenopathy/ Dermacentor-borne necrosis erythema lymphadenopathy/scalp eschar neck lymphadenopathy	<i>R slovaca, R raoultii, Candidatus R rioja</i>	Europe	Tick	Unknown	Occasional
Rickettsialpox	<i>Rickettsia akari</i>	United States, Korea, former USSR	Mite ¹	Mice	Occasional
Other					
Ehrlichiosis and anaplasmosis, human Monocytic	<i>Ehrlichia chaffeensis, Anaplasma equi, Ehrlichia canis</i>	Southeastern United States	Tick ¹	Dogs	Occasional
Granulocytic	<i>Anaplasma phagocytophilum, Ehrlichia ewingii</i>	Northeastern United States	Tick ¹	Rodents, deer, sheep	Occasional
Q fever	<i>Coxiella burnetii</i>	Worldwide	None ²	Cattle, sheep, goats	Occasional

¹Also serve as arthropod reservoirs by maintaining rickettsiae through transovarian transmission.

²Human infection results from inhalation of dust.

crowded, unsanitary living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. After biting a person infected with *R prowazekii*, the louse becomes infected by the organism, which persists in the louse gut and is excreted in its feces. When the same louse bites an uninfected individual, the feces gain entry

into the bloodstream when the person scratches the itching wound. Dry, infectious louse feces may also enter via the respiratory tract. Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa, Central and South America). Outbreaks have been reported from Peru, Burundi, and Russia. Because of aerosol transmissibility,

R. prowazekii is considered a possible bioterrorism agent. In the United States, cases occur among the homeless, refugees, and the unhygienic, most often in the winter.

R. prowazekii can survive in lymphoid and adipose (in endothelial reservoirs) tissues after primary infection, and years later, produce recrudescence of disease (**Brill-Zinsser disease**) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of *R. prowazekii* in the United States is flying squirrels, *Glaucomys volans*. Transmission to humans can occur through their ectoparasites, usually causing atypical mild disease. A case of recrudescence (Brill-Zinsser) disease 11 years after disease acquired by contact with flying squirrels is reported. Foci of sylvatic typhus are found in the eastern United States and are reported to occur in Brazil, Ethiopia, and Mexico.

Clinical Findings

A. Symptoms and Signs

(Table 32–2). Prodromal malaise, cough, headache, backache, arthralgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe and the fever is prolonged.

Other findings consist of conjunctivitis, mild vitritis, retinal lesions, optic neuritis, and hearing loss from neuropathy of the eighth cranial nerve, flushed facies, rales at the lung bases, abdominal pain, myalgias, and often splenomegaly. A macular rash (that may become confluent) appears first in the axillae and then over the trunk, spreading to the extremities but rarely involving the face, palms, or soles. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. There may be acute kidney injury, stupor, seizures, and delirium. Improvement begins 13–16 days after onset with a rapid drop of fever and typically a spontaneous recovery.

B. Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for *R. prowazekii* antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill-Zinsser disease), early antibodies are predominantly IgG. A PCR test exists, but its availability is limited. *R. prowazekii* is differentiated into 7 genotypes.

C. Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage lack enough specificity to permit diagnosis in nonepidemic situations. The rash is sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be

difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococemia, and measles.

Complications

Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, and uremia may occur.

Treatment

Treatment consists of either doxycycline (100 mg orally twice daily) or chloramphenicol (50–100 mg/kg/day in four divided doses, orally or intravenously) for 4–10 days. Chloramphenicol is considered less effective than doxycycline, but it is still the drug of choice in pregnancy. In epidemic conditions, a single dose of doxycycline can be effective and is less costly.

Prognosis

The prognosis depends greatly on the patient's age and immune status. In children under age 10 years, the disease is usually mild. The mortality rate is 10% in the second and third decades but in the past reached 60% in the sixth decade. Brill-Zinsser disease has a more gradual onset than primary *R. prowazekii* infection, fever and rash are of shorter duration, and the disease is milder and rarely fatal.

Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing.

A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious from the lice during the febrile period and perhaps 2–3 days after the fever returns to normal. Infected lice pass rickettsiae in their feces within 2–6 days after the blood meal and can be infectious earlier if crushed. Rickettsiae remain viable in a dead louse for weeks.

No vaccine is available for the prevention of *R. prowazekii* infection.

2. Endemic Flea-Borne Typhus (Murine Typhus)

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–4). Serosurveys of animals show high prevalence of antibodies to *R. typhi* in opossums, followed by dogs and cats. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea, which releases infected feces while sucking blood. Rare human cases in the developed world follow travel, usually

to Southeast Asia (in Bangladesh 67% of patients with febrile illness in one series showed IgM seropositivity), Africa (Burundi and Ethiopia have foci of infection), or the Mediterranean area although other pockets of infection are also known to occur in the Andes and the Yucatán. In the United States, cases are mainly reported from Texas and Southern California.

Endemic typhus resembles recrudescent epidemic typhus in that it has a gradual onset, less severe symptoms, and a shorter duration of illness than epidemic typhus (7–10 days versus 14–21 days). The presentation is nonspecific, including fever, headache, and chills. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk and fades fairly rapidly. Liver dysfunction occurs in the majority of cases. Peripheral facial paralysis and splenic infarction are reported to occur. Severe disease with mental confusion and signs of hepatic, cardiac, renal, and pulmonary involvement may develop. Postinfectious optic neuritis is rare and may occur weeks after successful treatment. Rare complications include a respiratory distress syndrome and a hemophagocytosis syndrome. Jaundice, bradycardia, and the absence of a headache are correlated with a delayed defervescence (in both epidemic and endemic typhus).

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after a rural exposure and with a different rash (centripetal versus centrifugal for epidemic or endemic typhus). Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific *R typhi* antigens. A fourfold rise in serum antibody titers between the acute and the convalescent phase is diagnostic.

Antibiotic treatment is the same as for epidemic typhus (see above). Ciprofloxacin (500–750 mg orally twice a day) and ampicillin (500 mg orally three times a day) are reportedly successful in pregnant women. Mortality is usually low with (1%) or without (4%) appropriate antibiotics. Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings.

3. Scrub Typhus (Tsutsugamushi Fever)

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to mites in endemic area of Southeast Asia, the western Pacific (including Korea), and Australia.
- ▶ Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- ▶ High fever, headache, myalgia, and a short-lived macular rash.
- ▶ Frequent pneumonitis, encephalitis, and cardiac failure.

▶ General Considerations

Scrub typhus is caused by *Orientia tsutsugamushi*, which is principally a parasite of rodents and is transmitted by larval trombiculid mites (chiggers). The disease is endemic in Korea, China, Taiwan, Japan, Pakistan, India, Thailand, Malaysia and Queensland, Australia (Table 32–4), which form an area known as the “tsutsugamushi triangle.” Scrub typhus is an increasingly recognized cause of acute febrile illness in India, being responsible for about 24% of cases in one series and is a recognized cause of fever of unknown origin. Transmission is often more common at higher altitudes. The mites live on vegetation but complete their maturation cycle by biting humans who come in contact with infested vegetation. Therefore, the disease is more common in rural areas within these countries, although an outbreak was reported among users of an urban park in Guangzhou, China. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers. Increasingly cases with travel to endemic areas are recognized.

▶ Clinical Findings

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache and backache develop. At the site of the bite, a papule evolves into a flat black eschar (the groin and the abdomen being the most common sites followed by the chest and axilla), a finding that is usually helpful for diagnosis and reported in 55% of a large Indian series. The regional lymph nodes are commonly enlarged and tender, and sometimes a more generalized adenopathy occurs. Fever rises gradually during the first week of infection, and the rash is usually macular and primarily on the trunk area. The rash can be fleeting or more severe, peaking at 8 days but lasting up to 21 days after onset of infection. The patient may become obtunded. Gastrointestinal symptoms, including nausea, vomiting, and diarrhea, occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. Both acalculous

cholecystitis and acute abdominal attacks are reported. An acute kidney injury is increasingly reported and renal abnormalities were present in over 80% of patients in one series. Transient parkinsonism, opsoclonus, or myoclonus may occur. Severe complications, such as pneumonitis, myocarditis and heart failure, encephalitis or aseptic meningitis, acute abdominal pain, peritonitis, granulomatous hepatitis, a hemophagocytic syndrome, disseminated intravascular coagulation, cerebrovascular hemorrhage or infarction, cranial nerve palsies, parkinsonian symptoms, ARDS, hemophagocytosis, or acute kidney disease may develop during the second or third week. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

B. Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Serologic testing with immunofluorescence and immunoperoxidase assays or commercial dot-blot ELISA dipstick assays are convenient diagnostic aids, but a conclusive diagnosis requires documentation of a fourfold increase between acute and convalescence titers of antibodies. An indirect immunofluorescence assay is the mainstay of serologic diagnosis and titers quickly lose sensitivity so should be read as soon as possible after collection. A rapid immunochromatographic test for IgM and IgG detection is more sensitive and specific than the standard immunofluorescence assay. PCR (from the eschar or blood) may be the most sensitive diagnostic test but remains positive even after the initiation of treatment. Culture of the organism (by mouse inoculation) from blood obtained in the first few days of illness is another diagnostic modality but requires a specialized BioSafety Level 3 laboratory. Filter paper immunofluorescent assays are as sensitive and specific as paired sera and may be especially useful in field settings.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, Q fever, hemorrhagic fevers, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. Empiric treatment for 3 days with doxycycline, 100 mg orally twice daily, or with minocycline, 100 mg intravenously twice daily, or for 7 days with chloramphenicol, 25 mg/kg/day orally or intravenously in four divided doses, eliminates most deaths and relapses. Chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia, where azithromycin or roxithromycin may become the medication of choice for children, pregnant women, and patients with refractory disease. Azithromycin is reportedly successfully given as 500 mg intravenously daily for 5 days.

Rifampin reduces the duration of fever by 1 day when used with doxycycline.

Poor prognostic factors include hypotension requiring vasopressors, ICU care, high APACHE-II scores, age over 60 years, absence of an eschar (making the diagnosis difficult) and laboratory findings such as leukocytosis or hypoalbuminemia. HIV infection does not appear to influence the severity of scrub typhus.

Prevention

Repeated application of long-acting miticides can make endemic areas safe. Insect repellents on clothing and skin as well as protective clothing are effective preventive measures. For short exposure, chemoprophylaxis with doxycycline (200 mg weekly) can prevent the disease but permits infection. No effective vaccines are available.

SPOTTED FEVERS

1. Rocky Mountain Spotted Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to tick bite in an endemic area.
- ▶ An influenza-like prodrome followed by chills, fever, severe headache, and myalgias; occasionally, delirium and coma.
- ▶ Red macular rash appears between the second and sixth days of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- ▶ Serial serologic examinations by indirect fluorescent antibody confirm the diagnosis retrospectively.

General Considerations

Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. Passive surveillance data from 2002 to 2007 reported cases from 46 states and the District of Columbia. More than

half (64%) of these cases were from only five states: North Carolina, Tennessee, Oklahoma, Missouri, and Arkansas. RMSF is endemic in Central and South America with a small fatal familial cluster reported from Panama (Table 32–4). Native Americans are at high risk for infection. The causative agent, *R. rickettsii*, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, *Dermacentor andersoni*, in the western United States, and the American dog tick, *D. variabilis*, in the eastern United States. Several hours of contact between the tick and the human host are required for transmission. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona and responsible for many Native American cases. Other hard-bodied ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals. There are 25 genotypes of *R. rickettsii* in four different groups, and potential genomic-clinical correlations are underway. Several other rickettsial species cause mild, nonlethal infections in the United States, including *R. parkeri*, *R. phillipi*, and *R. massiliae*. These are discussed in the “tick typhus” section.

In the United States, the estimated annual incidence of RMSF is increasing to as high as seven cases per million persons (primarily occurring from April through September), with a higher incidence among children and men. Better diagnostic capacity and improved surveillance are thought responsible for the changing epidemiology.

A Brazilian spotted fever with higher mortality than RMSF is now thought to be due to a virulent strain of *Rickettsia rickettsii*.

► Clinical Findings

A. Symptoms and Signs

RMSF can cause severe multiorgan dysfunction and fatality rates of up to 73% if left untreated, making it the most serious rickettsial disease. Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with the abrupt onset of high fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. The characteristic rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever. It initially involves the wrists and ankles, spreading *centrally* to the arms, legs, and trunk over the next 2–3 days. Involvement of the palms and soles is characteristic. Facial flushing, conjunctival injection, and hard palatal lesions (Figure 32–6) may occur. In about 10% of cases, however, no rash or only a minimal rash is seen. Cough and pneumonitis may develop and delirium, lethargy, seizures, stupor, and coma may also appear in more severe cases. Splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), adrenal hemorrhage, polyarticular arthritis, or uremia is occasionally present. ARDS and necrotizing vasculitis, when present, are of greatest concern.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. Cerebrospinal

▲ **Figure 32–6.** Hard palate lesion caused by Rocky Mountain spotted fever. (Public Health Image Library, CDC.)

fluid may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic or PCR demonstration of *R. rickettsii* in skin biopsy specimens (or cutaneous swabs of eschars or skin lesions). Performing such studies as soon as skin lesions become apparent and before antibiotics commence maximizes sensitivity. Children with fatal disease frequently have platelet counts less than 50,000 cells/mcL.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used. No commercial PCR technique is validated.

► Differential Diagnosis

The diagnosis is challenging because early symptoms resemble those of many other infections. The classic triad of fever, rash, and tick bite is rarely recognized, with up to 40% of patients not recalling a tick bite. Moreover, the rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Coinfections may mask the diagnosis. Blood cultures and examination of cerebrospinal fluid establish the latter. Some spotted fever rickettsioses may also mimic RMSF but will not be detected by routine serologic testing for RMSF.

► Treatment & Prognosis

Treatment with doxycycline at similar doses and duration as for epidemic typhus (100 mg orally twice daily for 4–10 days) is recommended, including for children. Similarly, chloramphenicol (50–100 mg/kg/day in four divided doses, orally or intravenously for 4–10 days) is the preferred alternative during pregnancy. Patients usually defervesce within 48–72 hours and therapy should be maintained for at least 3 days after defervescence occurs. Mild cases in low-risk individuals may be observed without treatment.

The reported mortality rate in the United States is about 3–5%. The following features are associated with increased

mortality: (1) infection in very young children, the elderly, or Native Americans; (2) the presence of atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms) and underlying chronic diseases; and (3) a delay in initiation of appropriate antibiotic therapy. Hemorrhage and acute kidney injury are associated with mortality in children. The usual cause of death is pneumonitis with respiratory or cardiac failure. Sequelae may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

▶ Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. The effectiveness of aggressive campaigns to decrease ticks in the community is under investigation in Native American communities with high RMSF attack rates. Prophylactic therapy after a tick bite is not currently recommended.

Vaughn MF et al. Seroepidemiologic study of human infections with spotted fever group Rickettsiae in North Carolina. *J Clin Microbiol*. 2014 Nov;52(11):3960–6. [PMID: 25187639]

2. Rickettsialpox

Rickettsialpox is an acute, self-limiting, febrile illness caused by *Rickettsia akari*, a parasite of mice, transmitted by the mite *Liponyssoides sanguineus* (Table 32–4). Infections are reported globally. Seroprevalence studies done on injection drug users in inner Baltimore showed antibody positivity as high as 16%. In New York, its association with poverty is very strong. The illness has also been found in farming communities. Crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. The primary lesion is a painless red papule that vesiculates and forms a black eschar followed by an incubation period of 7–12 days. Onset of symptoms is sudden, with chills, fever, headache, photophobia, and disseminated aches and pains. Two to 4 days later, a widespread papular eruption appears. The rash becomes vesicular and forms crusts that are shed in about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement

fixation or indirect fluorescent assays, is diagnostic. Conjugated anti-rickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. *R akari* can reportedly also be isolated from eschar biopsy specimens.

Treatment consists of oral doxycycline (200 mg/day) for 7 days. The disease is usually mild and self-limited without treatment, but occasionally severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications.

3. Tick Typhus (Rickettsial Fever)

The term “tick typhus” denotes a variety of spotted rickettsial fevers, often named by their geographic location (eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus), or by morphology (eg, boutonneuse fever). These illnesses are caused by various rickettsial organisms (eg, *R africae*, *R australis*, *R conorii*, *R japonica*, *R massiliae*, *R parkeri*, and *R sibirica*, and *R 364D*—recognized in California in 2013) and are transmitted by various tick species. Lymphangitis-associated rickettsiosis (LAR), caused by *R sibirica mongolitimoniae*, was first described in 1996 and has been reported in Europe only thus far, including a small outbreak in Spain) (Table 32–4). Dogs and wild animals, usually rodents and even reptiles, may serve as reservoirs for rickettsial fevers. Travel is a risk factor for disease, particularly among elderly ecotourists. In a series of 280 international travelers with rickettsial disease, the most common cause was spotted fever rickettsiosis (231 cases, 82.5% of the total) followed by scrub typhus (16, 5.7%).

Tick-borne rickettsioses are the main source of rickettsia infections in Europe and cause a syndrome similar to that seen in Mediterranean spotted fever. Newly recognized species include *R helvetica*, *R monacensis*, *R massiliae*, and *R aeschlimannii*. Another described syndrome is tick-borne lymphadenopathy/Dermacentor-borne-necrosis-erythema-lymphadenopathy/scalp eschar neck lymphadenopathy (TIBOLA/DEBONEL/SENLAT) associated with *R slovacca*, *Candidatus R rioja*, and *R raoultii* and characterized by tick bite, eschar on the scalp, and cervical lymphadenopathy.

The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Painful lymphadenopathy or lymphangitis may also occur. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular

edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis are observed. Neurologic manifestations, including encephalitis, internuclear ophthalmoplegia, coronary involvement, and the hemophagocytic syndrome, are rare.

The diagnosis is clinical, with serologic or PCR (culture can be used but is less sensitive than either) of the buffy coat of blood, or an eschar if one is available, used for confirmation. Treatment should be started upon clinical suspicion since delayed therapy is the usual cause of increased morbidity. Oral treatment with doxycycline (200 mg/day) or chloramphenicol (50–75 mg/kg/day in four divided doses) for 7–10 days is indicated. Caution is advised with the use of ciprofloxacin because it is associated with a poor outcome and increases the severity of disease in Mediterranean spotted fever. The combination of azithromycin and rifampin is effective and safe in pregnancy. Prevention entails protective clothing, repellents, and inspection for and removal of ticks.

Formerly classified as an endemic or murine typhus, the cat-flea typhus, caused by *Rickettsia felis* is now more properly classified as a spotted fever. The causative agent has been linked to the cat flea and opossum exposure. Most cases in the United States (southern Texas and California, and possibly Hawaii) occur in the spring and summer. Treatment is the same as for other rickettsial fevers.

OTHER RICKETTSIAL & RICKETTSIAL-LIKE DISEASES

1. Ehrlichiosis & Anaplasmosis

ESSENTIALS OF DIAGNOSIS

- ▶ Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- ▶ Nine-day incubation period, with variable clinical illness, ranging from asymptomatic to persistent or life threatening.
- ▶ Common symptoms are malaise, nausea, fever, and headaches.
- ▶ US cases are largely in elderly white men in the summer.
- ▶ Excellent response to therapy with tetracyclines.

▶ General Considerations

Ehrlichiae and anaplasmae are small tick-borne gram-negative obligate intracellular bacteria that infect monocytes or granulocytes. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* (Table 32–4). Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum*. *Ehrlichia ewingii* (infecting primarily dogs) can rarely cause human granulocytic ehrlichiosis (also referred to as *E ewingii* ehrlichiosis) similar to human granulocytic anaplasmosis. A third *Ehrlichia* species that infects humans appears to be related to *Ehrlichia muris*. An *Ehrlichia*-like organism, *Neorickettsia sennetsu*, is the etiologic agent of sennetsu fever, which is confined to western Japan.

Human monocytic ehrlichiosis is seen primarily in the south central states (especially Arkansas, Missouri, and Oklahoma) of the United States, although cases are also recognized in Israel, Japan, Mexico, South America, and Europe. Human granulocytic anaplasmosis is more frequent in the upper midwestern United States with most cases reported from Minnesota and Wisconsin although there is a secondary focus along the New England coast, especially in Rhode Island. Infections in Europe and China are also well documented with a newly diagnosed species from China being named *Anaplasma capra*. Human infection with *E ewingii* is limited to the Midwest and Southeast and occurs mainly among the immunocompromised with an infection identified from bone marrow in a resident of Arkansas with fever and pancytopenia. In North America, the major vectors for these pathogens are the Lone Star tick (*Amblyomma americanum* for *E chaffeensis* and *E ewingii*), the western black-legged tick (*Ixodes pacificus* for *E chaffeensis*), and *Ixodes scapularis* (the same vector for Lyme disease and babesiosis for *A phagocytophilum*). Reported incidences of both human monocytic and granulocytic ehrlichiosis are increasing and both are now at about 3 per million, respectively, with higher rates in the summer among whites and among men. Up to 4.9% of *Amblyomma americanum* and *D variabilis* ticks are seropositive for *Ehrlichia*.

The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white tail deer and the white-footed mouse, respectively. Other mammals are implicated as well. A nosocomial outbreak was reported from China (where nine patients had exposure to body fluids and none reported tick bites). Perinatal and blood product transmission of human granulocytic anaplasmosis is also documented.

▶ Clinical Findings

A. Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life threatening. Typically, after about a 9-day incubation period and a prodrome consisting of malaise, rigors, and nausea, worsening fever and headache develop. A pleomorphic rash may occur. Presentation in immunosuppressed patients (including transplant patients) and the

elderly tends to be more severe. Serious sequelae include acute respiratory failure and ARDS, encephalopathy, and acute kidney disease, which may mimic thrombotic thrombocytopenic purpura.

The symptoms of human granulocytic ehrlichiosis and *E. ewingii* infection are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent in human granulocytic ehrlichiosis and should prompt the consideration of other infections (eg, Lyme disease). Persistent fever and malaise are reported to occur for 2 or more years.

The clinical manifestations of anaplasmosis are similar to those of ehrlichiosis. Coinfection with anaplasmosis and Lyme disease or babesiosis may occur, but the clinical manifestations (including fever and cytopenias) are greater with anaplasmosis than with Lyme disease. A spirochete, *Borrelia miyamotoi*, may mimic anaplasmosis in its clinical manifestations.

B. Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae). An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay, if available, is a rapid diagnostic tool, especially for early disease.

▶ Treatment & Prevention

Treatment for all forms of ehrlichiosis is with doxycycline, 100 mg twice daily (orally or intravenously) for at least 10 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women and children. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis. Tick control is the essence of prevention and, as foci of new infection are identified (eg, Northern China), the area for such heightened control broadens. Transmission of *Ehrlichia chaffeensis* by renal transplantation is documented.

Sachdev SH et al. Severe life-threatening *Ehrlichia chaffeensis* infections transmitted through solid organ transplantation. *Transpl Infect Dis*. 2014 Feb;16(1):119–24. [PMID: 24330198]

2. Q Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to sheep, goats, cattle, or their products; some infections are laboratory acquired.
- ▶ An acute or chronic febrile illness with severe headache, cough, prostration, and abdominal pain.
- ▶ Extensive pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, or chronic fatigue syndrome.
- ▶ A common cause of culture-negative endocarditis.

▶ General Considerations

Q fever (for “query” in view of its formerly unknown cause), a reportable and significantly underestimated disease in the United States, is caused by *Coxiella burnetii*, an organism previously classified as a rickettsia but now considered a proteobacterium. Unlike rickettsiae, *C. burnetii* is usually transmitted to humans not by arthropods but by inhalation or ingestion. *Coxiella* infections occur globally, mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 32–4). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. *Coxiella* is resistant to heat and drying and remains infective in the environment for months.

Humans become infected by inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk (in particular raw milk), or products of conception of infected animals. Ingestion and skin penetration are other recognized routes of transmission. Outbreaks associated with other mammals such as cats and dogs are also described. A major outbreak in the Netherlands that began in 2007 was thought to be due to exposure to aborting ruminants and was associated with over 3000 cases. A common source outbreak occurred in Germany in 2014 among recipients of xenotransfusion entailing intramuscular injections of animal cells, given for diverse health reasons.

There is a known occupational risk for animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products. Outbreaks in military personnel returning from Iraq and Afghanistan were described. Transmission through aerosols is possible in that *Coxiella* can be pathogens of other organisms (free living amoebae), which are transmitted through air ducts and intrahospital transmission to a pregnant woman presumably from aerosols is documented. In the United States, over 60% of cases do not report an exposure to potentially infectious animals, but cases are more than twice as likely as noncases to report drinking raw milk. An epidemiologic study suggests that in French Guiana three-toed sloths may be a reservoir for *Coxiella* organisms. Seroprevalence studies show ubiquity of infection, with rates of 24% in French Guiana, 10% in China, 10–32% in Egypt where contact

with camels is deemed responsible and significant under recognition throughout sub-Saharan Africa.

Endocarditis, an uncommon but serious form of *Coxiella* infection, is linked to preexisting valvular conditions, immunocompromised states, urban residence, and raw milk ingestion. Delays in diagnosis often occur. Horizontal spread from one human to another does not seem to occur even in the presence of florid pneumonitis, but maternal-fetal infection can occur.

► Clinical Findings

A. Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 2–3 weeks, usually accompanied by headache, relative bradycardia, prostration, and muscle pains. The clinical course may be acute, chronic (duration 6 months or longer), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestations in the acute form (3.5% of community-acquired pneumonia in a German series was due to Q fever), whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aortic aneurysms, aseptic meningitis, encephalitis, hemolytic anemia, orchitis, acute kidney disease, iliopsoas abscess, spondylodiscitis, tenosynovitis, and regional (mediastinal) or diffuse lymphadenopathies. Cases of Q fever mimicking autoimmune and systemic inflammatory disease are reported. The most common presentation of chronic Q fever is culture-negative endocarditis, which occurs in less than 1% of infected individuals. It is found mainly in the setting of preexisting valve disease. Vascular infections, particularly of the aorta (causing mycotic aneurysms), are the second most common form of Q fever and are associated with a high mortality (25%). A post-Q fever chronic fatigue syndrome (1 year after acute infection with chronic symptoms not explained by chronic Q fever) is controversial and of unknown pathophysiology although the basis may be immunogenetic.

Reactivation of Q fever in pregnant women may cause spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, premature delivery, and oligohydramnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver function tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to *C burnetii* phase II antigen. A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic. Realtime PCR for *C burnetii* DNA is helpful only in early diagnosis of Q fever with *C burnetii* DNA becoming undetectable in serum as serologic responses develop. The positive predictive value of antibodies to phase II antigens in acute disease is at most 65%.

While chronic Q fever can be diagnosed on the basis of serologic tests done at 3- and 6-month intervals (with an IgG titer against phase I antigen of 1:1600 or greater), the

sensitivity of such serologies is often low, and it is recommended that clinical criteria be used for diagnosis of chronic disease. Diagnosis is often made at the time of valve replacement with PCR of tissue samples. *C burnetii* may also be isolated from affected valves using the shell-vial technique. The organism is highly transmissible to laboratory workers and culture techniques require a bio-safety level 3 setting. In one series, at 6 years after infection, reversion to seronegativity occurred in 7 of 38 patients, and none showed the organism in peripheral blood mononuclear cells. Antiphospholipid antibodies and anti-ADAMTS 13 antibodies may be present and account for thrombotic and other clinical symptoms.

C. Imaging

Radiographs of the chest show patchy pulmonary infiltrates, often more prominent than the physical signs suggest.

► Differential Diagnosis

Viral, mycoplasmal, and bacterial pneumonias, viral hepatitis, brucellosis, Legionnaire disease, Kawasaki disease, tuberculosis, psittacosis, and other animal-borne diseases must be considered. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease.

► Treatment & Prognosis

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops. In a Dutch series, long-term fatigue is documented after acute infection.

For chronic infection, there is no agreement on the type and duration of antimicrobial therapy. Most experts recommend a combination oral therapy with doxycycline (100 mg twice a day) plus ciprofloxacin (typically 750 mg twice a day) or rifampin (300 mg twice a day) or hydroxychloroquine (200 mg three times a day) for approximately 2 years or more for the treatment of endocarditis. A study reported in 1999 of 35 patients with Q fever endocarditis showed favorable outcomes with oral doxycycline (100 mg twice a day) plus oral hydroxychloroquine (200 mg three times a day) for 18 months for native valves and 24 months for prosthetic valves. There are rare reports of doxycycline resistance.

Serologic responses can be monitored during and after completion of therapy and treatment extended in the absence of favorable serologic response (considered a titer of 1:1600 or greater to phase I antigen). The general variability of serologic data, however, limits their usefulness and providers usually rely on clinical criteria. Patients should be monitored for at least 5 years due to risk of relapse. Heart valve replacement may be necessary in refractory disease. **Given the difficulty in treating endocarditis, transthoracic echocardiography is recommended for all patients with acute Q fever, and the same aforementioned therapy for 1 year should be offered in**

the presence of valvulopathy. In addition, patients undergoing routine valve surgery should have routine Q fever serologies in endemic countries and appropriate treatment if tests are positive for Q fever.

Because of the obstetric complications (which appear to have strain specificity) that occur among pregnant women in whom Q fever develops, a regimen of long-term trimethoprim-sulfamethoxazole (320/1600 mg orally for the duration of pregnancy) should be given to all infected pregnant women. However, a randomized controlled study of pregnant women in Holland did not show that serologic surveillance and treatment of seropositive women were effective in preventing obstetric complications. Other data from Denmark among pregnant women exposed in the past to *Coxiella* also suggest the risk of obstetric complications may not be high. The official recommendations nonetheless remain as stated.

▶ Prevention

Prevention is based on detection of the infection in livestock, including camels in the Middle East; reduction of contact with infected and, in particular, parturient animals or contaminated dust; special care when working with animal tissues; and effective pasteurization of milk. No vaccine is approved for use in the United States, although a whole-cell Q fever vaccine, with a 5-year efficacy of greater than 95%, is available in Australia for persons with high-risk exposures where some seroprevalence studies show 7% seropositivity.

C burnetii is a category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis with doxycycline (100 mg orally twice daily) for 5 days should be started 8–12 days after exposure.

Pregnant women should take trimethoprim-sulfamethoxazole (160 mg/800 mg orally twice daily) for the duration of the pregnancy.

KAWASAKI DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- ▶ Elevated erythrocyte sedimentation rate and C-reactive protein levels.

▶ General Considerations

Kawasaki disease is a worldwide multisystemic disease. It is also known as the “mucocutaneous lymph node syndrome.” It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs significantly more often in Asians or native Pacific Islanders than in whites. Its incidence appears to be increasing in Japan, where it was first described in 1967. Children with a history of allergic diseases are at increased risk for Kawasaki disease. It is an acute, self-limiting, mucocutaneous vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the tunica media and aneurysm formation. Several infectious agents (New Haven coronavirus, parvovirus, bocavirus, CMV, *Yersinia pseudotuberculosis*, meningococcus), bacterial superantigens, and genetic polymorphisms (confirmed in whole genome analysis) in components of the immune system (interleukin 10 and 18) are implicated in its pathogenesis. A “new” RNA virus was considered a trigger of the disease, based on the finding of intracytoplasmic inclusion bodies in ciliated bronchial epithelium of Kawasaki patients. Epidemiologic studies from Seattle show an increased risk with advanced maternal age, mother of foreign birth, maternal group B streptococcus colonization, and early infancy hospitalization. Whole genomic analysis, mostly from China, is identifying target gene products.

▶ Clinical Findings

A clinical diagnosis of “complete” Kawasaki disease requires, in the absence of other processes, explaining the current illness of fever and four of the following criteria for at least 5 days: bilateral nonexudative conjunctivitis, mucous membrane changes of at least one type (injected pharynx, erythema, swelling and fissuring of the lips, strawberry tongue), peripheral extremity changes of at least one type (edema, desquamation, erythema of the palms and soles, induration of the hands and feet, Beau

lines [transverse grooves of the nails]), a polymorphous rash, and cervical lymphadenopathy greater than 1.5 cm (most worrisome when retropharyngeal with edema is present). An “incomplete” form is diagnosed when only two criteria are met and accompanied by other laboratory or imaging findings. The classic syndrome is often preceded by nonspecific symptoms including irritability, vomiting, anorexia, cough, and diarrhea for up to 10 days. A Kawasaki shock syndrome is a presentation and a complication often misdiagnosed that occurs more often among children with neutrophilia, high C-reactive protein levels, and thrombocytopenia.

Major complications include arteritis and aneurysms of the coronary vessels, occurring in about 25% of untreated patients (and slightly over 10% of treated patients in a Danish review), on occasion causing myocardial infarction. The “incomplete” form appears more frequently to result in cardiac complications. The pathogenesis of infarction is often thrombus formation, vasospasm, stenosis, or aneurysm rupture. Coronary complications are more common among patients older than 6 years or younger than 1 year of age. Noninvasive diagnosis of coronary complications can be made with CT coronary angiography (the most sensitive test), magnetic resonance angiography or trans-thoracic echocardiography (advocated for early screening). Other factors associated with the development of coronary artery aneurysms are male sex, relentless fever (even after the administration of IVIG), high C-reactive protein, urticarial exanthems, anemia, hypoalbuminemia, hyponatremia, and thrombocytopenia or thrombocytosis. Pericardial effusions, myocarditis, and mitral regurgitation (usually mild) are also common. Coronary artery fistulas occur in up to 5% of patients and diastolic dysfunction is also reported. Systemic arteritis and aneurysms (often symmetric and in younger children), peripheral gangrene, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), a parapharyngeal abscess, and the hemophagocytic syndrome are also reported. Cases of pancreatitis and bile duct stenosis due to underlying vasculitis are reported. Cerebrospinal fluid pleocytosis is found in one-third of cases, and encephalitis is rarely reported. Other CNS complications include seizures, oculomotor palsies, and sensorineural hearing loss which, when sought, can be found in as many as 55% of cases. Rare case reports of atypical presentations (eg, retropharyngeal abscess) are described.

Differentiation from disseminated adenovirus infection is important and can be performed with rapid adenovirus assays.

▶ Treatment & Prevention

Every patient with a clinical diagnosis of Kawasaki disease (complete or incomplete) should be treated. IVIG (2 g/kg over 10–12 hours) is given within the first 10 days of illness. Patients in whom persistent fever, ongoing systemic inflammation, or aneurysm formation presents later should be offered IVIG as well. Concomitant aspirin should be started at 80–100 mg/kg/day orally (divided into four doses and not exceeding 4 g/day) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/day

until markers of acute inflammation normalize. Aspirin therapy is continued if coronary aneurysm develops. If fevers persist beyond 36 hours after the initial IVIG infusion, a second dose of IVIG at 2 g/kg should be given if no other source of fever is found. Rare cases of aseptic meningitis are reported with IVIG, and this complication may be hard to distinguish from the occasional CNS disease associated with Kawasaki syndrome itself although the time course and the cerebrospinal fluid differential (more polymorphonuclear with IVIG, more lymphocytic with Kawasaki syndrome) may help differentiate the two. Hemolytic anemia is another rare complication of IVIG. Methylprednisolone (30 mg/kg/day intravenously if possible for a maximum of 3 days) followed by tapering dose of corticosteroids in addition to IVIG administration improve coronary artery outcomes in severe Kawasaki disease. Routine childhood vaccinations should be given and live vaccines (eg, MMR) should be delayed for at least 9 months only if IVIG was administered (IVIG can block the immune response to live vaccines). If vaccine-preventable disease endemicity requires urgent vaccination, it is prudent to revaccinate 11 months after the IVIG and first vaccination were given.

Further options for refractory cases include TNF blockers (infliximab or etanercept), cyclophosphamide or cyclosporine, methotrexate, and plasmapheresis, but not further pulse corticosteroid or IVIG. Abciximab therapy may be associated with coronary vessel remodeling in large coronary artery aneurysms. An echocardiogram is essential in the acute phase of illness and 6–8 weeks after onset. Anticoagulation with warfarin or low-molecular-weight heparin (the latter is preferable for children where dosage adjustments are difficult using warfarin) is indicated along with aspirin, 81 mg orally daily, in patients with aneurysms greater than 8 mm in diameter. If myocardial infarction occurs, therapy with thrombolytics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestations of coronary artery aneurysms can occur as late as in the third or fourth decade of life with a study showing a prevalence of 5% coronary sequelae from Kawasaki disease among young adults evaluated with angiography. Data are equivocal on the development of accelerated atherosclerosis among those with a history of Kawasaki disease.

While secondary prevention of complications entails the modalities described above, primary prevention is difficult in the absence of a clear explanation for the disease.

▶ Prognosis

Cases that develop recurrent disease tend to more often show cardiac complications. Patients with a parental history of Kawasaki disease show more recurrent disease and more cardiac complications. Pregnant women with a history of Kawasaki disease have an increased risk of complications during pregnancy and of Kawasaki disease in their children. The long-term prognosis for adults with a history of Kawasaki disease but without coronary artery aneurysms is excellent. A heart-healthy lifestyle, however, is essential. The prognosis of patients with a history of cardiac complications requires regular follow-up (using

transthoracic echocardiography) with risk stratification based on published guidelines and under cardiologic supervision. The coronary artery severity in patients 1 month after the onset of disease is a correlate of late coronary outcomes. Children with Kawasaki disease show an increased prevalence of multiple other viral infections including adenoviruses, enteroviruses, rhinoviruses, and coronaviruses.

▶ **When to Refer**

All cases of Kawasaki disease merit referral to specialists.

Bacterial & Chlamydial Infections

Brian S. Schwartz, MD

33

INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

1. Pharyngitis

ESSENTIALS OF DIAGNOSIS

- ▶ Abrupt onset of sore throat, fever, malaise, nausea, and headache.
- ▶ Throat red and edematous, with or without exudate; cervical nodes tender.
- ▶ Diagnosis confirmed by culture of throat.

General Considerations

Group A beta-hemolytic streptococci (*Streptococcus pyogenes*) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

Clinical Findings

A. Symptoms and Signs

“Strep throat” is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The Centor clinical criteria for the diagnosis of streptococcal pharyngitis are temperature greater than 38°C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of scarlet fever is diffusely erythematous, resembling a sunburn, with superimposed fine red papules, and is most intense in the groin and axillas. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

B. Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and suppuration of cervical lymph nodes.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection.

Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by viruses such as adenoviruses, Epstein-Barr virus, primary HIV, or other bacteria such as *Fusobacterium necrophorum* and *Arcanobacterium haemolyticum* (which also may cause a rash). Pharyngitis and lymphadenopathy are common findings in primary HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; oropharyngeal candidiasis shows white patches of exudate and less erythema; and necrotizing

ulcerative gingivostomatitis (Vincent fusospirochetal gingivitis or stomatitis) presents with shallow ulcers in the mouth. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx. *F necrophorum* causes pharyngitis at a similar rate as group A beta-hemolytic streptococci in adolescents and young adults. *F necrophorum* pharyngitis is associated with the Lemierre syndrome, suppurative thrombophlebitis of the internal jugular vein, bacteremia, and metastatic infections. Early recognition and treatment of this syndrome is important.

▶ Treatment

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% in typical clinical settings. The positive predictive value of clinical criteria is low. Since macrolides are not reliable against *F necrophorum* infection, adolescents or young adults with pharyngitis, which is not confirmed to be due to group A beta-hemolytic streptococci, should be given penicillin or amoxicillin preferentially at the doses listed below. If the pharyngitis does not resolve quickly, symptoms worsen, or unilateral neck swelling develops, clinicians should consider suppurative complications such as peritonsillar abscess and the Lemierre syndrome.

A. Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

B. Penicillin VK

Penicillin VK, 250 mg orally four times daily or 500 mg orally twice daily for 10 days, is effective.

C. Amoxicillin

Amoxicillin, 1000 mg orally once daily or 500 mg orally twice daily for 10 days is another option.

D. Cephalosporins

Cephalexin, 500 mg orally twice daily for 10 days, cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, should be reserved for penicillin-allergic patients who do not have immediate-type hypersensitivity to penicillin.

E. Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg orally once daily for 5 days, is an alternative

for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents. Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally twice daily is effective.

▶ Prevention of Recurrent Rheumatic Fever

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

▶ When to Refer

Patients with peritonsillar or retropharyngeal abscess should be referred to an otolaryngologist.

▶ When to Admit

- Odynophagia resulting in dehydration.
- Suspected or known epiglottitis.

Cirilli AR. Emergency evaluation and management of the sore throat. *Emerg Med Clin North Am.* 2013 May;31(2):501–15. [PMID: 23601485]

Shulman ST et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis: 2012 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2012 Nov 15;55(10):1279–82. [PMID: 23091044]

van Driel ML et al. Different antibiotic treatments for group A streptococcal pharyngitis. *Cochrane Database Syst Rev.* 2013 Apr 30;4:CD004406. [PMID: 23633318]

2. Streptococcal Skin Infections

Group A beta-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

▶ Clinical Findings

A. Symptoms and Signs

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a “stuck-on” appearance (see Chapter 6).

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococcal infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for *Staphylococcus aureus* (eg, injection drug use, diabetes mellitus, wound infection) should cover this organism. Nafcillin, 1–2 g every 4–6 hours intravenously, and cefazolin, 1 g intravenously or intramuscularly every 8 hours, are reasonable choices. In the patient at risk for methicillin-resistant *S aureus* infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1 g intravenously every 12 hours, or daptomycin 4 mg/kg intravenously daily, should be used (Table 33–1).

Patients who do not require parenteral therapy may be treated with amoxicillin, 875 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalexin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin. In patients with recurrent cellulitis of the leg, maintenance therapy (for at least 1 year) with penicillin, 250 mg orally twice daily, can reduce the likelihood of relapse.

Stevens DL et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2014 Jul 15;59(2):147–59. [PMID: 24947530]

Thomas KS et al; U.K. Dermatology Clinical Trials Network's PATCH I Trial Team. Penicillin to prevent recurrent leg cellulitis. *N Engl J Med*. 2013 May 2;368(18):1695–703. [PMID: 23635049]

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock-like syndrome also occurs.

Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary in many cases.

Pneumonia and empyema often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis**. Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks. Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

Table 33–1. Empiric treatment of common skin and soft tissue infections (SSTI).

SSTI Type	Common Pathogens	Treatment
Purulent (abscess, furuncle, carbuncle, cellulitis with purulence)	<i>Staphylococcus aureus</i>	Incision and drainage is the primary treatment Consider the addition of antibiotics in select situations ¹ Oral antibiotic regimens Cephalexin 500 mg four times daily or dicloxacillin 500 mg four times daily Clindamycin 300–450 mg three or four times daily ² or one double-strength tablet of trimethoprim-sulfamethoxazole twice daily ² or doxycycline 100 mg twice daily ² Intravenous antibiotic regimens³ Cefazolin 1 g three times daily or nafcillin 1–2 g four to six times daily Vancomycin 1 g twice daily ² or daptomycin 4 mg/kg once daily ²
Nonpurulent (cellulitis, erysipelas)	Beta-hemolytic streptococci (<i>S aureus</i> less likely)	Oral antibiotic regimens Cephalexin 500 mg four times daily or dicloxacillin 500 mg four times daily Clindamycin 300–450 mg three or four times daily ² or amoxicillin 875 mg twice daily plus one double-strength tablet of trimethoprim-sulfamethoxazole twice daily ² Intravenous antibiotic regimens³ Cefazolin 1 g three times daily or nafcillin 1–2 g four to six times daily Vancomycin 1 g twice daily ² or daptomycin 4 mg/kg once daily

¹Antibiotic therapy should be given in addition to incision and drainage for purulent SSTI if the patient has any of the following: severe or extensive disease, symptoms and signs of systemic illness, purulent cellulitis/wound infection, comorbidities and extremes of age, abscess in area difficult to drain or on face/hand, associated septic phlebitis, or lack of response to incision and drainage alone.

²Regimens with activity against methicillin-resistant *S aureus*.

³Other regimens approved by the FDA for treatment of complicated skin and soft tissue infections include tigecycline at 100 mg intravenously once followed by 50 mg intravenously twice a day, ceftaroline at 600 mg twice a day for 7–14 days, dalbavancin at 1 g intravenously on day 1 and then 500 mg intravenously on day 8, oritavancin as a single intravenous dose of 1200 mg, and telavancin at 10 mg/kg intravenously once daily for 7–14 days.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. The very young, the elderly, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrotoxin (which also causes **scarlet fever**), a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A beta-lactam, such as penicillin, remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin should be considered for streptococcal toxic shock syndrome for possible therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Many dosing regimens have been used, including 0.5 g/kg once daily for 5–6 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

Carapetis JR et al. Effectiveness of clindamycin and intravenous immunoglobulin, and risk of disease in contacts, in invasive group A streptococcal infections. *Clin Infect Dis*. 2014 Aug 1; 59(3):358–65. [PMID: 24785239]

Waddington CS et al. Management of invasive group A streptococcal infections. *J Infect*. 2014 Nov;69(Suppl 1):S63–9. [PMID: 25307276]

4. Non-Group A Streptococcal Infections

Non-group A hemolytic streptococci (eg, groups B, C, and G) produce a spectrum of disease similar to that of group A streptococci. The treatment of infections caused by these strains is the same as for group A streptococci.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. Antepartum screening to identify carriers and peripartum antimicrobial prophylaxis are recommended in pregnancy. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for group A streptococci. Because of in vitro synergism, some experts recommend the addition of low-dose gentamicin, 1 mg/kg every 8 hours.

Viridans streptococci, which are nonhemolytic or alpha-hemolytic (ie, producing a green zone of hemolysis on blood agar), are part of the normal oral flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis.

Group D streptococci include *Streptococcus gallolyticus (bovis)* and the enterococci. *S gallolyticus (bovis)* is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is treated like viridans streptococci.

ENTEROCOCCAL INFECTIONS

Two species, *Enterococcus faecalis* and *Enterococcus faecium*, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with ampicillin 2 g every 4 hours or penicillin 3–4 million units every 4 hours; if the patient is penicillin-allergic, vancomycin 15 mg/kg every 12 hours intravenously can be given. If the patient has endocarditis or meningitis, gentamicin 1 mg/kg every 8 hours intravenously should be added to the regimen in order to achieve the bactericidal activity that is required to cure these infections. In cases of endocarditis, ceftriaxone 2 g every 12 hours may be given instead of gentamicin in combination with the ampicillin.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium*; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. Daptomycin, tigecycline, tedizolid, and oritavancin

are not approved by the FDA for the treatment of vancomycin-resistant strains of enterococci, although they are frequently active in vitro.

Quinupristin/dalfopristin is not active against strains of *E faecalis* and should be used only for infections caused by *E faecium*. The dose is 7.5 mg/kg intravenously every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium*. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with both quinupristin/dalfopristin and linezolid.

PNEUMOCOCCAL INFECTIONS

1. Pneumococcal Pneumonia

ESSENTIALS OF DIAGNOSIS

- ▶ Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- ▶ Consolidating lobar pneumonia on chest radiograph.
- ▶ Gram-positive diplococci on Gram stain of sputum.

▶ General Considerations

The pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. The mortality rate remains high in the setting of advanced age, multilobar disease, severe hypoxemia, extrapulmonary complications, and bacteremia.

▶ Clinical Findings

A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasionally hemoptysis, and pleuritic chest

pain. Rigors occur within the first few hours of infection but are uncommon thereafter. Bronchial breath sounds are an early sign.

B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (less than 10 epithelial cells and greater than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for *Streptococcus pneumoniae*, with sensitivity of 70–80% and specificity greater than 95%, can assist with early diagnosis.

▶ Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

▶ Treatment

A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Chapter 9 for specific recommendations) pending isolation and identification of the causative agent. Once *S pneumoniae* is identified as the infecting pathogen, any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial PO₂ greater than 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days;

levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are not highly penicillin-resistant (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is 1 mcg/mL or less). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours, is effective. Alternatively, a respiratory fluoroquinolone (eg, levofloxacin, 750 mg) can be used. The total duration of therapy is not well defined but 5–7 days is appropriate for patients who have an uncomplicated infection and demonstrate a good clinical response.

B. Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis, a common sequela of bacterial pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure from endocarditis may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

C. Penicillin-Resistant Pneumococci

Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC 2 mcg/mL or less; intermediate, MIC = 4 mcg/mL; resistant, MIC 8 mcg/mL or more. This change reflected results from studies demonstrating equivalent cure rates when high doses of parenteral penicillin were used for treatment of pneumococcal

pneumonia due to isolates with penicillin MIC 2 mcg/mL or less. Note, however, that these new breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis. In cases of pneumococcal pneumonia where the isolate has a penicillin MIC greater than 2 mcg/mL, cephalosporin cross-resistance is common, and a non- β -lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of pneumococci may be resistant to macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use. All blood and cerebrospinal fluid isolates should still be tested for resistance to penicillin. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations.

▶ Prevention

See Chapter 30 for discussion of pneumococcal vaccines.

▶ When to Refer

- All patients with suspected pneumococcal endocarditis or meningitis to an infectious disease specialist.
- Extensive disease.
- Seriously ill patient with pneumonia, particularly in the setting of comorbid conditions (eg, liver disease).
- Progression of pneumonia or failure to improve on antibiotics.

▶ When to Admit

- All patients in whom pneumococcal endocarditis or meningitis is suspected or documented should be admitted for observation and empiric therapy.
- All patients with pneumococcal pneumonia that is multilobar or associated with significant hypoxemia.
- Failure of outpatient pneumonia therapy, including inability to maintain oral intake and medications.
- Exacerbations of underlying disease (eg, heart failure) by pneumonia that would benefit from hospitalization.

2. Pneumococcal Meningitis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, headache, altered mental status.
- ▶ Meningismus.
- ▶ Gram-positive diplococci on Gram stain of cerebrospinal fluid.

▶ General Considerations

S pneumoniae is the most common cause of meningitis in adults. Head trauma with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

▶ Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash, and focal neurologic deficits, cranial nerve palsies, and obtundation are more prominent features.

B. Laboratory Findings

The cerebrospinal fluid typically has greater than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL (2.22 mmol/L), or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL (1500 mg/L) (see Chapter 30). Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or cerebrospinal fluid cultures are almost always positive.

▶ Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC greater than 0.06 mcg/mL) are often cross-resistant to the third-generation

cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. If the MIC of ceftriaxone or cefotaxime is 0.5 mcg/mL or less, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is 1 mcg/mL or more, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/day intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes. It is recommended that dexamethasone, 10 mg intravenously, be given immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. Patients with pneumococcal meningitis and AIDS who do not have access to resources may not benefit from dexamethasone. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- ▶ Localized erythema with induration and purulent drainage.
- ▶ Abscess formation.
- ▶ Folliculitis commonly observed.
- ▶ Gram stain of pus with gram-positive cocci in clusters; cultures usually positive.

▶ General Considerations

Approximately one-quarter of people are asymptomatic nasal carriers of *S aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. *S aureus* tends to cause more localized skin infections than streptococci, and abscess formation is common. The prevalence of methicillin-resistant

▲ **Figure 33–1.** Methicillin-resistant *Staphylococcus aureus* (MRSA) abscess of the neck. (From Edward Wright, MD; Reproduced, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

strains in community settings is increasing, and these strains have been associated with recurrent and severe skin and soft tissue infections, including necrotizing fasciitis.

► Clinical Findings

A. Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Figure 33–1). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of *S aureus* skin and soft tissues infection, has been reported with community strains of methicillin-resistant *S aureus*.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

► Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone may be sufficient for cutaneous abscess. For uncomplicated skin infections, oral antimicrobial therapy is satisfactory. Before the emergence of community methicillin-resistant strains of *S aureus*, an oral penicillinase-resistant penicillin or cephalosporin, such as dicloxacillin or cephalexin, 500 mg four times a day for 7–10 days, was the drug of choice for

empiric therapy. However, increasing prevalence of methicillin-resistant strains of *S aureus* among community isolates may necessitate use of other oral agents to which the isolate is susceptible in vitro, such as clindamycin, 300 mg three times daily; doxycycline or minocycline, 100 mg twice daily; or trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/day of the trimethoprim component. Because of the high prevalence of macrolide resistance among *S aureus* strains, these agents should not be used unless susceptibility is documented (see Table 33–1).

For more complicated infections with extensive cutaneous or deep tissue involvement or fever, parenteral therapy is indicated initially. A penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously or cefazolin 1 g intravenously or intramuscularly is preferred for infections caused by methicillin-susceptible isolates. In patients with a serious allergy to beta-lactam antibiotics or if the strain is methicillin-resistant, vancomycin, 1 g intravenously every 12 hours, is a drug of choice. If the local prevalence of methicillin resistance is high (eg, 10% or more), and particularly if the patient is seriously ill, vancomycin is indicated empirically pending strain isolation and determination of susceptibility.

Linezolid is FDA-approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of *S aureus* and clinically is as effective as vancomycin. The dose is 600 mg orally (bioavailability of 100%) or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized. Tedizolid, (an oxazolidinone, like linezolid) is also approved for treating skin and soft tissue infection at a dose of 200 mg orally once daily for 6 days. Other drugs FDA approved for treating skin and soft tissue infections include daptomycin, 4 mg/kg intravenously once daily for 7–14 days; tigecycline (a glycylcycline class antimicrobial), 100 mg intravenously once followed by 50 mg intravenously twice a day for 5–14 days; ceftaroline (a novel cephalosporin with activity against methicillin-resistant *S aureus*), 600 mg twice a day for 7–14 days; dalbavancin (a lipoglycopeptide), 1 g intravenously on day 1 and then 500 mg intravenously on day 8; oritavancin (a lipoglycopeptide), a single intravenous dose of 1200 mg; and telavancin (a lipoglycopeptide), 10 mg/kg intravenously once daily for 7–14 days. Telavancin is also approved for the treatment of hospital-acquired *S aureus* pneumonia but has been associated with nephrotoxicity.

2. Osteomyelitis

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms or signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic extremity reflexes).

► Clinical Findings

A. Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness and constitutional symptoms (fever, malaise, anorexia, night sweats). Fever is absent in one-third or more of cases. Back pain is often the only symptom in vertebral osteomyelitis and may be associated with an epidural abscess and spinal cord compression. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

B. Laboratory Findings

The diagnosis is established by isolation of *S aureus* from the blood, bone, or a contiguous focus of a patient with symptoms and signs of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile.

C. Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60–70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

► Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. Intravenous therapy is preferred, particularly

during the acute phase of the infection for patients with systemic toxicity. Cefazolin, 2 g every 8 hours, or alternatively, nafcillin or oxacillin, 9–12 g/day in six divided doses, are the drugs of choice for infection with methicillin-sensitive isolates. Patients with infections due to methicillin-resistant strains of *S aureus* or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/day intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough level of 15–20 mcg/mL. In patients with *S aureus* isolates susceptible to a fluoroquinolone and rifampin, that combination has been shown to be effective if given for 4 weeks following 2 weeks of induction therapy with an intravenous agent as above. Consultation with an infectious diseases specialist is recommended. The role of newer agents, such as daptomycin or linezolid, remains to be defined.

Surgical treatment is often indicated under the following circumstances: (1) staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, (2) other abscesses (psoas, paraspinal), (3) extensive disease, or (4) recurrent infection following standard medical therapy. Follow-up imaging may not be needed in patients who demonstrate clinical response to disease with improvement in symptoms and normalization of inflammatory markers.

3. Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection. Whenever *S aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48–96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. Given the relatively high risk of infective endocarditis in patients with *S aureus* bacteremia, transesophageal echocardiography is recommended for most patients as a sensitive and cost-effective method for excluding underlying endocarditis. However, transthoracic echocardiography may be sufficient in select patients considered to be at low risk for endocarditis, namely those who meet all the following criteria: (1) no permanent intracardiac device, (2) sterile follow-up blood cultures within 4 days after the initial set, (3) no hemodialysis dependence, (4) nosocomial acquisition of *S aureus* bacteremia, and (5) no clinical signs of infective endocarditis or secondary foci of infection.

Empiric therapy of staphylococcal bacteremia should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours, or daptomycin 6 mg/kg/day intravenously until results of susceptibility tests are known. If the *S aureus* isolate is methicillin-susceptible, treatment should be narrowed to cefazolin, 2 g every 8 hours or nafcillin or oxacillin, 2 g intravenously every 4 hours. Cefazolin is as effective as nafcillin or oxacillin and has been associated with fewer adverse events during treatment. In patients with methicillin-resistant *S aureus*, treatment should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours. Maintaining a vancomycin trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Daptomycin 6 mg/kg/day is also an FDA-approved option as long as the patient does not require treatment for concomitant *S aureus* pneumonia. Duration of therapy for *S aureus* bacteremia is 4–6 weeks of antibiotic therapy but a subset of patients with uncomplicated infection may be able to be treated for 14 days. A patient with uncomplicated bacteremia must meet all the following criteria: (1) infective endocarditis has been excluded, (2) no implanted prostheses are present, (3) follow-up blood cultures drawn 2–4 days after the initial set are sterile, (4) the patient defervesces within 72 hours of initiation of effective antibiotic therapy, and (5) no evidence of metastatic infection is present on examination. When present, infected central venous catheters should also be removed. Vancomycin treatment failures are relatively common, particularly for complicated bacteremia and among infections involving foreign bodies. Consultation with an infectious diseases specialist should be considered in all cases of *S aureus* bacteremia and particularly when vancomycin treatment fails.

▲ **Figure 33–2.** Morbilliform rash in toxic shock syndrome caused by *Staphylococcus aureus*. (Public Health Image Library, CDC.)

shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash (Figure 33–2) and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery. Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing *S aureus* strain can cause toxic shock syndrome and nonmenstrual cases of toxic shock syndrome are common. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection.

Important aspects of treatment include rapid rehydration, antistaphylococcal drugs, management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess.

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis, but rates may be increasing. Most human infections are caused by *Staphylococcus epidermidis*, *S haemolyticus*, *S hominis*, *S warnerii*, *S saprophyticus*, *S saccharolyticus*, and *S cohnii*. These common hospital-acquired pathogens are less virulent than *S aureus*, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is

4. Toxic Shock Syndrome

S aureus produces toxins that cause three important entities: “scalded skin syndrome” in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic

more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis. Immunosuppression and recent antimicrobial therapy are risk factors.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated. More sophisticated typing methods, eg, pulse-field gel electrophoresis of restriction enzyme digested chromosomal DNA, may be required to identify distinct strains.

Whenever possible, the intravascular device or foreign body suspected of being infected by coagulase-negative staphylococci should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to beta-lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice for suspected or confirmed infection caused by these organisms until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the infected device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, plus gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

CLOSTRIDIAL DISEASES

1. Clostridial Myonecrosis (Gas Gangrene)

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of pain and edema in an area of wound contamination.
- ▶ Prostration and systemic toxicity.
- ▶ Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- ▶ Gas in the tissue by palpation or radiograph.
- ▶ Gram-positive rods in culture or smear of exudate.

▶ General Considerations

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (*Clostridium perfringens*, *C ramosum*, *C bifermentans*, *C histolyticum*, *C novyi*, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

▶ Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not specific. The smear shows absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

▶ Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.

Treatment

Penicillin, 2 million units every 3 hours intravenously, is effective. Clindamycin may decrease the production of bacterial toxin, and some experts recommend the addition of clindamycin, 600–900 mg every 8 hours intravenously, to penicillin. Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Hyperbaric oxygen therapy has been used empirically but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

Yang Z et al. Interventions for treating gas gangrene. *Cochrane Database Syst Rev.* 2015 Dec 3;12:CD010577. [PMID: 26631369]

2. *Clostridium sordellii* Toxic Shock Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset after medical abortion.
- ▶ Abdominal pain.
- ▶ Absence of fever.
- ▶ Tachycardia, severe hypotension, capillary leak syndrome with edema.
- ▶ Profound leukocytosis, hemoconcentration.

General Considerations & Clinical Findings

C sordellii is a rare cause of endometritis and toxic shock syndrome following childbirth. Fatal cases of uterine infection following medically induced abortion with mifepristone have been reported. Onset of illness was within 4–5 days of ingestion of mifepristone and the clinical course fulminant. Infection appeared to be limited to the uterus, which showed necrosis, edema, hemorrhage, and acute inflammatory changes.

Treatment

Early recognition, aggressive resuscitation from shock, immediate surgical debridement with hysterectomy, and administration of an antimicrobial that is active against *C sordellii* are essential to survival. Based on in vitro susceptibility data, any of several agents should be active, including penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole. Whether a protein synthesis inhibitor to block further toxin production offers any advantage over a beta-lactam is unknown.

3. Tetanus

ESSENTIALS OF DIAGNOSIS

- ▶ History of wound and possible contamination.
- ▶ Jaw stiffness followed by spasms of jaw muscles (trismus).
- ▶ Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- ▶ Finally, painful convulsions precipitated by minimal stimuli.

General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *C tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. The vegetative bacteria produce tetanospasmin, a zinc metalloprotease that cleaves synaptobrevin, a protein essential for neurotransmitter release. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are the elderly, migrant workers, newborns, and injection drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by *C tetani*.

Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the larynx and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

► Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

► Prevention

Tetanus is preventable by active immunization (see Table 30–7). For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the doses, Tdap (tetanus toxoid, reduced-dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose. A single dose of Tdap is preferred to Td for wound prophylaxis if the patient has not been previously vaccinated with Tdap.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid is started concurrently. Table 33–2 provides a guide to prophylactic management.

► Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found more rapid resolution of spasms, fewer days of ventilatory support, and a shorter hospital stay in the intrathecal group. However, the exact immunoglobulin preparation that was used was not specified and the total dose was 4000 units.

Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary to control tetanic spasms. Penicillin, 20 million units intravenously daily in divided doses, is given to all patients—even those with mild illness—to eradicate toxin-producing organisms.

► Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

Yen C et al; Centers for Disease Control and Prevention (CDC). Missed opportunities for tetanus postexposure prophylaxis—California, January 2008–March 2014. *MMWR Morb Mortal Wkly Rep*. 2015 Mar 13;64(9):243–6. [PMID: 25763876]

4. Botulism

ESSENTIALS OF DIAGNOSIS

- ▶ History of recent ingestion of home-canned or smoked foods or of injection drug use and demonstration of toxin in serum or food.
- ▶ Sudden onset of diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- ▶ Pupils are fixed and dilated in most cases.

Table 33–2. Guide to tetanus prophylaxis in wound management.

History of Absorbed Tetanus Toxoid	Clean, Minor Wounds		All Other Wounds ¹	
	Tdap or Td ²	TIG ³	Tdap or Td ²	TIG ³
Unknown or < 3 doses	Yes	No	Yes	Yes
3 or more doses	No ⁴	No	No ⁵	No

¹Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

²Td indicates tetanus toxoid and diphtheria toxoid, adult form. Tdap indicates tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three doses, one of which is Tdap.

³Human tetanus immune globulin, 250 units intramuscularly.

⁴Yes if more than 10 years have elapsed since last dose.

⁵Yes if more than 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.

▶ General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *C botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is a zinc metalloprotease that cleaves a specific component of the synaptic vesicle membrane docking and fusion complex at the neuromuscular junction blocking release of the neurotransmitter acetylcholine. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have also been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in association with injection drug use) result from organisms present in the gut or wound that elaborate toxin *in vivo*.

▶ Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

B. Laboratory Findings

Toxin in patients' serum and in suspected foods can be demonstrated by mouse inoculation and identified with specific antiserum.

▶ Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

▶ Treatment

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help with procurement of equine serum heptavalent botulism antitoxin and for assistance in obtaining assays for toxin in

serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

ANTHRAX

ESSENTIALS OF DIAGNOSIS

- ▶ Appropriate epidemiologic setting, eg, exposure to animals or animal hides, or potential exposure from an act of bioterrorism.
- ▶ A painless cutaneous black eschar on exposed areas of the skin, with marked surrounding edema and vesicles.
- ▶ Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock; mediastinal widening and pleural effusions on chest radiograph.

▶ General Considerations

The death of a Florida photo editor from inhalational anthrax acquired from a letter deliberately contaminated with spores of *Bacillus anthracis* thrust this extremely rare infection into the public awareness. Between September 18 and November 21 of 2001, there were 13 cases of cutaneous anthrax and 11 cases of inhalational anthrax associated with exposure to anthrax spores in contaminated mail.

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. *B anthracis* is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious form of the organism. These are transmitted to humans from contact with contaminated animals, animal products, or animal hides, or from soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. Spores germinate into vegetative bacteria that multiply locally in cutaneous and

gastrointestinal anthrax but may also disseminate to cause systemic infection. Inhaled spores are ingested by pulmonary macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host.

► Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease as there is with inhalational anthrax. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary staphylococcal or streptococcal infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Illness occurs in two stages, beginning on average 10 days after exposure, but may have a latent onset 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur 2–5 days after ingestion of meat contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-ground and stool that may be blood-tinged or melenic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in early forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it),

blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish the diagnosis. Any suspected case of anthrax should be immediately reported to the CDC so that a complete investigation can be conducted.

C. Imaging

The chest radiograph is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, was present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

► Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidioidomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

► Treatment

Strains of *B anthracis* (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. *B anthracis* may express beta-lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is no longer recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of *B anthracis* used in bioterrorism, ciprofloxacin is considered the drug of choice (Table 33–3) for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin) are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line

Table 33–3. Antimicrobial agents for treatment of anthrax or for prophylaxis against anthrax.

First-line agents and recommended doses

Ciprofloxacin, 500 mg twice daily orally or 400 mg every 12 hours intravenously

Doxycycline, 100 mg every 12 hours orally or intravenously

Second-line agents and recommended doses

Amoxicillin, 500 mg three times daily orally

Penicillin G, 2–4 million units every 4 hours intravenously

Alternative agents with in vitro activity and suggested doses

Rifampin, 10 mg/kg/day orally or intravenously

Clindamycin, 450–600 mg every 8 hours orally or intravenously

Clarithromycin, 500 mg orally twice daily

Erythromycin, 500 mg every 6 hours intravenously

Vancomycin, 1 g every 12 hours intravenously

Imipenem, 500 mg every 6 hours intravenously

agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of infection, eg, fever, tachycardia and elevated white blood cell count. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days. Raxibacumab, a human monoclonal antibody directed against the protective antigen component of lethal toxin, is FDA approved for the treatment of inhalation anthrax when used in combination with recommended antibacterial treatments.

▶ Prevention

In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigational agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

The FDA has approved a vaccine for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B anthracis*. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel. Lastly, raxibacumab, a human

monoclonal antibody, is also approved for prevention of inhalation anthrax when other treatments are not available or appropriate.

▶ Prognosis

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. By contrast, the reported mortality rate for gastrointestinal and inhalational infections is up to 85%. Yet, the experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS

- ▶ Tenacious gray membrane at portal of entry in pharynx.
- ▶ Sore throat, nasal discharge, hoarseness, malaise, fever.
- ▶ Myocarditis, neuropathy.
- ▶ Culture confirms the diagnosis.

▶ General Considerations

Diphtheria is an acute infection caused by *Corynebacterium diphtheriae* that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy.

▶ Clinical Findings

A. Symptoms and Signs

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

B. Laboratory Findings

The diagnosis is made clinically but can be confirmed by culture of the organism.

Differential Diagnosis

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to *Arcanobacterium haemolyticum*, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

Prevention

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

Treatment

Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Ingestion of contaminated food product leads to primary infection.
- ▶ Undifferentiated fever in a pregnant woman in her third trimester.
- ▶ Altered mental status and fever in an elderly or immunocompromised patient.
- ▶ Obtain blood and cerebrospinal fluid cultures.
- ▶ Culture confirms the diagnosis.

General Considerations

Listeria monocytogenes is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by *L. monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, and delicatessen meats. In 2011, a multistate outbreak of *Listeria* infection was traced to contaminated cantaloupes, and in 2012, a multistate outbreak was traced to ricotta cheese. Both outbreaks were associated with significant morbidity and mortality in infected persons.

Clinical Findings

Five types of infection are recognized:

(1) **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus. This relatively benign disease for the mother may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at high risk for clinical neonatal listeriosis.

(2) **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

(3) **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

(4) **Meningitis** caused by *L. monocytogenes* affects infants under 2 months of age as well as older adults, ranking third after meningococcus and pneumococcus as common causes of bacterial meningitis. Cerebrospinal fluid shows a *neutrophilic* pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor (TNF) inhibitors such as infliximab.

(5) Finally, **focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

▶ Treatment

Ampicillin, 8–12 g/day intravenously in four to six divided doses (the higher dose for meningitis) is considered the treatment of choice. Gentamicin, 5 mg/kg/day intravenously once or in divided doses is synergistic with ampicillin against *Listeria* in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. In patients with penicillin allergies, trimethoprim-sulfamethoxazole has excellent intracellular and cerebrospinal fluid penetration and is considered an appropriate alternative. The dose is 10–20 mg/kg/day intravenously of the trimethoprim component. Mortality and morbidity rates still are high. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Preexisting organic heart lesion.
- ▶ Positive blood cultures.
- ▶ Evidence of vegetation on echocardiography.
- ▶ New or changing heart murmur.
- ▶ Evidence of systemic emboli.

▶ General Considerations

Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—*S aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illness and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Underlying valvular disease, less common than in the past, is present in about 50% of cases. Valvular disease alters blood flow and produces jet effects that disrupt the endothelial surface, providing a nidus for attachment and infection of microorganisms that enter the bloodstream. Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures. Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of *S aureus* endocarditis are attributable to health care-associated bacteremia.

Native valve endocarditis is usually caused by *S aureus*, viridans streptococci, enterococci, or HACEK organisms (an acronym for *Haemophilus aphrophilus* [now *Aggregatibacter aphrophilus*], *Actinobacillus actinomycetemcomitans* [now *Aggregatibacter actinomycetemcomitans*], *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species). Streptococcal species formerly accounted for the majority of native valve endocarditis cases, but the proportion of cases caused by *S aureus* has been increasing, and this organism is now the leading cause. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, *S aureus* accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

▶ Clinical Findings

A. Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (less than 38°C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by

▲ **Figure 33-3.** Splinter hemorrhages appearing as red lineal streaks under the nail plate and within the nail bed, in endocarditis, psoriasis, and trauma. (Reproduced, with permission, from Richard P. Usatine, MD.)

direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), sub-ungual (“splinter”) hemorrhages (Figure 33-3), Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet) (Figure 33-4), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients. Strokes and major systemic embolic events are present in about 25% of patients, and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.

B. Imaging

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic, but new conduction abnormalities suggest myocardial abscess formation. Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between

▲ **Figure 33-4.** Osler node causing pain within the pulp of the big toe and multiple painless flat Janeway lesions over the sole of the foot. (From David A. Kasper, DO, MBA; Reproduced, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. Transesophageal echocardiography is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

C. Diagnostic Studies

1. Blood cultures—Blood cultures establish the diagnosis. Three sets of blood cultures at least 1 hour apart before starting antibiotics are recommended to maximize the opportunity for a microbiologic diagnosis. Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to obtaining cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold further antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to organisms that require special media for growth (eg, *Legionella*,

Bartonella, *Abiotrophia* species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (*Tropheryma whippelii*, or pathogens of Q fever or psittacosis), or those that are slow-growing and may require prolonged incubation (eg, *Brucella*, anaerobes, HACEK organisms). *Bartonella quintana* has emerged as an important cause of culture-negative endocarditis.

2. Modified Duke criteria—Clinical criteria, referred to as the Modified Duke criteria, have been proposed for the diagnosis of endocarditis. Major criteria include: (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia; (2) evidence of endocardial involvement documented by echocardiography (eg, definite vegetation, myocardial abscess, or new partial dehiscence of a prosthetic valve); or (3) development of a new regurgitant murmur. Minor criteria include the presence of a predisposing condition; fever of 38°C or higher; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the patient's febrile illness has resolved within 4 days, endocarditis is unlikely.

► Complications

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right-sided versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S aureus* but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

► Prevention

In 2007, the American Heart Association made major revisions to their recommendation on antibiotic prophylaxis for infective endocarditis. The committee determined that

Table 33–4. Cardiac conditions with high risk of adverse outcomes from endocarditis for which prophylaxis with dental procedures is recommended.^{1,2}

Prosthetic cardiac valve
Previous infective endocarditis
Congenital heart disease (CHD) ³
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure ⁴
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device
Cardiac transplantation recipients in whom cardiac valvulopathy develops

²See Table 33–6 for prophylactic regimens.

³Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for other forms of CHD.

⁴Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after procedure.

only a few cases of infective endocarditis would be prevented by antibiotic prophylaxis for dental procedures even if the prophylactic therapy were 100% effective. Therefore, they limited their recommendations for prophylaxis to a small group of patients with predisposing congenital or valvular anomalies (Table 33–4) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal tissue (Table 33–5). Current antimicrobial recommendations are given in Table 33–6.

Table 33–5. Recommendations for administration of bacterial endocarditis prophylaxis for patients according to type of procedure.¹

Prophylaxis Recommended	Prophylaxis Not Recommended

Table 33–6. American Heart Association recommendations for endocarditis prophylaxis for dental procedures for patients with cardiac conditions.^{1–3}

Oral	Amoxicillin	2 g 1 hour before procedure
Penicillin allergy	Clindamycin	600 mg 1 hour before procedure
	or	
	Cephalexin	2 g 1 hour before procedure (contraindicated if there is history of a beta-lactam immediate hypersensitivity reaction)
	or	
	Azithromycin or clarithromycin	500 mg 1 hour before procedure
Parenteral	Ampicillin	2 g intramuscularly or intravenously 30 minutes before procedure
Penicillin allergy	Clindamycin	600 mg intravenously 1 hour before procedure
	or	
	Cefazolin	1 g intramuscularly or intravenously 30 minutes before procedure (contraindicated if there is history of a beta-lactam immediate hypersensitivity reaction)

¹Data from the American Heart Association. *Circulation*. 2007 Oct 9;116(15):1736–54.

²For patients undergoing respiratory tract procedures involving incision of respiratory tract mucosa to treat an established infection or a procedure on infected skin, skin structure, or musculoskeletal tissue known or suspected to be caused by *S aureus*, the regimen should contain an anti-staphylococcal penicillin or cephalosporin. Vancomycin can be used to treat patients unable to tolerate a beta-lactam or if the infection is known or suspected to be caused by a methicillin-resistant strain of *S aureus*.

³See Table 33–4 for list of cardiac conditions.

▶ Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis. Consultation with an infectious disease expert is strongly recommended when initiating treatment for infective endocarditis.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC 0.1 mcg/mL or less), penicillin G, 18 million units intravenously either continuously or in four to six equally divided doses or ceftriaxone 2 g intravenously once daily for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 3 mg/kg intravenously every 24 hours, is used with penicillin or ceftriaxone. The 2-week regimen is reasonable and can be considered in patients with uncomplicated endocarditis, rapid response to therapy, and no underlying kidney disease. For the patient unable to tolerate penicillin or ceftriaxone, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given with a desired trough level of 10–15 mcg/mL. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone and the clinician can consider adding 2 weeks of gentamicin at the start of therapy.

Viridans streptococci relatively resistant to penicillin (ie, MIC greater than 0.12 mcg/mL but less than or equal to 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 24 million units intravenously either continuously or in

four to six equally divided doses, is combined with gentamicin, 3 mg/kg intravenously every 24 hours for the first 2 weeks. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg intravenously every 12 hours for 4 weeks, should be administered. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone plus gentamicin as above.

Endocarditis caused by viridans streptococci with an MIC greater than 0.5 mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis.

B. Other Streptococci

Endocarditis caused by *S pneumoniae*, *S pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. *S pneumoniae* sensitive to penicillin (MIC less than 0.1 mcg/mL) can be treated with penicillin 18 million units intravenously either continuously or in four to six equally divided doses or cefazolin 6 g intravenously either continuously or in three equally divided doses, or ceftriaxone 2 g daily intravenously for 4 weeks. High-dose penicillin (24 million units) or a third-generation cephalosporin may be required for the treatment of endocarditis (without meningitis) caused by strains resistant to penicillin (MIC greater than 0.1 mcg/mL). The addition of vancomycin and rifampin to ceftriaxone may be considered in patients with *S pneumoniae* strains with cefotaxime MIC greater than 2 mcg/mL. Group A streptococcal infection can be treated with penicillin or ceftriaxone for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 3 mg/kg intravenously every

24 hours, to penicillin for the first 2 weeks of a 4- to 6-week course. Endocarditis caused by *S gallolyticus* (*bovis*) is associated with liver disease, especially cirrhosis, and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

C. Enterococci

For enterococcal endocarditis, penicillin or ampicillin alone is inadequate. The combination of penicillin or ampicillin with gentamicin had been the treatment of choice but in vitro studies have identified synergy between ampicillin and ceftriaxone, presumably caused by saturation of different penicillin-binding proteins. Subsequently, several clinical studies of the combination of ampicillin plus ceftriaxone have demonstrated clinical outcomes equivalent to the combination of ampicillin plus gentamicin. Therefore, recommended regimens are now ampicillin, 2 g intravenously every 4 hours, or penicillin G, 18–30 million units intravenously continuously in six equally divided doses plus gentamicin, 1 mg/kg intravenously every 8 hours. Another acceptable option is ampicillin (2 g intravenously every 4 hours) plus ceftriaxone 2 g intravenously every 12 hours. The recommended duration of therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis). The combination of ampicillin plus ceftriaxone is recommended for patients with creatinine clearance less than 50 mL/min or whose enterococcal isolates are resistant to gentamicin. In patients intolerant of penicillin and ampicillin or who have enterococcal isolate resistant to these agents, vancomycin plus gentamicin can be used.

Endocarditis caused by strains resistant to penicillin and vancomycin are particularly difficult to treat. Such cases must always be managed in consultation with an infectious diseases specialist.

D. Staphylococci

For methicillin-susceptible *S aureus* isolates, nafcillin or oxacillin, 12 g intravenously daily given continuously or in four to six divided doses or cefazolin, 6 g intravenously daily given continuously or in three divided doses for 6 weeks, is the preferred therapy. For patients with history of immediate type hypersensitivity to beta-lactams, a desensitization protocol should be undertaken. For patients with a history of nonanaphylactoid reactions to penicillins, cefazolin should be used. Patients who are infected with methicillin-resistant *S aureus* or who are unable to tolerate beta-lactam therapy should receive vancomycin, 30 mg/kg/day intravenously divided in two or three doses to achieve a goal trough level of 15–20 mcg/kg, or daptomycin intravenously at greater than or equal to 8 mg/kg/day. Aminoglycoside combination regimens are not recommended. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, beta-lactam antibiotics should not be used for this infection unless the isolate is demonstrated to

be susceptible. A combination of vancomycin, 30 mg/kg/day intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 3 mg/kg intravenously every 8 hours for the first 2 weeks is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin or daptomycin for methicillin-resistant strains), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

E. HACEK Organisms

HACEK organisms are slow-growing, fastidious gram-negative coccobacilli or bacilli (*H aphrophilus* [now *A aphrophilus*], *A actinomycetemcomitans*, *C hominis*, *E corrodens*, and *Kingella* species) that are normal oral flora and cause less than 5% of all cases of endocarditis. They may produce beta-lactamase, and thus the treatment of choice is ceftriaxone (or some other third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but fluoroquinolones have in vitro activity and should be considered.

F. Culture-Negative Endocarditis

Failure to culture microorganisms from patients with suspected infective endocarditis may be due to infection from organisms not recovered in routine microbiology testing or previous administration of antimicrobial agents before blood cultures were obtained. These cases must be managed with the assistance of an infectious disease specialist. Pathogens that are not able to be cultured by commonly used techniques include *Bartonella* species, *Chlamydia* species, *Brucella* species, and *Tropheryma whippelii*. Serologic testing should be performed in patients who have epidemiologic risk factors for these infections. Treatment should be directed at likely pathogens while awaiting serologic results; treatment of patients given prior antimicrobials before cultures were obtained must also consider likely pathogens.

G. Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with highly-resistant bacteria. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly

challenging is a large and fragile vegetation demonstrated by echocardiography in the absence of embolization. Most clinicians favor an operative approach, vegetectomy with valve repair if the patient is a good candidate. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

H. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage. The role of anticoagulant therapy during active prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. On the other hand, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. In patients with *S aureus* prosthetic valve endocarditis complicated by a central nervous system embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

▶ Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with *S aureus* or *Pseudomonas aeruginosa*, fever may persist for longer. Blood cultures should be obtained to document sterilization of the blood. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

▶ When to Refer

- Consider consulting an infectious diseases specialist in all cases of suspected infective endocarditis.
- Consult a cardiac surgeon in the situations mentioned in the Role of Surgery section above to prevent further embolic disease, heart failure, and other complications including death.

▶ When to Admit

Patients with infective endocarditis should be hospitalized for expedited evaluation and treatment.

[PMID: 17446442]

INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

BORDETELLA PERTUSSIS INFECTION (Whooping Cough)

ESSENTIALS OF DIAGNOSIS

- ▶ Predominantly in infants under age 2 years. Adolescents and adults are an important reservoir of infection.
- ▶ Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- ▶ Paroxysmal cough ending in a high-pitched inspiratory “whoop.”
- ▶ Absolute lymphocytosis, often striking; culture confirms diagnosis.

▶ General Considerations

Pertussis is an acute infection of the respiratory tract caused by *B pertussis* that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

▶ Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis is often not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be

requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

▶ Prevention

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide. In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is recommended (see Table 30–7 and www.cdc.gov/vaccines/schedules). The FDA licensed two tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) products (BOOSTRIX, GlaxoSmithKline and ADACEL, Sanofi Pasteur) in 2005. Adolescents aged 11–18 years (preferably between 11 and 12 years of age) who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Adults of all ages (including those older than age 64 years) should receive a single dose of Tdap. In addition, pregnant women should receive a dose of Tdap during each pregnancy regardless of prior vaccination history. The optimal timing for such Tdap administration is between 27 and 36 weeks of gestation, in order to maximize the antibody response of the pregnant woman and the passive antibody transfer to the infant. For any woman who was not previously vaccinated with Tdap and for whom the vaccine was not given during her pregnancy, Tdap should be administered immediately postpartum. The CDC has eliminated the recommendation that a 2-year period window is needed between receiving the Td and Tdap vaccines based on data showing that there is not an increased risk of adverse events.

▶ Treatment

Antibiotic treatment should be initiated in all suspected cases. Treatment options include erythromycin, 500 mg four times a day orally for 7 days; azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160 mg–800 mg orally twice a day for 7 days, also is effective. Treatment shortens the duration of carriage and may diminish the severity of coughing paroxysms. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis that are exposed within 3 weeks of the onset of cough in the index case.

OTHER *BORDETELLA* INFECTIONS

Bordetella bronchiseptica is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

MENINGOCOCCAL MENINGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, headache, vomiting, confusion, delirium, convulsions.
- ▶ Petechial rash of skin and mucous membranes in many.
- ▶ Neck and back stiffness with positive Kernig and Brudzinski signs is characteristic.
- ▶ Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- ▶ Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

▶ General Considerations

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. The frequency of outbreaks of meningitis caused by group C meningococcus has increased, and this serotype is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies.

▶ Clinical Findings

A. Symptoms and Signs

High fever, chills, and headache; back, abdominal, and extremity pains; and nausea and vomiting are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some. On examination, nuchal and back rigidity are typical. Positive Kernig and Brudzinski signs (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck) are specific but not sensitive findings. A petechial rash appearing in the lower extremities and at pressure points is found in most

cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough if the patient survives.

B. Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains greater than 1000 cells/mcL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

► Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in the elderly, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

► Prevention

Four meningococcal vaccines are now available. There are two vaccines with coverage against meningococcal serogroups A, C, Y, and W-135 and two with coverage against meningococcal serogroup B. The two vaccines effective for meningococcal serogroups A, C, Y, and W-135 are the meningococcal polysaccharide vaccine (MPSV4) indicated for vaccination of persons over age 55 and the conjugate vaccine (MCV4) indicated for persons aged 2–55 years. The two vaccines against meningococcal serogroup B are MenB-FHbp and MenB-4C are approved for persons age 10–25 years and are not interchangeable.

The Advisory Committee on Immunization Practices recommends immunization with a dose of MCV4 for preadolescents ages 11–12 with a booster at age 16 (see www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html). For ease of program implementation, persons aged 21 years or younger should have documentation of receipt of a dose of MCV4 not more than 5 years before enrollment to college. If the primary dose was administered before the sixteenth birthday, a booster dose should be administered before enrollment. Vaccine is also recommended as a two-dose primary series administered 2 months apart for persons aged 2 through 54 years with persistent complement deficiency, persons with functional or anatomic asplenia, and for adolescents with HIV infection. All other persons at increased risk for

meningococcal disease (eg, military recruits, microbiologists, or travelers to an epidemic or highly endemic country) should receive a single dose. One of the meningococcal serogroup B vaccines may be administered to persons 10 years of age or older who are at increased risk for meningococcal disease. These persons include those with persistent complement component deficiencies; persons with anatomic or functional asplenia; microbiologists routinely exposed to isolates of *Neisseria meningitidis*; and persons identified to be at increased risk because of a serogroup B meningococcal disease outbreak. Vaccination of persons aged 16–23 years may provide short-term protection against most strains of serogroup B meningococcal disease; the MenB vaccine is preferred for persons aged 16–18 years.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. Cases of fluoroquinolone-resistant meningococcal infections have been identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

► Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses— as few as 4 days if ceftriaxone is used—are also effective.

► When to Admit

All patients with suspected meningococcal infection including meningitis and meningococcemia should be admitted for evaluation and empiric intravenous antibiotic therapy.

Simon MS et al. Invasive meningococcal disease in men who have sex with men. *Ann Intern Med*. 2013 Aug 20;159(4):300–1. [PMID: 23778867]

INFECTIONS CAUSED BY HAEMOPHILUS SPECIES

H influenzae and other *Haemophilus* species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors. *Haemophilus* species colonize the upper respiratory tract in patients with chronic obstructive pulmonary disease and frequently cause purulent bronchitis.

Beta-lactamase-producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10–14 days, is adequate. For beta-lactamase-producing strains, use of the oral fixed-drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, oral cefuroxime axetil, 250 mg twice daily; or a fluoroquinolone (ciprofloxacin, 500 mg orally twice daily; levofloxacin, 500–750 mg orally once daily; or moxifloxacin, 400 mg orally once daily) for 7 days is effective. Azithromycin, 500 mg orally once followed by 250 mg daily for 4 days, is preferred over clarithromycin when a macrolide is the preferred agent. Trimethoprim-sulfamethoxazole (160/800 mg orally twice daily) can be considered, but resistance rates have been reported to be up to 25%.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia), ceftriaxone, 1 g/day intravenously is recommended pending determination of whether the infecting strain is a beta-lactamase producer. A fluoroquinolone (see above for dosages) can be used for the penicillin-allergic patients for a 10- to 14-day course of therapy.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. An important clue to the diagnosis is complaint of a severe sore throat despite an unimpressive examination of the pharynx. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and

obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Ceftriaxone, 1 g intravenously every 24 hours for 7–10 days, is the drug of choice. Trimethoprim-sulfamethoxazole or a fluoroquinolone (see above for dosage) may be used in the patient with serious penicillin allergy.

Meningitis, rare in adults, is a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy for suspected *H influenzae* meningitis should be with ceftriaxone, 4 g/day in two divided doses, until the strain is proved not to produce beta-lactamase. Meningitis is treated for 10–14 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours may reduce the incidence of long-term sequelae, principally hearing loss.

Collins S et al. Risk of invasive *Haemophilus influenzae* infection during pregnancy and association with adverse fetal outcomes. *JAMA*. 2014 Mar 19;311(11):1125–32. [PMID: 24643602]

INFECTIONS CAUSED BY MORAXELLA CATARRHALIS

M catarrhalis is a gram-negative aerobic coccus morphologically and biochemically similar to *Neisseria*. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M catarrhalis* is the predominant isolate, therapy is directed against it. *M catarrhalis* typically produces beta-lactamase and therefore is usually resistant to ampicillin and amoxicillin. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

LEGIONNAIRES DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Patients are often immunocompromised, smokers, or have chronic lung disease.
- ▶ Scant sputum production, pleuritic chest pain, toxic appearance.
- ▶ Chest radiograph: focal patchy infiltrates or consolidation.
- ▶ Gram stain of sputum: polymorphonuclear leukocytes and no organisms.

General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaires disease is more common in immunocompromised persons, in smokers, and in those with

chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

► Clinical Findings

A. Symptoms and Signs

Legionnaires disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires disease are more like typical pneumonia, with high fevers, a toxic patient, pleurisy, and grossly purulent sputum. Classically, this pneumonia is caused by *Legionella pneumophila*, though other species can cause identical disease.

B. Laboratory Findings

Several laboratory abnormalities can be associated with Legionnaires disease, which include hyponatremia, elevated liver enzymes, and elevated creatine kinase. Culture of *Legionella* species onto charcoal-yeast extract agar or similar enriched medium is the most sensitive method (80–90% sensitivity) for diagnosis and permits identification of infections caused by species and serotypes other than *L pneumophila* serotype 1. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting *Legionella* species. Direct fluorescent antibody stains and serologic testing are less sensitive because these will detect only *L pneumophila* serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production. Urinary antigen tests, which are targeted for detection of *L pneumophila* serotype 1, are also less sensitive than culture.

► Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin, 750 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

Del Castillo M et al. Atypical presentation of *Legionella pneumonia* among patients with underlying cancer: a fifteen-year review. *J Infect.* 2016 Jan;72(1):45–51. [PMID: 26496794]
 Haubitz S et al. Ruling out *Legionella* in community-acquired pneumonia. *Am J Med.* 2014 Oct;127(10):1010.e11–9. [PMID: 24813862]

GRAM-NEGATIVE BACTEREMIA & SEPSIS

Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and pressure ulcers.

Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40–60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15–20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less.

► Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature 36.4°C or less) at presentation, and 5% never develop a temperature above 37.5°C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobials, therapy should be continued for 10–14 days.

► Treatment

Several factors are important in the management of patients with sepsis.

A. Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and, in certain circumstances, giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

B. Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (central venous catheter) or draining it (abscess), a fatal disease becomes easily treatable.

C. Supportive Measures

The use of fluids, vasopressors, and corticosteroids in septic shock are discussed in Chapter 14; management of disseminated intravascular coagulation is discussed in Chapter 13.

D. Antibiotics

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the central nervous system, antibiotics that penetrate the blood-brain barrier should be used—eg, third- or fourth-generation cephalosporin—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–4 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for “synergism,” combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

Zhang D et al. Time to appropriate antibiotic therapy is an independent determinant of postinfection ICU and hospital lengths of stay in patients with sepsis. *Crit Care Med.* 2015 Oct;43(10):2133–40. [PMID: 26121071]

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. The taxonomy of *Salmonella* species has been confusing. All *Salmonella* serotypes are members of a single species, *Salmonella enterica*. Human infections are caused almost exclusively by *S enterica* subspecies *enterica*, of which three serotypes—*typhi*, *typhimurium*, and *choleraesuis*—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype *typhi*; (2) acute enterocolitis, caused by serotype *typhimurium*, among others; and (3) the “septicemic” type, characterized by bacteremia and focal lesions, exemplified by infection with serotype *choleraesuis*. All types are transmitted by ingestion of the organism, usually from contaminated food or drink.

1. Enteric Fever (Typhoid Fever)

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
- ▶ Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- ▶ Slow (stepladder) rise of fever to maximum and then slow return to normal.
- ▶ Leukopenia; blood, stool, and urine culture positive for salmonella.

▶ General Considerations

Enteric fever is a clinical syndrome characterized by constitutional and gastrointestinal symptoms and by headache. It can be caused by any *Salmonella* species. The term “typhoid fever” applies when serotype *typhi* is the cause. Infection is transmitted by consumption of contaminated food or drink. The incubation period is 5–14 days. *Salmonella* is an intracellular pathogen. Infection begins when organisms breach the mucosal epithelium of the intestines by transcytosis, an organism-mediated transport process through the cell via an endocytic vesicle. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than *typhi* usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine (particularly within 60 cm of the ileocecal valve). Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or central nervous system.

▶ Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill, appearing exhausted and often prostrated. There may be marked constipation, especially early, or “pea soup” diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient’s condition will gradually improve over 7–10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

B. Laboratory Findings

Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever. Relative bradycardia and leukopenia are typical.

► Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential as well.

► Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

► Prevention

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

► Treatment

A. Specific Measures

Because of increasing antimicrobial resistance, fluoroquinolones—such as ciprofloxacin 750 mg orally twice daily or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—have become the agents of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence appears to be increasing. When an infection is caused

by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/day and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective. In years past, ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole had been effective treatments but resistance has spread globally.

B. Treatment of Carriers

Chemotherapy often is unsuccessful in eradicating the carrier state. Ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective. Cholecystectomy may also achieve this goal. When the isolate is susceptible, treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful.

► Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do poorly. With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of chemotherapy.

Wain J et al. Typhoid fever. *Lancet.* 2015 Mar 21;385(9973):1136–45. [PMID: 25458731]

2. *Salmonella* Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis caused by numerous *Salmonella* serotypes. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool.

The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

In most cases, treatment of uncomplicated enterocolitis is symptomatic only. However, patients who are malnourished or severely ill, patients with sickle cell disease, and patients who are immunocompromised (including those who are HIV-positive) should be treated with ciprofloxacin, 500 mg orally twice a day; ceftriaxone, 1 g intravenously once daily; trimethoprim-sulfamethoxazole, 160 mg/80 mg orally twice a day; or azithromycin, 500 mg orally once daily for 7–14 days (14 days for immunocompromised patients).

Williams S et al. *Salmonella* in the tropical household environment—everyday, everywhere. *J Infect.* 2015 Dec;71(6):642–8. [PMID: 26416474]

3. *Salmonella* Bacteremia

Salmonella infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than typhi usually are isolated. This complication tends to occur in immunocompromised persons and is seen in HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg orally twice a day, is effective both for therapy of acute infection and for suppression of recurrence. Incidence of infections caused by drug-resistant strains may be on the rise.

Gibani MM et al. Control of invasive salmonella disease in Africa: is there a role for human challenge models? *Clin Infect Dis.* 2015 Nov 1;61(Suppl 4):S266–71. [PMID: 26449941]

SHIGELLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Diarrhea, often with blood and mucus.
- ▶ Crampy abdominal pain and systemic toxicity.
- ▶ White blood cells in stools; organism isolated on stool culture.

▶ General Considerations

Shigella dysentery is a common disease, often self-limited and mild but occasionally serious. *S sonnei* is the leading cause in the United States, followed by *S flexneri*. *S dysenteriae* causes the most serious form of the illness. Shigellae are invasive organisms. The infective dose is 10^2 – 10^3 organisms. There has been a rise in strains resistant to multiple antibiotics.

▶ Clinical Findings

A. Symptoms and Signs

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool often is mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

B. Laboratory Findings

The stool shows many leukocytes and red cells. Stool culture is positive for shigellae in most cases, but blood cultures grow the organism in less than 5% of cases.

▶ Differential Diagnosis

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *Escherichia coli*, *Campylobacter*, and *Yersinia enterocolitica*. Amebic dysentery may be similar clinically and is diagnosed by finding amoebas in the fresh stool specimen. Ulcerative colitis is also an important cause of bloody diarrhea.

▶ Complications

Temporary disaccharidase deficiency may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by *Shigella*. Hemolytic-uremic syndrome occurs rarely.

▶ Treatment

Treatment of dehydration and hypotension is lifesaving in severe cases. Recommended empiric antimicrobial therapy is either a fluoroquinolone (ciprofloxacin, 750 mg orally twice daily for 7–10 days, or levofloxacin, 500 mg orally once daily for 3 days) or ceftriaxone, 1 g intravenously once daily for 5 days. If the isolate is susceptible, trimethoprim-sulfamethoxazole, 160/80 mg orally twice daily for 5 days or azithromycin, 500 mg orally once daily for 3 days, is also effective. High rates of resistance to amoxicillin make it a less effective treatment option.

GASTROENTERITIS CAUSED BY *ESCHERICHIA COLI*

E coli causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler's diarrhea. Enteroinvasive *E coli* (EIEC) differs from other *E coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with *Shigella* species. EIEC is uncommon in the United States. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy against *Salmonella* and *Shigella*, such as ciprofloxacin 500 mg orally twice daily, shortens the clinical course, but the disease is self-limited.

Shiga-toxin-producing *E coli* (STEC) infection can result in asymptomatic carrier stage, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, or thrombotic thrombocytopenic purpura. Although *E coli* O157:H7 is responsible for most cases of STEC infection in the United States, recently in Europe, other STEC strains (such as *E coli* O104:H4) have been reported to cause severe disease. *E coli* O157:H7 has caused several outbreaks

of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger, unpasteurized apple juice, and spinach, while *E coli* O145 was recently linked to the consumption of contaminated lettuce. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. STEC identification can be difficult and the CDC recommends that all stools submitted for routine testing from patients with acute community-acquired diarrhea be simultaneously cultured for *E coli* O157:H7 and tested with an assay that detects Shiga toxins to detect non-O157 STEC, such as *E coli* O145. Antimicrobial therapy does not alter the course of the disease and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for STEC. Confirmed infections should be reported to public health officials.

CHOLERA

ESSENTIALS OF DIAGNOSIS

- ▶ History of travel in endemic area or contact with infected person.
- ▶ Voluminous diarrhea.
- ▶ Stool is liquid, gray, turbid, and without fecal odor, blood, or pus (“rice water stool”).
- ▶ Rapid development of marked dehydration.
- ▶ Positive stool cultures and agglutination of vibrios with specific sera.

▶ General Considerations

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/day. Death results from profound hypovolemia. Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by

ingestion of contaminated food or water. For over a century, cholera was rarely seen in the Western Hemisphere until an outbreak occurred in Peru, starting in the early 1990s and ending by 2001; the outbreak resulted in almost 400,000 cholera cases and more than 4000 deaths. Cholera again became a rare disease in the Western Hemisphere until late 2010. A massive earthquake in Haiti in January 2010 crumbled the country’s already fragile infrastructure. Later that fall, a cholera outbreak erupted that has continued and resulted in thousands of deaths.

▶ Clinical Findings

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray; turbid; and without fecal odor, blood, or pus (“rice water stool”). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

▶ Prevention

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1–4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

▶ Treatment

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of table salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobial therapy will shorten the course of illness. Several antimicrobials are active against *V cholerae*, including tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, fluoroquinolones, and azithromycin. Multiple drug-resistant strains are increasingly encountered, so susceptibility testing, if available, is advisable. A single 1 g oral dose of azithromycin is effective for severe cholera caused by strains with reduced susceptibility to fluoroquinolones, but resistance is emerging to this drug as well.

Luquero FJ et al. Use of *Vibrio cholerae* vaccine in an outbreak in Guinea. *N Engl J Med.* 2014 May 29;370(22):2111–20. [PMID: 24869721]

Schilling KA et al. Diarrheal illness among U.S. residents providing medical services in Haiti during the cholera epidemic, 2010 to 2011. *J Travel Med.* 2014 Jan;21(1):55–7. [PMID: 24383654]

INFECTIONS CAUSED BY OTHER *VIBRIO* SPECIES

Vibrios other than *V cholerae* that cause human disease are *Vibrio parahaemolyticus*, *V vulnificus*, and *V alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (greater than 20°C [82.4°F]) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases. *V parahaemolyticus* causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

V vulnificus and *V alginolyticus*—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia following ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.

Tetracycline at a dose of 500 mg orally four times a day for 7–10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V parahaemolyticus* and *V alginolyticus* produce beta-lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V vulnificus*.

Lee YC et al. Prognostic factor of mortality and its clinical implications in patients with necrotizing fasciitis caused by *Vibrio vulnificus*. *Eur J Clin Microbiol Infect Dis*. 2014 Jun; 33(6):1011–8. [PMID: 24419406]

Wong KC et al. Antibiotic use for *Vibrio* infections: important insights from surveillance data. *BMC Infect Dis*. 2015 Jun 11; 15:226. [PMID: 26062903]

INFECTIONS CAUSED BY *CAMPYLOBACTER* SPECIES

Campylobacter organisms are microaerophilic, motile, gram-negative rods. Two species infect humans: *Campylobacter jejuni*, an important cause of diarrheal disease, and *C fetus* subsp *fetus*, which typically causes systemic infection and not diarrhea. Dairy cattle and poultry are an

important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. *Campylobacter* gastroenteritis is associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. The differential diagnosis includes shigellosis, *Salmonella* gastroenteritis, and enteritis caused by *Y enterocolitica* or invasive *E coli*. The disease is self-limited, but its duration can be shortened with antimicrobial therapy. Either azithromycin, 1 g orally as a single dose, or ciprofloxacin, 500 mg orally twice daily for 3 days, is effective therapy. However, fluoroquinolone resistance among *C jejuni* isolates has been increasing, particularly in Southeast Asia, and susceptibility testing should be routinely performed.

C fetus causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C fetus* are often older, debilitated, or immunocompromised. Closely related species, collectively termed “campylobacter-like organisms,” cause bacteremia in HIV-infected individuals. Systemic infections respond to therapy with gentamicin, chloramphenicol, ceftriaxone, or ciprofloxacin. Ceftriaxone or chloramphenicol should be used to treat infections of the central nervous system because of their ability to penetrate the blood-brain barrier.

BRUCELLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of animal exposure, ingestion of unpasteurized milk or cheese.
- ▶ Insidious onset: easy fatigability, headache, arthralgia, anorexia, sweating, irritability.
- ▶ Intermittent and persistent fever.
- ▶ Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- ▶ Lymphocytosis, positive blood culture, positive serologic test.

▶ General Considerations

The infection is transmitted from animals to humans. *Bruceella abortus* (cattle), *B suis* (hogs), and *B melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placentae of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk or cheese. The

incubation period varies from a few days to several weeks. Brucellosis is a systemic infection that may become chronic. In the United States, brucellosis is very rare. Almost all US cases are imported from countries where brucellosis is endemic (eg, Mexico, Mediterranean Europe, Spain, South American countries).

▶ Clinical Findings

A. Symptoms and Signs

The onset may be acute, with fever, chills, and sweats, but more often is insidious with symptoms of weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Headache, abdominal or back pain with anorexia and constipation, and arthralgias are also common. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Fever, hepatosplenomegaly, and lymphadenopathy are the most common physical findings. Infection may present with or be complicated by specific organ involvement with signs of endocarditis, meningitis, epididymitis, orchitis, arthritis (especially sacroiliitis), spondylitis, or osteomyelitis.

B. Laboratory Findings

The organism can be recovered from cultures of blood, cerebrospinal fluid, urine, bone marrow, or other sites. Modern automated systems have shortened the time to detection of the organism in blood culture. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing.

▶ Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidioidomycosis.

▶ Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoenzephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

▶ Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/day orally for 6 weeks) plus rifampin (600 mg/day orally for 6 weeks) or streptomycin (1 g/day intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence

rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.

Rubach MP et al. Brucellosis in low-income and middle-income countries. *Curr Opin Infect Dis*. 2013 Oct;26(5):404–12. [PMID: 23963260]

TULAREMIA

ESSENTIALS OF DIAGNOSIS

- ▶ History of contact with rabbits, other rodents, and biting arthropods (eg, ticks in summer) in endemic area.
- ▶ Fever, headache, nausea, and prostration.
- ▶ Papule progressing to ulcer at site of inoculation.
- ▶ Enlarged regional lymph nodes.
- ▶ Serologic tests or culture of ulcer, lymph node aspirate, or blood confirm the diagnosis.

▶ General Considerations

Tularemia is a zoonotic infection of wild rodents and rabbits caused by *Francisella tularensis*. Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from a tick or insect bite. Hamsters and prairie dogs also may carry the organism. An investigation of an outbreak of pneumonic tularemia on Martha's Vineyard in Massachusetts implicated lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. *F tularensis* has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

▶ Clinical Findings

A. Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and soon ulcerates. Regional lymph nodes may become enlarged and tender and may suppurate. The local lesion may be on the skin of an extremity or in the eye. Pneumonia may develop from hematogenous spread of the organism or may be primary after inhalation of infected aerosols, which are responsible for human-to-human transmission. Following ingestion of infected meat or water, an enteric form may be manifested by gastrointestinal symptoms, stupor, and delirium. In any type of involvement, the spleen may be enlarged and tender and there may be non-specific rashes, myalgias, and prostration.

B. Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures of *F tularensis* may be hazardous to laboratory personnel, the diagnosis is usually made serologically. A positive agglutination test (greater than 1:80) develops in the second week after infection and may persist for several years.

▶ Differential Diagnosis

Tularemia must be differentiated from rickettsial and meningococcal infections, cat-scratch disease, infectious mononucleosis, and various bacterial and fungal diseases.

▶ Complications

Hematogenous spread may produce meningitis, perisplenic, pericarditis, pneumonia, and osteomyelitis.

▶ Treatment

Streptomycin is drug of choice for treatment of tularemia. The recommended dose is 7.5 mg/kg intramuscularly every 12 hours for 7–14 days. Gentamicin, which has good in vitro activity against *F tularensis*, is generally less toxic than streptomycin and probably just as effective. Doxycycline (200 mg/day orally) is also effective but has a higher relapse rate. A variety of other agents (eg, fluoroquinolones) are active in vitro but their clinical effectiveness is less well established.

Birdsell DN et al. *Francisella tularensis* subsp. *tularensis* group A.I, United States. *Emerg Infect Dis.* 2014 May;20(5):861–5. [PMID: 24755401]

PLAGUE

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to rodents in endemic area.
- ▶ Sudden onset of high fever, malaise, muscular pains, and prostration.
- ▶ Axillary or inguinal lymphadenitis (bubo).
- ▶ Bacteremia, pneumonitis, and meningitis may occur.
- ▶ Positive smear and culture from bubo and positive blood culture.

▶ General Considerations

Plague is an infection of wild rodents with *Yersinia pestis*, a small bipolar-staining gram-negative rod. It is endemic in California, Arizona, Nevada, and New Mexico. It is

transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. Following a flea bite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (buboes). They may then reach the bloodstream to involve all organs. When pneumonia or meningitis develops, the outcome is often fatal. The patient with pneumonia can transmit the infection to other individuals by droplets. The incubation period is 2–10 days. Because of its extreme virulence, its potential for dissemination and person-to-person transmission, and efforts to develop the organism as an agent of biowarfare, plague bacillus is considered a high-priority agent for bioterrorism.

▶ Clinical Findings

A. Symptoms and Signs

The onset is sudden, with high fever, malaise, tachycardia, intense headache, delirium, and severe myalgias. The patient appears profoundly ill. If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. There may be signs of meningitis. A pustule or ulcer at the site of inoculation and lymphangitis may be observed. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, the patient may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin.

Primary plague pneumonia is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram stain. Cultures from bubo aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

▶ Differential Diagnosis

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

▶ Prevention

Avoiding exposure to rodents and fleas in endemic areas is the best prevention strategy. Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Doxycycline, 100 mg twice daily for 7 days, is effective. No vaccine is available at this time.

Treatment

Therapy should be started immediately once plague is suspected. Either streptomycin (the agent with which there is greatest experience), 1 g every 12 hours intravenously, or gentamicin, administered as a 2-mg/kg loading dose, then 1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation, and prophylactic therapy is given to any person who came in contact with the patient.

GNOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Purulent and profuse urethral discharge, especially in men, with dysuria, yielding positive smear.
- ▶ Men: epididymitis, prostatitis, periurethral inflammation, proctitis.
- ▶ Women: cervicitis with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- ▶ Fever, rash, tenosynovitis, and arthritis with disseminated disease.
- ▶ Gram-negative intracellular diplococci seen in a smear or cultured from any site, particularly the urethra, cervix, pharynx, and rectum.

General Considerations

Gonorrhoea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2–8 days.

Classification

A. Urethritis and Cervicitis

In men, there is initially burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in men who have sex with men. Atypical sites of primary

infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and sterility. In pelvic inflammatory disease, anaerobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Gram stain of urethral discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Nucleic acid amplification tests are the preferred method for diagnosing all types of gonorrhoea given their excellent sensitivity and specificity. In women with suspected cervical infection, endocervical or vaginal swabs (clinician- or self-collected) as well as first catch AM urine specimen (later specimens have 10% reduced sensitivity) are options. In men with urethral infection, first catch AM urine is recommended. Nucleic acid amplification tests are also recommended by the CDC for oropharyngeal and rectal sites testing although they are not FDA approved for these specimen types. Cultures should still be obtained when evaluating a treatment failure to assess for antimicrobial resistance.

B. Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Two distinct clinical syndromes—either purulent arthritis or the triad of rash, tenosynovitis, and arthralgias—are commonly observed in patients with disseminated gonococcal infection, although overlap can be seen. The skin lesions can range from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. The tenosynovitis is often found in the hands and wrists and feet and ankles. These unique findings can help distinguish among other infectious syndromes. The arthritis can occur in one or more joints. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis. Rarely, gonococcal endocarditis or meningitis develops.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

Differential Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to *Chlamydia trachomatis*, *Gardnerella vaginalis*, *Trichomonas*, *Candida*, and many other pathogens associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such pathogens coexist in a patient. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Effective drugs taken in therapeutic doses within 24 hours of exposure can abort an infection. Partner notification and referral of contacts for treatment has been the standard method used to control sexually transmitted diseases. Expedited treatment of sex partners by patient-delivered partner therapy is more effective than partner notification in reducing persistence and recurrence rates of gonorrhea and chlamydia. This strategy is being increasingly adopted as a means of disease control.

Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the national prevalences of antibiotic-resistant organisms. Nationwide, strains of gonococci that are resistant to penicillin, tetracycline, or ciprofloxacin have been increasingly observed. Consequently, these drugs can no longer be considered first-line therapy. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient.

A. Uncomplicated Gonorrhea

Due to increasing resistance of *N gonorrhoeae* to cephalosporins, the CDC has updated its treatment recommendation for gonorrhea. Treatment for gonorrhea should include a higher dose of intramuscular ceftriaxone in combination with a second drug (azithromycin or doxycycline) regardless of concern for possible secondary infection with chlamydia. For uncomplicated gonococcal infections of the cervix, urethra, and rectum, the recommended treatment is ceftriaxone (250 mg intramuscularly) plus azithromycin (1000 mg orally as a single dose). In cases where an oral cephalosporin is the only option, cefixime, 400 mg orally as a single dose, can be combined with azithromycin as above. When azithromycin is not an option, doxycycline at 100 mg orally twice daily for 7 days can be substituted. Fluoroquinolones are no longer recommended for treatment due to high rates of microbial resistance. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient but is not currently available in the United States. Pharyngeal gonorrhea is also treated with ceftriaxone (250 mg intramuscularly) plus azithromycin (1000 mg orally as a single dose) but for

conjunctival gonorrhea the recommendation is for ceftriaxone (1 g intramuscularly) plus azithromycin (1000 mg orally as a single dose).

B. Treatment of Other Infections

Disseminated gonococcal infection (including arthritis and arthritis-dermatitis syndromes) should be treated with ceftriaxone (1 g intravenously daily) plus azithromycin (1000 mg orally as a single dose), until 48 hours after improvement begins, at which time therapy may be switched to cefixime (400 mg orally daily) to complete at least 1 week of antimicrobial therapy. Endocarditis should be treated with ceftriaxone (2 g every 24 hours intravenously) for at least 4 weeks.

Pelvic inflammatory disease requires cefoxitin (2 g parenterally every 6 hours) or cefotetan (2 g intravenously every 12 hours) plus doxycycline (100 mg every 12 hours). Clindamycin (900 mg intravenously every 8 hours) plus gentamicin (administered intravenously as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours) is also effective. Ceftriaxone (250 mg intramuscularly as a single dose) or cefoxitin (2 g intramuscularly) plus probenecid (1 g orally as a single dose) plus doxycycline (100 mg twice a day for 14 days), with or without metronidazole (500 mg twice daily for 14 days) is an effective outpatient regimen.

CHANCROID

Chancroid is a sexually transmitted disease caused by the short gram-negative bacillus *Haemophilus ducreyi*. The incubation period is 3-5 days. At the site of inoculation, a vesicopustule develops that breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. There may be multiple lesions due to autoinoculation. The adenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. These may become fluctuant and rupture spontaneously. With lymph node involvement, fever, chills, and malaise may develop. Balanitis and phimosis are frequent complications in men. Women may have no external signs of infection. The diagnosis is established by culturing a swab of the lesion onto a special medium.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and painless, with a hard base. Mixed sexually transmitted disease is very common (including syphilis, herpes simplex, and HIV infection), as is infection of the ulcer with fusiforms, spirochetes, and other organisms.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is effective treatment. Effective multiple-dose regimens are erythromycin,

500 mg orally four times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015 Jun 5;64(RR-03):1–137. Erratum in: MMWR Recomm Rep. 2015 Aug 28;64(33):924. [PMID: 26042815]

GRANULOMA INGUINALE

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found in tissue scrapings or secretions, is large (25–90 μm) and contains intracytoplasmic cysts filled with bodies (Donovan bodies) that stain deeply with Wright stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous membranes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base of granulation tissue. The lesion spreads by contiguity. The advancing border has a characteristic rolled edge of granulation tissue. Large ulcerations may advance onto the lower abdomen and thighs. Scar formation and healing occur along one border while the opposite border advances.

Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. The following recommended regimens should be given for 3 weeks or until all lesions have healed: doxycycline, 100 mg orally twice daily; or azithromycin, 1 g orally once weekly; or ciprofloxacin, 750 mg orally twice daily; or erythromycin, 500 mg orally four times a day.

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep. 2015 Jun 5;64(RR-03):1–137. Erratum in: MMWR Recomm Rep. 2015 Aug 28;64(33):924. [PMID: 26042815]

BARTONELLA SPECIES

Bartonella species are responsible for a wide variety of clinical syndromes. **Bacillary angiomatosis**, an important manifestation of bartonellosis, is discussed in Chapter 31. A variety of atypical infections, including retinitis, encephalitis, osteomyelitis, and persistent bacteremia and endocarditis have been described.

Trench fever is a self-limited, louse-borne relapsing febrile disease caused by *B quintana*. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3–5 days, with relapses. The patient

complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Recovery occurs regularly even in the absence of treatment.

Cat-scratch disease is an acute infection of children and young adults caused by *Bartonella henselae*. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, a papule or ulcer will develop at the inoculation site in one-third of patients. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis, peliosis hepatis, and retinitis—occur most commonly in immunocompromised patients such as persons with late stages of HIV or solid organ transplant recipients. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. Unexplained fever in patients with late stages of HIV infection is not uncommonly due to bartonellosis. *B quintana*, the agent of trench fever, can also cause bacillary angiomatosis and persistent bacteremia or endocarditis (which will be “culture-negative” unless specifically sought), the latter two entities being associated with homelessness. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or nucleic acid amplification tests are often required to establish a diagnosis.

The disseminated forms of the disease (bacillary angiomatosis, peliosis hepatis, and retinitis) require a prolonged course of antibiotic therapy often in combination with a second agent. Bacteremia and endocarditis can be effectively treated with a 6-week course of doxycycline (200 mg orally or intravenously in two divided doses per day) plus either gentamicin 3 mg/kg/day intravenously or rifampin 600 mg/day orally in two divided doses. Relapse may occur.

Zangwill KM. Cat scratch disease and other *Bartonella* infections. Adv Exp Med Biol. 2013;764:159–66. [PMID: 23654065]

ELIZABETHKINGIA SPECIES

Elizabethkingia species (previously known as *Flavobacterium* and *Chryseobacterium* species) are gram-negative rods that cause infection primarily in patients

with compromised immune systems or multiple other comorbidities. Outbreaks due to the subspecies *E meningoseptica* and *E anopheles* have been associated with contaminated water sources and have often occurred in health-care facilities. Meningitis and bacteremia as well as skin and bone infections have developed in patients infected with *Elizabethkingia*. Empiric treatment is piperacillin/tazobactam 4.5 g intravenously four times daily. However, *Elizabethkingia* species can be resistant to multiple antimicrobials. When an outbreak of *Elizabethkingia* species infections occurs in a health-care setting, the facility's infection control specialists must search for and eliminate the contaminated water source.

Moore LS et al. Waterborne *Elizabethkingia meningoseptica* in adult critical care. *Emerg Infect Dis*. 2016 Jan;22(1):9–17. [PMID: 26690562]

ANAEROBIC INFECTIONS

Anaerobic bacteria comprise the majority of normal human flora. Normal microbial flora of the mouth (anaerobic spirochetes, *Prevotella*, fusobacteria), the skin (anaerobic diphtheroids), the large bowel (bacteroides, anaerobic streptococci, clostridia), and the female genitourinary tract (bacteroides, anaerobic streptococci, fusobacteria) produce disease when displaced from their normal sites into tissues or closed body spaces.

Anaerobic infections tend to be polymicrobial and abscesses are common. Pus and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation may interfere with the delivery of antimicrobials to the site of anaerobic infection. Cultures, unless carefully collected under anaerobic conditions, may yield negative results.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.

1. Head & Neck Infections

Prevotella melaninogenica (formerly *Bacteroides melaninogenicus*) and anaerobic spirochetes are commonly involved in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, peritonsillar abscess, chronic otitis media, and mastoiditis. *F necrophorum* has been recognized as a common cause of pharyngitis in adolescents and young adults. *F necrophorum* infection has been associated with septic internal jugular thrombophlebitis (Lemierre syndrome) and causes septic pulmonary embolization. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Oral anaerobic organisms have been uniformly susceptible to penicillin, but there has been a recent trend of increasing penicillin resistance, usually due to beta-lactamase production. Therefore, ampicillin/sulbactam 1.5-3 g intravenously

every 6 hours (if parenteral therapy is required) or amoxicillin/clavulanic acid 875 mg/125 mg orally twice daily, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after symptoms and signs of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer.

Brook I. Anaerobic bacteria in upper respiratory tract and head and neck infections: microbiology and treatment. *Anaerobe*. 2012 Apr;18(2):214–20. [PMID: 22197951]

Brook I. Spectrum and treatment of anaerobic infections. *J Infect Chemother*. 2016 Jan;22(1):1–13. [PMID: 26620376]

2. Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10⁸ anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. Polymicrobial infection is the rule and anaerobes—particularly *P melaninogenica*, fusobacteria, and peptostreptococci—are common etiologic agents. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Penicillin-resistant *Bacteroides fragilis* and *P melaninogenica* are commonly isolated and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6–8 hours, is the treatment of choice for these infections. Metronidazole does not cover facultative streptococci, which often are present, and if used, a second agent that is active against streptococci, such as ceftriaxone 1 g intravenously or intramuscularly daily, should be added. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is an alternative; however, increasing prevalence of beta-lactamase producing organisms is a concern. Moxifloxacin, 400 mg orally or intravenously once daily, may be used. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) is generally recommended.

Bartlett JG. Anaerobic bacterial infection of the lung. *Anaerobe*. 2012 Apr;18(2):235–9. [PMID: 22209937]

Brook I. Spectrum and treatment of anaerobic infections. *J Infect Chemother*. 2016 Jan;22(1):1–13. [PMID: 26620376]

3. Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic central nervous system thrombophlebitis. The organisms reach the central nervous system by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, ceftriaxone, 2 g intravenously every 12 hours, plus metronidazole, 500 mg intravenously every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks but should be based on

follow-up imaging. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage.

Brook I. Spectrum and treatment of anaerobic infections. *J Infect Chemother.* 2016 Jan;22(1):1–13. [PMID: 26620376]

4. Intra-abdominal Infections

In the colon there are up to 10^{11} anaerobes per gram of content—predominantly *B fragilis*, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Agents that are active against *B fragilis* include metronidazole, chloramphenicol, moxifloxacin, tigecycline, ertapenem, imipenem, doripenem, ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam, and ceftolozane/tazobactam. Resistance to ceftoxitin, cefotetan, and clindamycin is increasingly encountered. Most third-generation cephalosporins have poor efficacy.

Table 33–7 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soilage, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

Table 33–7. Treatment of anaerobic intra-abdominal infections.

Community-onset
Oral therapy
Moxifloxacin 400 mg every 24 hours
Intravenous therapy
Moderate to moderately severe infections:
Ertapenem 1 g every 24 hours
or—
Ceftriaxone 1 g every 24 hours (or ciprofloxacin 400 mg every 12 hours, if penicillin allergic) plus metronidazole 500 mg every 8 hours
Severe infections:
Imipenem, 0.5 g every 6–8 hours or meropenem 1 g every 8 hours or doripenem 0.5 g every 8 hours or piperacillin/tazobactam 3.75 g every 6 hours
Health-care-associated
Intravenous therapy
Imipenem, 0.5 g every 6–8 hours or meropenem 1 g every 8 hours or doripenem 0.5 g every 8 hours or piperacillin/tazobactam 4.5 g every 6 hours
or—
Ceftazidime or cefepime 2 g every 8 hours plus metronidazole 0.5 g every 8 hours

Sawyer RG et al. Trial of short-course antimicrobial therapy for intraabdominal infection. *N Engl J Med.* 2015 May 21;372(21):1996–2005. [PMID: 25992746]

5. Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms and abscess drainage or early hysterectomy.

Mackeen A D et al. Antibiotic regimens for postpartum endometritis. *Cochrane Database Syst Rev.* 2015 Feb 2;2:CD001067. [PMID: 25922861]

6. Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, decubitus ulcers, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12–20 million units of penicillin G daily for 4–6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Propionibacteria, clostridia, and bacteroides occasionally cause endocarditis.

Brook I. Spectrum and treatment of anaerobic infections. *J Infect Chemother.* 2016 Jan;22(1):1–13. [PMID: 26620376]

7. Skin & Soft Tissue Infections

Anaerobic infections of the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in injection drug users and persons sustaining animal bites. There may be progressive tissue necrosis (Figure 33–5) and a putrid odor.

▲ **Figure 33-5.** Left foot gangrene, with plantar extension. (Used, with permission, from Dean SM, Satiani B, Abraham WT. *Color Atlas and Synopsis of Vascular Diseases*. McGraw-Hill, 2014.)

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and non-clostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure. Surgical consultation is obligatory to assist in diagnosis and treatment.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus piperacillin-tazobactam) should be instituted empirically and modified by culture results (see Table 30-5). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

ACTINOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of recent dental infection or abdominal trauma.
- ▶ Chronic pneumonia or indolent intra-abdominal or cervicofacial abscess.
- ▶ Sinus tract formation.

General Considerations

Actinomyces israelii and other species of *Actinomyces* occur in the normal flora of the mouth and tonsillar crypts. They are anaerobic, gram-positive, branching filamentous bacteria (1 μm in diameter) that may fragment into bacillary forms. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the gastrointestinal tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth. Interestingly, *T whipplei*, the causative agent of Whipple disease, is an actinomycete and therefore is related to the species that cause actinomycosis.

Clinical Findings

A. Symptoms and Signs

1. Cervicofacial actinomycosis—Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. “Sulfur granules”—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement. Cervicofacial or thoracic disease may occasionally involve the central nervous system, most commonly brain abscess or meningitis.

2. Thoracic actinomycosis—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion.

3. Abdominal actinomycosis—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the

exterior may develop. CT scanning reveals an inflammatory mass extended to involve bone.

B. Laboratory Findings

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections.

Treatment

Penicillin G is the drug of choice. Ten to 20 million units are given via a parenteral route for 4–6 weeks, followed by oral penicillin V, 500 mg four times daily. Alternatives include ampicillin, 12 g/day intravenously for 4–6 weeks followed by oral amoxicillin 500 mg three times daily or doxycycline 100 mg twice daily intravenously or orally. Response to therapy is slow. Therapy should be continued for weeks to months after clinical manifestations have disappeared in order to ensure cure. Surgical procedures such as drainage and resection may be beneficial.

With penicillin and surgery, the prognosis is good. The difficulties of diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

NOCARDIOSIS

Nocardia species are aerobic filamentous soil bacteria that can cause pulmonary and systemic nocardiosis. Common *Nocardia* species include members of the *Nocardia asteroides* complex and *Nocardia brasiliensis*. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

Clinical Findings

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. Even in the absence of clinical symptoms and signs of central nervous system infection, clinicians should consider brain imaging in patients with nocardiosis to rule out an occult abscess.

Nocardia species are usually found as delicate, branching, gram-positive filaments. They may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

Treatment

For isolated cutaneous infections, therapy is initiated with trimethoprim-sulfamethoxazole administered at a dosage of 5–10 mg/kg/day (based on trimethoprim) as an oral or intravenous formulation. Surgical procedures such as drainage and resection may be needed as adjunctive therapy. A higher dose of 15 mg/kg/day (based on trimethoprim) should be used for disseminated or pulmonary infections. Resistance to trimethoprim-sulfamethoxazole may be increasing and initiating treatment with two drugs while awaiting antibiotic susceptibilities in cases of disseminated or severe localized disease should be considered. Alternative agents or drugs that can be given in combination with trimethoprim-sulfamethoxazole include imipenem, 500 mg intravenously every 6 hours; amikacin, 7.5 mg/kg intravenously every 12 hours; or minocycline, 100–200 mg orally or intravenously twice daily. Consultation with an infectious diseases expert should be considered.

Response may be slow, and therapy should be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

INFECTIONS CAUSED BY MYCOBACTERIA

NONTUBERCULOUS MYCOBACTERIAL DISEASES

About 10% of mycobacterial infections are caused by nontuberculous mycobacteria. Nontuberculous mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often resistant to standard antituberculous drugs.

Egelund EF et al. Medications and monitoring in nontuberculous mycobacteria infections. *Clin Chest Med.* 2015 Mar; 36(1):55–66. [PMID: 25676519]

Henkle E et al. Nontuberculous mycobacteria infections in immunosuppressed hosts. *Clin Chest Med.* 2015 Mar; 36(1):91–9. [PMID: 25676522]

1. Pulmonary Infections

Mycobacterium avium complex (MAC) causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients, who typically have underlying pulmonary disease. Susceptibility testing for

macrolide-resistance should be performed on clinical isolates. Treatment of nodular or bronchiectatic pulmonary disease is clarithromycin (1000 mg orally three times per week) or azithromycin (500 mg orally three times per week) plus rifampin (600 mg orally three times per week) or rifabutin (300 mg orally three times per week) plus ethambutol (25 mg/kg orally three times per week). Patients with fibrocavitary lung disease or severe nodular or bronchiectatic disease should receive three-drug therapy with clarithromycin (500–1000 mg orally daily) or azithromycin (250 orally mg daily) plus rifampin (600 mg orally daily) or rifabutin (300 mg orally daily) plus ethambutol (15 mg/kg orally daily). Therapy is continued for at least 12 months after sterilization of cultures.

M kansasii can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most such infections occur in patients with preexisting lung disease, though 40% of patients have no known pulmonary disease. Microbiologically, *M kansasii* is similar to *M tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy with isoniazid, ethambutol, and rifampin for 2 years (or 1 year after sputum conversion) has been successful.

Less common causes of pulmonary disease include *M xenopi*, *M szulgai*, and *M goodii*. These organisms have variable sensitivities, and treatment is based on results of sensitivity tests. The rapid growing mycobacteria, *M abscessus*, *M chelonae*, and *M fortuitum* also can cause pneumonia in the occasional patient.

 van Ingen J. Microbiological diagnosis of nontuberculous mycobacterial pulmonary disease. *Clin Chest Med*. 2015 Mar; 36(1):43–54. [PMID: 25676518]

2. Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M tuberculosis* and can be a manifestation of disseminated disease. In children, the majority of cases are due to nontuberculous mycobacterial species, with MAC being the most common followed by *M scrofulaceum* in the United States and *M malmoense* and *M haemophilum* in Northern Europe. *M kansasii*, *M bovis*, *M chelonae*, and *M fortuitum* are less commonly observed. Unlike disease caused by *M tuberculosis*, which requires systemic therapy for 6 months, infection with nontuberculous mycobacteria

can be successfully treated by surgical excision without antituberculous therapy.

3. Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery.

M abscessus, *M chelonae*, and *M fortuitum* are frequent causes of these types of infections. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculosis drugs and may have susceptibility to clarithromycin, azithromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Given the multidrug-resistant nature of these organisms, obtaining antibiotic susceptibility testing is recommended. Therapy often includes surgical debridement along with at least two active antibiotics. Antibiotic therapy is usually continued for 3 months, although this must be determined based on clinical response.

M marinum infection (“swimming pool granuloma”) presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with clarithromycin, doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

M ulcerans infection (Buruli ulcer) is seen mainly in Africa and Australia and produces a large ulcerative lesion. Therapy consists of surgical excision and skin grafting.

4. Disseminated *Mycobacterium avium* Infection

MAC causes disseminated disease in immunocompromised patients, most commonly in patients in the late stages of HIV infection, when the CD4 cell count is less than 50/mcL. Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/day orally as a single dose, with or without rifabutin, 300 mg/day orally, is the treatment of choice. Azithromycin, 500 mg orally once daily, may be used instead of clarithromycin. Insufficient data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. MAC therapy may be discontinued in patients who have been treated with 12 months of therapy for disseminated MAC, who have no evidence of active disease, and whose CD4 counts exceed 100 cells/mcL for 6 months while receiving antiretroviral therapy (ART).

Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts of 50/mcL or less. In contrast to active infection, single-drug oral regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are appropriate. Clarithromycin or azithromycin is more effective and better tolerated than rifabutin, and therefore preferred. Primary prophylaxis for MAC infection can be stopped in patients who have responded to antiretroviral combination therapy with elevation of CD4 counts of greater than 100 cells/mcL for 3 months.

MYCOBACTERIUM TUBERCULOSIS INFECTIONS

Tuberculosis is discussed in Chapter 9. Further information and expert consultation can be obtained from the Francis J. Curry Tuberculosis Center at the Web site www.currytbcenter.ucsf.edu or by telephone, 415-502-4600, or fax, 415-502-4620.

TUBERCULOUS MENINGITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Gradual onset of listlessness, irritability, and anorexia.
- ▶ Headache, vomiting, and seizures common.
- ▶ Cranial nerve abnormalities typical.
- ▶ Tuberculosis focus may be evident elsewhere.
- ▶ Cerebrospinal fluid shows several hundred lymphocytes, low glucose, and high protein.

General Considerations

Tuberculous meningitis is caused by rupture of a meningeal tuberculoma resulting from earlier hematogenous seeding of tubercle bacilli from a pulmonary focus, or it may be a consequence of miliary spread.

Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

B. Laboratory Findings

The spinal fluid is frequently yellowish, with increased pressure, 100–500 cells/mcL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15–25% of cases. Nucleic acid amplification tests for rapid diagnosis of tuberculosis have variable sensitivity and specificity and none are FDA-approved for use in meningitis. Chest radiographs often reveal abnormalities compatible with tuberculosis but may be normal.

Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

Complications

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

Treatment

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis (see Table 9–16). Rifampin, isoniazid, and pyrazinamide all penetrate into cerebrospinal fluid well. The penetration of ethambutol is more variable, but therapeutic concentrations can be achieved, and the drug has been successfully used for meningitis. Aminoglycosides penetrate less well. Regimens that do not include both isoniazid and rifampin may be effective but are less reliable and generally must be given for longer periods.

Many authorities recommend the addition of corticosteroids for patients with focal deficits or altered mental status. Dexamethasone, 0.15 mg/kg intravenously or orally four times daily for 1–2 weeks, then discontinued in a tapering regimen over 4 weeks, may be used.

Török ME. Tuberculous meningitis: advances in diagnosis and treatment. *Br Med Bull.* 2015 Mar;113(1):117–31. [PMID: 25693576]

LEPROSY (Hansen Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Pale, anesthetic macular—or nodular and erythematous—skin lesions.
- ▶ Superficial nerve thickening with associated anesthesia.
- ▶ History of residence in endemic area in childhood.
- ▶ Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

▶ General Considerations

Leprosy (Hansen disease) is a chronic infectious disease caused by the acid-fast rod *M leprae*. The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South America, and the Pacific regions, and rarely seen sporadically in the southern United States.

▶ Clinical Findings

A. Symptoms and Signs

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; discrete erythematous, infiltrated nodules 1–5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The **lepromatous** type (also referred to as multibacillary leprosy) occurs in persons with defective cellular immunity. The course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin

skin test. In the **tuberculoid** type (paucibacillary leprosy), cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate (“borderline”) cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. *M leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

▶ Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

▶ Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

▶ Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases (ie, multibacillary disease), the World Health Organization recommends a triple oral drug-regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months although longer courses may be needed for patients with high burden of disease. For indeterminate and tuberculoid leprosy (paucibacillary disease), the recommendation is rifampin, 600 mg once a month, plus dapsone, 100 mg daily for 6 months.

Two reactional states—erythema nodosum leprosum and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum leprosum, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/day orally, or thalidomide, 300 mg/day orally (in the nonpregnant patient only), is effective for erythema nodosum leprosum. Improvement is expected within a few days after initiating prednisone, and thereafter the dose may be tapered over several weeks to avoid recurrence. Thalidomide is also tapered over several weeks to a 100-mg bedtime dose. Erythema nodosum leprosum is usually confined to the

first year of therapy, and prednisone or thalidomide can be discontinued. Thalidomide is ineffective for reversal reactions, and prednisone, 60 mg/d, is indicated. Reversal reactions tend to recur, and the dose of prednisone should be slowly tapered over weeks to months. Therapy for leprosy should not be discontinued during treatment of reactional states.

INFECTIONS CAUSED BY CHLAMYDIAE

Chlamydiaceae is a family of obligate intracellular parasites closely related to gram-negative bacteria. They include two important genera of human pathogens—*Chlamydia*, which includes the species of *Chlamydia trachomatis*, and *Chlamydophila*, which includes the species *Chlamydophila psittaci* (formerly known as *Chlamydia psittaci*) and *Chlamydophila pneumoniae* (formerly known as *Chlamydia pneumoniae*). The differentiation of genera is based on differences in intracellular inclusions, sulfonamide susceptibility, antigenic composition, and disease production. *C trachomatis* causes many different human infections involving the eye (trachoma, inclusion conjunctivitis), the genital tract (lymphogranuloma venereum, nongonococcal urethritis, cervicitis, salpingitis), or the respiratory tract in infants (pneumonitis). *C psittaci* causes psittacosis and *C pneumoniae* is a cause of respiratory tract infections.

CHLAMYDIA TRACHOMATIS INFECTIONS

1. Lymphogranuloma Venereum

ESSENTIALS OF DIAGNOSIS

- ▶ Evanescent primary genital lesion.
- ▶ Lymph node enlargement, softening, and suppuration, with draining sinuses.
- ▶ Proctitis and rectal stricture in women or in men who have sex with men.
- ▶ Positive complement fixation test.

General Considerations

Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted disease caused by *C trachomatis* types L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 5–21 days. After

the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. Inapparent infections and latent disease are not uncommon.

Clinical Findings

A. Symptoms and Signs

In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1–4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes lead to obstipation and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen in homosexual men.

B. Laboratory Findings

The complement fixation test may be positive (titers greater than 1:64), but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Nucleic acid detection tests are sensitive, but not FDA-approved for rectal specimens and cannot differentiate LGV from non-LGV strains.

Differential Diagnosis

The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

Treatment

If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice is doxycycline (contraindicated in pregnancy), 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is also effective. Azithromycin, 1 g orally once weekly for 3 weeks, may also be effective.

de Vries HJ et al. 2013 European guideline on the management of lymphogranuloma venereum. *J Eur Acad Dermatol Venerol.* 2015 Jan;29(1):1–6. [PMID: 24661352]

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015 Jun 5;64(RR-03):1–137. Erratum in: *MMWR Recomm Rep.* 2015 Aug 28;64(33):924. [PMID: 26042815]

2. Chlamydial Urethritis & Cervicitis

ESSENTIALS OF DIAGNOSIS

- ▶ *C. trachomatis* is a common cause of urethritis, cervicitis, and post-gonococcal urethritis.
- ▶ Diagnosis made by nucleic acid amplification of urine or swab specimen.

General Considerations

C. trachomatis immunotypes D–K are isolated in about 50% of cases of nongonococcal urethritis and cervicitis. In other cases, *Ureaplasma urealyticum* or *Mycoplasma genitalium* can be grown as a possible etiologic agent. *C. trachomatis* is an important cause of postgonococcal urethritis. Coinfection with gonococci and chlamydiae is common, and postgonococcal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection. Chlamydiae are a leading cause of infertility in females in the United States.

Clinical Findings

A. Symptoms and Signs

Females infected with chlamydiae may be asymptomatic or may have symptoms and signs of cervicitis, salpingitis, or pelvic inflammatory disease. The urethral or cervical discharge due to *C. trachomatis* tends to be less painful, less purulent, and watery compared with gonococcal infection.

B. Laboratory Findings

A patient with urethritis or cervicitis and absence of gram-negative diplococci on Gram stain and of *N. gonorrhoeae* on culture is assumed to have chlamydial infection until proven otherwise. The diagnosis should be confirmed, whenever possible, by the FDA-approved, highly sensitive nucleic acid amplification tests for use with urine or vaginal swabs. A negative nucleic acid amplification test for chlamydia reliably excludes the diagnosis of chlamydial urethritis or cervicitis and therapy need not be administered.

C. Screening

Active screening for chlamydial infection is recommended in certain settings: pregnant women; all sexually active women 25 years of age and under; older women with risk factors for sexually transmitted diseases; and men with risk factors for sexually transmitted diseases, such as HIV-positive men or men who have sex with men.

Treatment

Recommended regimens are a single oral 1-g dose of azithromycin (preferred and safe in pregnancy), 100 mg of doxycycline orally for 7 days (contraindicated in pregnancy), or 500 mg of levofloxacin once daily for 7 days

(also contraindicated in pregnancy). Presumptively administered therapy still may be indicated for some patients (such as for an individual with gonococcal infection in whom no chlamydial testing was performed or a test other than a nucleic acid amplification test was used to exclude the diagnosis, or an individual for whom a test result is pending but is considered unlikely to follow up, and for sexual contacts of documented cases). As for all patients in whom sexually transmitted diseases are diagnosed, studies for HIV and syphilis should also be performed.

Geisler WM et al. Azithromycin versus doxycycline for urogenital *Chlamydia trachomatis* infection. *N Engl J Med*. 2015 Dec 24; 373(26):2512–21. [PMID: 26699167]

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015 Jun 5;64(RR-03):1–137. Erratum in: *MMWR Recomm Rep*. 2015 Aug 28;64(33):924. [PMID: 26042815]

CHLAMYDOPHILA PSITTACI & PSITTACOSIS (Ornithosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, chills, and cough; headache common.
- ▶ Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- ▶ Contact with infected bird (psittacine, pigeons, many others) 7–15 days previously.
- ▶ Isolation of chlamydiae or rising titer of complement-fixing antibodies.

General Considerations

Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

Clinical Findings

The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

▶ Differential Diagnosis

The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

▶ Treatment

Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14–21 days. Erythromycin, 500 mg orally every 6 hours, may be effective as well.

Lagae S et al. Emerging *Chlamydia psittaci* infections in chickens and examination of transmission to humans. *J Med Microbiol.* 2014 Mar;63(Pt 3):399–407. [PMID: 24324029]

CHLAMYDOPHILA PNEUMONIAE INFECTION

C pneumoniae causes pneumonia and bronchitis. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of

community-acquired pneumonias, ranking second to mycoplasma as an agent of atypical pneumonia. A putative role in coronary artery disease has not held up to close scientific scrutiny.

Like *C psittaci*, strains of *C pneumoniae* are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg orally four times a day for 10–14 days, appears to be effective therapy. Fluoroquinolones, such as levofloxacin (500 mg once daily for 7–14 days) or moxifloxacin (400 mg once daily for 7–14 days), are active in vitro against *C pneumoniae* and probably are effective. It is unclear if empiric coverage for atypical pathogens in hospitalized patients with community-acquired pneumonia provides a survival benefit or improves clinical outcome.

Spirochetal Infections

Susan S. Philip, MD, MPH

SYPHILIS

NATURAL HISTORY & PRINCIPLES OF DIAGNOSIS & TREATMENT

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations (Table 34–1). Transmission occurs most frequently during sexual contact (including oral sex); sites of inoculation are usually genital but may be extragenital. The risk of acquiring syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through non-sexual contact, blood transfusion, or via the placenta from mother to fetus (congenital syphilis).

The natural history of acquired syphilis is generally divided into two major stages: **early (infectious) syphilis** and **late syphilis**. Between these stages is a symptom-free latent phase. In **early latent syphilis**, which is defined as the symptom-free interval lasting up to 1 year after initial infection, infectious lesions can recur. Infectious syphilis includes primary lesions (chancre and regional lymphadenopathy) appearing during **primary syphilis**, secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system [CNS], or liver) appearing during **secondary syphilis**, relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of CNS and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

Public health efforts to control syphilis focus on the diagnosis and treatment of early (infectious) cases and their partners.

Most cases of syphilis in the United States continue to occur in men who have sex with men (MSM). Globally, the World Health Organization (WHO) estimates 6 million total incident syphilis infections in 2012, equally in both

men and women, and a prevalence of 1% among pregnant women attending antenatal clinics. Preventing congenital syphilis is a major public health goal for the Centers for Disease Control (CDC) and WHO.

COURSE & PROGNOSIS

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Late syphilis may be highly destructive and permanently disabling and may lead to death. Many experts now believe that while infection is almost never completely eradicated in the absence of treatment, most infections remain latent without sequelae, and only a small number of latent infections progress to further disease.

CLINICAL STAGES OF SYPHILIS

1. Primary Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ History of sexual contact (may be unreliable).
- ▶ Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere.
- ▶ Nontender enlargement of regional lymph nodes.
- ▶ Fluid expressed from lesion contains *T pallidum* by immunofluorescence or darkfield microscopy.
- ▶ Serologic nontreponemal and treponemal tests.

▶ Clinical Findings

A. Symptoms and Signs

This is the stage of invasion and may pass unrecognized. The typical lesion is the **chancre** at the site or sites of inoculation, most frequently located on the penis (Figure 34–1), labia, cervix, or anorectal region. Anorectal lesions are especially common among MSM. Chancres also occur occasionally in the oropharynx (lip, tongue, or tonsil) and

Table 34–1. Stages of syphilis and common clinical manifestations.**Primary syphilis**

Chancere: painless ulcer with clean base and firm indurated borders
Regional lymphadenopathy

Secondary syphilis

Skin and mucous membranes
Rash: diffuse (may include palms and soles), macular, papular, pustular, and combinations
Condylomata lata
Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema

Generalized lymphadenopathy

Constitutional symptoms

Fever, usually low-grade

Malaise

Anorexia

Arthralgias and myalgias

Central nervous system

Asymptomatic

Symptomatic

Headache

Meningitis

Cranial neuropathies (II–VIII)

Ocular

Iritis

Iridocyclitis

Other

Renal: glomerulonephritis, nephrotic syndrome

Liver: hepatitis

Bone and joint: arthritis, periostitis

Late syphilis

Late benign (gummatous): granulomatous lesion usually involving skin, mucous membranes, and bones but any organ can be involved

Cardiovascular

Aortic regurgitation

Coronary ostial stenosis

Aortic aneurysm

Neurosyphilis

Asymptomatic

Meningovascular

Seizures

Hemiparesis or hemiplegia

Tabes dorsalis

Impaired proprioception and vibratory sensation

Argyll Robertson pupil

Shooting pains

Ataxia

Romberg sign

Urinary and fecal incontinence

Charcot joint

Cranial neuropathies (II–VIII)

General paresis

Personality changes Hyperactive reflexes

Argyll Robertson pupil

Decreased memory

Slurred speech

Optic atrophy

▲ **Figure 34–1.** Primary syphilis with a large chancere on the glans of the penis. (Used with permission from Joseph Engelman, MD; San Francisco City Clinic.)

rarely on the breast or finger or elsewhere. An initial small erosion appears 10–90 days (average, 3–4 weeks) after inoculation then rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins. This is associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Bacterial infection of the chancere may occur and may lead to pain. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chanceres may be present, particularly in HIV-positive patients. Although the “classic” ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad.

B. Laboratory Findings

1. Microscopic examination—In early (infectious) syphilis, darkfield microscopic examination by a skilled observer of fresh exudate from moist lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis but is usually only available in select clinics that specialize in sexually transmitted disease.

An immunofluorescent staining technique for demonstrating *T pallidum* in dried smears of fluid taken from early syphilitic lesions is available through some laboratories but is not widely available.

Polymerase chain reaction (PCR) testing is not yet commercially available in the United States but has many advantages as a tool for direct detection, including high sensitivity and ability to use a wide range of clinical specimen types.

2. Serologic tests for syphilis—(Table 34–2.) Serologic tests (the mainstay of syphilis diagnosis) fall into two general categories: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in the host after modification by *T pallidum*. (2) Treponemal tests use live or killed *T pallidum* as antigen to detect antibodies specific for pathogenic treponemes.

A. NONTREPONEMAL ANTIGEN TESTS—The most commonly used nontreponemal antigen tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma

Note: Central nervous system involvement may occur at any stage.

Table 34–2. Percentage of patients with positive serologic tests for syphilis.¹

Test	Stage		
	Primary	Secondary	Tertiary
VDRL or RPR	75–85%	99–100%	40–95%
FTA-ABS, TPPA, or MHA-TP	69–100%	100%	94–98%
IgG EIA	100%	100%	NA
CIA	98%	100%	100%

¹Based on untreated cases.

CIA, chemiluminescence assay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption assay; MHA-TP, microhemagglutination assay for *T pallidum*; RPR, rapid plasma reagin test; TPPA, *T pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory test.

reagin (RPR) tests, which measure the ability of heated serum to flocculate a suspension of cardioliipin–cholesterol–lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and have therefore been commonly used for routine screening. Quantitative expression of the reactivity of the serum, based on titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since **titers usually correlate with disease activity**. A different, enzyme immunoassay (EIA)-based screening algorithm is discussed below.

Nontreponemal tests generally become positive 4–6 weeks after infection or 1–3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage, with titers 1:16 or higher. These serologic tests are not specific and must be confirmed with treponemal-specific tests and closely correlated with other clinical and laboratory findings. The tests are positive in patients with non–sexually transmitted treponematoses (see below). More important, false-positive serologic reactions are frequently encountered in a wide variety of other conditions, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive reactions are usually of low titer and transient and may be distinguished from true positives by performing a treponemal specific-antibody test. False-negative results can be seen when very high antibody titers are present (**the prozone phenomenon**). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction. The RPR and VDRL tests are equally reliable, but RPR titers tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably performed at the same laboratory.

Nontreponemal antibody titers are used to assess adequacy of therapy. The rate of the VDRL or RPR decline depends on various factors. In general, persons with repeat infections, higher initial titers, more advanced stages of

disease, or those who are HIV-infected at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers decline but do not become nonreactive). Data based on recommended treatment regimens suggest that in primary and secondary syphilis it may take 6–12 months to see a fourfold decrease in titer.

B. TREPONEMAL ANTIBODY TESTS—These tests measure antibodies capable of reacting with *T pallidum* antigens. The *T pallidum* hemagglutination (TPHA) test and the *T pallidum* particle agglutination (TPPA) test are comparable in specificity and sensitivity to the fluorescent treponemal antibody absorption test (FTA-ABS). The TPPA test, because of ease of performance, has supplanted the FTA-ABS test as the means of confirming the diagnosis of syphilis following a positive nontreponemal test. Newer treponemal tests used in reverse screening algorithms include EIA and chemiluminescence assay (CIA).

In traditional screening, the treponemal tests are used to determine whether a positive nontreponemal antigen test is a false-positive result (see above) or is indicative of syphilis. Because of their great sensitivity, particularly in the late stages of the disease, these tests are also of value when there is clinical evidence of syphilis but the nontreponemal serologic test for syphilis is negative. Treponemal tests are reactive in many patients with primary syphilis and in almost all patients with secondary syphilis (Table 34–2). Although a reactive treponemal-specific serologic test remains reactive throughout a patient's life in most cases, it may (like nontreponemal antibody tests) revert to negative with adequate therapy. Final decisions about the significance of the results of serologic tests for syphilis must be based on a total clinical appraisal and may require expert consultation.

C. ENZYME IMMUNOASSAY (EIA)-OR CHEMILUMINESCENCE IMMUNOASSAY (CIA)-BASED SCREENING ALGORITHMS—Newer screening algorithms reverse the traditional test order and begin with an automated treponemal antibody test, (eg, EIA or CIA) and then follow up with a nontreponemal test (RPR or VDRL) if the treponemal test is positive. This algorithm is faster and decreases labor costs to laboratories when compared with traditional screening. Compared with traditional treponemal-specific tests, the EIAs have sensitivities of 95–100% and specificities of 99–100%.

The reverse algorithms can cause challenges in clinical management. A positive treponemal test with a negative RPR or VDRL may represent prior, treated syphilis; untreated latent syphilis; or a false-positive treponemal test. Such results should be evaluated with a second treponemal test as a “tie-breaker,” but interpretation of discordant results is not yet fully standardized and a clinician may benefit from an expert opinion. Reverse algorithms are recommended by several international organizations including the International Union against Sexually Transmitted Infections (IUSTI), but the CDC still recommend the traditional algorithm.

D. RAPID TREPONEMAL TESTS—A single rapid point of care treponemal test is approved for use in the United States, including in outreach and other nonlaboratory

settings. Other tests are available internationally and are commonly used in limited-resource settings. Sensitivity ranges from 62% to 100% and specificity from 83% to 95%.

3. Polymerase chain reaction—PCR has been increasingly evaluated and utilized worldwide for the diagnosis of genital ulcer disease, including syphilis, but these tests are not yet commercially available in the United States.

4. Cerebrospinal fluid examination—See Neurosyphilis section.

► Differential Diagnosis

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum, or neoplasm. **Any genital ulcer should be considered a possible primary syphilitic lesion.** Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.

► Prevention & Screening

Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health

measure. Latex or polyurethane condoms are effective but protect covered areas only. Men who have sex with men should be screened every 6–12 months, and as often as every 3 months in high-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs). Pregnant women should be screened at the first prenatal visit and again in the third trimester; a third screen at delivery should be performed if there are risk indicators, including poverty, sex work, illicit drug use, history of other sexually transmitted diseases, and residing in a community with high syphilis morbidity. Patients treated for other sexually transmitted diseases should also be tested for syphilis, and persons who have known or suspected sexual contact with patients who have syphilis should be evaluated and presumptively treated to abort development of infectious syphilis (see Treating Syphilis Contacts below).

► Treatment

A. Antibiotic Therapy

Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin resistant *T pallidum* (Table 34–3). In pregnant women,

Table 34–3. Recommended treatment for syphilis.¹

Stage of Syphilis	Treatment	Alternative ²	Comment
Early			
Primary, secondary, or early latent	Benzathine penicillin G 2.4 million units intramuscularly once	Doxycycline 100 mg orally twice daily for 14 days or Tetracycline 500 mg orally four times daily for 14 days or Ceftriaxone 1 g intramuscularly or intravenously daily for 8–10 days ³	
Late			
Late latent or uncertain duration	Benzathine penicillin G 2.4 million units intramuscularly weekly for 3 weeks	Doxycycline 100 mg orally twice daily for 28 days or Tetracycline 500 mg orally four times a day for 28 days	No routine cerebrospinal fluid evaluation unless neurologic, otologic or ocular abnormalities
Tertiary without neurosyphilis	Benzathine penicillin G 2.4 million units intramuscularly weekly for 3 weeks	Doxycycline 100 mg orally twice daily for 28 days or Tetracycline 500 mg orally four times a day for 28 days	Cerebrospinal fluid evaluation recommended in all patients
Neurosyphilis	Aqueous penicillin G 18–24 million units intravenously daily, given every 3–4 hours or as continuous infusion for 10–14 days	Procaine penicillin, 2.4 million units intramuscularly daily with probenecid 500 mg orally four times a day for 10–14 days or Ceftriaxone 2 g intramuscularly or intravenously daily for 10–14 days	Follow treatment with benzathine penicillin G 2.4 million units intramuscularly weekly for up to 3 weeks

¹Penicillin is the only documented effective treatment in pregnancy, so pregnant patients with true allergy should be desensitized and treated with penicillin according to stage of disease as above.

²Patients treated with alternative therapies require close clinical and serologic monitoring.

³Fewer data for ceftriaxone treatment, optimal dose or duration not known.

penicillin is the only option because it reliably treats the fetus (see below).

There are some alternatives to penicillin for nonpregnant patients, including doxycycline. There are also limited data for ceftriaxone, although optimum dose and duration are not well defined. Azithromycin has been shown to be effective but should be used with caution; it should not be used at all in MSM due to demonstrated resistance. All patients treated with a non-penicillin regimen must have particularly close clinical and serologic follow up.

B. Managing Jarisch–Herxheimer Reaction

The Jarisch–Herxheimer reaction, manifested by fever and aggravation of the existing clinical picture in the hours following treatment, is ascribed to the sudden massive destruction of spirochetes and is not an IgE-mediated allergic reaction. It is most common in early syphilis, particularly secondary syphilis where it can occur in 66% of cases.

The reaction may be blunted by simultaneous administration of antipyretics, although no proven method of prevention exists. In cases with increased risk of morbidity due to the Jarisch–Herxheimer reaction (including CNS or cardiac involvement and pregnancy), consultation with an infectious disease expert is recommended. Patients should be reminded that the reaction does not signify an allergy to penicillin.

C. Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or other chemicals should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.

D. Public Health Measures

Patients with infectious syphilis must abstain from sexual activity for 7–10 days after treatment. **All cases of syphilis must be reported to the appropriate local public health agency in order to identify and treat sexual contacts.** In addition, **all patients with syphilis should have an HIV test at the time of diagnosis.** In areas of high HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test result was negative.

E. Treating Syphilis Contacts

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis even if serologic tests are negative. Persons exposed more than 3 months previously should be treated based on serologic results; however, if the patient is unreliable for follow-up, empiric therapy is indicated.

▶ Follow-Up Care

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically and serologically every 6 months. **In primary and secondary syphilis, failure of nontreponemal antibody titers to**

decrease fourfold by 6–12 months may identify a group at high risk for treatment failure. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. In HIV-uninfected patients, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a thorough neurologic history and examination should be performed and lumbar puncture considered since unrecognized neurosyphilis can be a cause of treatment failure; and, if careful follow-up cannot be ensured (3-month intervals for HIV-positive individuals and 6-month intervals for HIV-negative patients), treatment should be repeated with 2.4 million units of benzathine penicillin G intramuscularly weekly for 3 weeks. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, the patient has been reinfected (more likely) or the therapy failed (if a non-penicillin regimen was used). In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

2. Secondary Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized maculopapular skin rash.
- ▶ Mucous membrane lesions, including patches and ulcers.
- ▶ Weeping papules (condyloma lata) in moist skin areas.
- ▶ Generalized nontender lymphadenopathy.
- ▶ Fever may be present.
- ▶ Meningitis, hepatitis, osteitis, arthritis, iritis may be present.
- ▶ Many treponemes in moist lesions by immunofluorescence or darkfield microscopy.
- ▶ Positive serologic tests for syphilis.

▶ Clinical Findings

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when **dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation.** The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but generally *not* vesicular) and generalized; involvement of the palms and soles (Figure 34–2) occurs in 80% of cases. Annular lesions simulating ringworm may be observed in dark-skinned individuals. Mucous membrane lesions may include mucous patches (Figure 34–3), which can be found on the lips, mouth, throat, genitalia, and anus. Specific lesions—**condylomata lata**

▲ **Figure 34-2.** Secondary syphilis lesions on the soles of the feet. (From Dr. Gavin Hart, Public Health Image Library, CDC.)

(Figure 34-4)—are fused, weeping papules on the moist areas of the skin and mucous membranes and are sometimes mistaken for genital warts. The mucous membrane lesions are highly infectious.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

The serologic tests for syphilis are positive in almost all cases (see Primary Syphilis). The moist cutaneous and mucous membrane lesions often show *T pallidum* on dark-field microscopic examination. A transient cerebrospinal fluid (CSF) pleocytosis is seen in 40% of patients with secondary syphilis. There may be evidence of hepatitis or nephritis (immune complex type) as circulating immune complexes are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions (Figure 34-5). Visceral lesions may suggest nephritis or hepatitis due to other causes.

▲ **Figure 34-3.** Secondary syphilis mucous patch of the tongue. (Used with permission from Kenneth Katz, MD, MSc, MSCE.)

▲ **Figure 34-4.** Secondary syphilis perianal condylomata lata. (Used with permission from Joseph Engelman, MD; San Francisco City Clinic.)

▶ Treatment

Treatment is as for primary syphilis unless CNS or ocular disease is present, in which case a lumbar puncture should be performed and, if positive, treatment for neurosyphilis

▲ **Figure 34-5.** Secondary syphilis rash of the buttocks and legs. (From J. Pledger, BSS/VD, Public Health Image Library, CDC.)

given (Table 34–3). See Primary Syphilis for follow-up care and treatment of contacts.

3. Latent Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Early latent syphilis: infection less than 1 year in duration.
- ▶ Late latent syphilis: infection more than 1 year in duration.
- ▶ No physical signs.
- ▶ History of syphilis with inadequate treatment.
- ▶ Positive serologic tests for syphilis.

▶ General Considerations

Latent syphilis is the clinically quiescent phase in the absence of primary or secondary lesions. **Early latent syphilis** is defined as the first year after primary infection and may relapse to secondary syphilis if undiagnosed or inadequately treated (see above). Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection.

Early latent infection can be diagnosed if there was documented seroconversion or a fourfold increase in nontreponemal titers in the past 12 months; the patient can recall symptoms of primary or secondary syphilis; or the patient had a sex partner with documented primary, secondary, or early latent syphilis.

After the first year of latent syphilis, the patient is said to be in the **late latent stage** and noninfectious to sex partners. Transmission to the fetus, however, can probably occur in any phase. There are (by definition) no clinical manifestations during the latent stage, and the only significant laboratory findings are positive serologic tests. A diagnosis of late latent syphilis is justified only when the history and physical examination show no evidence of tertiary disease or neurosyphilis. The latent stage may last from months to a lifetime.

▶ Treatment

Treatment of **early latent syphilis** and follow-up is as for primary syphilis unless CNS disease is present (Table 34–3). Treatment of **late latent syphilis** is shown in Table 34–3. The treatment of this stage of the disease is intended to prevent late sequelae. If there is evidence of CNS involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment for neurosyphilis. Titers may not decline as rapidly following treatment compared to early syphilis. Nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers (1:32 or higher) fail to decrease fourfold by 12–24 months or if symptoms or signs consistent with syphilis develop, an HIV test

should be repeated in HIV-uninfected patients, lumbar puncture should be performed, and re-treatment given according to the stage of the disease.

4. Late (Tertiary) Syphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Infiltrative tumors of skin, bones, liver (gummas).
- ▶ Aortitis, aneurysms, aortic regurgitation.
- ▶ CNS disorders, including meningovascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

▶ General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in developed countries in the modern antibiotic era. Late lesions are thought to represent a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction, with a relatively rapid onset and generally prompt response to therapy and (2) diffuse inflammation of a more insidious onset that characteristically involves the CNS and large arteries, is often fatal if untreated, and is at best arrested by treatment. **Gummas** may involve any area or organ of the body but most often affect the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized CNS involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, gastrointestinal system, cardiovascular system, and nervous system.

▶ Clinical Findings

A. Symptoms and Signs

1. Skin—Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (*lues maligna*) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate (Figure 34–6).

2. Mucous membranes—Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

3. Skeletal system—Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles. The pain is especially severe at night.

▲ **Figure 34-6.** Gumma of the nose due to long-standing tertiary syphilis. (From J. Pledger, Public Health Image Library, CDC.)

4. Eyes—Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of CNS syphilis.

5. Respiratory system—Respiratory involvement by late syphilis is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

6. Gastrointestinal system—Gummas involving the liver produce the usually benign, asymptomatic *hepar lobatum*. A picture resembling Laennec cirrhosis is occasionally produced by liver involvement. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

7. Cardiovascular system—Cardiovascular lesions (10–15% of late syphilitic lesions) are often progressive, disabling, and life-threatening. CNS lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation (Figure 34-7) and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

8. Nervous system (neurosyphilis)—See next section.

▶ Treatment

Treatment of tertiary syphilis (excluding neurosyphilis) is the same as late latent syphilis (Table 34-3); symptoms may not resolve after treatment. Positive serologic tests do not

▲ **Figure 34-7.** Ascending saccular aneurysm of the thoracic aorta in tertiary syphilis. (Public Health Image Library, CDC.)

usually become negative. Viable spirochetes are occasionally found in the eyes, in CSF, and elsewhere in patients with “adequately” treated syphilis, but claims for their capacity to cause progressive disease are speculative.

The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric, and CSF examinations. In the presence of definite CSF or neurologic abnormalities, one should treat for neurosyphilis.

5. Neurosyphilis

ESSENTIALS OF DIAGNOSIS

- ▶ Can occur at any stage of disease.
- ▶ Consider both clinical presentation and laboratory data.
- ▶ Carefully evaluate the neurologic examination in all patients and consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

▶ General Considerations

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. Asymptomatic CSF abnormalities and meningovascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than *tabes dorsalis* and general paresis (2–50 years after infection).

▶ Clinical Findings

A. Classification

1. Asymptomatic neuroinvasion—This form has been reported in up to 40% of patients with early syphilis and is

characterized by spinal fluid abnormalities (positive spinal fluid serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement. There are no clear data to support that these asymptomatic CSF abnormalities have clinical significance.

2. Meningovascular syphilis—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of acute or chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows increased cells (100–1000/mcL), elevated protein, and may have a positive serologic test (CSF VDRL) for syphilis. The symptoms of acute meningitis are rare in late syphilis.

3. Tabes dorsalis—This form is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, **Argyll Robertson pupils** (which react poorly to light but accommodate for near focus), and muscular hypotonia and hyporeflexia. Impaired proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg (“shooting” or “lightning” pains) may occur. Crises are also common in tabes: gastric crises, consisting of sharp abdominal pains with nausea and vomiting (simulating an acute abdomen); laryngeal crises, with paroxysmal cough and dyspnea; urethral crises, with painful bladder spasms; and rectal and anal crises. Crises may begin suddenly, last for hours to days, and cease abruptly. Neurogenic bladder with overflow incontinence is also seen. Painless trophic ulcers may develop over pressure points on the feet. Joint damage may occur as a result of lack of sensory innervation (Charcot joint, Figure 34–8). The CSF may have a normal or increased cell count, elevated protein, and variable results of serologic tests.

▲ **Figure 34–8.** Neuropathic arthropathy (Charcot joint) from tertiary syphilis. (From Susan Lindsley, Public Health Image Library, CDC.)

4. General paresis—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient may become slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

B. Laboratory Findings

See Serologic Tests for Syphilis, above; these tests should also be performed in cases of suspected neurosyphilis.

1. Indications for a lumbar puncture—In early syphilis (primary and secondary syphilis and early latent syphilis of less than 1 year’s duration), invasion of the CNS by *T pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients who have received standard therapy. Thus, unless clinical symptoms or signs of neurosyphilis or ophthalmologic involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture in *early syphilis* is not routinely recommended. In *latent syphilis*, routine lumbar puncture is not indicated since the yield is low and findings rarely influence therapeutic decisions. **CSF evaluation is recommended, however, if neurologic or ophthalmologic symptoms or signs are present, if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma).**

2. Spinal fluid examination—CSF findings in neurosyphilis are variable. In “classic” cases, there is an elevation of total protein, lymphocytic pleocytosis, and a positive CSF reagin test (VDRL). The serum nontreponemal titers will be reactive in most cases. In later stages of syphilis, normal CSF analysis in the presence of infection can occur, but it is unusual. False-positive reagin tests rarely occur in the CSF; a positive test confirms the presence of neurosyphilis. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, *a negative test does not exclude neurosyphilis*. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity, and a high serum titer of FTA-ABS may result in a positive CSF titer in the absence of neurosyphilis.

▶ Treatment

Neurosyphilis is treated with high doses of aqueous penicillin to achieve better penetration and higher levels of medication in the CSF than is possible with benzathine penicillin G (Table 34–3). There are limited data for using ceftriaxone to treat neurosyphilis as well, but because other regimens have not been adequately studied, patients with a history of an IgE-mediated reaction to penicillin may require skin testing for allergy to penicillin and, if positive, should be desensitized. Because of concerns about slowly dividing organisms that may persist after completing 10–14 days of therapy with short-acting aqueous penicillin G, many experts recommend subsequent administration of

2.4 million units of the longer-acting benzathine penicillin G intramuscularly once weekly for up to 3 weeks as additional therapy.

All patients treated for neurosyphilis should have nontreponemal serologic tests done every 3–6 months. Guidelines established by the CDC recommend spinal fluid examinations at 6-month intervals until the CSF cell count is normal; however, there are data to suggest that in certain patients normalization of serum titers are an acceptable surrogate for CSF response. In general, CSF white blood cell count and CSF VDRL normalize more quickly (usually in 12 months) than CSF protein concentration, which can remain abnormal for extended periods. If the serum nontreponemal titers do not normalize, the CSF analysis should be repeated. A second course of penicillin therapy may be given if the CSF cell count has not decreased at 6 months or is not normal at 2 years.

6. Syphilis in HIV-Infected Patients

Syphilis is common among HIV-infected individuals. Some data suggest that syphilis coinfection is associated with an increase in HIV viral load and a decrease in CD4 count that normalizes with therapy. Researchers from a prospective cohort study of HIV-infected individuals reported that they found no association with HIV disease progression in persons with syphilis coinfection. However, for optimal patient care as well as prevention of transmission to partners, **guidelines for the primary care of HIV-infected patients recommend routine syphilis screening.**

Interpretation of serologic tests should be the same for HIV-positive and HIV-negative persons. All HIV-positive patients in care should be screened at least annually to identify latent disease because by establishing a serologic history, unnecessary lumbar punctures and prolonged treatment for latent syphilis of uncertain duration can be avoided. If the diagnosis of syphilis is suggested on clinical grounds but reagent tests are negative, alternative tests should be performed. These tests include darkfield examination of lesions and direct fluorescent antibody staining for *T pallidum* of lesion exudate or biopsy specimens.

HIV-positive patients with primary and secondary syphilis should have careful clinical and serologic follow-up at 3, 6, 9, 12, and 24 months. HIV-infected patients with late latent syphilis, syphilis of uncertain duration, and neurosyphilis should be treated like HIV-negative individuals, with follow-up at 6, 12, 18, and 24 months. The use of antiretroviral therapy has been associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that CSF abnormalities are frequently seen if lumbar puncture is performed. The significance of these abnormalities is unknown, and similar abnormalities are frequently seen in non-HIV-infected patients with primary or secondary syphilis. Thus, **CSF testing is not recommended in those with uncomplicated disease and a normal neurologic examination.** In contrast, a lumbar puncture should be performed in all patients, regardless of HIV-infection status, if neurologic signs are present or if therapy has failed. Following treatment, CSF white blood cell counts normalize within 12 months

regardless of HIV status, while the CSF VDRL is slower to normalize in HIV-infected individuals, especially those with CD4 counts less than 200 cells/mL. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same.

Because clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens, few options exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up (Table 34–3). For neurosyphilis, limited efficacy data exist for ceftriaxone; therefore, penicillin regimens are optimal even if this requires skin testing and desensitization.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 19). In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only acceptable treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease (see above). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Tetracycline and doxycycline are contraindicated in pregnancy. Erythromycin should not be used because of failure to eradicate infection in the fetus, and insufficient data are available to justify a recommendation for ceftriaxone or azithromycin. Thus, women with a history of penicillin allergy should be skin tested and desensitized if necessary.

The infant should be evaluated immediately, as noted below, and at 6–8 weeks of age.

8. Congenital Syphilis

Congenital syphilis is a transplacentally transmitted infection that occurs in infants of untreated or inadequately treated mothers. The physical findings at birth are quite variable: The infant may have many or minimal signs or even no signs until 6–8 weeks of life (delayed form). The most common findings are on the mucous membranes and skin—maculopapular rash, condylomas, mucous membrane patches, and serous nasal discharge (snuffles). These lesions are infectious; *T pallidum* can easily be found microscopically, and the infant must be isolated. Other common findings are hepatosplenomegaly, anemia, or osteochondritis. These early active lesions subsequently heal, but if the disease is left untreated it produces the characteristic stigmas of congenital syphilis—interstitial keratitis, Hutchinson teeth, saddle nose, saber shins, deafness, and CNS involvement.

The presence of negative serologic tests at birth in both the mother and the infant usually means that the newborn is free of infection. However, recent infection near the time of delivery may result in negative tests because there has been insufficient time to develop a serologic response. Thus, it is necessary to maintain a high index of suspicion in infants born to high-risk mothers. All infants born to mothers with positive nontreponemal and treponemal antibody titers should have blood drawn for an RPR or VDRL test and, if positive, be referred to a pediatrician for further evaluation and therapy.

▶ When to Refer

- Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.
- Early (infectious) syphilis cases may be contacted for partner notification and treatment by local public health authorities.

▶ When to Admit

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch-Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

NON-SEXUALLY TRANSMITTED TREPONEMATOSES

A variety of treponemal diseases other than syphilis occur endemically in many tropical areas of the world. They are distinguished from disease caused by *T pallidum* by their nonsexual transmission via direct skin contact, their relatively high incidence in certain geographic areas and among children, and their tendency to produce less severe visceral manifestations. As in syphilis, skin, soft tissue, and bone lesions may develop, organisms can be demonstrated in infectious lesions with darkfield microscopy or immunofluorescence but cannot be cultured in artificial media; the serologic tests for syphilis are positive; molecular methods such as PCR and genome sequencing are available but

not widely used in endemic areas; the diseases have primary, secondary, and sometimes tertiary stages; and penicillin is the drug of choice. Treatment with penicillin in doses appropriate to primary syphilis (eg, 2.4 million units of benzathine penicillin G intramuscularly) is generally curative in any stage of the non-sexually transmitted treponematoses. In cases of penicillin hypersensitivity, tetracycline, 500 mg orally four times a day for 10–14 days, is usually the recommended alternative. In a randomized controlled trial, oral azithromycin (30 mg/kg once) was noninferior to benzathine penicillin G for the treatment of yaws in children.

YAWS (Frambesia)

Yaws is a contagious disease largely limited to tropical regions that is caused by *T pallidum* subspecies *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The “mother yaw,” a painless papule that later ulcerates, appears 3–4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions that are raised papillomas and papules that weep highly infectious material appear and last for several months or years. Painful ulcerated lesions on the soles are called “crab yaws” because of the resulting gait. Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. CNS, cardiac, or other visceral involvement is rare. See above for therapy. The World Health Organization has set a goal of eliminating yaws by the year 2020 using mass treatment with azithromycin.

PINTA

Pinta is a non-sexually transmitted spirochetal infection caused by *T pallidum* subspecies *carateum*. It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are most common on the extremities; and later show atrophy and depigmentation. Some cases show pigmentary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from “crab yaws.” See above for therapy.

ENDEMIC SYPHILIS (Bejel)

Endemic syphilis is an acute or chronic infection caused by *T pallidum* subspecies *endemicum*. It has been reported in a number of countries, particularly in the eastern Mediterranean area, often with local names: bejel in Syria, Saudi

Arabia, and Iraq, and dichuchwa, njovera, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and CNS involvement are rare. See above for therapy.

 Mitjà O et al. Advances in the diagnosis of endemic treponematoses: yaws, bejel, and pinta. *PLoS Negl Trop Dis.* 2013 Oct 24; 7(10):e2283. [PMID: 24205410]

SELECTED SPIROCHETAL DISEASES

RELAPSING FEVER

The infectious organisms in relapsing fever are spirochetes of the genus *Borrelia*. The infection has two forms: tick-borne and louse-borne. The main reservoir for tick-borne relapsing fever is rodents, which serve as the source of infection for ticks. **Tick-borne** relapsing fever may be transmitted transovarially from one generation of ticks to the next. Humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic but is not transmitted from person to person. In the United States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are uncommon in humans.

The **louse-borne** form is primarily seen in the developing world, and humans are the only reservoir. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

Clinical Findings

A. Symptoms and Signs

There is an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache. Hepatomegaly and splenomegaly may develop, as well as various types of rashes (macular, papular, petechial) that usually occur at the end of a febrile episode. Delirium occurs with high fever, and there may be various neurologic and psychic abnormalities. The attack terminates, usually abruptly, after 3–10 days. After an interval of 1–2 weeks, relapse occurs, but often it is somewhat milder. Three to ten relapses may occur before recovery in tick-borne disease, whereas louse-borne disease is associated with only one or two relapses.

B. Laboratory Findings

During episodes of fever, large spirochetes are seen in blood smears stained with Wright or Giemsa stain. The organisms can be cultured in special media but rapidly lose

pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-borrelia antibodies develop during the illness; sometimes the Weil-Felix test for rickettsioses and nontreponemal serologic tests for syphilis may also be falsely positive. Infection can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, causing some cases to be misdiagnosed as Lyme disease. PCR assays have been developed but are not widely available. CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

Postexposure prophylaxis with doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent recurrent fever following tick bites in highly endemic areas.

Treatment

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 600,000–800,000 units intramuscularly (adults) or 400,000 units intramuscularly (children), probably constitutes adequate treatment for louse-borne relapsing fevers; however, some experts advocate for longer courses of treatment to prevent persistent infection. Because of higher relapse rates, tick-borne disease is routinely treated with 0.5 g of tetracycline or erythromycin given orally four times daily for 10 days. If CNS invasion is suspected, penicillin G, 3 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously daily, should be given for 10–14 days. Jarisch-Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored (see Syphilis, above). One study in patients with louse-borne relapsing fever showed that administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction.

Prognosis

The overall mortality rate is usually about 5%. Fatalities are most common in old, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

Cutler SJ. Relapsing fever *Borreliae*: a global review. *Clin Lab Med.* 2015 Dec;35(4):847–65. [PMID: 26593261]

RAT-BITE FEVER

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme *Spirillum minus* (Asia), or the bacteria *Streptobacillus moniliformis* (North America). It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested dwellings, owners of pet rats, and laboratory workers are at greatest risk.

Clinical Findings

A. Symptoms and Signs

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses. Endocarditis is a rare complication of infection.

B. Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient's exudate or blood. It has not been cultured in artificial media.

Differential Diagnosis

Rat-bite fever must be distinguished from the rat-bite-induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever.

Treatment

Penicillin is given for 10–14 days. During the acute phase of illness, the intravenous route is used (1–2 million units every 4–6 hours) and once improvement has occurred, therapy is completed with oral medication, penicillin V 500 mg four times daily to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.

Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

Budair B et al. Septic arthritis secondary to rat bite fever: a challenging diagnostic course. *BMJ Case Rep.* 2014 Apr 2; 2014:204086. [PMID: 24695665]

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Clinical illness can vary from asymptomatic to fatal liver and kidney disease.
- ▶ Anicteric leptospirosis is the more common and milder form of the disease.
- ▶ Icteric leptospirosis (Weil syndrome) is characterized by impaired kidney and liver function, abnormal mental status, and hemorrhagic pneumonia and has a 5–40% mortality rate.

General Considerations

Leptospirosis is an acute and sometimes severe treponemal infection that is caused by multiple serotypes of the spirochete, *Leptospira interrogans*. The disease is distributed worldwide, and it is among the most common zoonotic infections. The leptospire are often transmitted to humans by the ingestion of food and drink contaminated by the urine of an infected animal. The organism may also enter through minor skin lesions and probably via the conjunctiva. Reports of recreational cases in international travelers have been increasing, following swimming or rafting in contaminated water, and occupational cases occur among sewer workers, rice planters, abattoir workers, and farmers. Sporadic urban cases have been seen in the homeless exposed to rat urine.

Clinical Findings

A. Symptoms and Signs

Anicteric leptospirosis, the more common and milder form of the disease, is often biphasic. After an incubation period of 2–20 days, the initial or “septicemic” phase begins with abrupt fever to 39–40°C, chills, abdominal pain, severe headache, and myalgias, especially of the calf muscles. There may be marked conjunctival suffusion. Leptospire can be isolated from blood, CSF, and tissues. Following a 1- to 3-day period of improvement in symptoms and absence of fever, the second or “immune” phase begins; however, in severe disease the phases may appear indistinct. Leptospire are absent from blood and CSF but are still present in the kidney, and specific antibodies appear. A recurrence of symptoms is seen as in the first phase of disease with the onset of meningitis. Uveitis (which can be unilateral or bilateral and usually involves the entire uveal tract), rash, and adenopathy may occur.

A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4–30 days, and complete recovery is the rule.

Icteric leptospirosis (Weil syndrome) is the most severe form of the disease, characterized by impaired kidney and liver function, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5–40% mortality rate. Symptoms and signs often are continuous and not biphasic.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, rickettsial disease, and relapsing fever.

B. Laboratory Findings

The leukocyte count may be normal or as high as 50,000/mcL (0.05/L), with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75%, and elevated creatinine (greater than 1.5 mg/dL) (132.6 μmol/L) is seen in 50% of cases. Serum creatine kinase is usually elevated in persons with leptospirosis and normal in persons with hepatitis. In cases with meningeal involvement, organisms may be found in the CSF during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient's blood (a test requiring expertise since false-positives are frequent in inexperienced hands) or by culture on a semi-solid medium (eg, Fletcher EMJH). Cultures take 1–6 weeks to become positive but may remain negative if antibiotics were started before culture was obtained. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests, including the microscopic agglutination test (considered the gold standard but not widely available), and enzyme-linked immunosorbent assay (ELISA). PCR molecular diagnostics are not widely available but appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor.

► Complications

Myocarditis, aseptic meningitis, acute kidney injury, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

► Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

Prophylaxis with doxycycline has been effective in trials but is not routinely recommended. Human vaccine is used in some limited settings but is not available in the United States.

► Treatment

Many cases are self-limited without specific treatment. Various antimicrobial medications, including penicillin,

ceftriaxone, and tetracyclines, show antileptospiral activity; however, meta-analysis has not demonstrated a clear survival benefit for any antibiotic. Doxycycline (100 mg every 12 hours orally or intravenously), penicillin (eg, 1.5 million units every 6 hours intravenously), and ceftriaxone (1 g daily intravenously) are used in severe leptospirosis. Jarisch–Herxheimer reactions may occur (see Syphilis, above). Although therapy for mild disease is controversial, most clinicians treat with doxycycline, 100 mg orally twice daily, for 7 days, or amoxicillin 50 mg/kg, divided into three doses daily. Azithromycin is also active, but clinical experience is limited.

► Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 40% for those over age 60 years.

► When to Admit

Patients with jaundice or other evidence of severe disease should be admitted for close monitoring and may require admission to an intensive care unit.

Haake DA et al. Leptospirosis in humans. *Curr Top Microbiol Immunol.* 2015;387:65–97. [PMID: 25388133]

Musso D et al. Laboratory diagnosis of leptospirosis: a challenge. *J Microbiol Immunol Infect.* 2013 Aug;46(4):245–52. [PMID: 23639380]

LYME DISEASE (Lyme Borreliosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Erythema migrans, a flat or slightly raised red lesion that expands with central clearing.
- ▶ Headache or stiff neck.
- ▶ Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.
- ▶ Wide geographic distribution, with most US cases in the Northeast, mid-Atlantic, upper Midwest, and Pacific coastal regions.

► General Considerations

This illness, named after the town of Old Lyme, Connecticut, is the most common tick-borne disease in the United States and Europe and is caused by genospecies of the spirochete *B burgdorferi*. In the United States, the causative genospecies is *B burgdorferi sensu strictu*, whereas in Europe and Asia *B garinii* and *B afzelii* predominate. Most US cases are reported from the mid-Atlantic, northeastern, and north central regions of the country. The true incidence of Lyme disease is not known for a number of reasons: (1) serologic tests are not standardized (see below); (2) clinical manifestations are nonspecific; and (3) even with reliable testing, serology is insensitive in early disease.

The tick vector of Lyme disease varies geographically and is *Ixodes scapularis* in the northeastern, north central, and mid-Atlantic regions of the United States; *Ixodes pacificus* on the West Coast; *Ixodes ricinus* in Europe; and *Ixodes persulcatus* in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of *B burgdorferi*, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Under experimental conditions, **ticks must feed for 24–36 hours or longer to transmit infections.** Most cases are reported in the spring and summer months. Human epidemiologic studies have indicated that the incidence of disease is significantly higher when tick attachment is for longer than 72 hours than if it is less than 72 hours, though rare cases have been documented with attachment of less than 24 hours. In addition, the percentage of ticks infected varies on a regional basis. In the northeastern and midwestern regions, 15–65% of *I scapularis* ticks are infected with the spirochete; in the western United States, only 2% of *I pacificus* are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Because the *Ixodes* tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use fine-tipped tweezers to pull firmly and repeatedly on the tick's mouth part—not the tick's body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

▶ Clinical Findings

Prior clinical description of Lyme disease divided the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (**erythema migrans**, see Figure 6–27); stage 2, weeks to months later, facial (cranial nerve VII) palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, CNS, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.

A. Symptoms and Signs

1. Stage 1, early localized infection—Stage 1 infection is characterized by erythema migrans. About 1 week after the tick bite (range, 3–30 days; median 7–10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing (“bulls-eye” lesion), often there is a

more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed. Most patients with erythema migrans will have a concomitant viral-like illness (the “summer flu”) characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of erythema migrans resolve in 3–4 weeks. Although the classic lesion of erythema migrans is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Chemical reactions to tick and spider bites (these usually recede in 24–48 hours, whereas erythema migrans increases in size in this time period), drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans. Southern tick-associated rash illness (STARI) has a similar appearance, but it occurs in geographically distinct areas of the United States.

Completely asymptomatic disease, without erythema migrans or flu-like symptoms, can occur but is very uncommon in the United States.

2. Stage 2, early disseminated infection—Up to 50–60% of patients with erythema migrans are bacteremic and within days to weeks of the original infection, secondary skin lesions develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever, headache (sometimes severe), neck pain, and generalized achiness are common with the skin lesions. Most symptoms are transient, although fatigue may persist for months. After hematogenous spread, the organism may sequester itself in certain areas and produce focal symptoms. Some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations. Cardiac involvement includes myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common CNS manifestation is aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial nerve VII neuropathy, ie, facial palsy (usually unilateral but can be bilateral, see Figure 24–2). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis and, rarely, panophthalmitis can also occur. Rarely, skin involvement can be manifested as a cutaneous hypopigmented lesion called a **borrelial lymphocytoma**.

3. Stage 3, late persistent infection—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients, but with early recognition and treatment of disease, this has decreased to less than 10%. The classic manifestation of late disease is a monarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. While these joints may be quite swollen, these patients generally report less pain compared to patients with bacterial septic arthritis. Even if untreated, the arthritis is self-limited,

resolving in a few weeks to months. Multiple recurrences are common but are usually less severe than the original disease. Joint fluid reflects an inflammatory arthritis with a mean white blood cell count of 25,000/mcL (0.025/L) with a predominance of neutrophils. Chronic arthritis develops in about 10% of patients. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection.

Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a more severe encephalomyelitis caused by *B garinii* is seen and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermittent paresthesias, often in a stocking glove distribution, or radicular pain.

The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is **acrodermatitis chronica atrophicans**. It has been described mainly in Europe after infection with *B afzelii*, a genospecies that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. Cases of diffuse fasciitis with eosinophilia, an entity that resembles scleroderma, have been rarely associated with infection with *B burgdorferi*.

B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The US Surveillance Case Definition specifies a person with **exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.**

Nonspecific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of more than 20 mm/h seen in 50% of cases, and mildly abnormal liver function tests are present in 30%. The abnormal liver function tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000–18,000/mcL) (0.011–0.018/L), and microscopic hematuria have been reported in 10% or less of patients.

Laboratory confirmation requires **serologic tests** to detect specific antibodies to *B burgdorferi* in serum, preferably by ELISA and not by indirect immunofluorescence assay (IFA), which is less sensitive and specific and can cause misdiagnosis. A two-test approach is recommended for the diagnosis of active Lyme disease, with all specimens positive or equivocal by ELISA then confirmed with a Western immunoblot assay that can detect both IgM and IgG antibodies. A positive immunoblot requires that antibodies are detected against two (for IgM) or five (for IgG) specific protein antigens from *B burgdorferi*.

If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. **A fourfold rise in antibody titer would be diagnostic of recent infection.** In patients with later stages of disease, almost all are antibody positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in illness, and antibiotic therapy early in disease can abort subsequent seroconversion.

The diagnosis of late **nervous system Lyme disease** is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Most patients have a history of previous erythema migrans or monarticular or polyarticular arthritis, and the vast majority have antibody present in serum. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal electrophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes; however, the CSF is usually normal and does not demonstrate local antibody production.

Caution should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test, immunofluorescent staining for cell wall-deficient forms of *B burgdorferi*, lymphocyte transformation tests, using PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive result. For these reasons, the CDC has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does *not* require laboratory confirmation. (Tests are often negative at this stage.)
2. Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of monarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [facial palsy], peripheral neuropathy or, rarely, encephalomyelitis—but *not* headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA or IFA followed by Western blot, as described above).

3. Patients with nonspecific symptoms without objective signs of Lyme disease should *not* have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positive tests.
4. The role of serologic testing in nervous system Lyme disease is unclear, as sensitivity and specificity of CSF serologic tests have not been determined. However, it is rare for a patient to have positive serologic tests on CSF without positive tests on serum (see below).
5. Other tests such as the T cell proliferative assay and urinary antigen detection have not yet been studied well enough to be routinely used.

Cultures for *B burgdorferi* can be performed but are not routine and are usually reserved for clinical studies.

PCR is very specific for detecting the presence of *Borrelia* DNA, but sensitivity is variable and depends on which body fluid is tested, the stage of the disease, and collection and testing technique. In general, PCR is more sensitive than culture, especially in chronic disease but is not available in many clinical laboratories. Testing should not be done on blood or urine but has been successfully performed on synovial fluid and CSF. A negative PCR result does not rule out disease.

► Complications

Based on several observational studies, *B burgdorferi* infection in pregnant women has not been associated with congenital syndromes, unlike other spirochetal illnesses such as syphilis.

Some patients and advocacy groups have claimed either a post-Lyme syndrome (in the presence of positive laboratory tests and after appropriate treatment) or “chronic Lyme disease” in which tests may all be negative. Both entities include nonspecific symptoms such as fatigue, myalgias, and cognitive difficulties (see Prognosis below). Expert groups are in agreement that there are no data to support that ongoing infection is the cause of either syndrome.

► Prevention

There is no human vaccine currently available. Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure will greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Prophylactic antibiotics following tick bites is recommended in certain high-risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal *I scapularis* has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with *B burgdorferi*; and

(4) there is no contraindication to the use of doxycycline (not pregnant, age greater than 8 years, not allergic). The medication of choice for prophylaxis is a single 200-mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given and the patient should be closely monitored for early disease, since short course prophylactic therapy with other agents has not been studied, and if early disease does develop, appropriate therapy is very effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days for possible coinfections.

► Coinfections

Lyme disease, **babesiosis** (see Chapter 35), and **human granulocytic anaplasmosis** (formerly human granulocytic ehrlichiosis) (see Chapter 32) are endemic in similar areas of the country and are transmitted by the same tick, *I scapularis*. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not “classic” for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. The complete blood count is usually normal in Lyme disease, but in patients with Lyme disease and babesiosis, anemia and thrombocytopenia are more common. Patients with Lyme disease and anaplasmosis are more likely to have leukopenia. Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.

Even in patients with documented Lyme disease, immunity is not complete. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) who do not develop antibody titers. Clinical manifestations and serologic response is similar to an initial infection.

► Treatment

Present recommendations for therapy are outlined in Table 34–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline is most commonly used and has the advantage of being active against *Anaplasma phagocytophilum* (formerly *Ehrlichia*). Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil, is as effective as doxycycline, but because of its cost it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the medications are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy.

Isolated facial palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 2–3 weeks. Although therapy does

Table 34–4. Treatment of Lyme disease.

Manifestations	Drug and Dosage
Tick bite	No treatment in most circumstances (see text); observe
Erythema migrans	Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 2–3 weeks
Neurologic disease	
Facial palsy (without meningitis)	Doxycycline, amoxicillin, or cefuroxime axetil as above for 2–3 weeks
Other central nervous system disease	Ceftriaxone, 2 g intravenously once daily, or penicillin G, 18–24 million units daily intravenously in six divided doses, or cefotaxime, 2 g intravenously every 8 hours—all for 2–4 weeks
Cardiac disease	
Atrioventricular block and myopericarditis ¹	An oral or parenteral (if more severe disease) regimen as described above can be used
Arthritis	
Oral dosage	Doxycycline, amoxicillin, or cefuroxime axetil as above for 28 days (see text)
Parenteral dosage	Ceftriaxone, cefotaxime, or penicillin G as above for 2–4 weeks
Acrodermatitis chronica atrophicans	Doxycycline, amoxicillin, or cefuroxime axetil as above for 3 weeks
“Chronic Lyme disease” or “post-Lyme disease syndrome”	Symptomatic therapy; prolonged antibiotics are <i>not</i> recommended

¹Symptomatic patients, those with second- or third-degree block and those with first-degree block with a PR interval \geq 300 milliseconds should be hospitalized for observation.

not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some clinicians perform lumbar puncture on all patients with facial palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone is most commonly used, but penicillin is equally efficacious. In European countries, doxycycline 400 mg/d orally for 14 days is frequently used and is comparable in efficacy to ceftriaxone.

Patients with atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 2–3 weeks. Hospitalization and observation is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval of 300 milliseconds or more. Once stabilized,

hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or cefuroxime axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days, and if this fails (persistent or recurrent joint swelling), to re-treat with an oral regimen for 28 days or switch to an intravenous regimen for 2–4 weeks. If arthritis persists after re-treatment, symptomatic therapy with non-steroidal anti-inflammatory drugs is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians may encounter patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks is costly and has been associated with significant adverse effects, including cholelithiasis and *Clostridium difficile* colitis. Parenteral therapy should be reserved for those most likely to benefit, ie, those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

► Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. Prolonged courses of antibiotic therapy for nonspecific symptoms that persist after completion of appropriate assessment (and treatment, if necessary) for Lyme disease is not recommended.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and an inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease.

▶ When to Refer

Consultation with an infectious diseases specialist with experience in diagnosing and treating Lyme disease can be helpful in atypical or prolonged cases.

▶ When to Admit

Admission for parenteral antibiotics is indicated for any patient with symptomatic CNS or cardiac disease as well as

those with second- or third-degree atrioventricular block, or first-degree block with a PR interval of 300 milliseconds or more.

Protozoal & Helminthic Infections

Philip J. Rosenthal, MD

35

PROTOZOAL INFECTIONS

AFRICAN TRYPANOSOMIASIS (Sleeping Sickness)

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to tsetse flies; chancre at bite site uncommon.
- ▶ **Hemolympathic disease:** Irregular fever, headache, joint pain, rash, edema, lymphadenopathy.
- ▶ **Meningoencephalitic disease:** Somnolence, severe headache, progressing to coma.
- ▶ Trypanosomes in blood or lymph node aspirates; positive serologic tests.
- ▶ Trypanosomes and increased white cells and protein in cerebrospinal fluid.

General Considerations

African trypanosomiasis is caused by the hemoflagellates *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*. The organisms are transmitted by bites of tsetse flies (genus *Glossina*), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal develop over 18–35 days in the fly; when the fly feeds again on a mammalian host, the infective stage is injected. Human disease occurs in rural areas of sub-Saharan Africa from south of the Sahara to about 30 degrees south latitude. *T b gambiense* causes West African trypanosomiasis, and is transmitted in the moist sub-Saharan savannas and forests of west and central Africa. *T b rhodesiense* causes East African trypanosomiasis, and is transmitted in the savannas of east and southeast Africa.

T b rhodesiense infection is primarily a zoonosis of game animals and cattle; humans are infected sporadically. Humans are the principal mammalian host for *T b gambiense*, but domestic animals can be infected. The number of reported cases increased from the 1960s to the 1990s and

has since decreased by about 80%. Total incidence has been estimated at about 20,000 cases per year, most of which are due to *T b gambiense*, and the largest number in the Democratic Republic of the Congo. Infections are rare among travelers, including visitors to game parks.

Clinical Findings

A. Symptoms and Signs

1. West African trypanosomiasis—Chancres at the site of the bite are uncommon. After an asymptomatic period that may last for months, **hemolympathic disease** presents with fever, headache, myalgias, arthralgias, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolympathic stage progresses over months to **meningoencephalitic disease**, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

2. East African trypanosomiasis—Chancres at the bite site are more commonly recognized with *T b rhodesiense* infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolympathic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

B. Laboratory Findings

Diagnosis can be difficult, and definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show

motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the **hemolymphatic stage**, detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. **Meningoencephalitic (or second stage) disease** is defined by the World Health Organization (WHO) as cerebrospinal fluid (CSF) showing at least five mononuclear cells per microliter, elevated protein, or presence of trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity for West African disease and can be performed in the field, but the diagnosis should be confirmed by identification of the parasites. Field-applicable immunochromatographic lateral flow rapid diagnostic tests that cost less than CATT and are simpler to perform are available; combining tests improves sensitivity and specificity. Molecular diagnostic tests, including PCR and field-friendly loop-mediated isothermal amplification (LAMP) appear to have excellent sensitivity and specificity, but these are not yet standardized or routinely available.

► Treatment

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of most available therapies. Treatment recommendations depend on the type of trypanosomiasis (Table 35–1), which is determined by geography, and stage of disease, which requires examination of CSF. Eflornithine, nifurtimox, suramin, and melarsoprol are available in the United States from the CDC Drug Service (www.cdc.gov/laboratory/drugservice).

A. West African Trypanosomiasis

1. Early stage infection—Pentamidine (4 mg/kg intramuscularly or intravenously every day or every other day for 7 days) is used to treat infection that does not involve the central nervous system (CNS). The side effects of pentamidine include immediate hypotension; tachycardia; gastrointestinal symptoms during administration; sterile abscesses; and pancreatic (hypoglycemia), liver, and kidney

abnormalities. An alternate drug is eflornithine (100 mg/kg/day intravenously every 6 hours for 14 days).

2. Late stage infection—The treatment of choice for CNS infection is a combination of intravenous eflornithine (400 mg/kg/day in two doses for 7 days) and oral nifurtimox (15 mg/kg/day in three doses for 10 days), which has improved efficacy and less toxicity than older regimens. Eflornithine, though less toxic than older trypanocidal drugs, can cause gastrointestinal symptoms, bone marrow suppression, seizures, and alopecia. The alternative agent is melarsoprol.

B. East African Trypanosomiasis

Pentamidine and eflornithine are not reliably effective, and early disease is treated with suramin. The dosing regimens of suramin vary (eg, 100–200 mg test dose, then 20 mg/kg [maximum 1 g] intravenously on days 1, 3, 7, 14, and 21 or weekly for five doses). Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Suramin does not enter the CNS, so East African trypanosomiasis involving the CNS is treated with melarsoprol (three series of 3.6 mg/kg/day intravenously for 3 days, with 7-day breaks between the series or a 10-day intravenous course with 0.6 mg/kg on day 1, 1.2 mg/kg on day 2, and 1.8 mg/kg on days 3–10). Melarsoprol also acts against West African disease, but eflornithine plus nifurtimox is preferred due to its lower toxicity. Immediate side effects of melarsoprol include fever and gastrointestinal symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered (dexamethasone 1 mg/kg/day intravenously for 2–3 days or oral prednisolone 1 mg/kg/day for 5 days, and then 0.5 mg/kg/day until treatment completion). In addition, increasing resistance to melarsoprol is a serious concern.

► Prevention & Control

Individual prevention in endemic areas should include long sleeves and pants, insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

Table 35–1. Treatment of African trypanosomiasis.

Disease	Stage	Treatment	
		First Line	Alternative
West African	Early	Pentamidine	Suramin Eflornithine
	CNS involvement	Eflornithine + nifurtimox	Melarsoprol
East African	Early CNS involvement	Suramin Melarsoprol	Pentamidine

CNS, central nervous system.

AMERICAN TRYPANOSOMIASIS (Chagas Disease)

ESSENTIALS OF DIAGNOSIS

Acute stage

- ▶ Inflammatory lesion at inoculation site.
- ▶ Fever.
- ▶ Hepatosplenomegaly; lymphadenopathy.
- ▶ Myocarditis.
- ▶ Parasites in blood is diagnostic.

Chronic stage

- ▶ Heart failure, cardiac arrhythmias.
- ▶ Thromboembolism.
- ▶ Megaesophagus; megacolon.
- ▶ Serologic tests are usually diagnostic.

▶ General Considerations

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite found only in the Americas; it infects wild animals and to a lesser extent humans from southern South America to the southern United States. An estimated 8–10 million people are infected, mostly in rural areas. Control efforts in endemic countries have decreased disease incidence to about 40,000 new infections and 12,500 deaths per year. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. In the United States, the vector is found, some animals are infected, and a few instances of local transmission have been reported.

T. cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion, organ or bone marrow transplantation, congenital transfer, or ingestion of food contaminated with vector feces. From the bloodstream, *T. cruzi* invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

▶ Clinical Findings

A. Symptoms and Signs

As many as 70% of infected persons remain asymptomatic. The **acute stage** is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Romaña sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy).

Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

An asymptomatic **latent period (indeterminate phase)** may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

Chronic Chagas disease generally manifests as abnormalities in cardiac and smooth muscle. Cardiac disease includes arrhythmias, heart failure, and embolic disease. Smooth muscle abnormalities lead to mega esophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including AIDS patients and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses and meningoencephalitis.

B. Diagnostic Testing

The diagnosis is made by detecting parasites in persons with suggestive findings who have resided in an endemic area. With **acute infection**, evaluation of fresh blood or buffy coats may show motile trypanosomes, and fixed preparations may show Giemsa-stained parasites. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. PCR is highly sensitive, and can be used to detect parasites in organ transplant recipients or after accidental exposure. When initial tests are unrevealing, xenodiagnosis using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

Chronic Chagas disease is usually diagnosed serologically. Many different serologic assays are available, but sensitivity and specificity are not ideal; confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. The diagnosis of chronic disease with PCR remains suboptimal.

▶ Treatment

Treatment is inadequate because the two drugs used, benznidazole and nifurtimox, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, but cure is achieved in only about 70% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of the disease. In a recent trial for Chagas cardiomyopathy, benznidazole significantly reduced parasite detection but not progression of cardiac disease. Nevertheless, there is general consensus that treatment should be considered in all *T. cruzi*-infected persons regardless of clinical status or time since infection. In particular, treatment is recommended for acute, congenital, and reactivated infections and for children and young adults with chronic disease. Both benznidazole and nifurtimox are available in the United States from the CDC Drug Service (www.cdc.gov/laboratory/drugservice).

Benznidazole is generally preferred due to better efficacy and safety profiles. It is given orally at a dosage of 5 mg/kg/day in two divided doses for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. Nifurtimox is given orally in daily doses of 8–10 mg/kg in four divided doses after meals for 90–120 days. Side effects include gastrointestinal (anorexia, vomiting) and neurologic (headaches, ataxia, insomnia, seizures) symptoms, which appear to be reversible and to lessen with dosage reduction. Patients with chronic Chagas disease may also benefit from antiarrhythmic therapy, standard therapy for heart failure, and conservative and surgical management of megacolon and megacolon.

▶ Prevention & Control

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides and pyrethroid-impregnated bed curtains, and screening of blood donors has achieved striking reductions in new infections. In endemic areas and ideally in donors from endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative.

LEISHMANIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Sand fly bite in an endemic area.
- ▶ **Visceral leishmaniasis:** irregular fever, progressive hepatosplenomegaly, pancytopenia, wasting.
- ▶ **Cutaneous leishmaniasis:** chronic, painless, moist ulcers or dry nodules.
- ▶ **Mucocutaneous leishmaniasis:** destructive nasopharyngeal lesions.
- ▶ Amastigotes in macrophages in aspirates, touch preparations, or biopsies.
- ▶ Positive culture, serologic tests, PCR, or skin test.

▶ General Considerations

Leishmaniasis is a zoonosis transmitted by bites of sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. Leishmaniasis is caused by about 20 species of *Leishmania*;

taxonomy is complex. Clinical syndromes are generally dictated by the infecting species, but some species can cause more than one syndrome.

An estimated 350 million persons are at risk for leishmaniasis. The estimated annual incidence of disease is 1–1.5 million new cases of cutaneous and 400,000 cases of visceral disease, leading to an estimated 40,000 deaths.

Visceral leishmaniasis (kala azar) is caused mainly by *Leishmania donovani* in the Indian subcontinent and East Africa; *Leishmania infantum* in the Mediterranean, Middle East, China, parts of Asia, and Horn of Africa; and *Leishmania chagasi* in South and Central America. Other species may occasionally cause visceral disease. Over 90% of cases occur in five countries: India, Bangladesh, Nepal, Sudan, and Brazil. In each locale, the disease has particular clinical and epidemiologic features. The incubation period is usually 4–6 months (range: 10 days to 24 months). Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduces mortality to 2–5%.

Old World cutaneous leishmaniasis is caused mainly by *Leishmania tropica*, *Leishmania major*, and *Leishmania aethiops* in the Mediterranean, Middle East, Africa, Central Asia, and Indian subcontinent. **New World cutaneous leishmaniasis** is caused by *Leishmania mexicana*, *Leishmania amazonensis*, and the species listed below for mucocutaneous disease in Central and South America. **Mucocutaneous leishmaniasis** (espundia) occurs in lowland forest areas of the Americas and is caused by *Leishmania braziliensis*, *Leishmania panamensis*, and *Leishmania peruviana*.

▶ Clinical Findings

A. Symptoms and Signs

1. Visceral leishmaniasis (kala azar)—Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, sweats, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar (“black fever”). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs, often due to secondary infections, within months to a few years. **Post-kala azar dermal leishmaniasis** may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules developing on preexisting lesions. **Viscerotropic leishmaniasis** has been reported in small numbers of American military personnel in the Middle East, with mild systemic febrile illnesses after *L. tropica* infections.

2. Old World and New World cutaneous leishmaniasis—Cutaneous swellings appear 2 weeks to several months after sand fly bites and can be single or multiple. Characteristics

▲ **Figure 35-1.** Skin ulcer due to cutaneous leishmaniasis. (From D. S. Martin, Public Health Image Library, CDC.)

of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Figure 35-1). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is common.

Leishmaniasis recidivans is a relapsing form of *L. tropica* infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. **Diffuse cutaneous leishmaniasis** involves spread from a central lesion to local dissemination of nodules and a protracted course. **Disseminated cutaneous leishmaniasis** involves multiple nodular or ulcerated lesions, often with mucosal involvement.

3. Mucocutaneous leishmaniasis (espundia)—In Latin America, mucosal lesions develop in a small percentage of persons infected with *L. braziliensis* and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common.

4. Infections in patients with AIDS—Leishmaniasis is an opportunistic infection in persons with AIDS. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

B. Laboratory Findings

Identifying amastigotes within macrophages in tissue samples provides a definitive diagnosis. In **visceral leishmaniasis**, fine-needle aspiration of the spleen for culture and

tissue evaluation is generally safe, and yields a diagnosis in over 95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases, and Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. PCR can also identify the infection. Serologic tests may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone. Numerous antibody-based rapid diagnostic tests are available; these have shown good specificity but limitations in sensitivity outside of India. For **cutaneous lesions**, biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States. In **mucocutaneous leishmaniasis**, diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

► Treatment

A. Visceral Leishmaniasis

The treatment of choice for visceral leishmaniasis is liposomal amphotericin B (approved by the FDA), which is generally effective and well tolerated but expensive. Standard dosing is 3 mg/kg/day intravenously on days 1-5, 14, and 21. Simpler regimens that have shown good efficacy in India include four doses of 5 mg/kg over 4-10 days and a single dose of 15 mg/kg, but efficacy appears to be lower in Africa. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow intravenous infusion of 1 mg/kg/day for 15-20 days or 0.5-1 mg/kg every second day for up to 8 weeks. A single infusion of an amphotericin B lipid emulsion, which is more affordable than liposomal preparations, showed excellent efficacy, albeit lower than that of the liposomal formulation. Infusion-related side effects with conventional or liposomal amphotericin B include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity.

Pentavalent antimonials remain the most commonly used drugs to treat leishmaniasis in most areas. Response rates are good outside India, but in India, resistance is a major problem. Two preparations are available, sodium stibogluconate in the United States and many other areas and meglumine antimonate in Latin America and francophone countries; the compounds appear to have comparable activities. In the United States, sodium stibogluconate can be obtained from the CDC Drug Service (www.cdc.gov/laboratory/drugservice).

Treatment with either antimonial is given once daily at a dose of 20 mg/kg/day intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and

28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of gastrointestinal symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

Miltefosine is the first oral drug for the treatment of leishmaniasis, and it is registered in India for this indication. It has demonstrated excellent results in India, but after over a decade of use, efficacy may be decreasing. It can be administered at a daily oral dose of 2.5 mg/kg in two divided doses for 28 days. A 28-day course of miltefosine (2.5 mg/kg/day) is also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects.

The aminoglycoside paromomycin (11 mg/kg/day intramuscularly for 21 days) was shown to be similarly efficacious to amphotericin B for the treatment of visceral disease in India, where it is approved for this indication. It is much less expensive than liposomal amphotericin B or miltefosine. Paromomycin has shown relatively poor efficacy in Africa. The drug is well tolerated; side effects include ototoxicity and reversible elevations in liver enzymes.

The use of drug combinations to improve treatment efficacy, shorten treatment courses, and reduce the selection of resistant parasites has been actively studied. In India, compared to a standard 30-day (treatment on alternate days) course of amphotericin, noninferior efficacy and decreased adverse events were seen with a single dose of liposomal amphotericin plus a 7-day course of miltefosine, a single dose of liposomal amphotericin plus a 10-day course of paromomycin, or a 10-day course of miltefosine plus paromomycin. In East Africa, compared to a standard 30-day course of sodium stibogluconate, similar efficacy was seen with a 17-day course of sodium stibogluconate plus paromomycin.

B. Cutaneous Leishmaniasis

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted. Standard therapy is with pentavalent antimonials for 20 days, as described above. Other treatments include those discussed above for visceral disease, azole antifungals, and allopurinol. In studies in South America, a 28-day course of miltefosine was superior to a 20-day course of meglumine antimoniate, and oral fluconazole also showed good efficacy. Topical therapy has included intralesional antimony, intralesional pentamidine, paromomycin ointment, cryotherapy, local heat, and surgical removal. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

C. Mucocutaneous Leishmaniasis

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L. braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

► Prevention & Control

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

MALARIA

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to anopheline mosquitoes in a malaria-endemic area.
- ▶ Intermittent attacks of chills, fever, and sweating.
- ▶ Headache, myalgia, vomiting, splenomegaly; anemia, thrombocytopenia.
- ▶ Intraerythrocytic parasites identified in thick or thin blood smears.
- ▶ **Complications of falciparum malaria:** cerebral malaria, severe anemia, hypotension, pulmonary edema, acute kidney injury, hypoglycemia, acidosis, and hemolysis.

General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and hundreds of thousands of deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where most deaths from malaria are in young children. Malaria is also common in travelers from nonendemic areas to the tropics.

Four species of the genus *Plasmodium* classically cause human malaria. *Plasmodium falciparum* is responsible for nearly all severe disease. It is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P falciparum*, except in Africa. *P vivax* uncommonly causes severe disease, although this outcome may be more common than previously appreciated. *Plasmodium ovale* and *Plasmodium malariae* are much less common causes of disease, and generally do not cause severe illness. *Plasmodium knowlesi*, a parasite of macaque monkeys, is now recognized to cause occasional illnesses, including some severe disease, in humans in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection. Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites also develop into sexual gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother to infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In *P vivax* and *P ovale*, parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections. For all plasmodial species, parasites may recrudescence following initial clinical improvement after suboptimal therapy.

In highly endemic regions, where people are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, young children, who are relatively nonimmune, are at high risk for severe disease from *P falciparum* infection, and this population is responsible for most deaths from malaria. Pregnant women are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

Clinical Findings

A. Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour (*P vivax* and *P ovale*) or 72-hour (*P malariae*) cycles, especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is characterized by signs of severe illness, organ dysfunction, or a high parasite load (peripheral parasitemia greater than 5% or greater than 200,000 parasites/mL). It is principally a result of *P falciparum* infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen.

Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe hemolysis; hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria and severe anemia. Cerebral malaria is a consequence of a single severe infection while severe anemia follows multiple malarial infections, intestinal helminths, and nutritional deficiencies. In a large trial of African children, acidosis, impaired consciousness, convulsions, renal impairment, and underlying chronic illness were associated with poor outcome.

Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P malariae* infection, immune complex glomerulopathy with nephrotic syndrome. HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

▲ **Figure 35–2.** Thin film Giemsa-stained micrograph with *Plasmodium falciparum* ring forms. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

B. Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis (Figures 35–2 through 35–5), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals, although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears at 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially greater than 10–20% of erythrocytes infected or greater than 200,000–500,000 parasites/mcL) or the presence of malarial pigment (a breakdown product of hemoglobin) in more than 5% of neutrophils is associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple “dipstick” format. These tests are not well standardized but are

▲ **Figure 35–3.** Thin film Giemsa-stained micrograph with *Plasmodium malariae* trophozoite. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

▲ **Figure 35–4.** Thin film Giemsa-stained micrograph with *Plasmodium vivax* schizont. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

widely available. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR and related molecular tests (eg, LAMP) are highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are of uncertain significance and not routinely treated, are common.

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

▶ Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after

▲ **Figure 35–5.** Thin film Giemsa-stained micrograph with *Plasmodium ovale* trophozoite. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

Table 35–2. Major antimalarial drugs.

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine ¹	4-Aminoquinoline	Treatment of <i>Plasmodium falciparum</i> , optimally in fixed combination with artesunate
Piperaquine ¹	4-Aminoquinoline	Treatment of <i>P falciparum</i> in fixed combination with dihydroartemisinin
Quinine	Quinoline methanol	Oral and intravenous ¹ (for severe infections) treatment of <i>P falciparum</i>
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> ; alternative for malaria chemoprophylaxis
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of <i>P falciparum</i> , optimally in combination with artesunate; intermittent preventive therapy
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine ¹	Phenanthrene methanol	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Lumefantrine	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Pyronaridine	Benzonaphthridine	Treatment of <i>P falciparum</i> malaria in fixed combination artesunate
Artemisinins (Artesunate, artemether, dihydroartemisinin)	Sesquiterpene lactone endoperoxides	Treatment of <i>P falciparum</i> in oral combination regimens for uncomplicated disease and parenterally for severe malaria

¹Not available in the United States.

Modified, with permission, from Katzung BG. *Basic & Clinical Pharmacology*. 11th edition. McGraw-Hill, 2009.

return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in non-immune individuals.

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

A. Non-Falciparum Malaria

The first-line drug for non-falciparum malaria from most areas remains chloroquine. Due to increasing resistance of *P vivax* to chloroquine, alternative therapies are recommended when resistance is suspected, particularly for infections acquired in Indonesia, Oceania, and South America. These infections can be treated with artemisinin-based combination therapies (ACTs) or other first-line regimens for *P falciparum* infections as discussed below. For *P vivax* or *P ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase [G6PD] deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated. Tafenoquine, which is related to primaquine, appears to offer similar efficacy with simpler dosing, but it also engenders

potential toxicity in those with G6PD deficiency, and it remains under study. *P malariae* infections need only be treated with chloroquine.

B. Uncomplicated Falciparum Malaria

P falciparum is resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the exceptions of Central America west of the Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding chemoprophylaxis should follow the same geographic considerations.

ACTs, all including a short-acting artemisinin and longer-acting partner drug, are first-line therapies in nearly all endemic countries. The WHO recommends six ACTs to treat falciparum malaria (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Quinine generally remains effective for falciparum malaria, but it must be taken for an extended period to cure disease and is poorly tolerated, and should best be reserved for the treatment of severe malaria and for treatment after another regimen has failed (Table 35–4).

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be

Table 35–3. WHO recommendations for the treatment of uncomplicated falciparum malaria.

Regimen	Notes
Artemether-lumefantrine (Coartem, Riamet)	Coformulated, first-line therapy in many countries. Approved in the United States.
Artesunate-amodiaquine (ASAQ)	Coformulated, first-line therapy in multiple African countries.
Artesunate-mefloquine	First-line therapy in parts of Southeast Asia and South America but efficacy decreasing in parts of Thailand.
Artesunate-pyronaridine	Coformulated. Most recently approved regimen; used in some Southeast Asian countries.
Artesunate-sulfadoxine-pyrimethamine	First-line in some countries, but efficacy lower than other regimens in most areas.
Dihydroartemisinin-piperaquine	Coformulated. First-line in some Southeast Asian countries but efficacy decreasing in parts of Cambodia.

World Health Organization: Guidelines for the Treatment of Malaria. World Health Organization. Geneva 2010. ISBN 978 92 4 154792 5.

admitted to the hospital due to risks of rapid progression of disease. A number of options are available for the treatment of uncomplicated falciparum malaria in the United States (Table 35–4).

C. Severe Malaria

Severe malaria is a medical emergency. Parenteral treatment is indicated for severe malaria, as defined above, and with inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals.

The standard of care for severe malaria is intravenous artesunate, which has demonstrated superior efficacy and better tolerability than quinine. In the United States, intravenous artesunate is available on an investigational basis through the CDC (for enrollment call 770-488-7788); if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinine (available in most countries but not the United States) or quinidine (available in the United States). In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective. Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia.

Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and hemofiltration or hemodialysis. With high parasitemia (greater than 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated, and it is generally no longer recommended.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine remains the drug of choice for the treatment of sensitive *P falciparum* and other species of malaria parasites (Table 35–4). Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so must be used with primaquine to eradicate *P vivax* and *P ovale* infections. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal, Mexico, and Hispaniola. Chloroquine-resistant *P vivax* has been reported from a number of areas, most notably Southeast Asia and Oceania.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events.

2. Amodiaquine, piperaquine, and pyronaridine

Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and artesunate-amodiaquine is one of the standard ACTs recommended to treat falciparum malaria (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that was previously heavily used in China and has been coformulated with dihydroartemisinin in an ACT. Piperaquine appears to be well tolerated and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum and vivax malaria. Due to the long half-life of piperaquine (~3 weeks), dihydroartemisinin-piperaquine offers the longest period of posttreatment prophylaxis of available ACTs. However, resistance to piperaquine appears to be emerging in southeast Asia, threatening the efficacy of dihydroartemisinin-piperaquine against *P falciparum*.

Pyronaridine is a benzonaphthyridine that was also previously used as a monotherapy to treat malaria in China.

Table 35–4. Treatment of malaria.

Clinical Setting	Drug Therapy ¹	Alternative Drugs
Chloroquine-sensitive <i>Plasmodium falciparum</i> and <i>Plasmodium malariae</i> infections	Chloroquine phosphate, 1 g at 0, followed by 500 mg at 6, 24, and 48 hours or— Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours	
<i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections	Chloroquine (as above), then (if G6PD normal) primaquine, 30 mg base daily for 14 days	For infections from Indonesia, Papua New Guinea, and other areas with suspected resistance: therapies listed for uncomplicated chloroquine-resistant <i>P falciparum</i> plus primaquine
Uncomplicated infections with chloroquine-resistant <i>P falciparum</i>	Coartem (artemether 20 mg, lumefantrine 120 mg), four tablets twice daily for 3 days or— Malarone, four tablets (total of 1 g atovaquone, 400 mg proguanil) daily for 3 days or— Quinine sulfate, 650 mg three times daily for 3–7 days Plus one of the following (when quinine given for < 7 days) Doxycycline, 100 mg twice daily for 7 days or— Clindamycin, 600 mg twice daily for 7 days	Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours or— Dihydroartemisinin-piperazine ² (dihydroartemisinin 40 mg, piperazine 320 mg), 4 tablets daily for 3 days or— ASAQ ² (artesunate 100 mg, amodiaquine 270 mg), two tablets daily for 3 days
Severe or complicated infections with <i>P falciparum</i>	Artesunate 2.4 mg/kg intravenously every 12 hours for 1 day, then daily ^{3,6}	Quinidine gluconate, ^{4–6} 10 mg/kg intravenously over 1–2 hours, then 0.02 mg/kg intravenously/min or— Quinidine gluconate, ^{4–6} 15 mg/kg intravenously over 4 hours, then 7.5 mg/kg intravenously over 4 hours every 8 hours or— Quinine dihydrochloride, ^{2,4–6} 20 mg/kg intravenously over 4 hours, then 10 mg/kg intravenously every 8 hours or— Artemether, ^{2,6} 3.2 mg/kg intramuscularly, then 1.6 mg/kg/day intramuscularly

¹All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See Centers for Disease Control and Prevention’s guidelines (phone: 877-FYI-TRIP; <http://www.cdc.gov/malaria/>) for additional information and pediatric dosing.

²Not available in the United States.

³Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

⁴Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.

⁵Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

⁶With all parenteral regimens, change to an oral regimen as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.

The medication acts against many drug-resistant strains of *P falciparum*, although resistance has been reported. The combination of artesunate plus pyronaridine has been well-tolerated and has shown excellent efficacy against *falciparum* and *vivax* malaria.

3. Mefloquine—Mefloquine is effective against many chloroquine-resistant strains of *P falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically

from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand).

For treatment of uncomplicated malaria, mefloquine can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate in Southeast Asia, where resistance to mefloquine has been seen but the combination remains effective in most areas. It should be taken with meals and swallowed with a large amount of water. Mefloquine is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no

chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash and, uncommonly, seizures and psychosis. There is an FDA black box warning about neuropsychiatric toxicity, including possibly rare, irreversible effects. Mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if these drugs are used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

4. Quinine and quinidine—Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy (Table 35–4). Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria.

Resistance of *P falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is the standard of care. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to an oral agent as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is an alternative first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (usually to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe

infections and in pregnant patients, who have increased sensitivity to insulin. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, but dangerous arrhythmias are uncommon when the drugs are administered appropriately. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine.

5. Primaquine—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale* (Table 35–4). Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or quinine. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes.

For *P vivax* and *P ovale* infections, chloroquine or other drugs are used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine (52.6 mg primaquine phosphate [30 mg base] daily) is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of *P vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine, and the drug may fail to eradicate liver forms.

Standard chemoprophylaxis does not prevent a relapse of *P vivax* or *P ovale* infections, since liver hypnozoites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area. Primaquine can also be used for chemoprophylaxis to prevent *P falciparum* and *P vivax* infection in persons with normal levels of G6PD.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. When a patient is deficient in G6PD, treatment strategies may consist of (1) withholding therapy and treating subsequent relapses, if they occur, with chloroquine; (2) treating patients with standard dosing, paying close attention to their hematologic status; or (3) treating with weekly primaquine (45 mg base) for 8 weeks. G6PD-deficient individuals of Mediterranean and Asian ancestry are most likely to have severe deficiency, while those of African ancestry usually have a milder biochemical defect. This difference can be taken into consideration in choosing a treatment strategy. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

6. Inhibitors of folate synthesis—Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS),

are used, generally in combination regimens, for the treatment and prevention of malaria, although the drugs are rather slow acting and now limited by resistance.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). The long half-lives of its components allow weekly dosing for chemoprophylaxis, but due to rare serious side effects with long-term dosing, this drug is no longer recommended for this purpose. For treatment, advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance is now a major problem.

Sulfadoxine-pyrimethamine is a component of two combination regimens for uncomplicated malaria recommended by the WHO (Table 35–3). Sulfadoxine-pyrimethamine plus artesunate has shown efficacy in some areas but is best replaced by more effective combination regimens in most areas. Amodiaquine plus sulfadoxine-pyrimethamine has shown quite good efficacy in Africa, despite increasing resistance to both components. It is recommended monthly during the rainy season for chemoprophylaxis in regions with seasonal malaria transmission and limited drug resistance. Another antifolate combination, trimethoprim-sulfamethoxazole (TMP-SMZ), is widely used to prevent coinfections in patients infected with HIV, and it offers partial protection against malaria.

7. Artemisinins—Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used for various indications in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. The WHO encourages availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. Of concern, delayed clearance of parasites and some clinical failures have been seen after treatment with artesunate in parts of Southeast Asia, heralding the emergence of artemisinin resistance in this region.

Artemisinins are playing an increasing role in the treatment of malaria, including multidrug-resistant *P. falciparum* malaria. However, due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, leading to use in conjunction with another agent. Also because of their short-half lives, they are not useful in chemoprophylaxis.

The ACTs that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product. Another ACT, artesunate plus mefloquine is used mostly outside of Africa; its efficacy may be declining in parts of Asia. Dihydroartemisinin-piperaquine is a newer ACT that has shown excellent efficacy and is the first-line regimen in some countries in Southeast Asia, but recent studies have shown declining efficacy in Cambodia. The newest ACT, artesunate-pyronaridine, is approved in Cambodia.

In studies of severe malaria, intramuscular artemether was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in

terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is available, although parenteral quinine and quinidine remain acceptable alternatives. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins are very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Neutropenia, anemia, hemolysis, and elevated levels of liver enzymes have been noted rarely. Hemolysis may occur weeks after therapy with intravenous artesunate. Artemisinins are teratogenic in animals, and they should be avoided in the first trimester of pregnancy for uncomplicated malaria. However, for severe malaria, for which all available treatments entail some risk, the WHO endorses the use of intravenous artesunate or quinine while additional data are gathered on artesunate safety.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and the antifolate proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States (Table 35–4). It also appears to be active against other species of malaria parasites. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter durations of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.

Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs (Table 35–4). Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation.

Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women (Table 35–4). The most common toxicities with clindamycin are gastrointestinal.

10. Halofantrine and lumefantrine—Halofantrine, a phenanthrene-methanol related to quinine, is effective against erythrocytic stages of all four human malaria species, but it is rarely used due to toxicity concerns.

Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riamet). Oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it requires twice-daily dosing. Despite this limitation, due to its reliable efficacy against falciparum malaria, Coartem is the first-line therapy for malaria in many malarious countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not generally cause QT prolongation or the serious cardiac toxicity seen with halofantrine.

▶ Prevention

Malaria is transmitted by night-biting anopheline mosquitoes. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, and improvement in mortality rates has been demonstrated. Extensive efforts are also underway to develop a malaria vaccine, and partial protection of African children has been demonstrated with the RTS,S vaccine, which is under development, but a vaccine offering a high level of protection is not anticipated in the near future. The availability of improved modalities to control mosquito

vectors and treat and prevent malaria has heightened enthusiasm for malaria elimination, and there have been important gains in some areas; however, control remains very challenging in highly endemic regions, and elimination is not expected in these areas in the foreseeable future.

When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov; 877-FYI-TRIP). Recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone for most other malarious areas, and doxycycline for areas with a high prevalence of multidrug-resistant falciparum malaria (principally parts of Southeast Asia) (Table 35–5). Recommendations should be checked regularly because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include ACTs, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Table 35–5. Drugs for the prevention of malaria in travelers.¹

Drug	Use ²	Adult Dosage (all oral) ³
Chloroquine	Areas without resistant <i>Plasmodium falciparum</i>	500 mg weekly
Malarone	Areas with multidrug-resistant <i>P falciparum</i>	1 tablet (250 mg atovaquone/100 mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant <i>P falciparum</i>	250 mg weekly
Doxycycline	Areas with multidrug-resistant <i>P falciparum</i>	100 mg daily
Primaquine ⁴	Terminal prophylaxis of <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections; alternative for <i>P falciparum</i> prophylaxis	30 mg base daily for 14 days after travel

¹Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see Centers for Disease Control and Prevention's guidelines (phone: 800-CDC-INFO; <http://wwwnc.cdc.gov/travel/>). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.

²Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

³For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.

⁴Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.

Reproduced, with permission, from Katzung BG. *Basic & Clinical Pharmacology*. 11th edition. McGraw-Hill, 2009.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, intermittent preventive therapy, whereby at-risk populations (in particular pregnant women and children) receive antimalarial therapy at set intervals, is of increasing interest. This strategy may decrease the incidence of malaria while allowing antimalarial immunity to develop. During pregnancy, intermittent preventive therapy with sulfadoxine-pyrimethamine, provided once during both the second and third trimesters, has improved pregnancy outcomes. In infants, therapy with sulfadoxine-pyrimethamine following standard immunization schedules has offered benefits. With increasing resistance the preventive efficacy of sulfadoxine-pyrimethamine is likely falling, and the long-acting ACT dihydroartemisinin-piperaquine is a promising replacement. In areas with seasonal malaria transmission and limited drug resistance, principally the Sahel sub-region of West Africa, the policy is to administer amodiaquine and sulfadoxine-pyrimethamine to children monthly during the transmission season.

▶ Prognosis

When treated appropriately, uncomplicated malaria generally responds well, with resolution of fevers within 1–2 days and a mortality of about 0.1%. Severe malaria can commonly progress to death, but many children respond well to therapy. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Pregnant women are at particular risk during their first pregnancy. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

▶ When to Refer

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for falciparum malaria; referral should not delay initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

▶ When to Admit

- Admission for non-falciparum malaria is only warranted if specific problems that require hospital management are present.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

BABESIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ History of tick bite or exposure to ticks.
- ▶ Fever, flu-like symptoms, anemia.
- ▶ Intraerythrocytic parasites on Giemsa-stained blood smears.
- ▶ Positive serologic tests.

▶ General Considerations

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild mammals. Most babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. The incidence of the disease appears to be increasing in some areas. Babesiosis is caused by *Babesia divergens* in Europe and by *Babesia venatorum* in China. Rare episodes of illnesses caused by other *Babesia*-like organisms have been reported from other areas. Babesiosis can also be transmitted by blood transfusion.

Clinical Findings

A. Symptoms and Signs

Serosurveys suggest that asymptomatic infections are common in endemic areas. With *B microti* infections, symptoms appear 1 to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and acute kidney injury, with death rates over 40%.

B. Laboratory Findings

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis (Figure 35–6). These can be confused with malaria parasites, but the morphology is distinctive. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. An indirect immunofluorescent antibody test for *B microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months. Diagnosis can also be made by PCR or by inoculation of hamsters or gerbils.

▲ **Figure 35–6.** Blood smear showing *Babesia* spp. rings with basophilic stippling. (From Dr. Mae Melvin, Public Health Image Library, CDC.)

Treatment

Most patients have a mild illness and recover without therapy. Standard therapy for mild to moderate disease is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily), which is equally effective and better tolerated than the alternative regimen, a 7-day course of quinine (650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). However, there is more experience using quinine plus clindamycin, and this regimen is recommended for severe disease. Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia greater than 10%.

TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.

Primary infection

- ▶ Fever, malaise, headache, sore throat.
- ▶ Lymphadenopathy.
- ▶ Positive IgG and IgM serologic tests.

Congenital infection

- ▶ Follows acute infection of seronegative mothers and leads to CNS abnormalities and retinochoroiditis.

Infection in immunocompromised persons

- ▶ Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
- ▶ Positive IgG but negative IgM serologic tests.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of mammals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to 20–30% or less, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80%. In the United States, *T gondii* is estimated to infect 1.1 million persons each year, with resultant chorioretinitis developing in 21,000 and vision loss in 4800.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. Primary infection in the immunocompetent person—

After ingestion, *T gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.

2. Congenital infection—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Neurologic findings can include seizures, psychomotor retardation, deafness, and hydrocephalus. Retinochoroiditis and other sight-threatening eye lesions may develop. Systemic findings include fever or hypothermia, jaundice, vomiting, diarrhea, hepatosplenomegaly, pneumonitis, myocarditis, and rash. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life. Hepatosplenomegaly and lymphadenopathy may develop in the first few months of life; CNS and eye disease often present later. The most common late presentation of congenital toxoplasmosis is retinochoroiditis.

3. Retinochoroiditis—This manifestation of congenital toxoplasmosis presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis also is seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. Disease in the immunocompromised person—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. In patients with

advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or, more rarely, transmission of infection. Reactivation also can occur in those with hematologic malignancies or treated with immunosuppressive drugs. With primary or reactivated disease in those with immunodeficiency due to malignancy or immunosuppressive drugs, toxoplasmosis is similar to that in individuals with AIDS, but pneumonitis and myocarditis are more common.

B. Diagnostic Testing

1. Identification of parasites—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. Serologic diagnosis—Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection, and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. During pregnancy and in newborns—Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. The pattern of positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is

needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease; this test should optimally be performed at 18 weeks of gestation. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant. Organisms may be identified by PCR; smears; or culture of blood, CSF, or tissue.

4. In immunocompetent individuals—Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer greater than 1:64 are suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunodeficient individuals—A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculosis, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, funduscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

▶ Treatment

A. Approach to Treatment

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month. Immunocompromised patients with active infection must be treated. For those with transient immunodeficiency,

therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

B. Medications

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200 mg loading dose, then 50–75 mg [1 mg/kg] orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folinic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative is clindamycin (600 mg orally four times daily) replacing sulfadiazine as the standard therapy regimen. Another alternative is replacement of sulfadiazine with TMP-SMZ. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for acute toxoplasmosis during pregnancy is spiramycin (1 g orally three times daily until delivery) to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

▶ Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. Irradiation, cooking to 66°C, or freezing to –20°C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For hematopoietic cell transplant recipients and advanced AIDS patients, chemoprophylaxis with TMP-SMZ (one double-strength tablet daily or two tablets three times weekly), used for protection against *Pneumocystis*, is effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

AMEBIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Organisms or antigen present in stools or abscess aspirate.
- ▶ Positive serologic tests with colitis or hepatic abscess, but these may represent prior infections.
- ▶ Mild to moderate colitis with recurrent diarrhea.
- ▶ Severe colitis including bloody diarrhea, fever, and abdominal pain, with potential progression to hemorrhage or perforation.
- ▶ Hepatic abscess with fever, hepatomegaly, and abdominal pain.

General Considerations

The *Entamoeba* complex contains three morphologically identical species: *Entamoeba dispar* and *Entamoeba moshkovskii*, which are avirulent, and *Entamoeba histolytica*, which may be an avirulent intestinal commensal or lead to serious disease. Disease follows penetration of the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery or extraintestinal disease, most commonly liver abscess.

E histolytica infections are present worldwide but are most prevalent in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Of the estimated 500 million persons worldwide infected with *Entamoeba*, most are infected with *E dispar* and an estimated 10% with *E histolytica*. The prevalence of *E moshkovskii* is unknown. Mortality from invasive *E histolytica* infections is estimated at 100,000 per year.

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

Clinical Findings

A. Symptoms and Signs

1. Intestinal amebiasis—In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea may begin within a week of infection, although an incubation period of 2–4 weeks is more common, with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days to weeks or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with more extensive diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

2. Extraintestinal amebiasis—The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

C. Diagnostic Testing

Diagnosis is by finding *E histolytica* or its antigen or by serologic tests. However, each method has limitations.

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. A commercially available stool antigen test (TechLab II) offers improved sensitivity (more than 90% for colitis); it requires fresh or frozen (not preserved) stool specimens. PCR-based tests are available but not used routinely. Colonoscopy of uncleaned bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling inflammatory bowel disease (Figure 35–7). Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

2. Hepatic abscess—Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The TechLab II antigen test can be used to test serum, with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative; the antigen test is positive in ~40% of cases. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage

leading to peritonitis from amebas or other (pyogenic or echinococcal) organisms.

D. Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

▶ Treatment

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 35–6). Asymptomatic infection with *E dispar* does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but with negative serology *E dispar* colonization is likely, and treatment is not indicated. Colonization with *E histolytica* is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30 mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Treatment of intestinal amebiasis requires metronidazole (750 mg orally three times daily for 10 days) or tinidazole (2 g orally once daily for 3 days for mild disease and 5 days for serious disease) plus a luminal agent (Table 35–6). Metronidazole has most commonly been used in the United States, but tinidazole offers simpler dosing and less side effects. Metronidazole often induces transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is coingested. Metronidazole should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Alternatives for the treatment of intestinal amebiasis are tetracycline (250–500 mg orally four times daily for 10 days) plus chloroquine (500 mg orally daily for 7 days). Emetine or dehydroemetine, which are not available in the United States, can be given subcutaneously or intramuscularly in a dose of 1–1.5 mg/kg/day; the maximum daily dose is 90 mg for dehydroemetine and 65 mg for emetine). These agents are effective but cardiotoxic with a narrow therapeutic range and should be used only until severe disease is controlled. They cause nausea, vomiting, and pain at the injection site.

▲ **Figure 35–7.** Gross pathology showing intestinal ulcers due to amebiasis. (From Dr. Mae Melvin, Public Health Image Library, CDC.)

Table 35–6. Treatment of amebiasis.¹

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate, ² 500 mg orally three times daily for 10 days or– Iodoquinol, 650 mg orally three times daily for 21 days or– Paromomycin, 10 mg/kg orally three times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or– Tinidazole, 2 g orally daily for 3 days plus– Luminal agent (see above)	Luminal agent (see above) plus either– Tetracycline, 250 mg orally three times daily for 10 days or– Erythromycin, 500 mg orally four times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or– Tinidazole, 2 g orally daily for 3 days plus– Luminal agent (see above)	Luminal agent (see above) plus either– Tetracycline, 250 mg orally three times daily for 10 days or– Dehydroemetine ² or emetine, ² 1 mg/kg subcutaneously or intramuscularly for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or– Tinidazole, 2 g orally daily for 3 days plus– Luminal agent (see above)	Dehydroemetine ² or emetine, ² 1 mg/kg subcutaneously or intramuscularly for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg orally twice daily for 2 days, then 500 mg daily for 21 days plus– Luminal agent (see above)

¹See text for additional details and cautions.

²Not available in the United States.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

▶ Prevention & Control

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of food; protection of food from fly contamination; handwashing; and, in endemic areas, avoidance of fruits and vegetables that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5 mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute diarrhea, especially in children in developing countries.
- ▶ Outbreaks of diarrhea secondary to contaminated water or food.
- ▶ Prolonged diarrhea in immunocompromised persons.
- ▶ Diagnosis mostly by identifying organisms in specially stained stool specimens.

▶ General Considerations

The causes of coccidiosis are *Cryptosporidium* species (*C parvum*, *C hominis*, and others); *Isospora belli*; *Cyclospora*

cayetanensis; and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler's diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

I belli and *C cayetanensis* appear to infect only humans. *C cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Cryptosporidiosis is a zoonosis (*C parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C hominus*. Cryptosporidia are highly infectious and readily transmitted in day care settings and households. They have caused large community outbreaks due to contaminated water supplies (causing ~400,000 illnesses in Milwaukee in 1993) and are the leading cause of recreational water-associated outbreaks of gastroenteritis. In the developing world cryptosporidiosis is a leading cause of childhood diarrhea. In a study of causes of moderate-to-severe diarrhea in Asia and Africa, *Cryptosporidium* was the second most commonly identified pathogen in children under 2 years of age.

Clinical Findings

A. Symptoms and Signs

1. Cryptosporidiosis—The incubation period appears to be 1–14 days. In developing countries, disease is primarily in children under 5 years of age, causing 5–10% of childhood diarrhea. Presenting symptoms in children include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts from 5 to 10 days. It is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection are also common.

Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common before the advent of highly active antiretroviral therapy, particularly with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

2. Isosporiasis—The incubation period for *I belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

3. Cyclosporiasis—*C cayetanensis* oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

4. Sarcocystosis—*Sarcocystis* infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

5. Microsporidiosis—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with *E bieneusi* and *E intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with

advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enterocytozoon*, *Encephalitozoon*, *Brachiola*, *Vittaforma*, *Pleistophora*, *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

B. Laboratory Findings

1. Cryptosporidiosis—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Various antigen detection methods, including immunofluorescence microscopy, ELISA, and immunochromatography, offer improved sensitivity and specificity, both over 90% with available assays, and these methods may be considered the optimal means of diagnosis.

2. Isosporiasis—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

3. Cyclosporiasis—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

4. Sarcocystosis—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

5. Microsporidiosis—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

▶ Treatment

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. Cryptosporidiosis—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a nonabsorbed aminoglycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

2. Isosporiasis—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with TMP-SMZ (160 mg/800 mg orally two to four times daily for 10 days, with the higher dosage for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/day orally). Maintenance therapy with low-dose TMP-SMZ (160 mg/800 mg daily or three times per week) or Fansidar (1 tablet weekly) prevents relapse in those with persistent immunosuppression.

3. Cyclosporiasis—Cyclosporiasis is also treated with TMP-SMZ (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (160 mg/800 mg three times weekly) helps prevent relapse. For patients intolerant of TMP-SMZ, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than TMP-SMZ.

4. Sarcocystosis—For sarcocystosis, no specific treatment is established, but patients may respond to therapy with albendazole or TMP-SMZ.

5. Microsporidiosis—Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E. bienewisi*, the most common microsporidian cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoplasty.

▶ Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidian oocysts, so other purification measures are

needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (handwashing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

GIARDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute diarrhea; may be profuse and watery.
- ▶ Chronic diarrhea with greasy, malodorous stools.
- ▶ Abdominal cramps, distention, flatulence, and malaise.
- ▶ Cysts or trophozoites in stools.

▶ General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *Giardia intestinalis* and *Giardia duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is 100,000 to 2.5 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to *Giardia*-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children's day care centers, and residential facilities, and may occur as a result of contamination of water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. Cysts are transmitted as a result of fecal contamination of water or

food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as ten cysts. After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

▶ Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernable infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is suspected, antigen assays may be simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%).

▶ Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once). The drugs are not universally

effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Albendazole (400 mg orally once daily for 5 days) and nitazoxanide (500 mg orally twice daily for 3 days) both appear to have similar efficacy and fewer side effects compared with metronidazole, although data are limited, and a recent meta-analysis suggested superiority in efficacy of tinidazole over albendazole. Nitazoxanide is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against *Giardia* include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects, and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but unlike metronidazole, tinidazole, and furazolidone is safe in pregnancy. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection. With a suggestive presentation but negative diagnostic studies, an empiric course of treatment may be appropriate. Household or day care contacts with an index case should be tested and treated if infected.

▶ Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size less than 1 μm are adequate. In day care centers, appropriate disposal of diapers and frequent handwashing are essential.

TRICHOMONIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Copious vaginal discharge in women.
- ▶ Nongonococcal urethritis in men.
- ▶ Motile trichomonads on wet mounts.

▶ General Considerations

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common sexually transmitted diseases, causing vaginitis in women and

nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

▶ Clinical Findings

A. Symptoms and Signs

T vaginalis is often harbored asymptotically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

B. Diagnostic Testing

Diagnosis is typically made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginosis (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Newer diagnostic tests include point-of-care antigen tests and nucleic acid amplification assays, both of which offer improved sensitivity compared to wet mount microscopy and excellent specificity.

▶ Treatment

The treatment of choice is tinidazole or metronidazole, each as a 2 g single oral dose. Tinidazole may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, furazolidone, or other experimental therapies (see Chapter 18).

HELMINTHIC INFECTIONS

TREMATODE (FLUKE) INFECTIONS

SCHISTOSOMIASIS (Bilharziasis)

ESSENTIALS OF DIAGNOSIS

- ▶ History of fresh water exposure in an endemic area.
- ▶ **Acute schistosomiasis:** fever, headache, myalgias, cough, urticaria, diarrhea, and eosinophilia.
- ▶ **Intestinal schistosomiasis:** abdominal pain, diarrhea, and hepatomegaly, progressing to anorexia, weight loss, and features of portal hypertension.
- ▶ **Urinary schistosomiasis:** hematuria and dysuria, progressing to hydronephrosis, hydronephrosis and urinary infections.
- ▶ Diagnosis based on characteristic eggs in feces or urine; biopsy of rectal or bladder mucosa; positive serology.

General Considerations

Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by six species of trematode blood flukes. Five species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present in Africa, the Arabian peninsula, South America, and the Caribbean; *Schistosoma japonicum*, which is endemic in China and Southeast Asia; *Schistosoma mekongi*, which is endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum* and *Schistosoma guineensis*, which occur in parts of Africa. *Schistosoma haematobium* causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East. Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission significantly in many areas, but high level transmission remains common in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with fresh water containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomes migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate, and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular the liver. Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and

inflammation, eventually leading to fibrosis. Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with fresh water contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

Clinical Findings

A. Symptoms and Signs

1. Cercarial dermatitis—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in non-tropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer's itch).

2. Acute schistosomiasis (Katayama syndrome)—A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S mansoni* or *S japonicum*. Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. Chronic schistosomiasis—Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydronephrosis, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine. The most widely used stool test is the Kato-Katz technique. Quantitative tests that yield more than 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species, but cannot distinguish acute and past infection. Sensitivity of the test is 99% for *S mansoni*, 95% for *S haematobium*, but less than 50% for *S japonicum*. Serology is of limited use in endemic

settings, but can be helpful in travelers from nonendemic regions. Point-of-care assays to detect circulating schistosome antigens in serum and urine are also available; the most widely used tests target circulating anodic and cathodic antigens. Antigen tests have better sensitivity than stool smears, especially for *S mansoni*; sensitivity is lower for *S haematobium*. Molecular tests for schistosomiasis have been developed but are not routinely used for diagnosis. In acute schistosomiasis, leukocytosis and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue cannot distinguish past or active disease. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease.

▶ Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S mansoni*, *S haematobium*, *S intercalatum*, and *S guineensis* infections and a dose of 60 mg/kg (in two or three doses) for *S japonicum* and *S mekongi*. Cure rates are generally greater than 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and metrifonate for *S haematobium* infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections. The anti-malarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

▶ Prevention

Travelers to endemic areas should avoid fresh water exposure. Vigorous towel drying after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has

shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent treatment to limit worm burdens.

LIVER, LUNG, & INTESTINAL FLUKES

FASCIOLIASIS

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe, and it has increasingly been recognized in travelers to these areas. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into fresh water, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver function tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract. Serologic assays have sensitivity and specificity greater than 90%, but cannot distinguish between past and current infection. Antigen tests with excellent sensitivity and specificity are available in veterinary medicine and show promise for humans.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The treatment of choice is triclabendazole, which is also used in

veterinary medicine, but is not available in the United States. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. Of concern, resistance to triclabendazole has been widely reported in animal infections. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/day orally in three divided doses on alternate days for 10–15 days); this drug is no longer available in the United States. Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Other potential therapies are emetine and dehydroemetine, both widely used in the past but quite toxic, and nitazoxanide. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. An estimated 15 million people are infected (13 million in China); in some communities, prevalence can reach 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. The stool Kato-Katz test is widely used; performing repeated tests improves sensitivity. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic assays for clonorchiasis with excellent sensitivity are available but cannot distinguish between past and current infection. Molecular tests have been developed but are not widely used.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which

appears to be somewhat less effective. Tribendimidine, which is approved in China, has shown efficacy for clonorchiasis similar to that of praziquantel.

PARAGONIMIASIS

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*. *Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected; rare infections caused by *Paragonimus kelli-cotti* have occurred in North America. Eggs are released into fresh water, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity more than 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

INTESTINAL FLUKES

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in fresh water, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small

intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months, manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

CESTODE INFECTIONS

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans

are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under Invasive Cestode Infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B₁₂ deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

► Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, a repeat treatment after 1 week and screening after therapy to document cure are appropriate with heavy infections. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Craig P et al. Intestinal cestodes. *Curr Opin Infect Dis.* 2007 Oct; 20(5):524–32. [PMID: 17762788]

INVASIVE CESTODE INFECTIONS

1. Cysticercosis

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to *T solium* through fecal contamination of food.
- ▶ Seizures, headache, and other findings of a focal CNS lesion.
- ▶ Brain imaging shows cysts; positive serologic tests.

General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries. In Latin America, it is estimated that 0.5–1.5 million people suffer from epilepsy secondary to cysticercosis.

Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting

symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis. ELISAs and related immunoblot assays have excellent sensitivity and specificity, but sensitivity is lower with only single or calcified lesions.

C. Imaging

With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT.

Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis, but some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures. Overall, most authorities recommend treatment of active lesions, in particular lesions with a high likelihood of progression, such as intraventricular cysts. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/day orally for 8 days) or praziquantel (50 mg/kg/day orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/day orally may improve outcomes. Combining albendazole plus praziquantel improved outcomes compared to albendazole alone in patients with multiple viable intraparenchymal cysts. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory

responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to dogs or wild canines in an endemic area.
- ▶ Large cystic lesions, most commonly of the liver or lung.
- ▶ Positive serologic tests.

General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the northern hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may

develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

Clinical Findings

A. Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

Treatment

Treatment of cystic hydatid disease has traditionally involved cautious surgical resection of cysts, with care not to rupture cysts during removal. Injection of a cysticidal agent was used to limit spread in the case of rupture. Newer management algorithms include treatment with albendazole, often in conjunction with surgery. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/day orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/day orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst

is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicalid agent (95% ethanol, hypertonic saline, or 0.5% cetrimide) is injected, and the cyst is reaspirated after about 15 minutes. PAIR includes a small risk of anaphylaxis, which has been reported in about 2% of procedures, but death due to anaphylaxis has been rare. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

INTESTINAL NEMATODE (ROUNDWORM) INFECTIONS

ASCARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- ▶ Nonspecific abdominal symptoms.
- ▶ Eggs in stool; adult worms occasionally passed.

General Considerations

Ascaris lumbricoides is the most common of the intestinal helminths, infecting about a quarter of the world's population, with estimates of about a billion infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge

ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces, usually with the Kato-Katz technique. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. In endemic areas, reinfection after treatment is common. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about a billion persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse. Chronic infections in children can lead to iron deficiency anemia, growth retardation, and clubbing of the fingers.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Eosinophilia is common. Treatment is typically with albendazole (400 mg/day orally) or mebendazole (200 mg/day orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. Recent randomized trials showed albendazole plus oxantel pamoate (31% cure; 96% egg reduction) to be superior to mebendazole, and albendazole plus oxantel pamoate (69% cure; 99% egg reduction) and albendazole plus ivermectin (28% cure; 95% egg reduction) to be superior to albendazole plus mebendazole. Oxantel pamoate has low efficacy against *Ascaris* and hookworm infection.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Iron deficiency anemia.
- ▶ Characteristic eggs and occult blood in the stool.

▶ General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 1 billion, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

▶ Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals.

Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

▶ Treatment

Treatment is with albendazole (single 400 mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). These drugs are teratogenic, but experience suggests that they are safe in children over 1 year of age and during the second and third trimesters of pregnancy. Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by the WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Hyperinfection syndrome in the immunocompromised.
- ▶ Larvae detected in stool.
- ▶ With hyperinfection, larvae detected in sputum or other fluids.
- ▶ Eosinophilia.

▶ General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular

importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation. The most dangerous manifestation of *S stercoralis* infection is the **hyperinfection syndrome**, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcoholism; or persons with AIDS. The risk seems greatest for those receiving corticosteroids.

▶ Clinical Findings

A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With **hyperinfection** large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative (see below).

▶ Treatment

Full eradication of *S stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg orally daily for 1–2 days). This treatment has replaced thiabendazole (25 mg/kg orally twice daily for 3 days), which is relatively poorly tolerated, and albendazole (400 mg orally twice daily for 3 days), which is less effective. For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated doses of antihelminthic therapy (eg, monthly ivermectin) may be required.

ENTEROBIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Nocturnal perianal pruritus.
- ▶ Identification of eggs or adult worms on perianal skin or in stool.

▶ General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-age children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time, they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short lifespan of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

▶ Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

▶ Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard handwashing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

INVASIVE NEMATODE (ROUNDWORM) INFECTIONS

TRICHINOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Ingestion of inadequately cooked pork or game.
- ▶ Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- ▶ Eosinophilia and elevated serum muscle enzymes.

▶ General Considerations

Trichinosis (or trichinellosis) is caused worldwide by *Trichinella spiralis* and related *Trichinella* species. The disease is spread by ingestion of undercooked meat, most commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, *Trichinella* larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks, with estimates of ~10,000 cases annually. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 20 infections are reported annually, mostly from ingesting wild game.

▶ Clinical Findings

A. Symptoms and Signs

Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after

ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

B. Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatinine kinase, lactate dehydrogenase, aspartate aminotransferase). A commercial ELISA assay is available in the United States. Serologic tests become positive 2 or more weeks after infection, but cross-reactivity can be seen with other parasites. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify *Trichinella* larvae. For maximal yield, biopsy material should be examined histologically, and a portion enzymatically digested to release larvae, but evaluation before 3 weeks after infection may not show muscle larvae. Serum and muscle biopsy analysis are available from the CDC.

▶ Treatment

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Infection is prevented by cooking to a temperature of at least 71°C for at least 1 minute. Irradiation of meat is also effective in eliminating *Trichinella* larvae, but freezing is not reliable.

Gottstein B et al. Epidemiology, diagnosis, treatment, and control of trichinellosis. *Clin Microbiol Rev.* 2009 Jan;22(1):127–45. [PMID: 19136437]

TOXOCARIASIS

▶ General Considerations

The dog roundworm *Toxocara canis*, the cat roundworm *Toxocara cati*, and less commonly other helminths may cause visceral larva migrans. *T canis* is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. Infection is spread

principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

▶ Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, typically with similar, but more severe manifestations than *T canis*.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an ELISA against a group of excreted antigens has shown good sensitivity and specificity. Most patients recover without specific therapy, although symptoms may persist for months.

▶ Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg orally twice daily for 5 days), mebendazole, thiabendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

Moreira GM et al. Human toxocariasis: current advances in diagnostics, treatment, and interventions. *Trends Parasitol.* 2014 Sep;30(9):456–64. [PMID: 25089038]

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the non-human parasites cannot complete their life cycles, so only cause cutaneous disease.

▶ Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by

▲ **Figure 35–8.** Cutaneous larva migrans on the foot. (Reproduced, with permission, from Richard P. Usatine, MD.)

serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 35–8). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

▶ Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.

FILARIASIS

LYMPHATIC FILARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic attacks of lymphangitis, lymphadenitis, and fever.
- ▶ Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- ▶ Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

▶ General Considerations

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*,

and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including sub-Saharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia. *Mansonella* are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

▶ Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Figure 35–9); genital involvement, including

▲ **Figure 35–9.** Elephantiasis of legs due to filariasis. (Public Health Image Library, CDC.)

epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W bancrofti* or *B malayi* infection but typically without microfilaremia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. *Mansonella* can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but during daylight hours in the South Pacific. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Serologic tests may be helpful but cannot distinguish past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available for detection of *W bancrofti*. These can be considered the diagnostic tests of choice and are increasingly used to guide control programs. However, cross-reactivity with *Loa loa* infections has been described. Due to potential severe toxicity, caution is appropriate before treatment with ivermectin for positive *W bancrofti* antigen tests in areas also endemic for *L loa* infection. Multiple molecular tests, including field-friendly LAMP assays, have been developed. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically

indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaremia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds.

► Treatment & Control

A. Drug Treatment

Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/day orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Doxycycline was also effective at controlling *Mansonella perstans* infection, which does not respond well to standard antifilarial drugs. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin; in some circumstances, more frequent dosing offers improved control.

ONCHOCERCIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- ▶ Conjunctivitis progressing to blindness.
- ▶ Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

General Considerations

Onchocerciasis, or river blindness, is caused by *Onchocerca volvulus*. An estimated 37 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in sub-Saharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simulium flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

Clinical Findings

A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision

loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

B. Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzotti test can be used; exacerbation of skin rash and pruritus after a 50-mg dose of diethylcarbamazine is highly suggestive of the diagnosis. This test should only be used after other tests are negative, since treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is also available. Eosinophilia is a common, but inconsistent finding. Antigen and antibody detection tests are under study.

Treatment & Control

The treatment of choice is ivermectin, which has replaced diethylcarbamazine due to a much lower risk of severe reactions to therapy. Ivermectin kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected lifespan of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline shows promise as a first-line agent to treat onchocerciasis because of its improved activity against adult worms compared to other agents and limited toxicity due to the slow action of the drug.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

Knopp S et al. Nematode infections: filariases. *Infect Dis Clin North Am.* 2012 Jun;26(2):359–81. [PMID: 22632644]

LOIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Subcutaneous swellings; adult worms migrating across the eye.
- ▶ Encephalitis, which may be brought on by treatment.
- ▶ Microfilariae in the blood.

General Considerations

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term “eye worm”). Adults can live for up to 17 years.

Clinical Findings

A. Symptoms and Signs

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings) develop in symptomatic persons. The swellings are nonerythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with

hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

B. Laboratory Findings

The diagnosis is established by identifying microfilariae in blood. Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test results. Molecular methods, including field-friendly LAMP assays, are available to rule out loiasis before administration of ivermectin for the control of other filarial infections.

Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment is with 8–10 mg/kg/day orally for 21 days; repeat courses may be needed. Mild side effects are common, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, entails a higher risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin. Doxycycline is not effective for loiasis.

Mycotic Infections

Samuel A. Shelburne, III, MD, PhD

Richard J. Hamill, MD

36

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Common normal flora but opportunistic pathogen.
- ▶ Gastrointestinal mucosal disease, particularly esophagitis, most common.
- ▶ Fungemia, arising from an intravenous catheter or the gastrointestinal tract occurs in patients who have sustained cutaneous or mucosal injury, undergone instrumentation, are receiving total parenteral nutrition, have kidney disease, or have received broad-spectrum antibiotics.

▶ General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, kidney disease, and the presence of intravascular catheters (especially when providing total parenteral nutrition). Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

▶ Clinical Findings

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include

pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization. However, signs and symptoms of true *Candida* urinary tract infections are indistinguishable from bacterial urinary tract infections and can include urgency, hesitancy, fever, chills, or flank pain.

C. Invasive Candidiasis

Invasive candidiasis can be (1) candidemia without deep-seated infection; (2) candidemia with deep-seated infection (typically eyes, kidney, or abdomen); and (3) deep-seated candidiasis in the absence of bloodstream infection. Varying ratios of these clinical entities depends on the predominating risk factors for affecting patients (ie, neutropenia, dialysis, postsurgical). The clinical presentation of candidemia varies from minimal fever to septic shock that can resemble a severe bacterial infection. The diagnosis of invasive *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in invasive infection.

Hepatosplenic candidiasis can occur following prolonged neutropenia in patients with underlying hematologic cancers, but this entity is less common in the era of widespread antifungal prophylaxis. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection that is most frequently associated with exposure to a healthcare setting. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery.

The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement.

Treatment

A. Mucosal Candidiasis

Therapy of **esophageal candidiasis** depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/day (or itraconazole solution, 10 mg/mL, 200 mg/day), for 10–14 days usually suffices. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/day; intravenous caspofungin, 50 mg/day; intravenous anidulafungin, 100 mg on day 1, then 50 mg/day; or intravenous micafungin, 150 mg/day. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Various topical azole preparations (eg, clotrimazole, 100 mg vaginal tablet for 7 days, or miconazole, 200 mg vaginal suppository for 3 days) are effective against **vulvovaginal candidiasis**. One 150 mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of invasive infection. When symptomatic funguria persists, oral fluconazole, 200 mg/day for 7–14 days, can be used.

C. Invasive Candidiasis

The 2016 guidelines for management of candidiasis recommend an echinocandin such as caspofungin (loading dose of 70 mg intravenously once, then 50 mg intravenously daily), micafungin (100 mg intravenously daily), or anidulafungin (loading dose of 200 mg intravenously once, then 100 mg intravenously daily). Fluconazole (loading dose of 800 mg [12 mg/kg] intravenously, then 400 mg [6 mg/kg] intravenously daily) is an acceptable alternative for less critically ill patients without recent azole exposure. Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. A dilated fundoscopic examination is recommended for all patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment for isolates known to be or likely to be susceptible to fluconazole.

Removal or exchange of intravascular catheters is generally recommended for patients with candidemia in whom the catheter is the suspected source of infection.

Non-*albicans* species of *Candida* account for over 50% of clinical bloodstream isolates and often have resistance patterns that are different from *C. albicans*. An echinocandin is recommended for treatment of *Candida glabrata* infection with a transition to oral fluconazole or voriconazole reserved for patients whose isolates are known to be susceptible to these agents. *C. glabrata* that is resistant to azoles and echinocandins is being increasingly reported. Similarly, *Candida krusei* is generally fluconazole-resistant and so should be treated with an alternative agent, such as echinocandin or voriconazole. Fluconazole may be optimal for *Candida parapsilosis* due to possible echinocandin resistance in such isolates.

Although the isolation of *Candida* species from mucosal sites raises the possibility of invasive candidiasis, randomized trials of empiric antifungal agents in such situations have not shown clear clinical benefit. Hepatosplenic candidiasis generally requires treatment for several months until lesion resolution.

D. Candidal Endocarditis

Best results are achieved with a combination of medical and surgical therapy. Lipid formulation amphotericin B (3–5 mg/kg/day) or high-dose echinocandin (caspofungin 150 mg/day, micafungin 150 mg/day, or anidulafungin 200 mg/day) is recommended as initial therapy. Step-down or long-term suppressive therapy for nonsurgical candidates may be done with fluconazole at 6–12 mg/kg/day for susceptible organisms.

In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections although the effect on mortality and the preferred agent remain debated.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Epidemiologically linked with exposure to bird and bat droppings; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- ▶ Most patients asymptomatic; respiratory illness most common clinical problem.

- ▶ Disseminated disease especially common in AIDS or other immunosuppressed states, with poor prognosis.
- ▶ Biopsy of affected organs with culture or urinary polysaccharide antigen most useful in disseminated disease.

▶ General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and Southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

▶ Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) **Acute pulmonary histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. Clinical manifestations can vary from a mild influenza-like illness to severe pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is commonly seen in patients with underlying HIV infection (with CD4 cell counts usually less than 100 cells/mcL) or other conditions of impaired cellular immunity. Disseminated histoplasmosis has also been reported in patients from endemic areas taking tumor necrosis factor (TNF)-blocking agents. It is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands; this results in adrenal insufficiency in about 50% of patients. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Chronic pulmonary histoplasmosis** is usually seen in older patients who have underlying chronic lung disease. Chest radiographs show various lesions including apical cavities, infiltrates, and nodules. (4) **Complications of pulmonary**

histoplasmosis include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to *Histoplasma* infection results in compromise of pulmonary vascular structures.

B. Laboratory Findings

Most patients with chronic pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with pancytopenia. Marked lactate dehydrogenase (LD) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase.

With pulmonary involvement, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of a first morning urine and serum polysaccharide antigen assays has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time but may take several weeks for growth. The urine antigen assay has a sensitivity of greater than 90% for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy.

▶ Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/day orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Duration of therapy ranges from weeks to several months depending on the severity of illness. Intravenous amphotericin B formulations are used in patients with more severe illness such as meningitis, with guidelines favoring the use of liposomal or lipid complex amphotericin formulations at a dose of 3 mg/kg/day over amphotericin B deoxycholate. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200 mg/day orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy. There is no clear evidence that antifungal or anti-inflammatory agents are of benefit for patients with granulomatous mediastinitis or fibrosing mediastinitis although oral itraconazole is often used. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Influenza-like illness with malaise, fever, backache, headache, and cough.
- ▶ Erythema nodosum common with acute infection.
- ▶ Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- ▶ Chest radiograph findings vary from pneumonitis to cavitation.
- ▶ Serologic tests useful; large spherules containing endospores demonstrable in sputum or tissues.

▶ General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area. Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America. Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of **primary coccidioidomycosis** occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized, etiology of community-acquired pneumonia in endemic areas.

Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial involvement has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be

particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In **primary coccidioidomycosis**, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test and enzyme-linked immunosorbent assay (ELISA) detect IgM antibodies and are both useful for diagnosis early in the disease process. Historically, a persistent rising IgG complement fixation titer (1:16 or more) has been considered suggestive of disseminated disease; in addition, immunodiffusion complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioid meningitis. These are found in over 90% of cases; *Coccidioides* antigen testing may augment (not replace) CSF antibody testing. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens of soft tissues and bone; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive.

C. Imaging

Radiographic findings vary, but patchy, nodular and lobar upper lobe pulmonary infiltrates are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft-tissue collections.

▶ Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter 30). Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–800 mg/day, or higher) although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/day is used initially by some clinicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/day intravenously, is generally given concurrently with intrathecal therapy but is not

sufficient alone for the treatment of meningeal disease. Once the patient is clinically stable, oral therapy with an azole, usually with fluconazole (400 mg daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Itraconazole, 400 mg orally daily divided into two doses, or fluconazole, 200–400 mg, or higher, orally once or twice daily should be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. Response to therapy should be monitored by following the clinical response and progressive decrease in serum complement fixation titers.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone and complicated pulmonary disease (eg, rupture of coccidioidal cavity).

► Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis with stroke and hydrocephalus that may require shunting. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (*Pneumocystis jirovecii* Pneumonia)

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, dyspnea, nonproductive cough.
- ▶ Bilateral diffuse interstitial disease without hilar adenopathy by chest radiograph.
- ▶ Bibasilar crackles on auscultation in many cases; others have no findings.
- ▶ Reduced partial pressure of oxygen.
- ▶ *P jirovecii* in sputum, bronchoalveolar lavage fluid, or lung tissue.

► General Considerations

Pneumocystis jirovecii, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P jirovecii* disease is rare in the general population,

serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The mode of transmission in primary infection is unknown, but the evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. De novo infection and reactivation of latent disease likely contribute to the mechanism of acute disease in older children and adults.

The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immunity. Cases occur commonly in patients with cancer or severe malnutrition and debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer and, most frequently, in patients with AIDS (Chapter 31).

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts less than 200/mcL. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

► Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is typically abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles, but others do not. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jirovecii* pneumonia, helping distinguish it from other causes of pneumonia.

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid

desaturation occurs if patients exercise before samples are drawn. Serologic tests are not helpful in diagnosis. The organism cannot be cultured, and definitive diagnosis depends on morphologic demonstration of the organisms in respiratory specimens using specific stains. The use of monoclonal antibody with immunofluorescence increases the sensitivity of diagnosis beyond Giemsa or methenamine silver stains. Polymerase chain reaction (PCR) of bronchoalveolar lavage is overly sensitive in that the test is often positive in colonized, noninfected persons but quantitative values may help with identifying infected patients, although precise cutoffs have not been established and may vary between different patient populations. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia.

Treatment

(Table 31–5.) It is appropriate to start empiric therapy for *P jirovecii* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The impact of resistance of *Pneumocystis* to TMP-SMZ is unclear, although increasing rates of mutations in the *DHPS* and *DHFR* genes that mediate TMP-SMZ resistance have been reported. The best-studied second-line option is a combination of primaquine and clindamycin, although dapsone/trime-thoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected medication for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see below). Some clinicians prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage of TMP/SMZ is 15–20 mg/kg/day (based on trimethoprim component) given orally or intravenously daily in three or four divided doses for 14–21 days. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

B. Primaquine/Clindamycin

A meta-analysis suggested that primaquine, 15–30 mg/day, plus clindamycin, 600 mg three times daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

C. Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This medication is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/day for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur.

D. Atovaquone

Atovaquone is approved by the US Food and Drug Administration (FDA) for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Atovaquone should be administered with a fatty meal.

E. Other Medications

Trimethoprim, 15 mg/kg/day in three divided doses daily, plus dapsone, 100 mg/day, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when Pao₂ on admission is less than 70 mm Hg or oxygen saturation is less than 90%) in conjunction with antimicrobials. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed. The role of prednisone in non-AIDS patients is unclear, especially in patients in whom symptoms developed following tapering doses of corticosteroids.

Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts less than 200 cells/mL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–4). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients, although the clinical characteristics of persons with these conditions who would benefit from *Pneumocystis* prophylaxis have not been clearly defined. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintained a CD4 count of greater than 200 cells/mL.

Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of fungal meningitis.
- ▶ Predisposing factors: Chemotherapy for hematologic malignancies, Hodgkin lymphoma, corticosteroid therapy, transplant recipients, TNF inhibitor therapy, HIV infection.
- ▶ Symptoms of headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- ▶ Demonstration of capsular polysaccharide antigen in cerebrospinal fluid is diagnostic.

General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *C. gattii* is a closely related species that also causes disease in humans although *C. gattii* may affect more ostensibly immunocompetent persons. It is a major cause of cryptococcosis in the Pacific Northwestern region of the United States and may result in more severe disease than *C. neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic malignancies under treatment, Hodgkin lymphoma, long-term corticosteroid therapy, solid-organ transplant, TNF-inhibitor therapy, or HIV infection.

Clinical Findings

A. Symptoms and Signs

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. *C. gattii* infection frequently presents with respiratory symptoms along with neurologic signs caused by space-occupying lesions in the central nervous system. Primary *C. neoformans* infection of the skin may mimic bacterial cellulitis, especially in persons receiving immunosuppressive therapy such as corticosteroids. Clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

B. Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungi. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas. Antigen testing by lateral flow assay appears to have improved sensitivity and specificity over the conventional latex agglutination test and can provide more rapid diagnostic results.

Treatment

Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Liposomal amphotericin B, 3–4 mg/kg/day intravenously for 14 days is the preferred agent for induction therapy, followed by an additional 8 weeks of fluconazole, 400 mg/day orally. This regimen has been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/day divided into four equal doses and given every 6 hours.

Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in kidney function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. **Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality.** The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Therapy is generally continued until cerebrospinal fluid cultures become negative. Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/day orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count greater than 100–200 cells/mL for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; published guidelines suggest this as an option.

▶ Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of non-candidal invasive fungal infection in stem cell or organ transplant recipients and in patients with hematologic malignancies.
- ▶ Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- ▶ Pulmonary, sinus, and central nervous system are most common disease sites.
- ▶ Detection of galactomannan by ELISA or PCR in serum or other body fluid samples is useful for early diagnosis and treatment.

▶ General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

▶ Clinical Findings

A. Allergic Forms of Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs in patients with preexisting asthma or cystic fibrosis who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. It also may complicate cystic fibrosis. Allergic aspergillus sinusitis produces a chronic sinus inflammation characterized by eosinophilic mucus and noninvasive hyphal elements.

B. Chronic Aspergillosis

Chronic pulmonary aspergillosis produces a spectrum of disease that usually occurs when there is preexisting lung damage but not significant immunocompromise. Disease manifestations range from aspergillomas that develop in a lung cavity to chronic fibrosing pulmonary aspergillosis in which the majority of lung tissue is replaced with fibrosis. Longstanding (longer than 3 months) pulmonary and systemic symptoms such as cough, shortness of breath, weight loss, and malaise are common.

C. Invasive Aspergillosis

Invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, particularly in patients who have undergone hematopoietic stem cell transplants; in those with prolonged, severe neutropenia; and in patients with chronic granulomatous disease. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host

disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. Detection of galactomannan by ELISA or *Aspergillus* DNA by PCR, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done and usefulness is decreased in patients receiving anti-mold prophylaxis (ie, voriconazole or posaconazole). Galactomannan levels and *Aspergillus* DNA PCR can be tested in serum or in bronchoalveolar lavage fluid, which may be more sensitive than serum. Higher galactomannan levels are correlated with increased mortality, and failure of galactomannan levels to fall in response to therapy portends a worse outcome. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign”).

▶ Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include voriconazole and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

▶ Treatment

A. Allergic Forms of Aspergillosis

For acute exacerbations of ABPA, oral prednisone is begun at a dose of 1 mg/kg/day and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole is increasingly being used. Itraconazole is the best studied agent for the treatment of allergic aspergillus sinusitis with topical corticosteroids being the cornerstone of therapy.

B. Chronic Aspergillosis

The most effective therapy for symptomatic aspergilloma remains surgical resection. Other forms of chronic aspergillosis are generally treated with at least 4–6 months of oral triazole therapy (itraconazole 200 mg twice daily, voriconazole 200 mg twice daily, or posaconazole 300 mg daily).

C. Invasive Aspergillosis

When invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution

of voriconazole (6 mg/kg intravenously twice on day 1 and then 4 mg/kg every 12 hours thereafter) is considered optimal therapy. A randomized controlled trial did not find an overall benefit with the addition of anidulafungin (200 mg on day 1 and then 100 mg daily) to voriconazole, but patients in whom galactomannan was detected who received combination therapy had better outcomes. Isavuconazole (372 mg of prodrug on days 1 and 2 and then 372 mg once daily) was equivalent to voriconazole. Alternatives include a lipid formulation of amphotericin B (3–5 mg/kg/day), caspofungin (70 mg intravenously on day 1 and then 50 mg/day thereafter), and posaconazole oral tablets (300 mg twice daily on day 1 and then 300 mg daily thereafter). Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy. Therapeutic drug monitoring should be considered for both voriconazole and posaconazole given variations in metabolism and absorption.

Surgical debridement is generally done for sinusitis, and there is increasing data regarding resection of focal pulmonary lesions, especially for treatment of life-threatening hemoptysis. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains high, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of non-*Aspergillus* invasive mold infection.
- ▶ Predisposing factors: poorly controlled diabetes, leukemia, bone marrow or organ transplant, trauma with wound contamination by soil.
- ▶ Pulmonary, rhinocerebral, and skin are most common disease sites.
- ▶ Rapidly fatal without multidisciplinary interventions.

▶ General Considerations

The term “mucormycosis” is applied to opportunistic infections caused by members of the genera *Rhizopus*,

Mucor, *Lichtheimia* (formerly *Absidia*), and *Cunninghamella*. Predisposing conditions include hematologic malignancy, stem cell transplantation, solid organ transplantation, diabetic ketoacidosis, chronic kidney disease, desferoxamine therapy, and treatment with corticosteroids or cytotoxic drugs.

Clinical Findings

Invasive disease of the sinuses, orbits, and the lungs may occur. Necrosis is common due to hyphal tissue invasion that may manifest as ulceration of the hard palate or nasal palate or hemoptysis. Widely disseminated disease can occur. No serologic or laboratory findings assist with diagnosis, and blood cultures are unhelpful. A reverse halo sign may be seen on chest CT. Biopsy of involved tissue remains the cornerstone of diagnosis, although cultures are frequently negative. The organisms appear in tissues as broad, branching nonseptate hyphae.

Treatment

Optimal therapy of mucormycosis involves reversal of predisposing conditions (if possible), surgical debridement, and prompt antifungal therapy. A prolonged course of a lipid preparation of intravenous amphotericin B (5 mg/kg with higher doses possibly given for CNS disease) should be started early. Based on in vitro susceptibility, posaconazole tablets 300 mg/day orally is generally used after disease has been stabilized. Combination therapy with amphotericin and posaconazole is not proven but is commonly used because of the poor response to monotherapy. Isavuconazole has in vitro activity against some agents of mucormycosis. Other azoles are not effective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for mucormycosis. Despite favorable animal studies, a pilot study in humans incorporating adjunctive iron chelation therapy with deferasirox demonstrated a higher mortality rate than antifungal therapy alone. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis remains guarded.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors and in a geographically limited area of the south central and

midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Chronic pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal airspace consolidation or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a thick-walled cell 5–20 μm in diameter that may have a single broad-based bud. It grows readily on culture. A urinary antigen test is available, but it has considerable cross reactivity with *Histoplasma*; it may be useful in monitoring disease resolution or progression. A serum enzyme immunoassay based on the surface protein BAD-1 has much better sensitivity and specificity than the urinary antigen test, but it is not yet commercially available.

Itraconazole, 200–400 mg/day orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.7–1.0 mg/kg/day intravenously (or lipid formulation amphotericin B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Smith JA et al. New developments in blastomycosis. *Semin Respir Crit Care Med.* 2015 Oct;36(5):715–28. [PMID: 26398538]

PARACOCIDIOIDOMYCOSIS (South American Blastomycosis)

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Cutaneous papules may ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Lymph node enlargement may follow mucocutaneous

lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. HIV-infected patients with paracoccidioidomycosis are more likely to have extrapulmonary dissemination and a more rapid clinical disease course.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in more than 80% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. TMP-SMZ (480 mg/1200 mg) twice daily orally is equally effective and less costly but associated with more adverse effects and longer time to clinical cure. Amphotericin B intravenously is the medication of choice for severe and life-threatening infection.

Shikanai-Yasuda MA. Paracoccidioidomycosis treatment. *Rev Inst Med Trop Sao Paulo.* 2015 Sep;57(Suppl 19):31–7. [PMID: 26465367]

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by organisms of the *Sporothrix schenckii* complex. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, lymphocutaneous spread along the lymphatics draining this area occurs, which may result in ulceration. Cavitory pulmonary disease occurs in individuals with underlying chronic lung disease.

Disseminated sporotrichosis is rare in immunocompetent persons but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with cellular immunodeficiencies, including AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. The usefulness of serologic tests is limited, but may be helpful in diagnosing disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 0.7–1.0 mg/kg/day, or a lipid amphotericin B preparation, 3–5 mg/kg/day are used for severe systemic infection. Surgery may be indicated for complicated pulmonary cavitory disease, and joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Mahajan VK. Sporotrichosis: an overview and therapeutic options. *Dermatol Res Pract.* 2014;2014:272376. [PMID: 25614735]

MYCETOMA (Eumycetoma & Actinomycetoma)

Mycetoma is a chronic local, slowly progressive destructive infection that usually involves the foot; it begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures with sinus tracts and extruding grains. Eumycetoma (also known as maduromycosis) is the term used to describe mycetoma caused by true fungi. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Causative species can often be suggested by the color of the characteristic grains and hyphal size within the infected tissues but definitive diagnosis requires culture.

The prognosis for eumycetoma is poor, though surgical debridement along with prolonged oral itraconazole therapy, 200 mg twice daily, or combination therapy including itraconazole and terbinafine may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

Nenoff P et al. Eumycetoma and actinomycetoma—an update on causative agents, epidemiology, pathogenesis, diagnostics and therapy. *J Eur Acad Dermatol Venereol.* 2015 Oct;29(10):1873–83. [PMID: 25726758]

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are now significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons in whom multiple, painful skin lesions develop; blood cultures are often positive. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue. The differentiation of *S apiospermum* and *Aspergillus* is

particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole). Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts.

Köhler JR et al. The spectrum of fungi that infects humans. *Cold Spring Harb Perspect Med*. 2014 Nov 3;5(1):a019273. [PMID: 25367975]

HOUSEHOLD MOLDS

ESSENTIALS OF DIAGNOSIS

- ▶ Molds are very common indoors where moisture exists in enclosed spaces.
- ▶ Most common indoor molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*.
- ▶ People most at risk for health problems include those with allergies, asthma, and underlying immunocompromising conditions.

Molds are commonly present in homes, particularly in the presence of moisture, and patients will commonly seek assessment for whether their illness is due to molds. Invasive disease due to environmental fungi can occur in the immunocompromised patient (eg, see section on Invasive Aspergillosis), but there are no data that mold exposure can induce immune dysfunction. Similarly, the concept of toxic-mold syndrome or cognitive impairment due to inhalation of mycotoxins has not been validated despite scrutiny by expert panels. Allergic symptoms (eg, asthma, hypersensitivity pneumonitis) can be worsened by environmental mold exposure, and reduction of household mold in such patients may lead to clinical improvement. The presence of mold in the household is typically easily discernable with visual inspection or detection by odor; if present, predisposing conditions should be corrected by individuals experienced in mold remediation.

ANTIFUNGAL THERAPY

Table 36–1 summarizes the major properties of currently available antifungal agents. Two different lipid-based amphotericin B formulations are used to treat systemic invasive fungal infections. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are approved for use. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive *Candida* infections, although resistance is beginning to emerge clinically; *C glabrata* in particular has shown resistance to this class of antifungals. Caspofungin acetate is also approved for use in refractory

Table 36–1. Agents for systemic mycoses.

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Amphotericin B	0.3–1.5 mg/kg/day intravenously	No	Poor	Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular acidosis, anemia	All major pathogens except <i>Scedosporium</i>
Amphotericin B lipid complex	5 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above
Amphotericin B, liposomal	3–6 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above
Anidulafungin	100 mg intravenous loading dose, followed by 50 mg/day intravenously in one dose	< 1%	Poor	Diarrhea, hepatic enzyme elevations, histamine-mediated reactions	Mucosal and invasive candidiasis
Caspofungin acetate	70 mg intravenous loading dose, followed by 50 mg/day intravenously in one dose	< 50% ¹	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia

(continued)

Table 36–1. Agents for systemic mycoses. (continued)

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Fluconazole	100–800 mg/day in one or two doses intravenously or orally	Yes	Yes	Nausea, rash, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis
Flucytosine (5-FC)	100–150 mg/kg/day orally in four divided doses	Yes	Yes	Leukopenia, ² rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis, ³ candidiasis, ³ chromomycosis
Isavuconazole	200 mg/day orally or intravenously once daily	No	Low in CSF, high in brain	Nausea, diarrhea, upper abdominal pain, dizziness	Broad range of activity including the <i>Mucorales</i>
Itraconazole	100–400 mg/day orally in one or two doses with a meal or carbonated beverage	No	Variable	Nausea, hypokalemia, edema, hypertension, peripheral neuropathy	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis
Ketoconazole	200–800 mg/day orally in one or two doses with a meal or carbonated beverage	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)
Micafungin sodium	150 mg intravenously in one dose (treatment) 50 mg (prophylaxis)	No	Poor	Rash, rigors, headache, phlebitis	Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation
Posaconazole	400–800 mg/day orally in one or two doses (oral suspension) or 300 mg orally once daily (tablets) or 300 mg intravenously twice daily for 2 days loading dose followed by 300 mg once daily	No	Yes	Nausea, vomiting, abdominal pain, diarrhea, and headache	Broad range of activity including the <i>Mucorales</i>
Terbinafine	250 mg/day orally in one dose	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations	Dermatophytes, sporotrichosis
Voriconazole	200–400 mg/day orally in two doses or 12 mg/kg intravenously as loading dose for 2 days followed by 6 mg/kg/day intravenously in two doses ⁵	Yes	Yes	Transient visual disturbances, rash, photosensitivity, fluoride excess with periostitis, peripheral neuropathy, squamous cell skin cancers, hepatic enzyme elevations ⁴	All major pathogens except the <i>Mucorales</i> and sporotrichosis

¹No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.²Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.³In combination with amphotericin B.⁴Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.⁵Some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive *Aspergillus* cases, *Fusarium* and *Scedosporium* infections, *Candida* esophagitis, deep *Candida* infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including the *Mucorales*. Some experts now recommend therapeutic drug monitoring in individuals with severe invasive fungal infections receiving these newer azoles because of unreliable serum levels due to either metabolic alterations as a result of genetic polymorphisms (voriconazole) or erratic absorption (posaconazole). A delayed-release tablet preparation of posaconazole provides more reliable pharmacokinetics. Isavuconazole has been approved for the treatment of aspergillosis and

mucormycosis; it is available in an intravenous form that does not utilize the cyclodextrin carrier like previous azoles as well as an oral form with relatively reliable pharmacokinetic properties.

Disorders Related to Environmental Emergencies

Jacqueline A. Nemer, MD, FACEP
Melissa C. Clark, MD

37

COLD & HEAT

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. In extreme temperatures, the body's thermoregulation may fail. This results in the core body temperature (CBT) moving toward the temperature of the external environment. Cold and heat exposure may cause a wide spectrum of conditions; the severity varies considerably among individuals. Many of these conditions are preventable with appropriate education and planning. Preventive measures should be implemented on an individual and population level.

The likelihood and severity of extreme temperature-related conditions depend on physiologic and environmental factors. Physiologic risk factors include extremes of age; cognitive impairment; poor physical conditioning/sedentary lifestyle or immobility; poor acclimatization; concurrent injury; prior temperature-related injury, and underlying medical conditions. Underlying medical conditions include cardiopulmonary, vascular, neurologic, psychiatric, musculoskeletal, immunologic, hematologic, endocrine [hypothyroidism, adrenal insufficiency, hypopituitarism], renal, hepatic, skin, and infectious diseases. Pharmacologic risk factors include medications, holistic or alternative treatments, illicit drugs, tobacco, and alcohol. There is a subset of medications associated with a particularly high likelihood of worsening temperature-related conditions, such as those that impact sweating and the central nervous system (ie, anticholinergics, stimulants, and sedatives) and those that affect cutaneous blood flow (peripheral vasoconstrictors or vasodilators). Environmental risk factors include weather conditions (humidity, wind, rain, snow, etc), inadequate clothing, inadequate housing, (homelessness, or housing with inadequate temperature control), occupational or recreational exposure.

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- ▶ Spectrum of preventable heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.
- ▶ **Heat stroke:** hyperthermia with cerebral dysfunction in a patient with heat exposure.
- ▶ **Best outcome:** early recognition, initiation of rapid cooling, and avoidance of shivering during cooling.
- ▶ **Best choice of cooling method:** whichever can be instituted the fastest with the least compromise to the patient. Delays in cooling result in higher morbidity and mortality in heat stroke victims.

▶ General Considerations

Heat-related illnesses are the most commonly seen environmental emergencies in US emergency departments. An estimated 326,497 cases presented to US emergency departments between 2006 and 2010, translating to a rate of 21.5 visits per 100,000 population/year. The amount of heat retained in the body is determined by internal metabolic function and environmental conditions (temperature, humidity). Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. Hyperthermia results from either compromised heat dissipation mechanisms or abnormally high heat production. Heat loss occurs primarily through sweating and peripheral vasodilation. Conduction (convection)—the direct transfer of heat from the skin to the surrounding air—occurs with diminishing efficiency as ambient temperature rises, especially above 37.2°C, the point at which heat transfer reverses direction. At normal temperatures, evaporation accounts for approximately 20% of the body's heat

loss, but at high temperatures it becomes the major mechanism for dissipation of heat; with vigorous exertion, sweat loss can be as much as 2.5 L/h. This mechanism diminishes as humidity rises.

There is a spectrum of preventable heat-related illnesses related to environmental exposure, ranging from mild forms, such as heat cramps, to severe forms, such as heat stroke. Risk factors related to exertion include longer duration of exertion, hot environment, insufficient acclimatization, and dehydration. Additional risk factors include skin disorders or other medical conditions that inhibit sweat production or evaporation, obesity, prolonged seizures, hypotension, reduced cutaneous blood flow (ie, vasoconstrictors, beta-adrenergic blocking agents, dehydration), reduced cardiac output, the use of drugs that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Medications that impair sweating include anticholinergics, antihistamines, phenothiazines, tricyclic antidepressants, monoamine oxidase inhibitors, and diuretics. Reduced cutaneous blood flow results from use of vasoconstrictors and beta-adrenergic blocking agents and dehydration results from use of alcohol. Illicit drugs, including stimulants, some hallucinogens and anti-psychotic agents, can cause increased muscle activity and thus generate increased body heat.

Classic (nonexertional) heat-related illness may occur in any individual in a hot relaxing environment (ie, hot bath, steam room, sunbathing, or sauna). It may also occur when a high-risk individual is in extreme heat environmental conditions (heat, humidity) even if that individual is not physically active.

Heat cramping results from dilutional hyponatremia as sweat losses are replaced with water alone. **Heat exhaustion** results from prolonged strenuous activity in a hot environment without adequate water or salt intake. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

Heat syncope or sudden collapse may result in unconsciousness from volume depletion and cutaneous vasodilation with consequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of heat syncope: it may occur during or immediately following exercise. **Heat stroke**, the hallmark of which is cerebral dysfunction with CBT over 40°C, presents in one of two forms: classic and exertional. **Classic (nonexertional) heat stroke** occurs in patients with impaired thermoregulatory mechanisms or in extreme environmental conditions. **Exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, and taking medications that interfere with heat-dissipating mechanisms (ie, anticholinergics, antihistamines, phenothiazines).

▶ Clinical Findings

For all types of heat related illnesses, skin temperature may not reflect core temperature; thus, it is important to use an internal rectal, foley, or esophageal thermometer when diagnosing and treating disorders due to heat. **Heat cramps**

are painful skeletal muscle contractions and severe muscle spasms with onset during or shortly after exercise. Examination findings typically include stable vital signs; normal or slightly increased CBT; moist and cool skin; and tender, hard, lumpy, painful muscles that may be twitching. The diagnosis is made clinically.

Heat exhaustion is diagnosed based on symptoms and clinical findings of a CBT slightly elevated but less than 40°C, increased pulse, and moist skin. Symptoms are similar to those of heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

With **heat syncope**, there is usually a history of prolonged vigorous physical activity or prolonged standing in a hot humid environment followed by a sudden collapse. The skin is cool and moist, the pulse is weak, and the systolic blood pressure is low.

Heat stroke is a life-threatening emergency; **the hallmark of heat stroke is cerebral dysfunction when the CBT is over 40°C**. Presenting symptoms include all findings seen in heat exhaustion with additional neurologic symptoms such as dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. Physical examination findings may be variable and therefore unreliable. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Providers should be vigilant in monitoring for kidney injury, liver failure, metabolic derangements, respiratory compromise, coagulopathy, and ischemia. Initial laboratory findings are nonspecific to this condition.

▶ Treatment

A. Heat Cramps

The patient must be moved to a shaded, cool environment and given oral rehydration solution to replace both electrolytes and water. *Oral salt tablets are not recommended*. The patient may have to rest for at least 2 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

B. Heat Exhaustion

Treatment consists of moving patient to a shaded, cool environment, providing adequate fluid and electrolyte replacement, and active cooling (ie, fans, cool packs) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. At least 48 hours of rest and rehydration are recommended.

C. Heat Syncope

Treatment consists of rest and recumbency in a shaded, cool place, and fluid and electrolyte replacement by mouth (or intravenously if necessary).

D. Heat Stroke

Initially, the patient's ABCs (airway, breathing, circulation) must be addressed and stabilized, then treatment is aimed at rapidly reducing the CBT (within 1 hour) while supporting circulation and perfusion. Monitoring includes vital signs, temperature, pulse oximetry, and cardiac rhythm. The patient should also be observed for complications such as hypovolemic or cardiogenic shock, metabolic abnormalities, cardiac arrhythmias, coagulopathy, acute respiratory distress syndrome (ARDS), hypoglycemia, rhabdomyolysis, seizures, organ dysfunction, infection, and severe edema that can progress to compartment syndrome. Circulatory failure in heat-related illness is mostly due to shock from relative or absolute hypovolemia. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Fluid input and output should be monitored closely. Clinicians must also assess for and treat concurrent conditions (infection; trauma; and drug effects).

Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Evaporative cooling is preferred for nonexertional heat stroke and conductive-based cooling for exertional heat stroke. **Evaporative cooling** is a noninvasive, effective, quick and easy way to reduce temperature. This method is done by placing the undressed patient in lateral recumbent position or supported in a hands-and-knees position to expose maximum skin surface to the air. Large fans circulate the room air while the entire undressed body is sprayed with lukewarm water (20°C). Inhalation of cool air or oxygen is also effective. **Conductive-based cooling** involves cool fluid infusion, gastric or bladder lavage, ice packs, and immersion into ice water or cool water. When immersion in ice water or cold water is available in the field, it is the preferred method of cooling for exertional heat stroke. Ice packs are most effective when covering the whole body, as opposed to the traditional method of just the axilla and groin. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have been successful in reducing CBT. Research suggests that brain cooling may lessen cerebrovascular injury from heat stroke.

Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications can be used to suppress shivering including magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.* Treatment should be continued until the CBT drops to 39°C.

▶ Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals should take steps to reduce personal risk factors and to gradually acclimatize to the hot environment.

Coaches, athletic trainers, athletes, and parents of young athletes must be educated about heat-related illness, specifically about prevention, risks, signs and symptoms, and treatment. Medical evaluation and monitoring should be

used to identify the individuals and the weather conditions that increase risk of heat-related disorders.

Those who are physically active in a hot environment should increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. *It is not recommended to have salt tablets available for use because of the risk of hypertonic hypernatremia.* Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments.

▶ Prognosis

Mortality is high from heat stroke; multiorgan dysfunction is the usual cause of heat stroke–related death. The patient is also at risk for rhabdomyolysis, ARDS, and inflammation even after temperature has normalized. Following heat stroke, immediate reexposure to ambient heat should be avoided.

▶ When to Refer

Potential consultants include surgeons for suspicion of compartment syndrome, nephrologist for kidney injury, and transplant surgeon for fulminant liver failure.

▶ When to Admit

All patients with suspected heat stroke must be admitted to the hospital with intensive care capability for close monitoring.

ACCIDENTAL SYSTEMIC HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Systemic hypothermia is a CBT below 35°C.
- ▶ Accurate CBT measurement must be obtained using a low-reading core temperature probe that measures as low as 25°C.
- ▶ The CBT must be over 32°C before terminating resuscitation efforts.
- ▶ Extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass should be considered in hypothermic patients with hemodynamic instability or cardiac arrest.

▶ General Considerations

Systemic hypothermia is defined as CBT below 35°C. This may be primary (from exposure to prolonged ambient extremely low temperature) or secondary (due to thermoregulatory dysfunction). Both may be present at the same time.

Hypothermia should be considered in any patient with prolonged exposure to an ambient cold environment, especially in any patients with prior cold weather injury as well as risk factors listed in Cold & Heat section. In prolonged or repetitive cold exposure, hypothermia ensues if the body's thermoregulatory responses become impaired.

▶ Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient's underlying health and circumstances of hypothermia. Laboratory studies should assess acid-base status, electrolyte derangements (particularly potassium and glucose), coagulopathy, kidney failure, rhabdomyolysis and liver or pancreas dysfunction. Inaccurate laboratory values will occur if the blood sample is warmed to 37°C for the testing. All patients should be evaluated for associated conditions (ie, hypoglycemia, trauma, infection, overdose, and peripheral cold injury).

Accurate CBT measurement must be obtained using a low-reading core temperature probe that measures as low as 25°C. **Hypothermia stage I** is typically seen when the CBT is between 32°C and 35°C and is defined by shivering and possibly poor judgement or coordination but hemodynamic stability and a normal level of consciousness. **Stage II** correlates with CBT 28–32°C. Shivering stops; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The electrocardiogram (ECG) may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V₃, and V₆) (Figure 37-1). When the CBT is below

▲ **Figure 37-1.** Electrocardiogram shows leads II and V₅ in a patient whose body temperature is 24°C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers, and gradually resolve with rewarming. Osborn waves have an extra positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V₃, and V₆).

28°C, the likelihood of hemodynamic instability and cardiac arrest increase dramatically.

Stage III (CBT 24–28°C) is characterized by loss of consciousness but present vital signs. **Stage IV** (CBT less than 24°C) is the loss of vital signs. Coma, loss of reflexes, rigor mortis, asystole, or ventricular fibrillation may falsely lead the clinician to assume that patient is dead despite reversible hypothermia.

▶ Treatment

Rewarming is the initial, imperative treatment for all hypothermic patients. Resuscitation begins with rapid assessment and support of airway, breathing and circulation, simultaneously with the initiation of rewarming, and prevention of further heat loss. All cold, wet clothing must be removed and replaced with warm, dry clothing and blankets.

Mild or stage I hypothermia can be treated by passive external rewarming (ie, removing wet clothing and providing dry clothes) and active external rewarming (ie, a warm environment, warm blankets, and warm beverages). In contrast to those with more severe hypothermia, it is safe and recommended for the uninjured patient with mild hypothermia to become physically active to generate heat. **Active external rewarming** is highly effective and safe for mild hypothermia. This is a noninvasive method of applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Warm bath immersion limits the ability to monitor the patient or treat other coexisting conditions. Patients with mild hypothermia and previous good health usually respond well to passive and active external warming.

Stage II and III hypothermia are treated with more aggressive rewarming in addition to external rewarming strategies. This requires close monitoring of vital signs, pulse oximetry and cardiac rhythm during rewarming. Warm intravenous fluids (38–42°C) are considered minimally invasive and effective.

As hypothermia becomes more severe there are increased complications of both hypothermia itself and rewarming. Complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming lactic acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation, and other cardiac arrhythmias. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient. Extreme caution must be taken when handling the hypothermic patient to avoid triggering potentially fatal arrhythmias in a phenomenon known as rescue collapse.

Patients with hemodynamic instability or cardiac arrest should be transferred to a facility with extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass capability.

In patients who go into cardiac arrest (stage IV), the presence of hypothermia calls for modification of typical resuscitation algorithms. *High quality CPR should be continued until the patient's CBT is at least 32°C.* There is a discrepancy between the recommendations on use and

dosing of epinephrine in cardiac arrest of the severely hypothermic patient. The European Resuscitation Council recommends withholding epinephrine until warmed to 30°C, and decreasing the frequency from 30°C to 35°C. The American Heart Association permits dosage as usual in conjunction with rewarming. ECMO or cardiopulmonary bypass should be done in patients with hypothermia who are in cardiac arrest except when patients have fatal hyperkalemia (10–12 mmol/L) or evidence of death from a traumatic cause such as decapitation or asphyxiation in an avalanche. Studies show great success with ECMO and bypass in such cases, documenting 47–63% of patients returning to full neurologic function.

Any hypothermic patient with return of spontaneous circulation must be monitored very closely because of the high likelihood of subsequent multiorgan system failure.

► When to Admit

Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged observation.

HYPOTHERMIA OF THE EXTREMITIES

ESSENTIALS OF DIAGNOSIS

- ▶ Extremities suffering cold-induced injuries should not be exercised, rubbed, or massaged during rewarming.
- ▶ Rewarming of extremities affected by cold-induced injuries must be performed as soon as possible after there is no risk of refreezing.

► Clinical Findings

Cold-induced injuries to the extremities range from mild to severe. Cold exposure of the extremities produces immediate localized vasoconstriction followed by generalized vasoconstriction. Tissue damage may result from ischemia and intravascular thromboses, endothelial damage, or by actual freezing. Freezing (frostbite) may occur when the temperature drops or in the presence of wind, water, immobility, malnutrition, or vascular disease.

► Prevention

“Keep warm, keep dry, and keep moving.” Individuals should wear warm, dry clothing. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet clothing, socks, and shoes should be replaced with dry ones. Those most at risk are people with underlying diseases or medications that decrease tissue perfusion and those with environmental exposure to a prolonged cold environment. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

FROSTNIP & CHILBLAIN (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury causing local paresthesias of the involved area that completely resolve with passive external rewarming.

Chilblains or **erythema pernio** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma, secondary infection, and further cold exposure.

IMMERSION FOOT OR TRENCH FOOT

Immersion foot (or hand) is caused by prolonged immersion in cold water or mud, usually below 10°C. **Prehyperemic stage** is marked by early symptoms of cold and anesthesia of the affected area. **Hyperemic stage** follows with hot sensation, intense burning, and shooting pains. **Posthyperemic stage** occurs with ongoing cold exposure; the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm. This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene.

Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid further cold injury and water immersion. Affected parts are elevated to aid in removal of edema fluid. Pressure sites (ie, heels) are protected with cushions. Bed rest is required until all ulcers have healed.

FROSTBITE

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows the reperfusion of the frozen tissues, with damaged endothelial cells and progressive microvascular thrombosis resulting in

further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, prickling, itching, and pallor. With increasing severity, deep frostbite involves deeper structures. The skin appears white or yellow, loses its elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, gangrene, paresthesias and stiffness may occur.

▶ Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia, concurrent conditions, and injury. Avoid secondary exposure to cold. Early use of systemic analgesics is recommended for nonfrozen injuries. The patient should be hydrated orally or parenterally to avoid hypovolemia and to improve perfusion.

1. Rewarming—Rapid rewarming at temperatures slightly above normal body temperature may significantly decrease tissue necrosis and reverse the tissue crystallization. **If there is any possibility of refreezing, the frostbitten part should not be thawed.** Ideally the frozen extremity should not be used. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. In the absence of a thermometer, the temperature should be checked by an unaffected extremity, ideally of a caregiver rather than the patient. Water in this temperature range feels warm but not hot to the normal hand or wrist. If warm water is not available then passive thawing in a warm environment should be allowed. Dry heat (ie, stove or open fire) is not recommended because it is more difficult to regulate, and increases likelihood of accidental burns. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. **In the early stage, rewarming by exercise, rubbing, or friction is contraindicated.** The patient must be kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, occlusive dressings, or bandages are not applied. Blisters should be left intact unless signs of infection supervene.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis must be considered. Infection risk may be reduced by aseptic wound care. Nonadherent sterile gauze and fluffy dressing should be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically.

B. Medical and Surgical Treatment Options

With the availability of telemedicine, specialists are able to provide advice on early field treatment of cold-injured patients in remote areas, thereby improving outcome. Clinicians must watch for evidence of compartment syndrome and need for fasciotomy. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Reduction of amputation rates have been

shown from use of intravenous infusions of synthetic prostaglandins and from tissue plasminogen activators. Intra-arterial thrombolytic administration within 24 hours of exposure has resulted in improved tissue perfusion and has reduced amputation. There is insufficient evidence to recommend hyperbaric oxygen, heparin, or sympathectomy.

C. Follow-Up Care

Patient education must include ongoing care of the cold injury and prevention of future hypothermia and cold injury. Gentle, progressive physical therapy to promote circulation should be instituted as tolerated. Debridement and amputation should be considered only after it is established that the tissues are necrotic.

▶ Prognosis

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved extremity may be at increased susceptibility for discomfort and injury upon re-exposure to cold. Neuropathic sequelae include pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

▶ When to Admit

- Management of tissue damage, comorbidities, associated injuries.
- Need for hospital-based interventions.
- Psychosocial factors (cognitive impairment, inadequate living situation) that could compromise patient safety or recovery.

DROWNING

ESSENTIALS OF DIAGNOSIS

- ▶ The first requirement of rescue is immediate rescue breathing *and* CPR.
- ▶ Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- ▶ Clinical manifestations are hypoxemia, pulmonary edema, and hypoventilation.

▶ General Considerations

Drowning, as defined by the World Health Organization is the “process resulting in primary respiratory impairment from submersion in a liquid medium.” Drowning may result in aspiration, laryngospasm, hypoxemia, and acidemia. Outcomes from drowning range from life without morbidity to death. Morbidity may be immediate or delayed. The asphyxia of drowning is usually due to aspiration of fluid but it may result from airway obstruction caused by laryngeal spasm while the victim is gasping under water. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours. Disseminated intravascular coagulation may also lead to bleeding after asphyxiation from drowning.

▶ Clinical Findings

A. Symptoms and Signs

The patient's appearance may vary from asymptomatic to marked distress with abnormal vital signs. Signs and symptoms include dyspnea, cough, wheezing, chest pain, dysrhythmia, hypotension, cyanosis, and apnea. The patient may experience headache, neurologic deficits, and altered level of consciousness. Hypothermia is highly likely with cold water or prolonged submersion.

B. Laboratory Findings

Arterial blood gas results are helpful in determining the degree of injury since initial clinical findings may appear benign. PaO₂ is usually decreased; PaCO₂ may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario. Metabolic acidosis is common.

▶ Prevention

Education and prevention are critical given the high burden of disease from drowning.

Preventive measures should be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the following: (1) use of alcohol or other drugs, (2) inadequate water safety skills, (3) poor physical health, (4) hyperventilation, (5) sudden acute illness (eg, hypoglycemia, seizure, dysrhythmia, myocardial infarction, asthma flare), (6) acute trauma (particularly brain or spinal cord injury, or both), (7) venomous stings or bites, (8) decompression sickness, (9) dangerous water conditions (temperature and turbulence), and (10) carbon monoxide exposure from boat motors.

▶ Treatment

A. First Aid

1. *The first requirement of rescue is immediate basic life support treatment and CPR.* At the scene, immediate measures to combat hypoxemia are critical to improve outcome.
2. Patient must be assessed for hypothermia, hypoglycemia, concurrent medical conditions and associated trauma, especially brain and cervical spine injury.

3. Rescuer should not attempt to drain water from the victim's lungs.
4. Resuscitation and basic life support efforts must be continued until CBT reaches 32°C.

B. Subsequent Management

1. Ensure optimal ventilation and oxygenation—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Oxygen saturation should be maintained at 90% or higher via supplemental oxygen, continuous positive airway pressure (CPAP), positive end-expiratory pressure (PEEP) or intubation and mechanical ventilation.

Serial physical examinations and chest radiographs should be performed to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing. Nasogastric suctioning can decompress the stomach.

2. Cardiovascular support—Intravascular volume status must be monitored and supported by vascular fluid replacement, vasopressors, or diuretics as needed.

3. Correction of blood pH and electrolyte abnormalities

Metabolic acidosis is present in 70% of drowning victims, but this typically corrects through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral and spinal cord injury—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock.

5. Hypothermia—CBT should be measured and managed as appropriate (see Accidental Systemic Hypothermia, above).

▶ Course & Prognosis

Respiratory damage is often severe in the minutes to hours following a drowning. With respiratory supportive treatment, improvements typically occur quickly over the first few days following the drowning. Long-term complications of drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. Prognosis is directly correlated with the patient's age, submersion time, rapid prehospital resuscitation and rapid transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

▶ When to Admit

Most patients with significant drowning or concurrent medical or traumatic conditions require inpatient monitoring following the event. This includes continuous monitoring of cardiorespiratory, neurologic, renal and metabolic function. Pulmonary edema may not appear for 24 hours.

THERMAL BURNS

ESSENTIALS OF DIAGNOSIS

- ▶ Estimates of the burn location, size and depth greatly determine treatment plan.
- ▶ The first 48 hours of burn care offer the greatest impact on morbidity and mortality of a burn victim.

The first 48 hours after thermal burn injury offer the greatest opportunity to impact the survival of the patient. Early surgical intervention, wound care, enteral feeding, glucose control and metabolic management, infection control, and prevention of hypothermia and compartment syndrome have contributed to significantly lower mortality rates and shorter hospitalizations.

▶ General Considerations

A. Classification

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since this figure will quantify the parameters of resuscitation.

1. Extent—In adults, the “rule of nines” (Figure 37–2) is useful for rapidly assessing the extent of a burn. It is important to view the entire patient to make an accurate assessment of skin findings on initial and subsequent

▲ **Figure 37–2.** Estimation of body surface area in burns.

examinations. One rule of thumb is that the palm of an open hand constitutes 1% total body surface area in adults. Only second- and third-degree burns are included in calculating the total burn surface area. First- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

2. Depth—Judgment of depth of injury is difficult. The **first-degree burn** may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, which is referred to as a **second-degree burn**. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures, referred to as a **third-degree burn**. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

Deep second- and third-degree burns are treated in a similar fashion. Neither will heal appropriately without early debridement and grafting; the resultant skin is thin and scarred.

B. Survival after Burn Injury

Transfer to a burn unit is indicated for large burn size, circumferential burn, or burn involving a joint or high-risk body part, and patients with comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support through parenteral or enteral feeding.

C. Associated Injuries or Illnesses

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Smoke inhalation (see Chapter 9) must be suspected when a burn victim is found in an enclosed space, or in close proximity to the fire. Clinical findings include singed nasal or facial hairs, carbonaceous sputum, or an elevated carboxyhemoglobin level. Severe burns from any source may result in similar complications (ie, infections, respiratory compromise, multiorgan dysfunction, venous thromboembolism, and gastrointestinal complications).

D. Systemic Reactions to Burn Injury

When burns greater than approximately 20% of total body surface area are present, systemic metabolic derangements may occur and require intensive support. The inflammatory cascade can result in shock. In addition, coagulopathy may develop.

▶ Treatment

A. Initial Resuscitation

The clinician must proceed with a full trauma assessment, starting with “ABCDE” (airway, breathing, circulation, disability, exposure). Serial assessments of airway and breathing are necessary since endotracheal intubation or cricothyotomy may be needed for major burn victims,

particularly those with possible inhalation injury. Generalized edema may develop during fluid resuscitation, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an ARDS picture in 24–48 hours, especially with severe inhalation injury.

Generalized capillary leak results from burn injury over more than 20% of total body surface area. This often necessitates intravascular volume replacement with large volumes of crystalloid. There are many guidelines for fluid resuscitation. The most widely recognized is the **Parkland formula** (<http://www.mdcalc.com/parkland-formula-for-burns/>) in which the fluid requirement in the first 24 hours is estimated as 4 mL/kg × body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period, based on the time of injury rather than time of arrival to medical care. The remaining fluid is delivered over the next 16 hours. An extremely large volume of fluid may be required. Deep electrical burns and inhalation injury may increase the fluid requirement.

B. Management

1. Pain control—Pain control is critical in these patients. Treatment is with opioids and nonsteroidal anti-inflammatory drugs.

2. Chemoprophylaxis—

A. TETANUS IMMUNIZATION—Tetanus status should be verified and updated in all burn patients. (See Chapter 33.)

B. ANTIBIOTICS—All nonsuperficial depth wounds should be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

3. Surgical management—

A. ESCHAROTOMY—As edema fluid accumulates, ischemia may develop under any constricting eschar if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb.

B. FASCIOTOMY—Fasciotomy is indicated for any compartment syndrome. Clinicians must vigilantly monitor patients for early signs of compartment syndrome, particularly in those with circumferential burns.

C. DEBRIDEMENT, DRESSINGS, AND TOPICAL AND SYSTEMIC ANTIBIOTIC THERAPY—Minor burn wounds should be debrided at the bedside to determine the depth of the burn and then thoroughly cleansed. Thereafter, daily wound care should consist of debridements as needed, topical antibiotics, and wound dressing. Patient compliance and adequate pain control is essential for successful outpatient treatment. The wound should be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is a critically important intervention. Topical antibiotics should be applied. Silver nylon dressings have been shown to be beneficial in decreasing length of stay, controlling pain, and preventing infection.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries. Healthcare-associated infections are increasingly common.

D. WOUND MANAGEMENT—The goal of therapy after fluid resuscitation is rapid and stable closure of the wound.

E. ABDOMINAL COMPARTMENT SYNDROME—Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompression may be indicated to improve ventilation and oxygen delivery, but even after this surgery, survival remains low.

C. Patient Support

Burn patients require extensive supportive care, both physiologically and psychologically. It is important to maintain normal CBT and avoid hypothermia (by maintaining environmental temperature at or above 30°C) in patients with burns over more than 20% of total body surface area. Burn patients are at risk for many complications such as respiratory injury, ARDS or respiratory failure unresponsive to maximal ventilatory support, sepsis, multiorgan failure, and venous thromboembolism.

Burn patients require careful assessment and provision of optimal nutritional needs since their metabolism is higher and they require more energy, nutrients, and antioxidants for wound healing. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

► Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia from poor glucose control is a predictor of worse outcomes. Complications most commonly include sepsis; gangrene requiring limb amputation; or neurologic, cardiac, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following burn injury.

► When to Refer

- Transfer to a burn unit is indicated for large burn size, circumferential burn, or burn involving a joint or high-risk body part, and patients with comorbidities.

► When to Admit

- Significant burns (based on location and extent).
- Patients with significant comorbidities and suboptimal home situations.

ELECTRICAL INJURY

ESSENTIALS OF DIAGNOSIS

- ▶ Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- ▶ Resuscitation must be attempted before assuming the electrical injury victim is dead; clinical findings are unreliable.
- ▶ Skin findings may be misleading and are not indicative of the degree of deeper tissue injury.

▶ General Considerations

Electricity-induced injuries are common and most are preventable. These inquiries occur by exposure to electrical current of low voltage, high voltage, or lightning. Electrical current type is either alternating current (AC) or direct current (DC). Electricity causes acute damage by direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and associated trauma.

Alternating current (AC) is bidirectional electrical flow that may cause muscle tetany, which prolongs the duration and amount of current exposure. AC current can be low voltage or high voltage. **Low voltage** (less than 1000 V) is typically household AC current that ranges in severity from minor injury to significant damage and death. **High voltage** (greater than 1000 V) is most often related to occupational exposure and is associated with deep tissue damage and higher morbidity and mortality. **Direct current (DC)** is unidirectional electrical flow (ie lightning, batteries, and automotive electrical systems). It is more likely to cause a single intense muscle contraction and asystole. **Lightning** differs from other high-voltage electrical shock in that lightning is massive DC current of millions of volts lasting a very brief duration (a small fraction of a second).

The extent of damage depends on the following factors: voltage (high or low, whether greater or less than 1000 volts), current type, tissue resistance, moisture, pathway; duration of exposure; associated trauma and comorbidities. Current is the most important determinant of tissue damage. Current passes through the tissues of least resistance, and this energy produces heat causing direct thermal injury. Tissue resistance varies throughout the body. Nerve cells are the most vulnerable, and bone is the most resistant to electrical current.

▶ Clinical Findings

Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current.

Skin damage does not correlate with the degree of injury. Not all electrical injuries cause skin damage; only very minor skin damage may be present with massive internal injuries. Symptoms and signs may range from tingling, superficial skin burns, and myalgias to coma, paralysis, massive tissue damage, or death. The presence of entrance

and exit burns signifies an increased risk of deep tissue damage. The entrance and exit points on the skin are the most damaged. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. If the current passes through the heart or brainstem, death may be immediate due to ventricular fibrillation, asystole, or apnea.

Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive and unreliable and a viable victim of electrical current injury may appear dead on examination.

▶ Complications

Complications include respiratory arrest; autonomic dysfunction (resulting in pupils that are fixed, dilated, or asymmetric); dysrhythmias; altered mental status; seizures; paralysis; headache; pneumothorax; vascular injury; tissue edema and necrosis; compartment syndrome; associated traumatic injuries (ruptured ear drums, fractures from falls or muscle contractions); rhabdomyolysis; acute kidney injury; hypovolemia from third spacing; infections; ocular complications (ie, acute or delayed cataract formation); sepsis; gangrene requiring limb amputation; neurologic, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following electrical injury.

▶ Treatment

A. Emergency Measures

The patient must be assessed and treated as a trauma victim. The victim must be safely separated from the electrical current prior to initiation of CPR or other treatment. Resuscitation must then be initiated since clinical findings of death are unreliable.

B. Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by a full trauma protocol. Fluid resuscitation is important to maintain adequate urinary output. Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, renal function tests, liver biochemical tests, urinalysis, urine myoglobin, serum creatine kinase, and cardiac enzymes. ECG does not show typical patterns of ischemia since the electrical damage is epicardial. Victims must be evaluated for hidden injury (eg, ophthalmic, otologic, muscular, compartment syndromes), organ injury (myocardium, liver, kidney, pancreas), blunt trauma, dehydration, skin burns, hypertension, posttraumatic stress, acid-base disturbances, and neurologic damage.

Electrical burn injury remains the most underrecognized and devastating burn injury, sometimes leading to amputations (often because of unrecognized compartment syndromes) and acute kidney injury, resulting in part from rhabdomyolysis (see Chapter 22).

Superficial skin may appear deceptively benign, leading to a delayed or completely overlooked diagnosis of deep tissue injury. When electrical injury occurs, extensive deep tissue necrosis should be suspected. Deep tissue necrosis

leads to profound tissue swelling, which results in a high risk of a compartment syndrome. Early debridement of devitalized tissues and tetanus prophylaxis may reduce the risks of infection.

Pain management is important before, during, and after initial treatment and rehabilitation. Multimodal approach to pain is the most effective. Interventions include medications (opioids, acetaminophen, nonsteroidal anti-inflammatory drugs), heat therapy, massage, and cognitive-behavioral therapy.

► Prognosis

Prognosis depends on the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications.

► When to Refer

- Surgical specialists may be needed to perform fasciotomy for compartment syndrome or devitalized tissue debridement or microvascular reconstruction.
- Ophthalmologists should evaluate patients for possible ocular complications, and patients should be referred to ENT for tympanic membrane rupture or hearing loss.

► When to Admit

Indications for hospitalization include high voltage exposure; dysrhythmia or ECG changes; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

RADIATION EXPOSURE

ESSENTIALS OF DIAGNOSIS

- Damage from radiation is determined by the source, type, quantity, duration, bodily location, and susceptibility and accumulation of exposures of the person.
- Clinicians and patients should be educated regarding the risks of medical diagnostic radiation. These radiation risks must be weighed against the benefits of the medical imaging needed.

terrorism) exposure. With advancements in nuclear technology in the fields of medicine, energy, and industry, there is a growing risk of radiation exposure to patients, occupational workers, and the public. The extent of damage due to radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; the degree of disruption to DNA; metabolic and cellular function; and the age, underlying condition, susceptibility, and accumulative exposures of the victim.

Radiation occurs from both nonionizing and ionizing radiation sources. **Nonionizing radiation** is low energy, resulting in injuries related to local thermal damage (ie, microwave, ultraviolet, visible light, and radiowave). **Ionizing radiation** is high energy, causing bodily damage in several ways (ie, cellular disruption, DNA damage, and mutations). Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate (ie, alpha or beta particles, neutrons, and protons). Exposure may be external, internal, or both.

International Commission on Radiological Protection (ICRP) website provides the most up-to-date recommendations for protection against ionizing radiation (<http://www.icrp.org/index.asp>).

► Clinical Findings

Radiation exposure results in acute and delayed effects. Acute effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). This may be manifested as mucositis, nausea, vomiting, gastrointestinal edema and ulcers, skin burns, and bone marrow suppression over hours to days after exposure. Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction.

Clinicians must be educated to recognize and treat acute radiation sickness also referred to as **acute radiation syndrome**. Acute radiation syndrome is due to an exposure to high doses of ionizing radiation over a brief time course. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases, prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow. The Centers for Disease Control and Prevention offers web-based information for clinicians regarding acute radiation syndrome (<http://emergency.cdc.gov/radiation/arsphysicianfactsheet.asp>).

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, cardiopulmonary, and cerebrovascular symptoms and signs from initial exposure and over time.

► Therapeutic Radiation Exposure

Radiation therapy has been a successful component in the treatment of many malignancies. These radiation-treated cancer survivors have a higher risk of development of a second malignancy; obesity; and pulmonary, cardiac and thyroid dysfunction as well as an increased overall risk for chronic health conditions and mortality.

Exposure to radiation may occur from environmental, occupational, medical care, accidental, or intentional (ie,

▶ Medical Imaging Radiation Exposure

Medical imaging with ionizing radiation exposure (ie, computed tomography [CT] and nuclear medicine studies) has dramatically increased over the past few decades. Medical imaging radiation exposure has become a growing concern for the healthcare professionals and the public. Research has found significantly large variability in the radiation dose for the same study among different machines and different clinicians, within and across institutions, with radiation doses varying by as much as a factor of 10. These findings highlight the urgent safety need for standardization and regulation of radiation dosing for medical diagnostics and for clinician and public education.

American College of Radiology (ACR) offers “ACR Appropriateness Criteria” which are evidence-based guidelines created by expert panels to serve as a reference for best practices for imaging decisions by healthcare providers (<http://www.acr.org/Quality-Safety/Appropriateness-Criteria>). Clinicians and patients must carefully weigh the risks and benefits of radiation exposure when deciding on an imaging test.

▶ Occupational & Environmental Radiation Exposure

The National Nuclear Security Administration’s Radiation Emergency Assistance Center provides 24-hour access to expert consultation services over the telephone or via email (telephone: 1-865-576-1005 or email: <https://orise.ornl.gov/reacts/>). The National Nuclear Security Administration is part of the International Emergency Management and Cooperation, an international collaborative of foreign governments to establish an infrastructure worldwide for emergency preparedness and support, including radiation exposure. The Centers for Disease Control and Prevention “Radiation Emergency” website (<http://emergency.cdc.gov/radiation/>) is a useful resource for professionals.

▶ Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatments focus on the dose, route, and effects of exposure.

▶ Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Death is usually due to hematopoietic failure gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection.

Carcinogenesis is related to the radiation type, total dose, duration, accumulation of exposure, and to the susceptibility of the victim. The younger the victim’s age at the time of exposure, the greater the risk of acute and long-term damage from radiation. Radiation-related cancer risks persist throughout the exposed person’s lifespan.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is a growing concern for the iatrogenic increase in radiation-induced cancer risks.

There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

▶ When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.

ENVIRONMENTAL DISORDERS RELATED TO ALTITUDE

DYSBARISM & DECOMPRESSION SICKNESS

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms temporally related to recent altitude or pressure changes (ie, scuba diving).
- ▶ Early recognition and prompt treatment of decompression sickness are extremely important.
- ▶ Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- ▶ Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

▶ General Considerations

Dysbarism and decompression sickness are physiologic problems that result from altitude changes and the effects of environmental pressure on gases in the body during underwater descent and ascent. These are most likely to occur when scuba diving is followed closely by travel to high altitudes, or when the scuba diver is not adherent to the conservative dive guidelines for dive duration, course, depth, and surface times.

As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. During the ascent, gases in the body expand.

Dysbarism results from barotrauma when gas compression or expansion occurs in parts of the body that are noncompressible or have limited compliance. Pulmonary overinflation syndrome is one of the most serious and potentially fatal results of barotrauma. Pulmonary

overinflation syndrome is due to an inappropriately rapid ascent causing alveoli rupture and air bubble extravasation into tissue planes or even the cerebral circulation.

Decompression sickness occurs when the ascent is too rapid and gas bubbles form and cause damage depending on their location (ie, coronary, pulmonary, spinal or cerebral blood vessels, joints, soft tissue). These gas bubbles cause damage due to mechanical disruption of tissue, local inflammatory response, occlusion of blood flow, platelet activation, endothelial dysfunction, and capillary leakage. Decompression sickness symptoms depends on the size and number and location of gas bubbles released (notably nitrogen). Risk of decompression sickness depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver's age, weight, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude (scuba dive) and high altitude (air travel or ground ascent). Predisposing factors for decompression sickness include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt (ie, patent foramen ovale), diver's overall health, dehydration, alcohol and medication effects, and panic attacks. Decompression sickness may also occur in those who take hot showers after cold dives.

Preventive measures include diver education; pre-dive medical screening and dive planning; strict adherence to dive course, timing, and depths; and a slow and controlled ascent plus proper control of buoyancy. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive, especially following multiple dives.

▶ Clinical Findings

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 36 hours later. Decompression sickness symptoms include pain in the joints ("the bends"); skin pruritus or burning (skin bends); cardiac symptoms (acute coronary syndrome, conduction abnormalities); spinal cord or cerebral symptoms (focal neurologic dysfunction or "dissociation" symptoms that do not follow typical distribution neuroanatomy patterns); labyrinthine decompression sickness ("the staggers," central vertigo); pulmonary decompression sickness ("the chokes," inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear and sinus; coma and death.

Decompression sickness involving the brain and spinal cord may occur by different mechanisms due to air bubbles causing arterial occlusion, venous obstruction, or in situ toxicity.

The clinician must assess for associated conditions of hypothermia, hypoglycemia, hypovolemia, drowning, trauma, envenomations, or concurrent medical conditions.

▶ Treatment

Early recognition and prompt treatment are extremely important. Decompression sickness must be considered if

symptoms are temporally related to recent diving or altitude or pressure changes within the past 48 hours. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Hyperbaric oxygen treatment is commonly recommended for decompression sickness symptoms. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild decompression sickness symptoms resolve. Nonsteroidal anti-inflammatory drugs, acetaminophen or aspirin may be given for pain control if there are no contraindications. Opioids should be used very cautiously, since these may obscure the response to recompression.

▶ When to Admit

Rapid transportation to a hyperbaric treatment facility for recompression is imperative for decompression sickness. The Divers Alert Network is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org).

HIGH-ALTITUDE ILLNESS

ESSENTIALS OF DIAGNOSIS

- ▶ The severity of the high-altitude illness is affected by the rate and height of ascent, and the individual's susceptibility.
- ▶ Prompt recognition and medical treatment of early symptoms of high-altitude illness may prevent progression.
- ▶ Clinicians should assess other conditions which may coexist or mimic symptoms of high altitude illness (severe dehydration, hyponatremia, or hypoglycemia, trauma, or infection).
- ▶ Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

▶ General Considerations

As altitude increases, hypobaric hypoxia results due to a decrease in both barometric pressure and oxygen partial pressure. High-altitude medical problems are due to

hypobaric hypoxia at high altitudes (usually greater than 2000 meters or 6560 feet). High-altitude illness includes a spectrum of disorders categorized by end-organ effects (mostly cerebral and pulmonary), and exposure duration (acute and long-term). Acute high-altitude conditions are **acute mountain sickness (AMS)**, **high-altitude cerebral edema (HACE)**, and **high-altitude pulmonary edema (HAPE)**. Long-term exposure to high altitude over months or years with inadequate acclimatization can result in sub-acute mountain sickness and chronic mountain sickness (Monge disease).

Acclimatization occurs as a physiologic response to the rise in altitude and increasing hypobaric hypoxia. Physiologic changes include increases in alveolar ventilation and oxygen extraction by the tissues and increased hemoglobin level and oxygen binding. High-altitude illness results when the hypoxic stress is greater than the individual's ability to acclimatize. Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility, and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors (rapid rate and height of ascent and total change in altitude).

Individual susceptibility factors include underlying conditions such as cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders (ie, sickle cell disease), pregnancy, neurologic condition, recent surgery, and many other chronic medical conditions. Those with symptomatic cardiac or pulmonary disease should avoid high altitudes.

Patient assessment for high-altitude illness should also include evaluation for other conditions, which may coexist or may present in a similar manner.

1. High-Altitude–Associated Neurologic Conditions: AMS & HACE

There is a spectrum of neurologic conditions caused by high altitude, ranging from AMS to the more serious form HACE. Clinicians must rely on patient's report of symptoms to determine the severity of AMS. In addition to the patient's report of symptoms, HACE includes neurologic examination findings.

AMS includes symptoms such as headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, difficulty sleeping. Later symptoms include irritability, difficulty concentrating, anorexia, insomnia, and increased headaches.

HACE includes the severe symptoms of AMS and results from cerebral vasogenic edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters (8250 feet) but may occur at lower elevations. Hallmarks are altered mental status, ataxia, severe lassitude, and encephalopathy. Examination findings may include confusion, ataxia, urinary retention or incontinence, focal neurologic deficits, papilledema, and seizures. Symptoms may progress to obtundation, coma, and death.

▶ Treatment

Definitive treatment is immediate descent. Descent should be at least 610 meters (2000 feet), and it should continue until symptoms improve. Descent is essential if the symptoms are persistent, severe, worsening or if HACE or HAPE are present. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief but they should not delay descent.

Initial treatment involves oxygen administration to keep the pulse oximetry S_pO_2 to greater than 90%.

Acetazolamide (250 mg twice daily) is an effective medication for treatment of mild symptoms of AMS.

Dexamethasone is most effective for moderate to severe AMS (4 mg orally every 6 hours). Dexamethasone is the primary treatment for HACE (8 mg once then 4 mg every 6 hours). Acetazolamide can be added as an adjunct in severe HACE cases. In most individuals, symptoms clear within 24–48 hours.

It is imperative that the clinician also assess for other conditions that may mimic or coexist with AMS and HACE (ie, dehydration, exhaustion, hypoglycemia, hypothermia, hyponatremia, trauma, infection).

If HAPE symptoms and signs are present along with HACE, nifedipine or a selective phosphodiesterase inhibitor may be added for pulmonary vasodilation. The clinician must be cautious when using combinations of vasodilators.

2. Acute HAPE

HAPE is the leading cause of death from high altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at altitudes above 3000 meters (9840 feet), although it may occur at lower levels. Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion should be avoided. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens.

Physical findings may include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, rales, and rhonchi. The clinician must assess for other potential medical conditions because the clinical picture may resemble other etiologies (pneumonia, viral upper respiratory tract infection, mucous plugging, bronchospasm, or acute coronary syndrome). Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. Prompt recognition and medical attention of early symptoms of HAPE may prevent progression.

▶ Treatment

Immediate descent (at least 610 meters [2000 feet]) is essential although this may not be immediately possible, and may not alone improve symptoms.

The patient must rest, reclined with head elevated. Supplemental oxygen must be administered to maintain pulse oximetry reading S_pO_2 greater than 90%. Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible, but should not delay descent.

Nifedipine (30 mg slow extended-release tablets every 12 hours) can be used as an adjunct if the other therapies (descent, oxygen, or portable hyperbarics) are not successful or available. Selective phosphodiesterase inhibitors (tadalafil, 10 mg orally every 12 hours; sildenafil, 50 mg orally every 8 hours) are used for HAPE prevention but may also provide effective symptom relief as an alternative or if nifedipine is not available. Administering nifedipine plus a phosphodiesterase inhibitor as pulmonary vasodilators is not recommended because this combination may also lower the mean arterial pressure and decrease cerebral perfusion. Treatment for ARDS (see Chapter 9) is required for some patients. If neurologic symptoms are present concurrently with HAPE and do not resolve with improved oxygenation, dexamethasone should be added according to HACE treatment guidelines.

3. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at high altitudes (above 4500 meters) for a prolonged period of time. Symptoms of dyspnea and cough are probably due to hypoxic pulmonary hypertension and secondary heart failure. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

4. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such a hypobaric hypoxic environment. It is difficult to differentiate from chronic pulmonary disease.

► Prevention of High-Altitude Disorders

Pre-trip preventive measures include participant education, medical prescreening, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel and during the trip. Preventive efforts during ascent include reduced food intake; avoidance of alcohol, tobacco, and unnecessary physical activity during travel.

Gradual ascent is the most effective way to allow acclimatization. Low-risk ascension rate is 2 or more days to arrive at 2500–3000 meters. The altitude reached during waking hours is not as important as the altitude at which this hiker sleeps. If the terrain does not allow a sleeping elevation increase below 500 meters, an extra rest day should be added before or after the increased sleep elevation more than 500 meters.

Drug prophylaxis may be prescribed for AMS and HACE if no contraindications exist. Prophylactic low-dose acetazolamide (125 mg twice daily orally) has been shown to reduce the incidence and severity of AMS and HACE when started 3 days prior to ascent and continued for

48–72 hours at high altitude. Dexamethasone is an alternative prophylactic medication for AMS and HACE (2 mg every 6 hours or 4 mg every 12 hours orally beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days).

Individuals with a past history of HAPE should use drug prophylaxis to reduce the risk of recurrence. Nifedipine, 30 mg extended-release every 12 hours started the day before ascent and continued through the fourth day at target elevation, or through the seventh day if the ascent rate was faster, is recommended. Salmeterol can be added at doses of 125 mcg by inhaler every 12 hours beginning 24 hours prior to ascent. This can be used as an adjunct to nifedipine but not as monotherapy.

Phosphodiesterase inhibitors (eg, tadalafil 10 mg orally twice a day or sildenafil 50 mg orally every 8 hours) may be beneficial in the treatment of HAPE based on their physiologic effects of decreased pulmonary arterial pressures and pulmonary vasodilation. This drug class may be used if nifedipine is not available but should not be administered along with nifedipine since the additive vasodilation effects may increase the patient's risk of hypotension and cerebral hypoperfusion.

► When to Admit

- All patients with HACE or HAPE must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent.
- Pulmonary symptoms and hypoxia may be worsened by complications such as pulmonary embolism, secondary respiratory infection, bronchospasms, mucous plugging, or acute coronary syndrome.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends on the nature and severity of the traveler's preflight condition and factors such as travel duration, frequency and use of inflight exercise, cabin altitude pressure, availability of medical supplies, and presence of health care professionals on board. Air travel passengers are susceptible to a wide range of flight-related problems: pulmonary (hypoxemia, gas expansion), venous thromboembolism (VTE), infectious, cardiac, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, and substance-related.

These air-travel risks are higher for those air travelers with preexisting medical conditions.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight due to cabin altitude. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers.

Any form of prolonged travel involving immobilization has been associated with increased risk of VTE (referred to as “traveler’s thrombosis”), although air travel has been the main focus of medical review. Conditions that place long-distance travelers at high risk for VTE include the following: (1) travel involving immobilization for 4 or more hours, (2) hypercoagulable disorders (ie, Factor V Leiden, deficiencies in proteins C and S or antithrombin, elevated factor VIII, hyperprothrombinemia, antiphospholipid syndrome), and (3) acquired risks (previous VTE, recent surgery, stroke or trauma, active malignancy, obesity, pregnancy or postpartum, oral contraceptives or hormone therapy, advanced age, immobilization or limited mobility, inflammatory bowel disease, and nephrotic syndrome)

Air travel is not advised for anyone who is “incapacitated” or has any “unstable conditions.” The Air Transport Association of America defines an **incapacitated passenger** as “one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers.” **Unstable conditions** include active pneumothorax, advanced pulmonary hypertension, acute worsening of an underlying lung disease, poorly controlled hypertension, dysrhythmias, angina, valvular disease, heart failure, or acute psychiatric condition; severe anemia or symptomatic sickle cell disease; recent myocardial infarction; cerebrovascular accident; poorly controlled seizure disorder; deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease (influenza, tuberculosis, measles, chickenpox, zoster, or other communicable virulent infections).

► Pregnancy

Long travel increases risk of VTE for the pregnant traveler. Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. The clinician’s authorization is required if travel is essential during the ninth

month of pregnancy or earlier in a complicated pregnancy. Pregnant travelers are at higher risk for infection transmission and air travel radiation exposure.

► Prevention

Air travel complications may be reduced by the following preventive measures: passenger prescreening, passenger education, and in-flight positioning and activity. Prescreening evaluation is recommended for all high-risk patients including preexisting requirement of oxygen, continuous positive pressure or ventilator support, underlying restrictive or obstructive lung disease, comorbidities worsened by hypoxemia (pulmonary hypertension, cardiac or cerebrovascular disease), previous respiratory distress during air travel, recent pneumothorax, and being within 6 weeks of an acute respiratory illness.

Air travel education should include risk reduction of VTE, infectious diseases, and exacerbations of underlying medical conditions. Patients and clinicians can check the World Health Organization website for the most updated information on travel health risks and infectious diseases (<http://www.who.int/ith/en/>). Patients requiring oxygen therapy or CPAP must be reminded to make prior arrangements for oxygen provision prior to departure and upon arrival at their destinations.

All long-distance travelers can reduce VTE risk by avoiding constrictive clothing, staying well-hydrated, changing position frequently, avoiding cramped position, avoiding leg crossing, engaging in frequent in-flight leg stretching exercises at least every hour, and walking for 5 minutes every hour. Clinicians should assess those with high risk of VTE prior to air travel to determine whether anticoagulation is indicated (see Table 14–14).

Poisoning

Kent R. Olson, MD

38

INITIAL EVALUATION: POISONING OR OVERDOSE

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose but not yet exhibit any manifestations of toxicity. It is important to: (1) quickly assess the potential danger, (2) consider gut decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.

▶ Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a regional poison control center. (In the United States, dialing 1-800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION

Call your regional poison control center
U.S. toll-free 1-800-222-1222

▶ Observation of the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility (opioids, anticholinergics, salicylate) or may cause a delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed. Before discharge,

psychiatric evaluation should be performed to assess suicide risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

▶ Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

▶ Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *A*irway, *B*reathing, *C*irculation, and *D*rugs (dextrose, thiamine, and naloxone or flumazenil), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the

patient is intoxicated by an opioid or a benzodiazepine and responds to intravenous naloxone or flumazenil.

2. Breathing—Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial or venous blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory depression, bronchospasm, pulmonary aspiration, or non-cardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a pulse oximetry device capable of detecting these forms of hemoglobin is used.

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs—

A. DEXTROSE AND THIAMINE—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid point of care blood sugar test rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or in the intravenous fluids.

B. OPIOID ANTAGONISTS—Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). **Note:** Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory.

C. FLUMAZENIL—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** Flumazenil should **not** be given if the patient has coingested a potential convulsant drug, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.* **Note:** Flumazenil has a short duration of effect (2–3 hours), and re sedation requiring additional doses may occur.

HYPOTHERMIA

▶ Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and

central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

▶ Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

▶ Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, beta-blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other anti-psychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum or zinc phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

▶ Treatment

Most hypotensive patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted (eg, as with *Amanita phalloides* mushroom poisoning). Monitoring the central venous pressure (CVP) can help determine whether further fluid therapy is needed. If fluid therapy is not successful after adequate volume replacement, give dopamine or norepinephrine by intravenous infusion. Consider bedside cardiac ultrasound or pulmonary artery catheterization (or both) if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For beta-blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 units/kg/h intravenously) euglycemic therapy may also be used (see the sections on Beta-Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in some cases of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil.

Kryshnal DO et al. In vitro studies indicate intravenous lipid emulsion acts as lipid sink in verapamil poisoning. *J Med Toxicol.* 2015 Nov 9. [Epub ahead of print] [PMID: 26553277]
 Woodward C et al. High dose insulin therapy, an evidence-based approach to beta blocker/calcium channel blocker toxicity. *Daru.* 2014 Apr 8;22(1):36. [PMID: 24713415]

HYPERTENSION

► Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, performance-enhancing products (containing caffeine, phenylephrine, ephedrine, or yohimbine), monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure greater than 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

► Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is higher than 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2–3 mg intravenously. For persistent hypertension, administer phentolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, *add* propranolol, 1–5 mg intravenously, or esmolol, 25–100 mcg/kg/min intravenously, or labetalol 0.2–0.3 mg/kg intravenously. **Caution:** Do not give beta-blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed alpha-adrenergic stimulation.

Le Roux G et al. Recreational phenethylamine poisonings reported to a French poison control center. *Drug Alcohol Depend.* 2015 Sep 1;154:46–53. [PMID: 26205314]

ARRHYTHMIAS

► Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

► Treatment

Hypoxia or electrolyte imbalance should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:**

Table 38–1. Common toxins or drugs causing arrhythmias.¹

Arrhythmia	Common Causes
Sinus bradycardia	Beta-blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates
Atrioventricular block	Beta-blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium
Sinus tachycardia	Beta-agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants
Wide QRS complex	Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, bupropion, lamotrigine, diphenhydramine (severe overdose)
QT interval prolongation and torsades de pointes	Arsenic, class Ia and class III antiarrhythmics, citalopram, droperidol, lithium, methadone, pentamidine, sertraline, sotalol, and many other drugs ²
Ventricular premature beats and ventricular tachycardia	Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride, theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes).

¹Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia, hypomagnesemia).

²<https://crediblemeds.org/>

Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class Ia antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus infusion. (See discussion of tricyclic antidepressant poisoning.) **Caution:** Avoid class Ia antiarrhythmic agents (eg, procainamide, disopyramide) and amiodarone, which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies (see discussion of cardiac glycoside poisoning).

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

 Tormoehlen LM et al. Hydrocarbon toxicity: a review. *Clin Toxicol (Phila)*. 2014 Jun;52(5):479–89. [PMID: 24911841]

SEIZURES

Assessment & Complications

Seizures may be due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, cocaine, isoniazid (INH), chlorinated insecticides, tramadol, and theophylline. The onset of seizures may be delayed for up to 18–24 hours after extended-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 1–2 minutes, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is preferred over phenytoin or levetiracetam.) Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

HYPERTHERMIA

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially methylenedioxymethamphetamine [MDMA; “Ecstasy”]), atropine and other anticholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (“serotonin syndrome”). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic

Table 38–2. Seizures related to toxins or drugs requiring special consideration.¹

Toxin or Drug	Comments
Methylenedioxymethamphetamine (MDMA; “Ecstasy”)	Seizures may also be due to hyponatremia or hyperthermia.
Isoniazid	Administer pyridoxine.
Lithium	May indicate need for hemodialysis.
Organophosphates	Administer pralidoxime (2-PAM) and atropine in addition to usual anticonvulsants.
Strychnine	“Seizures” are actually spinally mediated muscle spasms and usually require neuromuscular paralysis and mechanical ventilation.
Theophylline	Seizures indicate need for hemodialysis.
Tricyclic antidepressants	Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity.

¹See text for dosages.

malignant syndrome [NMS]). (See section on schizophrenia and other psychotic disorders in Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature higher than 40–41°C) can rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, acute kidney injury, and coagulopathy (see Chapter 37).

Treatment

Treat hyperthermia aggressively by removing the patient’s clothing, spraying the skin with tepid water, and fanning. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continued nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, or chlorpromazine, 25 mg intravenously or 50 mg intramuscularly, has been used to treat serotonin syndrome.

Paden MS et al. Hyperthermia caused by drug interactions and adverse reactions. *Emerg Med Clin North Am.* 2013 Nov;31(4):1035–44. [PMID: 24176477]

ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Be aware that some antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

Gasco L et al. Insufficient stocking of cyanide antidotes in US hospitals that provide emergency care. *J Pharmacol Pharmacother.* 2013 Apr;4(2):95–102. [PMID: 23761707]

Marraffa JM et al. Antidotes for toxicological emergencies: a practical review. *Am J Health Syst Pharm.* 2012 Feb 1; 69(3):199–212. [PMID: 22261941]

Table 38–3. Some toxic agents for which there are specific antidotes.¹

Toxic Agent	Specific Antidote
Acetaminophen	<i>N</i> -Acetylcysteine
Anticholinergics (eg, atropine)	Physostigmine
Anticholinesterases (eg, organophosphate pesticides)	Atropine and pralidoxime (2-PAM)
Benzodiazepines	Flumazenil (rarely used) ²
Carbon monoxide	Oxygen (hyperbaric oxygen of uncertain benefit)
Cyanide	Sodium nitrite, sodium thiosulfate; hydroxocobalamin
Digitalis glycosides	Digoxin-specific Fab antibodies
Heavy metals (eg, lead, mercury, iron) and arsenic	Specific chelating agents
Isoniazid	Pyridoxine (vitamin B ₆)
Methanol, ethylene glycol	Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole)
Opioids	Naloxone, nalmefene
Snake venom	Specific antivenin
Sulfonylurea oral hypoglycemic drugs	Glucose, octreotide

¹See text for indications and dosages.

²May induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Direct the irrigating stream so that it will flow across the eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6 and 8. An amphoteric decontamination solution (Diphoterine, Prevor) is used in some countries for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying; in some cases, when the interval after ingestion has been more than 1–2 hours and the ingestant is non-life-threatening, even charcoal is withheld (eg, if the estimated benefit is outweighed by the potential risk of pulmonary aspiration of charcoal). Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours. In these cases, aggressive gut decontamination may be indicated.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be

more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Emesis

Emesis using syrup of ipecac can partially evacuate gastric contents if given very soon after ingestion. However, it is no longer used in the routine management of ingestions because it increases the risk of pulmonary aspiration and may delay or prevent the use of oral activated charcoal.

B. Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most useful when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may stimulate vomiting and pulmonary aspiration in an obtunded patient.

1. Indications—Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose), for collection and examination of gastric contents for identification of the poison, and make it easier to administer charcoal and oral antidotes.

2. Contraindications—Do *not* use lavage for stuporous or comatose patients with depressed airway protective reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

3. Technique—In obtunded or comatose patients, the danger of aspiration pneumonia is reduced by performing endotracheal intubation with a cuffed tube before the procedure. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37–40 F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50- to 100-mL aliquots of fluid until the return fluid is clear. Use lukewarm tap water or saline.

C. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated

doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs.

D. Catharsis

1. Indications—Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal slurry. There is no clinical evidence to support their use, and some agents (eg, sorbitol) can provoke vomiting, increasing the risk of pulmonary aspiration.

2. Contraindications and cautions—Do not give a cathartic to patients with suspected intestinal obstruction. Avoid sodium-based cathartics in patients with hypertension, advanced kidney disease, and heart failure and avoid magnesium-based cathartics in patients with advanced kidney disease. Sorbitol (an osmotic cathartic found in some prepackaged activated charcoal slurry products) can cause hypotension and dehydration due to third-spacing and also causes intestinal cramping and vomiting.

E. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

F. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Some drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. To alkalinize the urine, add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4); (2) Poisoning with deep

Table 38–4. Recommended use of hemodialysis in poisoning.

Poison	Common Indications ¹
Carbamazepine	Seizures, severe cardiotoxicity; serum level > 60 mg/L
Ethylene glycol	Acidosis, serum level > 50 mg/dL
Lithium	Severe symptoms; level > 4–5 mEq/L, especially if renal impairment Note: dialysis of uncertain value; consult with medical toxicologist
Methanol	Acidosis, serum level > 50 mg/dL
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, serum level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication)
Theophylline	Serum level > 90–100 mg/L (acute) or seizures and serum level > 40–60 mg/L (chronic)
Valproic acid	Serum level > 900–1000 mg/L or deep coma, severe acidosis

¹See text for further discussion of indications.

CNS, central nervous system; CWHD, continuous venovenous hemodialysis.

coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) Poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (including continuous venovenous hemodiafiltration and similar techniques) is of uncertain benefit for elimination of most poisons but has the advantage of gradual removal of the toxin and correction of any accompanying acidosis, and its use has been reported in the management of lithium intoxication.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using repeat dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine, and pseudoephedrine.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, gamma-hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely

dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmol gap, electrolytes and anion gap, glucose, creatinine, blood urea nitrogen (BUN), creatine kinase, urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

A. Osmol Gap

The osmol gap (Table 38–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Other common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen and salicylates. Massive acetaminophen overdose can cause early-onset anion gap metabolic acidosis.

Table 38–5. Use of the osmol gap in toxicology.

The osmol gap (Delta osm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.	
Calculated osmolality (osm)	$= 2[\text{Na}^+ (\text{mEq/L})] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$
Delta osm = Measured osmolality – Calculated osmolality = 0 ± 10	
Serum osmolality may be increased by contributions of exogenous substances such as alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration. Contact a medical toxicologist or poison control center for assistance in calculating and interpreting the osmol gap.	

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

C. Toxicology Laboratory Testing

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient because results usually do not return in time to influence clinical management. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

Table 38–6. Specific quantitative levels and potential therapeutic interventions.¹

Drug or Toxin	Treatment
Acetaminophen	Specific antidote (N-acetylcysteine) based on serum level
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Carbamazepine	High level may indicate need for hemodialysis
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (eg, DigiFab) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols); serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both

¹Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

Many hospitals can perform a quick but limited urine screen for “drugs of abuse” (typically these screens include only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, methadone, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone are often not detected by routine opioid immunoassays.

▶ Abdominal Radiographs

A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

▶ When to Refer

Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

▶ When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6- to 8-hour observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

SELECTED POISONINGS

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by

cellular glutathione. With acute acetaminophen overdose (greater than 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as those who chronically abuse alcohol and patients taking INH, are at increased risk for developing hepatotoxicity. Hepatic toxicity may also occur after overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/day for several days. The amount of acetaminophen in US oral prescription combination products (eg, hydrocodone/acetaminophen) is limited by the FDA to no more than 325 mg per tablet.

▶ Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, acute kidney injury, and death. Rarely, massive ingestion (eg, serum levels greater than 500–1000 mg/L [33–66 mmol/L]) can cause early onset of acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels which can make it difficult to interpret the nomogram. The nomogram is also not useful after repeated overdose.

▶ Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p. 1582) if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

B. Specific Treatment

If the serum or plasma acetaminophen level falls above the line on the nomogram (Figure 38–1), treatment with *N*-acetylcysteine is indicated; it can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to about 5% with water, juice, or soda. If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously. The conventional oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

The FDA-approved 21-hour intravenous regimen of acetylcysteine (Acetadote) calls for a loading dose of 150 mg/kg

▲ **Figure 38-1.** Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. Patients with serum levels above the line after acute overdose should receive antidotal treatment. (Adapted, with permission, from Daly FF et al. Guidelines for the management of paracetamol poisoning in Australia and New Zealand—explanation and elaboration. A consensus statement from clinical toxicologists consulting to the Australasian poisons information centres. *Med J Austr.* 2008;188:296. © Copyright The Medical Journal of Australia. The Medical Journal of Australia does not accept responsibility for any errors in translation.)

given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with *N*-acetylcysteine is most effective if it is started within 8–10 hours after ingestion.

ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

Treatment

A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do *not* give bicarbonate or other neutralizing agents, and do *not* induce vomiting. Some experts recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may also reveal the extent of injury. Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may

be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (**Caution:** *Do not use calcium chloride.*) Use of a Bier-block technique or intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.

Zhang Y et al. Injuries following a serious hydrofluoric acid leak: First aid and lessons. *Burns.* 2015 Nov;41(7):1593–8. [PMID: 26188892]

ALKALIES

The strong alkalis are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalis cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

▶ Treatment

A. Ingestion

Dilute immediately with a glass of water. Do *not* induce emesis. Some gastroenterologists recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances, in order to remove residual material.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage; CT scanning may also aid in assessment. If a radiograph reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Amphoteric solutions may be more effective than water or saline and some are available in Europe (Diphtherine, Prevor). Check pH with pH test paper, and repeat irrigation for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist for further treatment.

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely abused for their euphorogenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine (“crystal meth,” “crank”), MDMA (“Ecstasy”), ephedrine (“herbal ecstasy”), and methcathinone (“cat” or “khat”). Methcathinone derivatives and related synthetic chemicals such as methylenedioxypyrovalerone (MDPV) have become popular drugs of abuse and are often sold as purported “bath salts.” Amphetamine-like reactions have also been reported after use of synthetic cannabinoids (eg, “Spice” and “K2”). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see also Theophylline & Caffeine section).

▶ Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in

intracranial hemorrhage, aortic dissection, or myocardial infarction. Ischemic colitis has been reported. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines or the cocaine metabolite benzoylecgonine in the urine. Note that many drugs can give a false-positive result on the immunoassay for amphetamines.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter (see p. 1580). Rapidly lower the body temperature (see hyperthermia, p. 1580) in patients who are hyperthermic (temperature higher than 39–40°C). Give intravenous fluids to prevent myoglobinuric kidney injury in patients who have rhabdomyolysis.

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or nitroprusside, or a combined alpha- and beta-adrenergic blocker such as labetalol (10–20 mg intravenously). Do not administer a pure beta-blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed alpha-adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting beta-blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above (see p. 1580). Treat hyponatremia as outlined in Chapter 21.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides, the so-called “superwarfarins” such as brodifacoum, difenacoum, and related compounds) inhibit the clotting mechanism by blocking hepatic synthesis of vitamin K–dependent clotting factors. After ingestion of “superwarfarins,” inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose. Newer oral anticoagulants

include the direct thrombin inhibitor dabigatran and the factor Xa inhibitors rivaroxaban, apixiban, and edoxaban. Some of these, especially dabigatran, are largely eliminated by the kidney and may accumulate in patients with renal insufficiency.

Excessive anticoagulation may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces.

Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normalized ratio, INR). The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after overdose of warfarin or “superwarfarins.” **Note:** The newer oral anticoagulants (dabigatran, rivaroxaban, apixiban, and edoxaban) do not predictably alter the prothrombin time; however, a normal INR suggests no significant toxicity.

If the patient has ingested an acute overdose, administer activated charcoal (see p. 1582).

B. Specific Treatment

In cases of warfarin and “superwarfarin” overdose, do not treat prophylactically with vitamin K—wait for evidence of anticoagulation (elevated prothrombin time). If the INR is elevated, give phytonadione (vitamin K₁), 10–25 mg orally, and increase the dose as needed to restore the prothrombin time to normal. Doses as high as 200 mg/day have been required after ingestion of “superwarfarins.” Give fresh-frozen plasma, prothrombin complex concentrate, or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time. If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

Vitamin K does not reverse the anticoagulant effects of the direct-acting oral anticoagulants (dabigatran, rivaroxaban, apixiban, and edoxaban), but specific reversal agents have been developed and are now approved by the FDA: idarucizumab for dabigatran reversal and andexanet for reversal of the factor Xa inhibitors. The efficacy of fresh frozen plasma and clotting factor concentrates is uncertain.

Stevenson JW et al. An observational case series of dabigatran and rivaroxaban exposures reported to a poison control system. *Am J Emerg Med.* 2014 Sep;32(9):1077–84. [PMID: 24908445]

ANTICONVULSANTS

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders and some are also used for treatment of mood disorders or pain.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine intoxication causes drowsiness, stupor and, with high levels, atrioventricular block, coma, and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels over 20 mg/L (85 mcmol/L), although severe poisoning is usually associated with concentrations greater than 30–40 mg/L (127–169 mcmol/L). Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants **gabapentin**, **levetiracetam**, **vigabatrin**, and **zonisamide** generally cause somnolence, confusion and dizziness; **felbamate** can cause crystalluria and kidney injury after overdose, and may cause idiosyncratic aplastic anemia with therapeutic use; **lamotrigine**, **topiramate**, and **tiagabine** have been reported to cause seizures after overdose.

▶ Treatment

A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube (see p. 1582). For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see p. 1582). Combined multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

B. Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid-induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine

(eg, carbamazepine levels greater than 60 mg/L [254 mcmol/L] or valproic acid levels greater than 800 mg/L [5544 mcmol/L]).

ANTIPSYCHOTIC DRUGS

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antipsychotic agents, and sometimes as antiemetics and potentiators of analgesic and hypnotic drugs.

Therapeutic doses of phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, lurasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25).

▶ Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p. 1582) for large or recent ingestions. For severe hypotension, treatment with intravenous fluids and vasopressor agents may be necessary. Treat hyperthermia as outlined on p. 1580. Maintain cardiac monitoring.

B. Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants.

Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle rigidity but is not a true antidote. For severe hyperthermia, rapid neuromuscular paralysis (see p. 1580) is preferred.

ARSENIC

Arsenic is found in some pesticides and industrial chemicals and is used as a chemotherapeutic agent. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

Treatment

A. Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage (see p. 1582). Activated charcoal is of uncertain benefit because it binds arsenic poorly. Administer intravenous fluids to replace losses due to vomiting and diarrhea.

B. Antidote

For patients with severe acute intoxication, administer a chelating agent. The preferred drug is 2,3-dimercaptopropanesulfonic acid (DMPS, Unithiol) (3–5 mg/kg intravenously every 4 hours); although there is no FDA-approved commercial formulation of DMPS in the United States, it can be obtained from some compounding pharmacies. An alternative parenteral chelator is dimercaprol (British anti-Lewisite, BAL), which comes as a 10% solution in peanut oil, and is given 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. When gastrointestinal symptoms allow, switch to the oral chelator succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice regarding chelation.

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. Symptoms of toxicity include dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. Physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive diphenhydramine overdose may mimic tricyclic antidepressant cardiotoxic poisoning.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p. 1582). External cooling and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures (see p. 1580).

B. Specific Treatment

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. **Caution:** Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and the drug should be avoided in patients with cardiotoxic effects from tricyclic antidepressants or other sodium channel blockers.

Dawson AH et al. Pharmacological management of anticholinergic delirium—theory, evidence and practice. *Br J Clin Pharmacol.* 2016 Mar;81(3):516–524. [PMID: 26589572]

Phillips MA et al. Use of a physostigmine continuous infusion for the treatment of severe and recurrent antimuscarinic toxicity in a mixed drug overdose. *J Med Toxicol.* 2014 Jun;10(2):205–9. [PMID: 24798647]

BETA-ADRENERGIC BLOCKERS

There are a wide variety of beta-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–6). The most toxic beta-blocker is propranolol, which not only blocks beta-1 and beta-2 adrenoceptors but also has direct membrane-depressant and central nervous system effects.

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with beta-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include beta-blockers.

Treatment

A. Emergency and Supportive Measures

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary.

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal (see p. 1582).

B. Specific Treatment

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by beta-blockade. High-dose insulin (0.5–1 units/kg/h intravenously) along with glucose supplementation has been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose.

Cole JB et al. A blinded, randomized, controlled trial of three doses of high-dose insulin in poison-induced cardiogenic shock. *Clin Toxicol (Phila)*. 2013 May;51(4):201–7. [PMID: 23530460]

Graudins A et al. Calcium channel antagonist and beta-blocker overdose: antidotes and adjunct therapies. *Br J Clin Pharmacol*. 2016 Mar;81(3):453–461. [PMID: 26344579]

CALCIUM CHANNEL BLOCKERS

In therapeutic doses, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these

effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal (see p. 1582). In addition, whole bowel irrigation (see p. 1582) should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

Treat symptomatic bradycardia with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker. For hypotension, give calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to as much as twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. High doses of insulin (0.5–1 units/kg intravenous bolus followed by 0.5–1 units/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and case reports of calcium channel blocker poisoning. Methylene blue (1–2 mg/kg) was reported to reverse refractory shock due to profound vasodilation in a patient with amlodipine poisoning.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater, generator, or other appliance. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness,

abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels greater than 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A specialized pulse oximetry device, the Masimo pulse CO-oximeter, is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

▶ Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyl dopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a

result of peripheral alpha-adrenergic effects in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine and apraclonidine are used as ophthalmic preparations for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

▶ Treatment

A. Emergency and Supportive Measures

Give activated charcoal (see p. 1582). Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

B. Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unpredictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

COCAINE

See Amphetamines & Cocaine.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

▶ Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor

of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (greater than 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see p. 1582). Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, there are two available cyanide antidote regimens. The conventional cyanide antidote package (Nithiodote) contains sodium nitrite (to induce methemoglobinemia, which binds free cyanide) and sodium thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer 3% sodium nitrite solution, 10 mL intravenously followed by 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g). **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin.

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose

of hydroxocobalamin is 5 g intravenously (children’s dose is 70 mg/kg). **Note:** Hydroxocobalamin causes red discoloration of skin and bodily fluids that may last several days and can interfere with some laboratory tests.

DIETARY SUPPLEMENTS & HERBAL PRODUCTS

Unlike prescription and over-the-counter pharmaceuticals, dietary supplements do not require FDA approval, do not undergo the same premarketing evaluation of safety and efficacy as drugs, and purveyors may or may not adhere to good manufacturing practices and quality control standards. Supplements may cause illness as a result of intrinsic toxicity, misidentification or mislabeling, drug-herb reactions, or adulteration with pharmaceuticals. If you suspect a dietary supplement or herbal product may be the cause of an otherwise unexplained illness, contact the FDA (1-888-463-6332) or the regional poison control center (1-800-222-1222), or consult one of the following online databases: <http://www.naturaldatabase.com> and <http://www.fda.gov/food/dietarysupplements/default.htm>.

Table 38–7 lists selected examples of clinical toxicity from some of these products.

Table 38–7. Examples of potential toxicity associated with some dietary supplements and herbal medicines.

Product	Common Use	Possible Toxicity
Azarcon (Greta)	Mexican folk remedy for abdominal pain, colic	Contains lead (see pp. 1596–1597)
Comfrey	Gastric upset, diarrhea	Contains pyrrolizidine alkaloids, can cause hepatic veno-occlusive disease
Creatine	Athletic performance enhancement	Nausea, diarrhea, abdominal cramps; elevated serum creatinine
Ginkgo	Memory improvement, tinnitus	Antiplatelet effects, hemorrhage; abdominal pain, diarrhea
Ginseng	Immune system; stress	Decreased glucose; increased cortisol
Guarana	Athletic performance enhancement, appetite suppression	Contains caffeine: can cause tremor, tachycardia, vomiting
Kava	Anxiety, insomnia	Drowsiness, hepatitis, skin rash
Ma huang	Stimulant; athletic performance enhancement	Contains ephedrine: anxiety, insomnia, hypertension, tachycardia, seizures
Spirulina	Body building	Niacin-like flushing reaction
Yohimbine	Sexual enhancement	Hallucinations, hypertension, tachycardia
Zinc	Cold/flu symptoms	Nausea, oral irritation, anosmia

Adapted, with permission, from Table II-30 by Haller C in *Herbal and Alternative Products In: Olson KR (ed.) Poisoning & Drug Overdose*, 5th edition, McGraw Hill, 2007.

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides paralyze the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. A number of plants (eg, oleander, foxglove, lily-of-the-valley) contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p. 1582). Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

B. Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; DigiFab). Estimation of the DigiBind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration, as described below. More effective binding of digoxin may be achieved if the dose is given partly as a bolus and the remainder as an infusion over a few hours.

1. From the ingested dose—Number of vials = approximately $1.5\text{--}2 \times$ ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) \times body weight (kg) $\times 10^{-2}$. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels may be falsely high for several hours before tissue distribution is complete, and overestimation of the DigiBind or DigiFab dose is likely.

3. Empiric dosing—Empiric titration of DigiBind or DigiFab may be used if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) favors retaining a residual level of digitalis activity. Start with one or two vials and reassess the patient's clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is entirely based on response to empiric dosing.

Note: After administration of digoxin-specific Fab antibody fragments, serum digoxin levels may be falsely elevated depending on the assay technique.

Roberts DM et al. Pharmacological treatment of cardiac glycoside poisoning. *Br J Clin Pharmacol*. 2016 Mar;81(3):488–95. [PMID: 26505271]

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlordiazepoxide, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem and zaleplon, and the muscle relaxant carisoprodol. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels over 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected (see p. 1582). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in 0.2–0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** Flumazenil should rarely be used because it may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

Penninga EI et al. Adverse events associated with flumazenil treatment for the management of suspected benzodiazepine intoxication—a systematic review with meta-analyses of randomised trials. *Basic Clin Pharmacol Toxicol.* 2016 Jan; 118(1):37–44. [PMID: 26096314]

Zanoni S et al. Altered mental status due to pruno intoxication. *J Emerg Med.* 2014 Jun;46(6):767–8. [PMID: 24680101]

GAMMA-HYDROXYBUTYRATE (GHB)

GHB is a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (“date-rape” drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and gamma-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

Schep LJ et al. The clinical toxicology of gamma-hydroxybutyrate, gamma-butyrolactone and 1,4-butanediol. *Clin Toxicol (Phila).* 2012 Jul;50(6):458–70. [PMID: 22746383]

HYPOGLYCEMIC DRUGS

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, alpha-glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), and newer peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 27). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in patients with impaired kidney function or after intentional drug overdose. Table 27–7 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Figure 27–2 the extent and duration of various types of insulins.

Clinical Findings

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a “depot” effect (see Figure 27–2). Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given (see Table 27–8).

Treatment

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 mL intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose greater than 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

Consider hemodialysis for patients with metformin overdose accompanied by severe lactic acidosis (lactate greater than 20 mmol/L or pH < 7.0).

Glatstein M et al. Octreotide for the treatment of sulfonyleurea poisoning. *Clin Toxicol (Phila)*. 2012 Nov;50(9):795–804. [PMID: 23046209]

IRON

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children's preparations contain about 12–15 mg of iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60–90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes. Carbonyl iron is a powdered form of elemental iron. It is not as irritating to the gastrointestinal tract as the iron salts and appears to be safer.

▶ Clinical Findings

Ingestion of less than 30 mg/kg of iron usually produces only mild gastrointestinal upset. Ingestion of more than 40–60 mg/kg may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels greater than 350–500 mcg/dL are considered potentially toxic, and levels greater than 1000 mcg/dL are usually associated with severe poisoning. A plain abdominal radiograph may reveal radiopaque tablets.

▶ Treatment

A. Emergency and Supportive Measures

Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation to remove unabsorbed pills from the intestinal tract (see p. 1582). Activated charcoal is not effective but may be appropriate if other ingestants are suspected.

B. Specific Treatment

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, greater than 800–1000 mcg/dL)—administer 10–15 mg/kg/h by constant intravenous infusion; higher doses (up to 40–50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of an iron-deferoxamine complex in the urine may give it a “vin rosé” appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. **Caution:** Prolonged infusion of deferoxamine (more than 36–48 hours) has been associated with development of

acute respiratory distress syndrome (ARDS)—the mechanism is not known.

Wolters JM et al. Fatal unsuspected iron ingestion. *Emerg Med Australas*. 2014 Apr;26(2):204–5. [PMID: 24708016]

ISONIAZID

INH is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain gamma-aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.

▶ Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

▶ Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote.

Administer activated charcoal (see p. 1582) after large recent ingestion, but with caution because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

Skinner K et al. Isoniazid poisoning: pharmacokinetics and effect of hemodialysis in a massive ingestion. *Hemodial Int*. 2015 Oct;19(4):E37–40. [PMID: 25779481]

LEAD

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare

after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

► Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels below 10 mcg/dL are usually considered nontoxic, although that limit has been lowered to 5 mcg/dL in children. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels greater than 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

► Treatment

A. Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation (see p. 1582), endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level over 60 mcg/dL (or three successive monthly levels greater than 50 mcg/dL) or construction workers with any single blood lead level above 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (1-800-222-1222) should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 mcg/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels greater than 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m²/kg/day (approximately 50 mg/kg/day) in four to six divided doses or as a continuous intravenous infusion. Most clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LITHIUM

Lithium is widely used for the treatment of bipolar depression and other psychiatric disorders. The only normal route of lithium elimination is via the kidney, so patients with chronic kidney disease are at risk for accumulation of lithium resulting in gradual onset (chronic) toxicity. Intoxication resulting from chronic accidental overmedication or renal impairment is more common and usually more severe than that seen after acute oral overdose.

► Clinical Findings

Mild to moderate toxicity causes lethargy, confusion, tremor, ataxia, and slurred speech. This may progress to myoclonic jerking, delirium, coma, and convulsions. Recovery may be slow and incomplete following severe intoxication. Laboratory studies in patients with chronic intoxication often reveal an elevated serum creatinine and an elevated BUN/creatinine ratio due to underlying volume contraction. The white blood cell count is often elevated. ECG findings include T-wave flattening or inversion, and sometimes bradycardia or sinus node arrest. Nephrogenic diabetes insipidus can occur with overdose or with therapeutic doses. Lithium levels may be difficult to interpret. Lithium has a low toxic: therapeutic ratio and chronic intoxication can be seen with levels only slightly above the therapeutic range (0.8–1.2 mEq/L). In contrast, patients with acute ingestion may have transiently very high levels (up to 10 mEq/L reported) without any symptoms before the lithium fully distributes into tissues. **Note:** Falsely high lithium levels (as high as 6–8 mEq/L) can be measured if a

green-top blood specimen tube (containing lithium heparin) is used instead of a red- or marbled-top tube.

▶ Treatment

After acute oral overdose, consider gastric lavage (see p. 1582) or whole bowel irrigation (see p. 1582) to prevent systemic absorption (lithium is not adsorbed by activated charcoal). In all patients, evaluate renal function and volume status, and give intravenous saline-containing fluids as needed. Monitor serum lithium levels, and seek assistance with their interpretation and the need for dialysis from a medical toxicologist or regional poison control center (1-800-222-1222). Consider hemodialysis if the patient is markedly symptomatic or if the serum level exceeds 4–5 mEq/L, especially if renal function is impaired. Continuous renal replacement therapy may be an effective alternative to hemodialysis.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, “chemo,” etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias. Newer drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists (street names include “spice” and “K2”), *Salvia divinorum*, and mephedrone and related cathinone derivatives. See www.erowid.org for very thorough descriptions of a variety of hallucinogenic substances.

▶ Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures

as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube (see p. 1582).

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with beta-blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

Bäckberg M et al. Phencyclidine analog use in Sweden—intoxication cases involving 3-MeO-PCP and 4-MeO-PCP from the STRIDA project. *Clin Toxicol (Phila)*. 2015 Nov;53(9):856–64. [PMID: 26295489]

Harris CR et al. Synthetic cannabinoid intoxication: a case series and review. *J Emerg Med*. 2013 Feb;44(2):360–6. [PMID: 22989695]

MERCURY

Mercury poisoning may occur by ingestion of inorganic mercuric salts, organic mercury compounds, or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from highly contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects. Nearly all fish have some traces of mercury contamination; the US Environmental Protection Agency (EPA) advises consumers to avoid swordfish, shark, king mackerel, and tilefish because they contain higher levels. Fish and shellfish that are generally low in mercury content include shrimp, canned light tuna (not albacore “white” tuna), salmon, pollock, and catfish. Dental fillings composed of mercury amalgam pose a very small risk of chronic mercury poisoning and their removal is rarely justified. Some imported skin lightening creams contain toxic quantities of mercury.

▶ Treatment

A. Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage, and administer activated charcoal (see p. 1582). For acute

ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Unithiol (DMPS) is a chelator that can be given orally or parenterally, but is not commonly available in the United States; it can be obtained from some compounding pharmacies. Maintain urinary output. Treat oliguria and anuria if they occur.

B. Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, although some authors recommend a trial of succimer or unithiol (contact a regional poison center or medical toxicologist for advice).

Koirala S et al. Notes from the field: acute mercury poisoning after home gold and silver smelting—Iowa, 2014. *MMWR Morb Mortal Wkly Rep.* 2015 Dec 18;64(49):1365–6. [PMID: 26678598]

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerine in various liquid medications (cough syrup, teething medicine, acetaminophen) causing numerous deaths in Haiti, Panama, and Nigeria.

► Clinical Findings

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and acute kidney injury. **Note:** Point-of-care analytical devices common used in the emergency department may falsely measure glycolic acid (a toxic metabolite of ethylene glycol) as lactic acid.

► Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a nasogastric

tube (see p. 1582). Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propanil (an herbicide), nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

► Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the “chocolate brown” color of methemoglobin, but they have normal PO₂ results on arterial blood gas determinations. Conventional pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. (A newer pulse oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see p. 1582). Repeat-dose activated charcoal may enhance dapsone elimination.

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides* and related species,

which contain potent cytotoxins (amatoxins). Ingestion of even a portion of one amatoxin-containing mushroom may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings

A. Symptoms and Signs

Amatoxin-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal cramps, vomiting and profuse diarrhea, followed by hepatic necrosis, hepatic encephalopathy, and frequently acute kidney injury in 1–2 days. Cooking the mushrooms does not prevent poisoning.

Monomethylhydrazine poisoning (*Gyromitra* and *Helvella* species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours.

The clinical effects of these and other mushrooms are described in Table 38–8.

Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or

Table 38–8. Poisonous mushrooms.

Toxin	Genus	Symptoms and Signs	Onset	Treatment
Amanitin	<i>Amanita</i> (<i>A ocreata</i> , <i>A phalloides</i> , <i>A verna</i> , <i>A virosa</i>)	Severe gastroenteritis followed by delayed hepatic failure and acute kidney injury after 48–72 hours	6–24 hours	Supportive. Correct dehydration. Give repeated doses of activated charcoal orally. Consider intravenous silibinin (Legalon-SIL).
Muscarine	<i>Inocybe</i> , <i>Clitocybe</i>	Muscarinic (salivation, miosis, bradycardia, diarrhea)	30–60 minutes	Supportive. Give atropine, 0.5–2 mg intravenously, for severe cholinergic symptoms and signs.
Ibotenic acid, muscimol	<i>Amanita muscaria</i> ("fly agaric")	Anticholinergic (mydriasis, tachycardia, hyperpyrexia, delirium)	30–60 minutes	Supportive. Give physostigmine, 0.5–2 mg intravenously, for severe anticholinergic symptoms and signs.
Coprine	<i>Coprinus</i>	Disulfiram-like effect occurs with ingestion of ethanol	30–60 minutes	Supportive. Abstain from ethanol for 3–4 days.
Monomethylhydrazine	<i>Gyromitra</i>	Gastroenteritis; occasionally seizures, hemolysis, hepatic failure, and acute kidney injury	6–12 hours	Supportive. Correct dehydration. Pyridoxine, 2.5 mg/kg intravenously, may be helpful for seizures.
Orellanine	<i>Cortinarius</i>	Nausea, vomiting; acute kidney injury after 1–3 weeks	2–14 days	Supportive.
Psilocybin	<i>Psilocybe</i>	Hallucinations	15–30 minutes	Supportive.
Gastrointestinal irritants	Many species	Nausea and vomiting, diarrhea	1/2–2 hours	Supportive. Correct dehydration.

administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p. 1582). Administer intravenous fluids to replace massive losses from vomiting and diarrhea.

B. Specific Treatment

A variety of purported antidotes (eg, thioctic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe but is currently only commercially available in the United States as a nutritional supplement given orally. The European intravenous product (Legalon-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

OPIATES & OPIOIDS

Prescription and illicit opiates and opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of misuse and abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

► Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone is associated with QT interval prolongation and torsades de pointes. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated

dosing in patients with chronic kidney disease. Propoxyphene prolongs the QRS interval and may cause seizures; it is no longer available in the United States. Wound botulism has been associated with skin-popping, especially involving “black tar” heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology “opiate” screening.

► Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal (see p. 1582) for recent large ingestions.

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.2–2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). **Caution:** The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare “nerve agents” (such as GA [tabun], GB [sarin], GD [soman] and VX) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorexia, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube followed by administration of activated charcoal (see p. 1582). If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a more specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose, and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on

the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

Treatment

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized crackles or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

Tormoehlen LM et al. Hydrocarbon toxicity: a review. *Clin Toxicol (Phila).* 2014 Jun;52(5):479–89. [PMID: 24911841]

SALICYLATES

Salicylates (aspirin, methyl salicylate, bismuth subsalicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic

metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

▶ Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. (A normal anion gap sometimes occurs due to salicylate interference with the chemistry analyzer, falsely raising the measured chloride.) Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. Central nervous system intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L or 7.2 mcmol/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL (4.3–5 mcmol/L). The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

▶ Treatment

A. Emergency and Supportive Measures

Administer activated charcoal orally (see p. 1582). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin (see p. 1582). The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation (see p. 1583). Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall during the apneic period.

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq

(two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, greater than 100–120 mg/dL [1000–1200 mg/L or 7.2–8.6 mcmol/L] after acute overdose or greater than 60–70 mg/dL [600–700 mg/L or 4.3–5 mcmol/L] with subacute or chronic intoxication).

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–9. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

▶ Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally (see p. 1582).

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H₂-blocker cimetidine, 300 mg intravenously, are usually effective.

Chan TY. Epidemiology and clinical features of ciguatera fish poisoning in Hong Kong. *Toxins (Basel).* 2014 Oct 20; 6(10):2989–97. [PMID: 25333356]

Table 38–9. Common seafood poisonings.

Type of Poisoning	Mechanism	Clinical Presentation
Ciguatera	Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.	1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.
Paralytic shellfish poisoning	Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

Treatment

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crovalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours have been recommended, but many clinicians give additional doses only if needed. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 1–2 vials of specific antivenom as soon as possible. **Note:** Pfizer/Wyeth no longer makes coral snake antivenom in the United States and remaining supplies are dwindling. To locate antisera for this or exotic snakes, call a regional poison control center (1-800-222-1222).

SPIDER BITES & SCORPION STINGS

The toxin of most species of spiders in the United States causes only local pain, redness, and swelling. That of the more venomous black widow spiders (*Latrodectus mactans*) causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare).

Stings by most scorpions in the United States cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

► Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral opioids or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may transiently relieve muscle rigidity, though its effectiveness is unproven. *Latrodectus* antivenom is possibly more effective, but because of concerns about acute hypersensitivity reactions (horse serum-derived), it is often reserved for very young or elderly patients or those who do not respond promptly to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproved value.

C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. An FDA-approved specific antivenom is available for *Centruroides* stings.

THEOPHYLLINE & CAFFEINE

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine in energy drinks, herbal or dietary supplement products can produce similar toxicity.

► Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels greater than 100 mg/L (555 mcmol/L). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 mcmol/L]) in patients with chronic intoxication.

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p. 1582). Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations (see p. 1582).

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, greater than 100 mg/L [555 mcmol/L] after acute overdose or greater than 60 mg/L [333 mcmol/L] with chronic intoxication).

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive beta-adrenergic stimulation—may respond to beta-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer generation antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome.

Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (greater than 0.12 s; Figure 38–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval and torsades de pointes have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia

▲ Figure 38–2. Cardiac arrhythmias resulting from tricyclic antidepressant overdose. **A:** Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). **B** and **C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998.)

may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity.

Administer activated charcoal (see p. 1582) and consider gastric lavage (see p. 1582) after recent large ingestions. All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has responded to intravenous lipid emulsion (Intralipid), 1.5 mL/kg repeated one or two times if needed. Plasma exchange using albumin has been reported successful in a few cases.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

Cancer

Patricia A. Cornett, MD
Tiffany O. Dea, PharmD

39

► Etiology

Cancer is the second most common cause of death in the United States. In 2015, an estimated 1,658,370 cases of cancer were diagnosed, and 589,430 persons died as a result of cancer. Based on current statistics, one in three Americans will be diagnosed with cancer in their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the death rates from cancer are decreasing. Compared to the 1991 cancer death rate of 215.1 per 100,000 population, the 2009 rate of 173.1 per 100,000 represents a 20% reduction in its death rate. Importantly, death rates have declined in the four most common cancer types (lung, colon-rectum, breast, and prostate). The largest declines in death rates have been seen in chronic myeloid leukemia, stomach and colorectal cancer, and non-Hodgkin lymphoma.

Reductions in cancer mortality reflect a successful implementation of a broad strategy of prevention, detection, and treatment. Due to these improvements, the number of cancer survivors is increasing. In 2015, an estimated 14.5 million people were alive in whom cancer had been diagnosed at some point previously; that number is projected to grow to 18.9 million in 2024.

► Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; it is estimated that at least 30% of all cancer deaths in the United States are directly linked to tobacco. In 2013, a total of 174,100 cancer deaths in the United States could be directly attributed to tobacco abuse. Clear evidence links at least 15 cancers to tobacco use. The most dramatic link is with lung cancer; 80% of lung cancer cases occur in smokers. Remarkably, among individuals who are long-term survivors of a tobacco-related cancer, almost 10% continue to use tobacco products, increasing their risk of yet another cancer.

Tobacco cessation directed toward the individual should start with the clinician providing counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches,

gum, or lozenges; and prescription medication with bupropion or varenicline (see Chapter 1).

On a societal level, state or local laws regulating tobacco use in restaurants, the workplace, and other public places have resulted in declines in tobacco use. Countermarketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key recipients of these messages are children; 80% of smokers will start by age 18.

There are encouraging signs of success with tobacco control. The prevalence of smoking for US adults based on the 2015 National Health Interview Survey is 17.0%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females.

For those Americans who do not use tobacco, the most modifiable risk factors would be nutrition and physical activity. Prudent recommendations to reduce cancer risk are to (1) avoid tobacco, (2) be physically active, (3) maintain a healthy weight, (4) consume a diet rich in fruits, vegetables, and whole grains, (5) lower consumption of saturated and trans dietary fats, (6) limit alcohol use, and (7) avoid excess sun exposure.

Another modifiable risk factor is radiation from radiographic studies. A 2009 study reported that the use of computed tomography (CT) in diagnostic algorithms exposes individuals to significant radiation doses that may increase the lifetime risk of developing cancer. Both standardization of CT radiation doses and limiting testing have been important steps in minimizing this risk. Both the American Society of Hematology and the American Society of Clinical Oncology have guidelines, inspired by the American Board of Internal Medicine Foundation's "Choosing Wisely" campaign, for limiting radiographic testing, particularly when used in surveillance for treated cancer patients.

▶ Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see www.cancerstaging.org). Rules for staging for individual cancers are established and published by the American Joint Committee on Cancer (AJCC). The elements used for staging are tumor location, size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and presence or absence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas.

Other characteristics of cancers, not reflected in the TNM stage, may be used as another indicator of prognosis and guidelines for treatment. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Cancer specimens should also be sent for targeted molecular diagnostic testing, when appropriate. Examples include testing for *HER2* in breast and gastric cancers, *K-ras* and *BRAF* mutations in colorectal cancers, *BRAF* mutations in melanoma, and

epidermal growth factor receptor (EGFR), *K-ras* mutations and the *ALK* fusion gene in lung cancer.

TYPES OF CANCER

LUNG CANCER

Sunny Wang, MD

BRONCHOGENIC CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ New cough, or change in chronic cough.
- ▶ Dyspnea, hemoptysis, anorexia, weight loss.
- ▶ Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- ▶ Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

▶ General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates 221,220 new diagnoses and 158,040 deaths from lung cancer in the United States in 2015, accounting for approximately 13% of new cancer diagnoses and 27% of all cancer deaths. More Americans die of lung cancer than of colorectal, breast, and prostate cancers combined.

Cigarette smoking causes 85–90% of cases of lung cancer. The causal connection between cigarettes and lung cancer is established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer.

Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas, asbestos, metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis.

The median age at diagnosis of lung cancer in the United States is 70; it is unusual under the age of 40. The combined relative 5-year survival rate for all stages of lung cancer is currently 17%.

Five histologic categories of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. **Squamous cell carcinomas** (22% of cases, based on US SEER data 2007–2011) arise from the bronchial epithelium and often present as an intraluminal mass. They are usually centrally located and more likely than other types of bronchogenic carcinoma to present with hemoptysis. Squamous cell carcinomas stain for P63 and P40 on

immunohistochemistry. **Adenocarcinomas** (42% of cases) arise from mucous glands or from any epithelial cell within or distal to the terminal bronchioles. They usually present as peripheral nodules or masses and stain for TTF-1 and Napsin-A on immunohistochemistry. **Adenocarcinomas in situ** (formerly **bronchioloalveolar cell carcinomas**) spread along preexisting alveolar structures (lepidic growth) without evidence of invasion. **Large cell carcinomas** (2% of cases) are a heterogeneous group of undifferentiated cancers that share large cells and do not fit into other categories. Large cell carcinomas are typically aggressive and have rapid doubling times. They present as central or peripheral masses. Cancers that are not better differentiated on pathologic review other than non-small cell carcinomas (NSCLC) or carcinomas not otherwise specified make up about 16% of cases. **Small cell carcinomas** (13% of cases) are tumors of bronchial origin that typically begin centrally, infiltrating submucosally to cause narrowing of the bronchus without a discrete luminal mass. They are aggressive cancers that often involve regional or distant metastasis on presentation.

For purposes of staging and treatment, bronchogenic carcinomas are divided into small cell lung cancer (SCLC) and the other four types, labeled NSCLC. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6–18 weeks. The four histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and for advanced disease, chemotherapy is tailored to specific histologies and molecular mutations.

► Clinical Findings

Lung cancer is symptomatic at diagnosis in over 75% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, either nonspecific chest pain or pain from bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–40). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Lambert-Eaton myasthenic syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. **Sputum cytology** is highly specific but insensitive; the yield is highest when there are lesions in the central airways. **Thoracentesis** (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10–90%) depending on the size of the lesion and its location. The use of fluorescence bronchoscopy improves the ability to identify early endobronchial lesions, and endobronchial and transesophageal endoscopic ultrasound enhance the direction and yield of FNA of mediastinal nodes. Electromagnetic navigational bronchoscopy has emerged, allowing bronchoscopic approaches to small peripheral nodules. While the diagnostic yield of CT-guided FNA of peripheral nodules approaches 80–90%, the rates of pneumothorax are significant (15–30%), especially in those with emphysema. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best chance for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into summary stages I–IV, and these are used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIB and stage IV disease do not benefit from surgery (Table 39–2). Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in selected cases as part of multimodality therapy.

SCLC is traditionally divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). It is also recommended to stage SCLC according to the TNM staging system.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful

predictor of disease course. All patients should have measurement of a complete blood count (CBC), serum electrolytes, calcium, creatinine, liver tests, lactate dehydrogenase, and albumin.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is key for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT imaging is less accurate at determining invasion of the chest wall (sensitivity 62%) or mediastinum (sensitivity 60–75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging alone does not provide definitive staging information. CT imaging helps determine where to biopsy, and how the mediastinum should be sampled.

Positron emission tomography (PET) using 2-[¹⁸F] fluoro-2-deoxyglucose (FDG) is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When mediastinal lymph nodes smaller than 1 cm are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows lymph nodes larger than 1 cm, the sensitivity and specificity are 95% and 76%, respectively.

The combination of PET and CT imaging has improved preoperative staging compared with CT or PET alone. Whole body fusion PET-CT imaging is most useful to confirm lack of regional or metastatic disease in NSCLC patients who are candidates for surgical resection. If regional lymph nodes are less than 1 cm and without FDG uptake with no distant metastases seen on PET-CT, the mediastinum is often sampled at surgical resection if the patient is a surgical candidate. If there are lymph nodes larger than 1–2 cm with or without FDG uptake, or if there are sites of potential metastatic disease, attempts to determine malignant involvement include endobronchial ultrasound, endoscopic ultrasound with transesophageal needle aspiration, mediastinoscopy, CT-guided FNA, or limited thoracotomy to biopsy suspected regional or metastatic disease.

Disadvantages of PET imaging include limited resolution below 1 cm and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections. PET-CT scans are also inadequate for evaluating brain metastases due to the high FDG uptake there. Obtaining an MRI of the brain is important to rule out brain metastases in patients with SCLC and in patients with NSCLC with at least stage II disease or poorly differentiated histologies.

2. Preoperative assessment—See Chapter 3.

3. Pulmonary function testing—Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with

Table 39–2. Five-year survival rates for non–small cell lung cancer, based on TNM staging.

Stage	TNM subset	5-Year Survival for Clinical TNM	5-Year Survival for Pathologic TNM
0	Carcinoma in situ		
IA	T1a/T1b, N0M0	50–80%	73%
IB	T2aN0M0	47%	58%
IIA	T1a/T1b, N1M0 T2aN1M0 T2bN0M0	36%	46%
IIIB	T2bN1M0 T3N0M0	26%	36%
IIIA	T1/T2, N2M0 T3, N1/N2, M0 T4, N0/N1, M0	19%	24%
IIIB	T4N2M0 Any T, N3, M0	7%	9%
IV	Any T, Any N, M1a/M1b	2%	13%

Data from multiple sources. Modified and reproduced, with permission, from Tsim S et al. Staging of non-small-cell lung cancer (NSCLC): a review. *Respir Med.* 2010 Dec;104(12):1767–74. and Goldstraw P et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM Classification of malignant tumours. *J Thorac Oncol.* 2007 Aug;2(8):706–14.

good lung function (preoperative FEV₁ 2 L or more) are at low risk for complications from lobectomy or pneumonectomy. If the FEV₁ is less than 2 L, then an estimated postoperative FEV₁ should be made. A predicted post-lung resection FEV₁ greater than 800 mL (or greater than 40% of predicted FEV₁) is associated with a low incidence of perioperative complications. High-risk patients include those with a predicted postoperative FEV₁ less than 700 mL (or less than 40% of predicted FEV₁). In these patients and in those with borderline spirometry, cardiopulmonary exercise testing may be helpful. A maximal oxygen uptake ($\dot{V}O_2$) of greater than 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with a $\dot{V}O_2$ of less than 10 mL/kg/min have a very high mortality rate at thoracotomy.

4. Screening—Screening with low-dose helical CT scans has been shown to improve mortality rates for lung cancer. The National Lung Screening Trial, a multicenter randomized US trial involving over 53,000 current and former heavy smokers, showed that screening annually with low-dose helical CT for 3 years yielded a 20% relative reduction in lung cancer mortality and 6.7% reduction in all-cause mortality compared to chest radiography. Given these findings, US professional organizations, including the US Preventive Services Task Force, have recommended screening with low-dose helical CT for lung cancer. Recent analysis of the National Lung Screening Trial data showed cost-effective estimates of \$81,000 per quality-adjusted life years (QALY) gained and \$52,000 per life year gained, but with wide variation in estimates according to specific subsets. The results of ongoing European trials on lung cancer screening, in particular the NELSON trial in the Netherlands, are awaited. The implications of widespread screening of smokers raise issues of high rates of false positives, surgical and medical complications from additional testing, risks of cumulative exposure to radiation, and risks of increasing patient anxiety and stress on an already limited pool of resources. Improved risk stratification to target a higher risk population for low-dose CT screening may help alleviate these costs and concerns. Smoking cessation policies and efforts should be integrated with any screening program.

▶ Treatment

A. Non-Small Cell Lung Carcinoma

Cure of NSCLC is unlikely without resection. Therefore, the initial approach to the patient is determined by answering two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II and select cases of stage IB are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes when

treated with resection alone. They should undergo multimodality treatment that includes chemotherapy or radiotherapy, or both. Stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Stage IV patients are treated with chemotherapy or symptom-based palliative therapy, or both.

Surgical approach affects outcome. In 1994, the North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group ($P = 0.008$) and a trend toward an increase in overall death rate (increase of 30%, $P = 0.08$) and increase in cancer-related death rate (increase of 50%, $P = 0.09$), compared with patients receiving lobectomy. However, for patients who cannot tolerate lobectomy, a sublobar resection (wedge resection or segmentectomy) may be considered. Given improved technology in detecting smaller tumors, a large randomized study is evaluating sublobar resection versus lobectomy for patients with peripheral tumors smaller than 2 cm. VATS has become an acceptable and reasonable alternative to standard thoracotomy, if there are no anatomic or surgical contraindications, based on large case series showing equivalent long-term outcomes and less short-term morbidity. Radiation therapy following surgery is considered for margin-positive disease or pathologic mediastinal lymph node involvement.

Patients with clinical stage I primary NSCLC, who are not candidates for surgery because of significant comorbidity or other surgical contraindication, may be candidates for stereotactic body radiotherapy. Stereotactic body radiotherapy, which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. For clinical stage I NSCLC, 3-year local control rates with stereotactic body radiotherapy exceed 90%, and 3-year survival is estimated at over 55%. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I/II NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or select stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and a subset of stage IB disease where primary tumor size exceeds 4 cm. The Lung Adjuvant Cisplatin Evaluation Collaborative Group, a meta-analysis of the five largest cisplatin-based adjuvant trials, reported a 5% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery ($P = 0.005$) in patients

with at least stage II disease. For patients with poor performance status (Eastern Cooperative Oncology Group Score of 2 or more), there is no evidence of survival benefit for adjuvant chemotherapy; rather, it may be detrimental.

Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival in patients with stage IIIB and stage IV NSCLC compared with supportive care alone, with median survival increased from 5 months to a range of 7–11 months. Palliative chemotherapy also leads to improved quality of life and symptom control, with first-line therapy involving a platinum-based regimen. Platinum-based doublet regimens consist of cisplatin or carboplatin (agents that bind DNA to form adducts that inhibit their synthesis and function) combined with another agent, such as pemetrexed, gemcitabine, taxane, or vinorelbine. The choice of chemotherapeutic agent should be tailored to histologic subtype in NSCLC. For nonsquamous histologies, patients have modestly improved overall survival when treated with a platinum agent plus pemetrexed (an inhibitor of folate-dependent enzymes important in purine and pyrimidine synthesis). Patients with squamous cell lung carcinomas have modestly improved overall survival when a platinum agent is combined with gemcitabine (a deoxycytidine analog that inhibits DNA synthesis). For good performance status patients with nonsquamous histologies, bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) can be added to a traditional platinum doublet regimen with further modest increase in survival benefit. Maintenance chemotherapy, that is, ongoing chemotherapy after an induction period of 4–6 cycles, has also been shown to improve overall survival. Finally, immune checkpoint inhibition with programmed cell-death-1 (PD-1) inhibitors (nivolumab and pembrolizumab) are playing important roles in the treatment of NSCLC. PD-1 inhibitors release T cells from the inhibitory signals they receive from tumor cells via the PD-1 pathway, restoring antitumor immunity. They are recommended as second-line treatment for both nonsquamous and squamous cell lung cancers.

With the advent of molecular profiling, targeted therapy has played a pivotal role in NSCLC. For patients with *EGFR* mutations, an *EGFR* tyrosine kinase inhibitor (erlotinib, gefitinib, or afatinib) rather than platinum-based chemotherapy is the first-line treatment. Response rates with *EGFR* inhibitors in patients with *EGFR* mutation are at least 70%, and median overall survival is estimated at 21–33 months. *EGFR* mutations are found in approximately 10–15% of the white population and 30–40% in the Asian population and are usually found among nonsmokers to light-smokers, females, and persons with nonsquamous histologies (particularly adenocarcinomas). Resistance to erlotinib or gefitinib generally occurs in 1 year, and a common mechanism of resistance is the development of a T790M mutation. Osimertinib, another *EGFR* tyrosine kinase inhibitor, has been FDA-approved for the treatment of patients with the T790M mutation, with response rates up to 60%. Approximately 5% of all patients with NSCLC carry another mutation, the *EML4-ALK* fusion gene product. This is usually found in a

comparatively younger population, with adenocarcinoma histology, and nonsmoking to light-smoking history. In a phase III trial of *ALK*-rearranged lung cancer patients, treatment with crizotinib (an *ALK*, *cMET* and *ROS-1* tyrosine kinase inhibitor) showed a response rate over 70% compared with a rate of 45% among those treated with standard first-line chemotherapy, and an improvement in median progression-free survival of 10.9 vs 7 months, respectively. At 1 year, however, resistance develops in most patients taking crizotinib. Ceritinib and alectinib, second-generation *ALK* inhibitors, have been shown to induce response rates of 50% in those patients with *ALK*-rearranged lung cancers resistant to crizotinib. Approximately 1% of NSCLC harbor *ROS1* rearrangements, and are usually found among nonsmokers or light smokers and lung adenocarcinomas. *ROS1* rearranged lung cancers also respond to crizotinib with response rates over 70%. Finally, *K-ras* mutations are found among 25% of patients with adenocarcinomas, are associated with smoking, and indicate a poor prognosis. Unfortunately, there is still no effective targeted approach to therapy for *K-ras* mutated lung cancers. These mutations (*EGFR*, *EML4-ALK*, *ROS1*, and *K-ras*) are mutually exclusive. Difficulties may arise when only small fine-needle aspirate biopsies are obtained; clinicians are recommended to get at least core biopsies for sufficient tissue for molecular analysis.

B. Small Cell Lung Carcinoma

Response rates of SCLC to cisplatin and etoposide are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and 5% in extensive-stage disease (Table 39–3). Thoracic radiation therapy improves survival in patients with limited SCLC and is given concurrently with chemotherapy. Consolidative thoracic radiation therapy may be indicated for patients with extensive disease who have a significant response to chemotherapy and remain free of brain metastases. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited stage disease who respond to chemotherapy

Table 39–3. Median survival for small cell lung carcinoma following treatment.

Stage	Mean 2-Year Survival	Median Survival
Limited	20–40%	15–20 months
Extensive	5%	8–13 months

Data from multiple sources, including Van Meerbeeck JP et al. Small-cell lung cancer. *Lancet*. 2011 Nov 12;378(9804):1741–55.

and a subset of patients with extensive stage disease who have had an excellent response to chemotherapy.

Occasionally, very early limited-stage disease (T1N0M0) may be detected on initial imaging. It may also be identified after a peripheral nodule proves to be SCLC on resection. These patients are recommended to receive adjuvant chemotherapy following surgery given the high risk of micrometastases in SCLC. Five-year survival following resection of and adjuvant chemotherapy for stage I SCLC can reach up to 50%.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea, hemoptysis, endobronchial obstruction, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a *solitary* brain metastasis improves quality of life and survival when combined with radiation therapy if there is no evidence of other metastatic disease. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5). In addition to standard oncologic care, early consultation with—or referral to—a palliative care specialist is recommended in advanced disease to aid in symptom management and can modestly improve survival.

► Prognosis

The 5-year survival rate for lung cancer is approximately 17%. Predictors of survival include the type of tumor (SCLC versus NSCLC), molecular typing, the stage of the tumor, the patient's performance status, and weight loss in the past 6 months. Patients with targetable mutations (*EGFR* and *ALK*) have better overall survival when compared with those without mutations due to superior efficacy of targeted drug therapy.

PULMONARY METASTASIS

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, infections (including abscesses, septic emboli, and atypical infections), sarcoidosis, rheumatoid nodules, and granulomatosis with polyangiitis. Metastases to the lungs are found in 20–55% of patients with various metastatic malignancies. Most are intraparenchymal. Carcinoma of the kidney, breast, rectum, colon, and cervix and malignant melanoma are the most likely primary tumors. Head and neck cancers with extensive or lower cervical nodal involvement have a 30% risk for distant metastasis; half of these metastases present in the lungs. Pulmonary metastases are common in patients with osteosarcomas and develop in approximately 20% of patients with soft tissue sarcomas.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

► Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available. For example, an elevated prostate-specific antigen (PSA) may indicate prostate cancer, and beta-human chorionic gonadotropin (beta-hCG) and alpha-fetoprotein point to germ cell tumors. Based on the clinical setting, imaging studies should be ordered. If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, VATS, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveals the diagnosis.

To determine a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, PSA and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) and napsin-A are relatively specific for primary lung adenocarcinoma, while the former can be positive in cases of SCLC and thyroid carcinoma and the latter can be positive in papillary and clear cell renal cell carcinomas. An adenocarcinoma that demonstrates negative TTF-1 and napsin-A staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Mammography should be considered in women to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET-CT scan is helpful in identifying the site of a primary cancer and identifying other areas of extrathoracic metastasis.

▶ Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (such as testis, colorectal, and kidney).

Surgical resection should be considered only if the primary tumor is under control, if the patient has adequate cardiopulmonary reserve to tolerate resection, if all of the metastatic tumor can be resected, if effective nonsurgical approaches are not available, and if any extrathoracic metastasis has been excluded. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, and (3) pleural involvement. Unfavorable prognostic factors also include shorter disease-free interval from primary tumor treatment to presentation of metastases and a larger number of metastases. To date, there have been no randomized data confirming the benefit of metastatectomy for pulmonary metastasis, with one randomized clinical trial in the UK currently enrolling patients (the Pulmonary Metastatectomy in Colorectal Cancer [PulMiCC] trial). Retrospective data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. Patients who are not surgical candidates but have solitary or limited metastatic disease to the lungs may be candidates for stereotactic radiotherapy, radioablation, or cryotherapy. For patients with unresectable progressive disease, chemotherapy tailored to the primary tumor can be offered, and diligent attention to palliative care is essential (see Chapter 5).

MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Unilateral, nonpleuritic chest pain and dyspnea.
- ▶ Distant (more than 20 years earlier) history of exposure to asbestos.
- ▶ Pleural effusion or pleural thickening or both on chest radiographs.
- ▶ Malignant cells in pleural fluid or tissue biopsy.

▶ General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum

(20% of cases). About three-fourths of pleural mesotheliomas are diffuse (usually malignant) tumors, and the remaining one-fourth are localized (usually benign). Men outnumber women by a 3:1 ratio. Numerous studies have confirmed the association of **malignant pleural mesothelioma** with exposure to asbestos (particularly the amphibole form). The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and other asbestos products (pipes, textiles, paints, tiles, gaskets, panels). Although cigarette smoking significantly increases the risk of bronchogenic carcinoma in asbestos workers and aggravates asbestosis, there is no association between smoking and mesothelioma.

► Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 72–74 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

► Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic

structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia.

► Treatment

Chemotherapy is the mainstay of treatment, with surgery only included in multimodality treatment if there is localized disease that can be surgically resected and no evidence of mediastinal nodal involvement. The optimal surgical approach is still under debate. For localized disease, surgical options include pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) or extrapleural pneumonectomy (a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm). Limited nonrandomized data have shown that a trimodality approach for localized disease with extrapleural pneumonectomy, adjuvant radiation, and (neoadjuvant or adjuvant) chemotherapy can prolong survival in highly selected patients. However, the benefit of extrapleural pneumonectomy has been brought into question with the results of the Mesothelioma and Radical Surgery (MARS) trial. This small randomized study, comparing extrapleural pneumonectomy with no extrapleural pneumonectomy after induction chemotherapy in 50 patients, showed that extrapleural pneumonectomy offers no survival benefit and may cause more harm. In advanced disease, palliative chemotherapy with cisplatin and pemetrexed can achieve response rates of 30–40%, extend median overall survival to 12 months, and improve quality of life. Other alternative chemotherapy regimens include gemcitabine, anthracyclines, or vinorelbine. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

► Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from diagnosis ranges from 7 months to 17 months. Five-year survival is 5–10%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survivals less than 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male gender, nodal involvement, elevated lactate dehydrogenase, high white blood cell count, low hemoglobin, and high platelet count.

HEPATOBIILIARY CANCERS

Lawrence S. Friedman, MD

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ In Western countries, usually a complication of cirrhosis.
- ▶ Characteristic CT and MRI features and elevated serum alpha-fetoprotein may obviate the need for a confirmatory biopsy.

General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas.

Hepatocellular carcinomas are associated with cirrhosis in 80% of cases. In Africa and most of Asia, hepatitis B virus (HBV) infection is a major etiologic factor, and a family history of hepatocellular carcinoma increases the risk synergistically. In the United States and other Western countries, incidence rates have risen rapidly (over twofold since 1978, with slowing of the rate increase since 2006), presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C virus (HCV) infection and nonalcoholic fatty liver disease. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age older than 55 years (although there has been an increase in the number of younger cases), Asian or Hispanic ethnicity, family history in a first-degree relative, overweight, obesity (especially in early adulthood), alcohol use (especially in combination with obesity), tobacco use, diabetes mellitus, hypothyroidism (in women), a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. The risk of hepatocellular carcinoma is higher in persons with a viral rather than nonviral cause of cirrhosis and may be increased in persons with autoimmune diseases. Other associations include high levels of HBV replication; HBV genotype C; hepatitis D coinfection; elevated serum ALT levels in persons with chronic hepatitis B (in whom antiviral therapy to suppress HBV replication appears to reduce the risk); HCV genotypes 1b and 3; hemochromatosis (and possibly the C282Y carrier state); aflatoxin exposure (associated with mutation of the *TP53* gene); alpha-1-antitrypsin (alpha-1-antitrypsin) deficiency; tyrosinemia; and radiation exposure. In

patients with the metabolic syndrome, hepatocellular carcinoma may arise from a hepatocellular adenoma in the absence of cirrhosis. Evidence for an association with long-term use of oral contraceptives is inconclusive. While sulfonylurea and insulin use may increase the risk of hepatocellular carcinoma, consumption of coffee, vegetables, white meat, fish, and n-3 polyunsaturated fatty acids; aspirin use; and statin and metformin use in diabetic patients appear to be protective. The fibrolamellar variant of hepatocellular carcinoma generally occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, unique genomic profiles, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver. Hepatoblastoma, the most common malignant liver tumor in infants and young children, occurs rarely in adults.

Clinical Findings

A. Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from a necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. Alpha-fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks and levels are not elevated in patients with fibrolamellar hepatocellular carcinoma); however, mild elevations (10–200 ng/mL [10–200 mcg/L]) are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. Cytologic study of ascitic fluid rarely reveals malignant cells.

C. Imaging

Multiphasic helical CT and MRI with contrast enhancement are the preferred imaging studies for determining the

location and vascularity of the tumor; MRI may be more sensitive than CT, and imaging with gadoteric acid increases sensitivity. Lesions smaller than 1 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasonography is less sensitive and more operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasonography has sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is thus associated with false-positive results. In selected cases, endoscopic ultrasonography (EUS) may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions smaller than 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions 1 cm or larger, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm (3a) or tumor involving a major branch of the portal or hepatic vein (3b); and T4: tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1, regional lymph node metastasis; M1, distant metastasis; F0, no to moderate hepatic fibrosis; F1, severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Pugh stage, tumor stage, and liver tests and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

▶ Screening & Prevention

Surveillance for the development of hepatocellular carcinoma is recommended in patients with chronic hepatitis B (beginning as early as age 20 in Africans, age 40 in Asians or those with a family history of hepatocellular carcinoma, and age 50 in others) or cirrhosis caused by HCV, HBV, or alcohol. Whether surveillance for hepatocellular carcinoma leads to a survival advantage over clinical diagnosis is uncertain. The standard approach is ultrasonography and alpha-fetoprotein testing every 6 months, although the value of alpha-fetoprotein screening has been questioned because of its low sensitivity. CT and MRI are considered too expensive for screening, but the sensitivity of ultrasonography for detecting early hepatocellular carcinoma is only 63%. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year, and patients with tumors detected by surveillance have a less advanced stage on

average and greater likelihood that treatment will prolong survival than those not undergoing surveillance. In a population of patients with cirrhosis, over 60% of nodules smaller than 2 cm in diameter detected on a screening ultrasonography prove to be hepatocellular carcinoma. Mass vaccination programs against HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis B and of hepatitis C in patients with cirrhosis also reduces the subsequent risk of hepatocellular carcinoma.

▶ Treatment

Surgical resection of a solitary hepatocellular carcinoma may result in cure if liver function is preserved (Child-Pugh class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor less than 5 cm or three or fewer tumors each less than 3 cm in diameter [Milan criteria]) and in those with expanded (University of California, San Francisco) criteria of one tumor less than or equal to 6.5 cm or three or fewer tumors less than or equal to 4.5 cm. Patients with stage 2 hepatocellular carcinoma meeting the Milan criteria receive an additional 28 points on their Model for End-Stage Liver Disease (MELD) score after 6 months on the waiting list (see Chapter 16), markedly increasing their chances of undergoing transplantation. However, liver transplantation is often impractical because of the donor organ shortage, and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum alpha-fetoprotein level 455 ng/mL (455 mcg/L) or higher, or a MELD score 20 or more have poor posttransplantation survival. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), TACE with drug-eluting beads, transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. Radiofrequency ablation of, cryotherapy of, microwave ablation of, or injection of absolute ethanol into tumors smaller than 2 cm may prolong survival in patients who are not candidates for resection and have tumors that are accessible; these interventions may also provide a “bridge” to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors larger than 2 cm in diameter (but is not effective for those larger than 5 cm) and can be performed after TACE in select cases. Cryoablation may result in slower tumor progression than radiofrequency ablation for tumors that are 3.1–4 cm in diameter. Sorafenib (an oral multikinase

inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]), prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is standard care in these patients. The modified Response Evaluation Criteria in Solid Tumors (mRECIST) are used to assess treatment response based on tumor shrinkage and viability after locoregional and antiangiogenic treatment. Meticulous efforts at palliative care are essential for patients in whom disease progresses despite treatment or in whom advanced tumors, vascular invasion, or extrahepatic spread are present. Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related hepatocellular carcinoma, the serum alpha-fetoprotein level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. A serum alpha-fetoprotein level greater than or equal to 200 ng/mL (200 milli-international units/mL) or increases of greater than 15 ng/mL/month predict worse outcomes in patients awaiting liver transplantation. In patients who are not eligible for surgery, an elevated serum C-reactive protein level is associated with poor survival. Contrary to traditional opinion, the fibrolamellar variant does not have a better prognosis than conventional hepatocellular carcinoma without cirrhosis.

When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

CARCINOMA OF THE BILIARY TRACT

ESSENTIALS OF DIAGNOSIS

- ▶ Presents with obstructive jaundice, usually painless, often with dilated biliary tract.
- ▶ Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- ▶ A dilated gallbladder may be palpable (Courvoisier sign).
- ▶ Diagnosis by cholangiography with biopsy and brushings for cytology.

General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease; the incidence may be decreasing in the United States. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter (particularly with hypocholeic foci on EUS), mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Genetic factors include *K-ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be seen on initial presentation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 10–25% of all hepatobiliary malignancies and 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70, with a slight male predominance, and more common in Asia. About 50% arise at the confluence of the hepatic ducts (perihilar, or so-called Klatskin, tumors), and 40% arise in the distal extrahepatic bile duct (the incidence of which has risen since 1990); the remainder are intrahepatic or peripheral (the incidence of which rose dramatically from the 1970s to the early 2000s).

Staging for extrahepatic cholangiocarcinoma is as follows: T1, tumor is confined to bile duct; T2, tumor spreads beyond the wall of the bile duct (2a) or to the adjacent liver (2b); T3, tumor spreads to unilateral branches of the portal vein or hepatic artery; T4, tumor spreads to main portal vein or its branches bilaterally, common hepatic artery, second-order biliary radicals bilaterally, or various combinations; N1, regional lymph node metastasis; M1, distant metastasis. Staging for intrahepatic cholangiocarcinoma is as follows: T1, solitary tumor without vascular invasion; T2, solitary tumor with vascular invasion or multiple tumors 5 cm or smaller; T3, multiple tumors larger than 5 cm or involving major branch of portal or hepatic veins; T4, tumor invades adjacent organ (except gallbladder) or perforation of visceral peritoneum; N1, regional lymph node metastasis; and M1, distant metastasis. Other staging systems consider the patient's performance status, tumor extent and form, vascular encasement, hepatic lobe atrophy, underlying liver disease, and peritoneal metastasis. The frequency of carcinoma in persons with a choledochal cyst has been reported to be over 14% at 20 years, and surgical excision is recommended. Most cases of cholangiocarcinoma are sporadic. There is an increased incidence of cholangiocarcinoma in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; smoking; and past exposure to Thorotrast, a contrast agent. In diabetic patients, metformin use is associated with a reduced risk of intrahepatic cholangiocarcinoma. In Southeast Asia, hepatolithiasis, chronic typhoid carriage, and infection of the bile ducts with helminths (*Clonorchis sinensis*, *Opisthorchis viverrini*) are associated with an increased risk of cholangiocarcinoma. Hepatitis C virus (and possibly hepatitis B virus) infection, cirrhosis, HIV infection, nonalcoholic fatty liver disease, diabetes mellitus, obesity, and tobacco smoking are risk factors for intrahepatic cholangiocarcinoma. Mixed hepatocellular carcinoma-cholangiocarcinoma is a tumor that is being recognized increasingly.

► Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier sign); however, this clinical

generalization has been proven to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. The serum CA 19-9 level is elevated in up to 85% of patients and may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis) but is neither sensitive nor specific.

C. Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tract and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of hepatocellular carcinoma, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either endoscopic retrograde or percutaneous transhepatic cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens for polysomy improve sensitivity. EUS with FNA of tumors, peroral cholangioscopy, confocal laser endomicroscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation, but FNA can result in tumor seeding and is often avoided if the tumor is potentially resectable.

► Treatment

In young and fit patients, curative surgery for gallbladder carcinoma may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role

of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Factors predicting shorter survival for intrahepatic cholangiocarcinoma include large tumor size, multiple tumors, lymph node metastasis, and vascular invasion. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a longer duration of patency, but they are associated with a higher rate of stent migration and cholecystitis due to occlusion of the cystic duct and are not associated with longer survival. For perihilar tumors, insertion of a unilateral stent rather than bilateral stents may suffice. Plastic stents are less expensive initially, but not in the long term, because they are more prone to occlude than metal ones; they may be considered in patients expected to survive only a few months. Photodynamic therapy in combination with stent placement prolongs survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Endoscopic retrograde cholangiopancreatography (ERCP)-directed radiofrequency ablation is another emerging option. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy with gemcitabine alone, but the combination of cisplatin and gemcitabine prolongs survival by about 3 months in patients with locally advanced or metastatic cholangiocarcinoma. Few patients survive for more than 24 months. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II perihilar cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

▶ When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

▶ When to Admit

- Biliary obstruction.
- Cholangitis.

CARCINOMA OF THE PANCREAS & AMPULLA OF VATER

ESSENTIALS OF DIAGNOSIS

- ▶ Obstructive jaundice (may be painless).
- ▶ Enlarged gallbladder (may be painful).
- ▶ Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

▶ General Considerations

Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. Pancreatic carcinomas account for 2% of all cancers and 5% of cancer deaths. Risk factors include age, tobacco use (which is thought to cause 20–25% of cases), heavy alcohol use, obesity, chronic pancreatitis, diabetes mellitus, prior abdominal radiation, family history, and possibly gastric ulcer and exposure to arsenic and cadmium. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of pancreatic cancer. In diabetic patients, metformin use may reduce the risk of pancreatic cancer slightly, but insulin use and glucagon-like peptide-1-based therapy (eg, sitagliptin) may increase the risk. About 7% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. In 5–10% of cases, pancreatic cancer occurs as part of a hereditary syndrome, including familial breast cancer (carriers of *BRCA-2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (*PSS1* mutation), familial atypical multiple mole melanoma (*p16/CDKN2A* mutation), Peutz-Jeghers syndrome (*STK11/LKB1* mutation), ataxia-telangiectasia (*ATM* mutation), and Lynch syndrome (hereditary nonpolyposis colorectal cancer [*MLH1*, *MSH2*, *MSH6* mutations]). Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone-releasing hormone, adrenocorticotrophic hormone, and others) or nonfunctional. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel-Lindau disease) are benign. However, mucinous cystic neoplasms (defined by the presence of ovarian

stroma) (10–45% of cystic pancreatic neoplasms), intraductal papillary mucinous neoplasms (21–33%), solid pseudopapillary tumors (less than 5%, primarily in young women), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of pancreatic adenocarcinoma, unless the cystic neoplasm is at least locally advanced.

► Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasional patients (often aged 40 years or older) present with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by a neoplasm (Courvoisier sign), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph's) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proven useful for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis. Plasma chromogranin A levels are elevated in 88–100% of patients with pancreatic neuroendocrine tumors.

C. Imaging

Multiphase thin-cut helical CT is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT identifies metastases, delineates the extent of the tumor, and allows for percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would preclude attempts at surgical resection, but it is used less commonly since the advent of multiphase helical CT.

EUS is more sensitive than CT for detecting pancreatic cancer and equivalent to CT for determining nodal involvement and resectability. A normal EUS excludes pancreatic cancer. EUS may also be used to guide FNA for tissue diagnosis, tumor markers, and DNA analysis. ERCP may clarify an ambiguous CT or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography is used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter detected by endoscopy, EUS, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, EUS, and ERCP and features of the cyst fluid on gross, cytologic, and genetic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (greater than 200 ng/mL [200 mcg/L]) and *K-ras* mutations; and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

► Staging

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than 2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4: tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor); N1: regional lymph node metastasis; M1: distant metastasis.

► Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes up to 30% of patients with pancreatic carcinoma. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for cancers strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant or neoadjuvant chemotherapy with gemcitabine or fluorouracil (or both), possibly combined with irradiation, is of benefit (Table 39–4). Chemoradiotherapy downstages about 30% of patients with locally

Table 39–4. Treatment choices for cancers responsive to systemic agents.

Diagnosis	Current Treatment of Choice	Other Treatments
Acute lymphoblastic leukemia (ALL)	Induction combination chemotherapy: Vincristine, prednisone, daunorubicin, asparaginase, intrathecal methotrexate Consolidation combination chemotherapy: Cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) alternated with cytarabine, methotrexate Maintenance chemotherapy: Methotrexate, 6-mercaptopurine Philadelphia chromosome–positive ALL: Add imatinib or dasatinib to above regimen	Liposomal vincristine, blinatumomab, clofarabine, nelarabine (T cell ALL), nilotinib, bosutinib, ponatinib (Philadelphia chromosome–positive ALL), autologous or allogeneic transplantation for high risk or at relapse
Acute myeloid leukemia (AML)	Combination chemotherapy: Cytarabine, daunorubicin or Cytarabine, idarubicin or Cytarabine, daunomycin, cladrabine	Mitoxantrone, doxorubicin, cladribine, fludarabine, 5-azacytidine, decitabine, clofarabine
Chronic myeloid leukemia (CML)	Imatinib mesylate or nilotinib or dasatinib	Ponatinib, bosutinib, omacetaxine, allogeneic bone marrow transplantation
Chronic lymphocytic leukemia (CLL)	Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR) or Bendamustine, rituximab Single-agent chemotherapy: Fludarabine, or Bendamustine or Chlorambucil	Alemtuzumab, ofatumumab, obinutuzumab, ibrutinib, idelalisib, lenalidomide, pentostatin, cladribine, cyclophosphamide, vincristine, doxorubicin, prednisone
Hairy cell leukemia	Cladribine (2-chlorodeoxyadenosine)	Pentostatin, rituximab, interferon-alpha, vemurafenib
Hodgkin lymphoma (stages III and IV)	Combination chemotherapy: Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD) or Doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, prednisone (Stanford V) or Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone (BEACOPP)	Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP) or Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP) or Ifosfamide, carboplatin, etoposide (ICE) or Mesna, ifosfamide, mitoxantrone, etoposide (MIME); stem cell transplantation for high risk or first relapse Brentuximab vedotin
Non-Hodgkin lymphoma (intermediate and high grade)	Combination chemotherapy: Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab (CHOP-R) or Etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, rituximab (R-EPOCH) (for double rearrangements)	Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP) or Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP) or Ifosfamide, carboplatin, etoposide (ICE) or Mesna, ifosfamide, mitoxantrone, etoposide (MIME); transplantation for high risk or first relapse
Non-Hodgkin lymphoma (low grade)	Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR) or Fludarabine, rituximab (FR) or Bendamustine, rituximab or Cyclophosphamide, vincristine, doxorubicin, prednisone, rituximab (CHOP-R), or Cyclophosphamide, vincristine, prednisone, rituximab (CVP-R) or Lenalidomide, rituximab	Chlorambucil, rituximab, ¹³¹ I tositumomab, ⁹⁰ Y ibritumomab tiuxetan, bendamustine, lenalidomide, idelalisib, ibrutinib, belinostat (T cell lymphoma), autologous or allogeneic transplantation
Multiple myeloma	Combination chemotherapy (transplant candidates): Bortezomib, dexamethasone, thalidomide or Bortezomib, dexamethasone, lenalidomide or Dexamethasone, lenalidomide Followed by autologous or miniallogeneic stem cell transplantation Combination chemotherapy (non-transplant candidates): Lenalidomide, dexamethasone, or Melphalan, prednisone, bortezomib, or Melphalan, prednisone, lenalidomide, or Melphalan, prednisone, thalidomide	Cyclophosphamide, liposomal doxorubicin, carfilzomib, pomalidomide, panobinostat, ixazomib, elotuzumab, daratumumab

(continued)

Table 39–4. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Waldenström macroglobulinemia	Plasmapheresis alone or followed by combination chemotherapy: Bortezomib with or without rituximab, or Thalidomide with or without rituximab, or Rituximab, cyclophosphamide, prednisone, or Carfilzomib, rituximab, dexamethasone	Cladribine, ibrutinib, ofatumumab, chlorambucil, bendamustine, alemtuzumab, everolimus, autologous bone marrow transplantation
Polycythemia vera	Phlebotomy, hydroxyurea, aspirin	Anagrelide, radiophosphorus ³² P, interferon-alpha
Non–small cell lung cancer	Combination chemotherapy: Cisplatin, vinorelbine, or Cisplatin, etoposide, or Paclitaxel, carboplatin, or Cisplatin, gemcitabine (squamous histology) Cisplatin, pemetrexed (nonsquamous histology) All regimens with or without bevacizumab Erlotinib, gefitinib or afatinib (<i>EGFR</i> mutation positive), or Crizotinib (<i>ALK</i> mutation positive)	Docetaxel, cetuximab, pembrolizumab, nivolumab, osimertinib, necitumumab, ramucirumab, cabozantinib (<i>RET</i> rearrangement), trastuzumab, afatinib (<i>HER2</i> mutation positive), crizotinib (<i>ROS1</i> rearrangement or <i>ALK</i> mutation positive), vemurafenib or dabrafenib or dabrafenib plus trametinib (<i>BRAF</i> V600E mutation positive)
Small cell lung cancer	Combination chemotherapy: Cisplatin, etoposide, or Carboplatin, etoposide, or Cisplatin, irinotecan	Irinotecan, cyclophosphamide, doxorubicin, vincristine, topotecan, gemcitabine, paclitaxel, bendamustine, temozolomide
Mesothelioma	Combination chemotherapy: Cisplatin, pemetrexed, or Carboplatin, pemetrexed, or Gemcitabine, cisplatin	Vinorelbine
Head and neck cancer	Combination chemotherapy: Cisplatin, fluorouracil, or Paclitaxel, carboplatin, or Docetaxel, cisplatin, fluorouracil, or Cisplatin or cetuximab with radiation therapy	Methodrexate
Esophageal and esophagogastric junction cancer	Combination chemotherapy: Cisplatin, fluorouracil, or Paclitaxel, carboplatin, or Oxaliplatin, fluorouracil	Irinotecan, oxaliplatin, capecitabine, epirubicin, docetaxel, ramucirumab (esophagogastric junction cancer)
Uterine cancer	Hormone therapy: Progestins, tamoxifen, aromatase inhibitors or Combination chemotherapy: Cisplatin, doxorubicin, or Docetaxel, carboplatin, or Carboplatin, paclitaxel	Liposomal doxorubicin, bevacizumab, topotecan, temsirolimus, docetaxel
Ovarian cancer	Combination chemotherapy: Paclitaxel, carboplatin with or without bevacizumab, or Docetaxel, carboplatin, or Paclitaxel, cisplatin	Gemcitabine, liposomal doxorubicin, topotecan, cyclophosphamide, etoposide, bevacizumab, pemetrexed, olaparib
Cervical cancer	With radiation: Cisplatin Combination chemotherapy: Cisplatin, paclitaxel with or without bevacizumab, or Cisplatin, topotecan, or Carboplatin, paclitaxel, or Cisplatin, gemcitabine, or Topotecan, paclitaxel with or without bevacizumab	Docetaxel, ifosfamide, vinorelbine, irinotecan, mitomycin, fluorouracil, docetaxel, pemetrexed, topotecan, altretamine
Breast cancer	Adjuvant hormone therapy: <i>Premenopausal:</i> Tamoxifen <i>Postmenopausal:</i> Aromatase inhibitors (anastrozole, letrozol, exemestane) Adjuvant chemotherapy (without trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, or Docetaxel, cyclophosphamide, or Doxorubicin, cyclophosphamide, or Doxorubicin, cyclophosphamide, docetaxel Adjuvant chemotherapy (with trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, trastuzumab with or without pertuzumab, or Docetaxel, carboplatin, trastuzumab with or without pertuzumab	Eribulin, capecitabine, mitoxantrone, cisplatin, etoposide, vinblastine, fluorouracil, ixabepilone, pertuzumab, gemcitabine, lapatinib, toremifene, fulvestrant, palbociclib raloxifene

(continued)

Table 39–4. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Choriocarcinoma (trophoblastic neoplasms)	Single-agent chemotherapy: Methotrexate or dactinomycin for low-risk disease Combination chemotherapy: Etoposide, methotrexate, dactinomycin, cyclophosphamide, vincristine (EMA-CO) for high-risk disease	Vinblastine, cisplatin, mercaptopurine, chlorambucil, doxorubicin
Testicular cancer	Combination chemotherapy: Cisplatin, etoposide (EP), or Bleomycin, etoposide, cisplatin (BEP), or Etoposide, mesna, ifosfamide, cisplatin (VIP)	Vinblastine, paclitaxel, gemcitabine, oxaliplatin
Kidney (renal cell) cancer	Single-agent chemotherapy: Sunitinib or temsirolimus or bevacizumab or sorafenib or pazopanib or axitinib, or interleukin-2	Interferon-alpha, cabozantinib, nivolumab
Bladder cancer	Combination chemotherapy: Gemcitabine, cisplatin, or Methotrexate, vinblastine, doxorubicin, cisplatin (MVAC), or Cisplatin, methotrexate, vinblastine (CMV)	Carboplatin, paclitaxel, docetaxel, fluorouracil, pemetrexed
Prostate cancer	Hormone therapy: Luteinizing hormone-releasing agonist (leuprolide, goserelin, triptorelin, degarelix) with or without an antiandrogen (flutamide, bicalutamide, nilutamide)	Ketoconazole, docetaxel, abiraterone, enzalutamide, mitoxantrone, cabazitaxel, sipuleucel-T, prednisone, Radium (Ra)-223
Brain cancer (anaplastic astrocytoma and glioblastoma multiforme)	Single-agent chemotherapy with radiation therapy: Temozolomide	Bevacizumab, irinotecan, procarbazine, carmustine, lomustine, cyclophosphamide
Neuroblastoma	Combination chemotherapy: Cyclophosphamide, doxorubicin, cisplatin, etoposide	Vincristine, topotecan, irinotecan, ifosfamide, carboplatin, 13-cis-retinoic acid, ¹³¹ I-MIBG, dinutuximab, autologous or allogeneic transplantation
Thyroid cancer	Single-agent chemotherapy: Radioiodine (¹³¹ I) or sorafenib, or sunitinib or pazopanib or lenvatinib, vandetanib (medullary thyroid cancer)	Doxorubicin, dacarbazine, cabozantinib
Adrenal cancer	Single-agent chemotherapy: Mitotane	Doxorubicin, etoposide, cisplatin
Stomach (gastric) cancer	Combination chemotherapy: Epirubicin, cisplatin, fluorouracil, or Docetaxel, cisplatin, fluorouracil, or Fluorouracil, leucovorin, oxaliplatin Trastuzumab added for <i>HER2</i> -overexpressing adenocarcinomas	Capecitabine, irinotecan, paclitaxel, ramucirumab
Pancreatic cancer	Combination chemotherapy: Gemcitabine, cisplatin, or Gemcitabine, paclitaxel, or Gemcitabine, erlotinib, or Fluorouracil, leucovorin, irinotecan, oxaliplatin (FOLFIRINOX) Single-agent chemotherapy: Gemcitabine	Capecitabine
Colon cancer	Combination chemotherapy: Fluorouracil, leucovorin, oxaliplatin (FOLFOX6), or Capecitabine, oxaliplatin (CapeOx), or Fluorouracil, leucovorin, irinotecan (FOLFIRI) each regimen with or without bevacizumab	Cetuximab, panitumumab, regorafenib, ziv-aflibercept, trifluridine/tipiracil
Rectal cancer	Chemotherapy with radiation: Fluorouracil or capecitabine; For adjuvant or advanced disease treatment, same regimens used with colon cancer	Cetuximab, irinotecan, panitumumab, regorafenib, ziv-aflibercept, trifluridine/tipiracil
Anal cancer	Combination chemotherapy with radiation: Fluorouracil, mitomycin or capecitabine, mitomycin	Cisplatin
Carcinoid	Octreotide LAR or lanreotide	Doxorubicin, dacarbazine, temozolomide, streptozocin, oxaliplatin, fluorouracil, everolimus
Osteogenic sarcoma	Combination chemotherapy: Cisplatin, doxorubicin, or Methotrexate, cisplatin, doxorubicin or Doxorubicin, cisplatin, doxorubicin, or Ifosfamide, cisplatin, epirubicin	Cyclophosphamide, gemcitabine, docetaxel, etoposide, sorafenib, Radium (Ra)-223, Samarium (Sm)-153 (lexidronam)-ethylene diamine tetramethylene phosphate (EDTMP)

(continued)

Table 39–4. Treatment choices for cancers responsive to systemic agents.(continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Soft tissue sarcomas	Combination chemotherapy: Doxorubicin, dacarbazine (AD), or Doxorubicin, ifosfamide, mesna (AIM), or Mesna, doxorubicin, ifosfamide, dacarbazine (MAID) Single-agent chemotherapy: Eribulin, pazopanib; imatinib or sunitinib or regorafenib (gastrointestinal stromal tumors)	Liposomal doxorubicin, methotrexate, gemcitabine, docetaxel, temozolomide, epirubicin, pazopanib; sorafenib, nilotinib, dasatinib, pazopanib (gastrointestinal stromal tumors)
Melanoma	Combination chemotherapy (non- <i>BRAF</i> mutation): nivolumab/ ipilimumab Combination chemotherapy (<i>BRAF</i> mutation): dabrafenib/ trametinib or vemurafenib/cobimetinib Single-agent chemotherapy (non- <i>BRAF</i> mutation): pembrolizumab or nivolumab Single-agent chemotherapy (<i>BRAF</i> mutation): vemurafenib or dabrafenib or cobimetinib	Dacarbazine, temozolomide, imatinib, paclitaxel, carboplatin
Hepatocellular cancer	Single-agent chemotherapy: Sorafenib	Doxorubicin
Kaposi sarcoma	Single-agent chemotherapy: Liposomal doxorubicin or liposomal daunorubicin	Paclitaxel, vinblastine, vincristine, etoposide, thalidomide

advanced disease to allow resection. When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient's anticipated survival is less than 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent tumor ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with the combination of oxaliplatin, irinotecan, fluorouracil, and leucovorin (FOLFIRINOX) and with the combination of gemcitabine and albumin-bound paclitaxel. The addition of erlotinib (an inhibitor of the EGFR receptor), capecitabine (an oral fluoropyrimidine), or a platinum agent may improve survival but also increases toxicity. The high rate of *K-ras* mutations in pancreatic cancer limits the benefit of erlotinib. Celiac plexus nerve block (under CT or endoscopic ultrasound guidance) or thoracoscopic splanchnicectomy may improve pain control.

Surgical resection is the treatment of choice for neuroendocrine tumors, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, peptide-receptor radionuclide therapy, and chemoembolization. There is a growing consensus that asymptomatic incidental pancreatic cysts 2 cm or smaller are at low risk for harboring invasive carcinoma; the cysts

may be monitored by imaging tests (MRI) in 1 year and then every 2 years for 5 years if no changes are observed, with EUS and FNA if a cyst enlarges to at least 3 cm and another high-risk feature (dilated main pancreatic duct, presence of a solid component) develops. Other guidelines have been proposed.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudopapillary tumors (which have a 15% risk of malignant transformation), and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be monitored with serial imaging if they (1) are asymptomatic and exhibit benign features; (2) have a diameter less than 3 cm (some authorities recommend a diameter 1.5 cm or smaller, but even lesions 3 cm or larger may be monitored in elderly persons with no other worrisome cyst features); and (3) lack non-enhancing mural nodules, a thick wall, an abrupt change in the caliber of the pancreatic duct with distal pancreatic atrophy, or possibly bile duct dilatation and gallbladder adenomyomatosis. Most such lesions with benign features remain stable on follow-up, but the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

► Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and reported 5-year

survival rates range from 2% to 5%. Tumors of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, or with a genetic syndrome associated with an increased risk of pancreatic cancer, screening with EUS and helical CT or MRI/MRCP should be considered beginning at age 40–45 or 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

▶ When to Refer

All patients with carcinoma involving the pancreas and the ampulla of Vater should be referred to a specialist.

▶ When to Admit

Patients who require surgery and other interventions should be hospitalized.

ALIMENTARY TRACT CANCERS

Pelin Cinar, MD, MS
Kenneth R. McQuaid, MD

ESOPHAGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Progressive solid food dysphagia.
- ▶ Weight loss common.
- ▶ Endoscopy with biopsy establishes diagnosis.

▶ General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. In the United States, **squamous cell cancer** is much more common in blacks than in whites. Squamous cell cancer has a high incidence in certain regions of China and Southeast Asia. Half of all cases occur in the distal third of the esophagus. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. **Adenocarcinoma** is more common in whites. It is increasing dramatically in incidence and now is more common than squamous carcinoma in the United States. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus. Obesity also is strongly associated with adenocarcinoma, even after controlling for gastroesophageal reflux.

▶ Clinical Findings

A. Symptoms and Signs

Most patients with esophageal cancer present with advanced, incurable disease. Over 90% have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheo-esophageal fistula, characterized by coughing on swallowing or pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, obstructive, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation. Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheo-esophageal fistula such as pneumonia.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

▶ Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, EUS with guided FNA biopsy of lymph nodes should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies, prior to invasive surgery. Bronchoscopy is sometimes required in esophageal cancers above the carina to exclude tracheobronchial extension. Laparoscopy to exclude occult peritoneal carcinomatosis should be considered in patients with tumors at or near the gastroesophageal junction (see Gastric Adenocarcinoma).

▶ Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

▶ Treatment

The approach to esophageal cancer depends on the tumor stage, patient preference and functional status, and the expertise of the surgeons, oncologists, gastroenterologists, and radiotherapists. It is helpful to classify patients into two general categories.

A. Therapy for “Curable” Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced clinicians, endoscopic mucosal resection of Tis and T1a cancers achieves equivalent long-term survival with less morbidity (see Barrett Esophagus, Chapter 15). Patients with larger tumors or deeper tumors invasive to the submucosa (T1b) have higher rates of lymph node metastasis. Frequent posttreatment endoscopic surveillance is required to ensure no residual or recurrent tumor.

1. Surgery with or without neoadjuvant chemoradiation therapy—There are multiple surgical approaches to the resection of invasive (non-superficial) but potentially “curable” esophageal cancers (stage Ib, II, or IIIA). Accepted techniques include en bloc transthoracic excision of the

esophagus with extended lymph node dissection, transhiatal esophagogastrectomy (entailing laparotomy with cervical anastomosis), and minimally invasive esophagectomy techniques. Meta-analysis data suggest equivalent oncologic outcomes from minimally invasive esophagectomy and conventional open techniques. Removal of at least 15 lymph nodes is recommended for optimal surgical staging in patients who have not received neoadjuvant therapy; the optimal number of lymph nodes after neoadjuvant therapy is not known though similar lymphadenectomy is recommended by expert guidelines.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. If regional lymph node metastases have occurred (stages IIB and III), the rate of cure with surgery alone is reduced to less than 20%. Meta-analysis of trials comparing neoadjuvant (preoperative) therapy followed by surgery with surgery alone suggests a 13% absolute improvement in 2-year survival with combined therapy. Preoperative (neoadjuvant) chemoradiation therapy is recommended for stage IIA, IIB, and III tumors in fit patients. The preferred neoadjuvant chemotherapy regimen used with radiation is weekly carboplatin plus paclitaxel, based on the 2012 randomized phase III CROSS trial that demonstrated improvement in median survival from 24 months with surgery alone to 49.4 months with neoadjuvant chemoradiation ($P = 0.003$). As an alternative, a combination of cisplatin plus 5-fluorouracil may be used along with radiation. Perioperative chemotherapy without radiation is also appropriate for tumors of the gastroesophageal junction based on the randomized, multicenter, phase III MAGIC trial.

2. Chemotherapy plus radiation therapy without surgery—Combined treatment with chemotherapy and radiation is superior to radiation alone and has achieved long-term survival rates in up to 25% of patients. Chemoradiation alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score greater than 2). Chemoradiation alone as definitive, non-surgical therapy is more likely to achieve long-term disease-free survival in patients with squamous cell carcinoma than in patients with adenocarcinoma.

3. Supportive care during definitive therapy—Patients with significant tumor obstruction may require local measures such as esophageal stent placement or percutaneous feeding tube insertion to maintain adequate hydration and nutrition during neoadjuvant chemoradiation or chemotherapy. Multidisciplinary consultation is required to determine the optimal procedure. Consultation with a nutritionist also is appropriate to optimize nutrition perioperatively.

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4) that is unresectable or distant metastases (M1) (stage IIIB and stage IV). Surgery is not warranted in these patients. Since prolonged survival can be achieved

in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and institutional experience. Many patients with advanced disease may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5).

1. Chemotherapy or chemoradiation—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIB) who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in those patients with metastatic disease who still have good functional status and expected survival of at least several months. Three-drug combinations commonly include a fluoropyrimidine (5-fluorouracil or capecitabine), a platinum drug (cisplatin or oxaliplatin), and either epirubicin or a taxane (docetaxel or paclitaxel). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. In patients with metastatic distal esophageal and gastroesophageal junction adenocarcinomas positive for amplification of the *HER2* gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab (see Chapter 17) to chemotherapy is associated with prolonged survival based on the randomized, phase III ToGA trial. In addition, ramucirumab, a monoclonal antibody targeting the VEGF receptor-2, demonstrated a survival advantage in patients with adenocarcinoma of the gastroesophageal junction after progression on first-line therapy when used both as monotherapy and in combination with paclitaxel.

2. Local therapy for esophageal obstruction—Patients with advanced esophageal cancer often have a poor functional and nutritional status. Radiation therapy alone to the area of esophageal obstruction may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. This can generally be performed in a short course over a few weeks or less but may be complicated by temporary worsening of dysphagia and odynophagia. For patients with frank obstruction or near obstruction, local antitumor therapies may be preferred. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents (alone or followed by radiation). Palliative feeding tube placement may be considered for hydration and nutrition in selected cases if the obstruction is not amenable or if it is refractory to stenting, radiation, or other local therapies. Stents are most commonly used because of their relative ease of placement. Although dysphagia and quality of life are improved, patients seldom can eat normally after stent placement. Complications occur in 20–40% and include perforation, migration, and tumor ingrowth.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to a gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic antitumor therapy (stent).
- Patients with metastatic disease and obstructive tumors not amenable or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for gastric or jejunal tube placement for liquid artificial nutrition.
- Patients with curable and resectable disease for whom neoadjuvant therapy may be appropriate (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemotherapy or chemoradiotherapy, or for palliative chemotherapy, respectively.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted. Acute complications such as perforation, bleeding, aspiration, or fistula also may require admission.

GASTRIC ADENOCARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Dyspeptic symptoms with weight loss in patients over age 40 years.
- ▶ Iron deficiency anemia: occult blood in stools.
- ▶ Abnormality detected on upper gastrointestinal series or endoscopy.

▶ General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. However, its incidence has declined rapidly over the last 70 years, especially in western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in *Helicobacter pylori*. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there are an estimated 22,220 new cases and 10,990 deaths/year. The incidence is higher in Latinos, African Americans, and Asian Americans.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). The incidence of **intestinal-type gastric**

cancer has declined significantly but it is still the more common type (70–80%); it occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to *H pylori*), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic *H pylori* gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to *H pylori*. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

Diffuse gastric cancer accounts for 20–30% of gastric cancer. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, and has a worse prognosis than intestinal-type cancer. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Familial diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology, and confers poor prognosis. Many of these families have a germline mutation of E-cadherin *CDH1*, which is inherited in an autosomal dominant pattern and carries a greater than 60% lifetime risk of gastric cancer. Prophylactic gastrectomy should be considered in patients known to carry this mutation.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a favorable prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

▶ Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive

dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in less than 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver test abnormalities, particularly elevation of alkaline phosphatase, may be present if there is metastatic liver spread. Circulating tumor markers do not have established clinical validity in screening, diagnosis, or management of gastric cancer.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 55 years with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions.

D. Imaging

Once a gastric cancer is diagnosed, preoperative evaluation with CT of chest and abdomen (including pelvis in females) and EUS is indicated to delineate the local extent of the primary tumor as well as to evaluate for nodal or distant metastases. EUS is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection. PET or combined PET-CT imaging is recommended for detection of distant metastasis.

▶ Screening

Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed there to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening is not recommended in the United States.

▶ Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there are involvement of 1–6, 7–15, or more than

15 regional nodes. M1 signifies the presence of metastatic disease. Sampling of at least 15 lymph nodes is recommended during surgical staging (see Curative Surgical Resection below). A staging laparoscopy prior to definitive surgery to exclude peritoneal carcinomatosis should be considered in patients with stage T1b or greater disease without radiographic evidence of distant metastases. Pathologic review should include (1) grade of tumor; (2) histologic subtype; (3) depth of invasion; (4) whether lymphatic or vascular invasion is present; and (5) if there is known metastatic disease, the status of HER2 protein expression by immunohistochemistry or fluorescent in situ hybridization or both.

▶ Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

▶ Treatment

A. Curative Surgical Resection

Surgical resection is the only therapy with curative potential. Laparoscopic techniques achieve similar outcomes and lower overall complication rates as open gastrectomy. After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in selected patients with small (less than 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with EUS. Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable. The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Vitamin B₁₂ supplementation is required after gastrectomy. For patients with localized gastric cancer that is resectable, current National Comprehensive Cancer Network (NCCN) treatment guidelines recommend gastrectomy with extended (D1), or modified regional (D2), lymph node dissection and sampling of 15 or more lymph nodes.

B. Perioperative Chemotherapy or Chemoradiation

The use of perioperative chemotherapy or adjuvant chemoradiation is associated with improved survival in patients

with localized or locoregional gastric adenocarcinoma who undergo surgical resection. The choice of treatment depends on the location and extent of tumor, type of surgery, patient comorbidities and performance status, and institutional experience. Treatment of tumors arising in the gastroesophageal junction may be treated following algorithms for esophageal primary tumors; multidisciplinary treatment decision-making involving the surgeon, radiation oncologist, and medical oncologist is imperative.

C. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to “curative” surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, a surgical diversion with gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months. Multiple chemotherapy regimens have demonstrated activity in metastatic gastric adenocarcinoma. Two-drug combination regimens are preferred for first-line therapy, with most common regimens including a fluoropyrimidine or a taxane agent plus a platinum agent. A three-drug combination of epirubicin or docetaxel plus cisplatin and 5-fluorouracil, or a modification thereof, may be appropriate for first-line treatment in medically fit patients. A 2009 randomized, phase III study showed that addition of the biologic agent trastuzumab to standard chemotherapy prolonged survival in the subset (approximately 15%) of patients with advanced gastric adenocarcinomas harboring amplification of the EGFR-2 (HER2). Trastuzumab is not recommended for combination with anthracyclines such as epirubicin, however, due to risk for cardiotoxicity. After progression on first-line chemotherapy, treatment with irinotecan prolonged survival compared to best supportive care in a randomized, phase III trial. Ramucirumab, a monoclonal antibody targeting the VEGF receptor-2, demonstrated a survival advantage in patients with gastric or gastroesophageal junction adenocarcinoma after progression on first-line therapy when used both as monotherapy and in combination with paclitaxel.

► Prognosis

The long-term survival of gastric carcinoma is approximately 28%. However, 5-year survival in patients who undergo successful curative resection exceeds 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 60% long-term survival. Patients with stage III tumors have a poor prognosis (less than 30% long-term survival) and should be considered for enrollment in

clinical trials. Tumors of the diffuse type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron deficiency anemia, melena, or new-onset of dyspepsia (especially if age 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred for endoscopy.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer, including staging laparoscopy if indicated.
- Prior to surgery, patients should be referred to an oncologist to determine the role for neoadjuvant chemotherapy or adjuvant chemoradiation or chemotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome and vitamin B₁₂ deficiency, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of palliative chemotherapy or chemoradiation.

► When to Admit

Patients with protracted vomiting, inability to maintain hydration or nutrition, or acute bleeding.

GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms of dyspepsia, weight loss, or anemia.
- ▶ Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass or infiltrating lesions; diagnosis established by endoscopic biopsy.
- ▶ Abdominal CT and EUS required for staging.

General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread is essential because the prognosis and treatment of primary and secondary gastric lymphomas are different. Primary lymphoma is the second most common gastric malignancy, accounting for 3% of gastric cancers. More than 95% of these are non-Hodgkin B cell lymphomas. Most primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT).

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

Clinical Findings & Staging

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma.

Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy; FNA is not adequate. EUS is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy and should be performed, if available. All patients should undergo staging with CT scanning of chest, abdomen, and pelvis. For patients with diffuse large B-cell lymphomas involving the stomach, combination PET-CT imaging, bone marrow biopsy with aspirate, tumor lysis laboratory tests, and viral hepatitis and HIV serologies also may be required for staging and management (see Chapter 13).

Treatment

Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type that are low-grade and localized to the stomach wall (stage IE) or perigastric lymph nodes (stage IIE₁) have an excellent prognosis. EUS should be performed to accurately determine tumor stage. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in approximately 75% of cases of stage IE and approximately 55% with stage II₁ low-grade lymphoma. Remission may take as long as a year, and relapse occurs in about 2% of cases per year. Endoscopic surveillance after *H pylori* eradication is recommended every 6 months for 2 years to look for recurrence. In patients whose tumors harbor specific gene translocations, including t(11;18) (API2-MALT1), t(1;14), or t(14;18), rates of remission after *H pylori* eradication are lower, and treatment with radiation may be required. Patients with localized marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy or rituximab, if not a candidate for radiation. Data from a 2010 study, however, suggest that many patients with minimal disease after successful *H pylori* eradication may be observed closely without further therapy. The long-term survival of low-grade MALT lymphoma for stage I is over 90% and for stage II is 35–65%. Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. Diffuse large B-cell or other higher grade lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are treated according to stage and subtype of lymphoma (see Chapter 13).

Ding W et al. Gastrointestinal lymphoma in Southwest China: subtype distribution of 1,010 cases using the WHO (2008) classification in a single institution. *Acta Haematol.* 2016;135(1):21–8. [PMID: 26303279]

GASTRIC CARCINOID TUMORS

Gastric carcinoids are rare neuroendocrine tumors that make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. The majority of carcinoids are caused by hypergastrinemia and occur in association with either pernicious anemia (75%) (type 1) or Zollinger-Ellison syndrome (5%) (type 2). Initial diagnostic work-up includes serum gastrin level, upper endoscopy, and EUS. Gastrin level should be obtained 1 week after the patient has stopped taking proton pump inhibitors.

For patients with hypergastrinemia (suspected of type I or type II carcinoid), serum vitamin B₁₂ and intrinsic factor antibody levels should be obtained to exclude pernicious anemia. Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with multiple endocrine neoplasia type 1 (MEN 1), in which chromosomal loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, smaller than 1 cm, have a low potential for metastatic spread, and thus are unlikely to cause development of the carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance, or with observation. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Octreotide therapy may be appropriate for patients with underlying gastrinoma and Zollinger-Ellison syndrome. Patients with tumors larger than 2 cm should undergo endoscopic or surgical resection (see Small Intestinal Adenocarcinomas below).

Type 3 gastric carcinoid tumors arise sporadically, independent of gastrin production, and account for up to 20% of gastric carcinoids. Most sporadic gastric carcinoids are solitary, larger than 2 cm, and have a strong propensity for hepatic or pulmonary metastases and thus the carcinoid syndrome at initial presentation. CT or MRI should be obtained to evaluate for metastatic disease. Localized sporadic carcinoids should be treated with radical gastrectomy and regional lymphadenectomy.

GASTROINTESTINAL MESENCHYMAL TUMORS

Gastrointestinal mesenchymal tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract but most commonly in the stomach (60%) and small intestine (30%). Approximately 85–90% of GISTs have mutations in *KIT*. Other mesenchymal tumors, such as leiomyomas, which derive from smooth muscle cells, generally stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms (most commonly bleeding, pain, or obstruction). At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS with guided FNA biopsy is the optimal study for diagnosing gastric mesenchymal tumors and distinguishing them from other submucosal lesions. Percutaneous biopsy may confer risk of bleeding or intra-abdominal seeding. CT abdomen and pelvis, MRI and PET imaging are useful in the diagnosis and staging. PET imaging also may be useful to monitor response to treatment.

While almost all GISTs have malignant potential, the risk of developing metastasis is increased with tumor size greater than 2 cm, nongastric location, and mitotic index greater than 5 mitoses per 50 high-powered field. It is difficult to distinguish benign from malignant tumors before resection by endoscopic ultrasonographic appearance or FNA. In general, lesions are more likely benign if they are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on endoscopic ultrasonogram.

Surgery is recommended for all patients with tumors that are 2 cm or larger, increasing in size, have an endoscopic ultrasonographic appearance suspicious for malignancy, or are symptomatic. The management of asymptomatic benign-appearing gastric lesions 2 cm or smaller in size is problematic. Because of the low but real long-term risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients; however, other patients may be followed up with serial endoscopic ultrasonographic examinations or, in selected cases, endoscopic resections. After complete surgical resection, GISTs recur within 5 years in over half of patients. The majority of recurrences are within the first 3 years. Adjuvant therapy with the tyrosine kinase inhibitor imatinib delays recurrence and prolongs survival. Adjuvant imatinib is recommended for all high-risk patients for at least 1 year, though the 5-year recurrence-free survival rate is significantly better following 3 years than 1 year of such therapy (65.6% vs 47.9%). After surgical resection, patients should have surveillance with history and physical examination and CT of the abdomen and pelvis every 3–6 months. Neoadjuvant therapy with imatinib may be considered for patients with localized GIST tumors who are deemed to be at high risk for resection because of comorbidities, tumor size, or tumor location. A biopsy is required to confirm the diagnosis of GIST prior to initiation of neoadjuvant imatinib.

Untreated metastatic GIST tumors are aggressive and carry a poor prognosis. Imatinib induces disease control in up to 85% of patients with metastatic disease with a progression-free survival of 20–24 months and median overall survival of almost 5 years. Imatinib-resistant tumors may respond to high-dose imatinib or to sunitinib, another multi-targeted kinase inhibitor that is approved as second-line therapy for metastatic GIST. Patients in whom metastatic GIST develops after imatinib and sunitinib therapy may respond to the multi-targeted kinase inhibitor regorafenib. In the randomized, phase III GRID trial, patients treated with regorafenib had a significant improvement in progression-free survival compared to those receiving placebo (4.8 months vs 0.9 months). Regorafenib is now FDA approved to treat advanced GIST and is included in the NCCN guidelines for patients with treatment-refractory metastatic GIST.

MALIGNANCIES OF THE SMALL INTESTINE

1. Small Intestinal Adenocarcinomas

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The incidence is rare, with approximately 6000 new diagnoses per year in the United States. Overall, prognosis is poor, with 5-year

disease-specific survival of 65% for stage I, 48% for stage II, 35% for stage III, and 4% for stage IV disease (overall, 32% of patients are stage IV at diagnosis). The ampulla of Vater is the most common site of small bowel carcinoma. The incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Periodic endoscopic surveillance to detect early ampullary neoplasms is therefore recommended. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients.

2. Small Intestinal Lymphomas

Lymphomas may arise primarily in the gastrointestinal tract or involve it secondarily in patients with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the small intestine. There is an increased incidence of small intestinal lymphomas in patients with AIDS, immunosuppressive therapy, and Crohn disease. The most common histologic subtype is non-Hodgkin extranodal marginal zone (MALT) B cell lymphoma. Enteropathy-associated T cell lymphomas appear to be increasing in incidence in the United States. They are associated with the diagnosis of celiac disease. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. Other types of intestinal lymphomas include primary intestinal follicular cell lymphoma, mantle cell lymphoma, and Burkitt lymphoma (see Chapter 13).

Presenting symptoms or signs of primary small bowel lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and bone marrow biopsy are required to determine stage.

Treatment depends on the tumor histologic subtype and stage of disease (see Chapter 13). Surgical resection of primary intestinal lymphoma, if feasible, may be appropriate for localized tumors. In patients with limited disease (stage IE) in whom resection is performed with negative margins, the role of adjuvant chemotherapy is unclear. Locoregional radiation should be considered if surgical margins are positive. Patients with more extensive disease generally are treated according to the tumor histology.

3. Intestinal Carcinoid Tumors

ESSENTIALS OF DIAGNOSIS

- ▶ Majority are asymptomatic and discovered incidentally at endoscopy or surgery.
- ▶ Carcinoid syndrome occurs in less than 10%; hepatic metastases are generally present.
- ▶ Risk of metastasis related to tumor size and location.

▶ General Considerations

Gastrointestinal carcinoid tumors are generally slow growing neuroendocrine tumors that account for approximately one-third of tumors arising in the small bowel. Gastrointestinal carcinoid tumors most commonly occur in the small intestine (45%) but are also found in the rectum (20%), appendix (17%), and colon (11%), with the remainder occurring in the stomach (less than 10%; see Gastric Carcinoid Tumors above). Carcinoid tumors may contain a variety of hormones, including serotonin, somatostatin, gastrin, and substance P, each of which may or may not be secreted.

Small intestinal carcinoids most commonly arise in the distal ileum within 60 cm of the ileocecal valve. Up to 30% are multicentric. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rates for patients with locoregional and metastatic small bowel carcinoids are approximately 65% and 35%, respectively. The risk of metastatic spread increases when the tumor is 1 cm or larger and when it is larger than 2 cm with invasion beyond muscularis propria. Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are smaller than 1 cm, and 90% are smaller than 2 cm. However, in patients with appendiceal carcinoid tumors larger than 2 cm, approximately 90% develop nodal and distant metastases; right hemicolectomy is recommended in these cases.

Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination and often locally excised by biopsy or snare polypectomy before the histologic diagnosis is known. Endorectal ultrasound is usually recommended to assess the size, presence and depth of invasion, and presence of lymph node metastases. Rectal carcinoids smaller than 1 cm virtually never metastasize and are treated effectively with local endoscopic or transanal excision. Larger tumors are associated with the development of metastasis in 10%. Hence, a more extensive cancer resection operation is warranted in fit patients with rectal carcinoid tumors larger than 1–2 cm or with high risk features (such as invasion of muscularis propria or evidence of nodal involvement), or both.

▶ Clinical Findings

A. Symptoms and Signs

Most lesions smaller than 1–2 cm are asymptomatic and difficult to detect by endoscopy or imaging studies. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, bleeding, or bowel infarction. Appendiceal and rectal carcinoids usually are small and asymptomatic but large lesions can cause bleeding, obstruction, or altered bowel habits. **Carcinoid syndrome** occurs in less than 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases.

Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectases.

B. Laboratory Findings

Serum chromogranin A (CgA) is elevated in the majority of neuroendocrine tumors, although its sensitivity for small, localized carcinoid tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) and platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Because certain foods and medications can interfere with 5-HIAA levels, these should be withheld for 48 hours prior to a 24-hour urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Abdominal CT or enterography may reveal kinking of the bowel, but because the lesion is extraluminal, the diagnosis may be overlooked for several years. Somatostatin receptor scintigraphy, which is positive in up to 90% of patients with metastatic carcinoid, is routinely used in staging. Most patients with carcinoid syndrome have liver metastasis on abdominal imaging.

▶ Treatment & Outcomes

Small intestinal carcinoids generally are indolent tumors with slow spread. Patients with disease confined to the small intestine should be treated with surgical excision. There is no proven role for adjuvant therapy after complete resection. Five-year survival rates for patients with stage I and II disease are 96% and 87%, respectively. In patients with resectable disease who have lymph node involvement (stage III), the 5-year survival is 74%; however, by 25 years, less than 25% remain disease free. Even patients with metastatic disease may have an indolent course with a 5-year survival of 43%.

In patients with advanced disease, therapy historically has been deferred until the patient is symptomatic, although one phase III, randomized, placebo-controlled trial demonstrated that early initiation of somatostatin analog therapy significantly delayed time to progression of hepatic metastases compared to placebo (14.3 vs 6 months, respectively). Conventional cytotoxic chemotherapy agents do not achieve significant responses in carcinoid tumors and have not been associated with improved outcomes. Radiolabeled somatostatin analogs are used in Europe but are currently under investigation in the United States as another treatment modality for patients with somatostatin-receptor positive advanced carcinoid tumors. In patients

with metastatic disease, surgery should be directed toward palliation of obstructive symptoms or bleeding.

In patients with carcinoid syndrome, the somatostatin analog octreotide, 150–250 mcg subcutaneously three times daily or administered as a long-acting intramuscular depot formulation administered monthly, inhibits hormone secretion from the carcinoid tumor. This results in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, in 90% of patients for a median period of 1 year. Thereafter, many patients stop responding to octreotide. In selected patients with refractory carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. Hepatic artery occlusion, liver-directed debulking procedures, and chemotherapy also may provide symptomatic improvement in some patients with hepatic metastases.

4. Small Intestine Sarcoma

Most small intestine sarcomas arise from stromal tumors (GISTs) that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above).

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with antiretroviral therapy. It can also occur in the setting of immunosuppression after organ transplant. It is caused by infection with human herpesvirus 8 (HHV8). Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Widespread involvement may be best treated by systemic chemotherapy using single-agent therapy or combinations of pegylated-doxorubicin (Doxil), paclitaxel, vincristine, bleomycin, or etoposide. Surgery or radiation may be indicated for isolated high-risk lesions.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Personal or family history of adenomatous or serrated polyps or colorectal cancer are important risk factors.
- ▶ Symptoms or signs depend on tumor location.
- ▶ Proximal colon: fecal occult blood, anemia.
- ▶ Distal colon: change in bowel habits, hematochezia.
- ▶ Diagnosis established with colonoscopy.

▶ General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Colorectal cancer will develop in approximately 6% of Americans and 40% of those will die of the disease. In 2014, there were an estimated 96,830 new cases of colon cancer and 40,000 new cases of rectal cancer in the United States, with combined estimated 50,310 deaths. Between 1996 and 2010, the mortality has decreased by 46%. During this same period, the percent of patients 50 years or older who were screened for colorectal cancer has increased to 66.1%.

Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. The majority of colorectal cancers are

thought to arise from malignant transformation of an adenomatous polyp (tubular, tubulovillous, or villous adenoma) or serrated polyp (hyperplastic polyp, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are “advanced” (ie, polyps at least 1 cm in size, adenomas with villous features or high-grade dysplasia, or serrated polyps with dysplasia) are associated with a greater risk of cancer. Approximately 85% of sporadic colorectal cancers arise from adenomatous polyps and have loss of function of one or more tumor suppressor genes (eg, *p53*, *APC*, or *DCC*) due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as *K-ras* and *B-raf* is present in a subset of colorectal cancers with prognostic and therapeutic implications discussed further below.

Approximately 10–20% of colorectal cancers arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions that leads to inactivation of the DNA mismatch repair gene *MLH1*, resulting in microsatellite instability, and activation of mutations of the *BRAF* gene. Serrated colon cancers have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes (eg, familial adenomatous polyposis) or hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome). These conditions are discussed further in Chapter 15.

► Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years.

B. Family History of Neoplasia

A family history of colorectal cancer is present in approximately 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. (See Chapter 15 for discussion of inherited polyposis syndromes.) Approximately 6% of the Ashkenazi Jewish population has a missense mutation in the *APC* gene (*APC I1307K*) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member was younger than 45 years when the cancer was diagnosed. Patients with two first-degree relatives have a fourfold increase, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if they were younger than 60 years when the polyp was detected or if the polyp was 10 mm or larger.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 8 years after disease onset in patients with ulcerative colitis and Crohn colitis (see Chapter 15).

D. Dietary and Lifestyle Factors and Chemoprevention in Colorectal Cancer Risk

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective studies have not shown a reduction in colon cancer or recurrence of adenomatous polyps with diets that are low in fat; are high in fiber, fruits or vegetables; or that include calcium, folate, beta-carotene, or vitamin A, C, D, or E supplements.

A US Preventive Services Task Force meta-analysis of cohort and case-control studies suggest that prolonged (more than 6 years) regular use of aspirin (at least 325 mg twice weekly) or NSAIDs is associated with a 22–33% relative risk reduction in the incidence of colorectal cancer. Two prospective, blinded clinical trials have shown that daily low-dose aspirin (80–325 mg) reduces the number of recurrent adenomas at 1–3 years in patients with a history of colorectal adenomas or cancer; however, two large randomized controlled trials in the United States did not demonstrate a reduction in colorectal cancer incidence in patients taking low-dose aspirin over 5–10 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), the US Preventive Services Task Force concluded that it should not be prescribed as a chemopreventive agent in people without polyps or with small adenomas unless there are other medical indications. Long-term administration of low-dose aspirin may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, it does not obviate the need for colonoscopy screening and surveillance.

Retrospective analysis of randomized phase III trial data and a meta-analysis have shown that patients with higher levels of pre- and post-diagnosis physical activity experience reduced colorectal cancer-specific mortality

and all-cause mortality. Maintaining a healthy body weight, a healthy diet, and a physically active lifestyle are recommended in colorectal cancer survivors.

E. Other Factors

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening).

► Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Screening for Colorectal Neoplasms, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A CBC is obtained to look for evidence of anemia. Elevated liver function tests, particularly the alkaline phosphatase, are suspicious for metastatic disease. Carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer but is not appropriate for screening. A preoperative CEA level greater than 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation.

C. Colonoscopy

Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging (Figure 39–1). Colonoscopy permits biopsy for pathologic confirmation of malignancy. In patients in whom the colonoscope is unable to reach the cecum (less than 5% of cases) or when a nearly

▲ **Figure 39–1.** Colon cancer. There is a large fungating mass within the right colon. This mass is hemircumferential and nearly obstructing and occluding the lumen of the colon. (Used, with permission, from Michelle Nazareth, MD.)

obstructing tumor precludes passage of the colonoscope, barium enema or CT colonography examination should be performed.

D. Imaging

Chest, abdominal, and pelvic CT scans are required for preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography is more accurate than CT scanning for the detection of hepatic metastases. For rectal cancers (generally defined as tumors arising 12 cm or less proximal to the anal verge), pelvic MRI or endorectal ultrasonography is required to determine the depth of penetration of the cancer through the rectal wall (T stage) and perirectal lymph nodes, informing decisions about preoperative (neoadjuvant) chemoradiotherapy and operative management. PET is not routinely used for staging or surveillance in colorectal cancers.

► Staging

The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant therapy.

► Differential Diagnosis

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

Treatment

A. Surgery

Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. For colon cancer, multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy.

For rectal carcinoma, preoperative (neoadjuvant) chemoradiation with 5-fluorouracil is recommended in all node-positive tumors, and in T3 and greater tumors, due to increased risk of local recurrence (see below). After neoadjuvant therapy, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the clinical approach. In carefully selected patients with small, mobile (less than 4 cm), well-differentiated T1 or T2 rectal tumors that are less than 8 cm from the anal verge, transanal excision may be considered. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum by either open or laparoscopic surgery reduces local recurrence to 5%. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (eg, leak, dehiscence, stricture) and defecatory complaints (eg, increased stool frequency, and incontinence). With unresectable rectal cancer, the patient may be palliated with a diverting colostomy or placement of an expandable wire stent.

B. Systemic Chemotherapy for Colon Cancer

Chemotherapy and radiotherapy have been demonstrated to improve overall and tumor-free survival in selected patients with colorectal cancers depending on stage.

1. Stage I—Because of the excellent 5-year survival rate (90–100%), no adjuvant therapy is recommended.

2. Stage II (node-negative disease)—The 5-year survival rate is approximately 80%. A significant survival benefit from adjuvant chemotherapy has not been demonstrated in most randomized clinical trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease who are at higher risk for recurrence (perforation, obstruction, T4 tumors, or fewer than 12 lymph nodes sampled) may benefit from adjuvant chemotherapy.

3. Stage III (node-positive disease)—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly

increases disease-free survival as well as overall survival up to 30% and is recommended for all fit patients. Large, well-designed studies of adjuvant therapy for stage III colon cancer reported a higher rate of disease-free survival at 5 years for patients treated for 6 months postoperatively with a combination of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX) (73.3%) than with 5-fluorouracil and leucovorin (FL) alone (67.4%). The addition of oxaliplatin is associated with an increased incidence of diarrhea, myelosuppression, and peripheral sensory neuropathy, all of which generally are reversible. Based on these studies, FOLFOX currently is the preferred adjuvant therapy for most patients with stage III colon cancer (see Table 39–11). The addition of a biologic agent (bevacizumab or cetuximab) to FOLFOX does not improve outcomes in the adjuvant setting.

4. Stage IV (metastatic disease)—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and an additional 30% eventually develop metastasis. A subset of these patients has limited disease that is potentially curable with surgical resection. Resection of isolated liver or lung metastases may result in long-term (over 5 years) survival in 35–55% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, radiofrequency or microwave coagulation, embolization, hepatic intra-arterial chemotherapy) may provide long-term tumor control. The majority of patients with metastatic disease do not have resectable (curable) disease. In the absence of other treatment, the median survival is less than 12 months; however, with current therapies, median survival approaches 24 months. The goals of therapy for patients with metastatic colorectal cancer are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Currently, either FOLFOX (the addition of oxaliplatin to 5-fluorouracil and folinic acid) or FOLFIRI (the addition of irinotecan to 5-fluorouracil and folinic acid) is the preferred first-line treatment regimens for fit patients. For convenience, oral capecitabine (instead of intravenous 5-fluorouracil and leucovorin) can be used in combination with oxaliplatin; however, combination with irinotecan is not recommended due to increased toxicity (diarrhea). Addition of a biologic agent to combination chemotherapy improves response rates and overall survival and is recommended in the first-line of treatment in suitable patients. Bevacizumab is a monoclonal antibody targeting VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolongs mean survival 2–5 months compared with either regimen alone (see Table 39–11). Cetuximab and panitumumab are monoclonal antibodies targeting EGFR. Activating codon 12 and 13 *K-ras* gene mutations downstream of EGFR are present in approximately 35% of patients with metastatic colorectal cancer and are a biomarker for nonresponse to cetuximab and panitumumab, for which reason the use of these agents is restricted to patients with tumors wild-type for *K-ras*. In stage IV patients with *K-ras* wild-type tumors, the addition of panitumumab or cetuximab to FOLFOX or FOLFIRI prolongs survival by approximately 4 months. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation, or

serious bleeding, in up to 5% of patients. EGFR-targeted agents cause an acneiform rash in the majority of patients. Cetuximab is associated with severe infusion reactions in approximately 2–5%.

When disease progresses despite treatment either with FOLFOX or with FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy is switched to the alternate regimen; patients may respond to the alternate regimen, prolonging mean survival to more than 20 months. The novel anti-angiogenic agent, aflibercept, is FDA-approved for use in second-line colorectal cancer in combination with FOLFIRI. Palliative therapy with cetuximab or panitumumab can benefit patients with *K-ras* wild-type tumors whose disease has progressed after first-line and second-line chemotherapies. The multi-targeted kinase inhibitor, regorafenib, was approved by the FDA in 2012 for patients with metastatic, refractory colorectal cancer after progression on standard regimens based on results of the randomized, phase III CORRECT trial showing improved overall survival compared to placebo. In 2015, trifluridine/tipiracil (TAS-102) was FDA approved for the treatment of patients with metastatic colorectal cancer who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, an anti-VEGF biologic product and, if KRAS wild-type cancer, an anti-EGFR monoclonal antibody. It was noted to result in improved overall survival (7.1 vs 5.3 months compared to placebo).

C. Neoadjuvant and Adjuvant Therapy for Rectal Cancer

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local tumor recurrence with surgery alone (approximately 25%) attributed in part to the difficulty of achieving adequate surgical resection margins and to lack of serosal encasement of the rectum. When initial imaging studies suggest stage I disease, surgery may be performed first (see Surgery above). For stage II and III tumors by clinical staging (including endorectal ultrasound or pelvic MRI), preoperative chemoradiation with 5-fluorouracil or capecitabine as a radiation-sensitizing agent improves disease-free survival and decreases pelvic recurrence rate (see Table 39–11). Preoperative chemoradiation has been shown to be superior to postoperative chemoradiation with lower local recurrence and toxicity rates in the randomized, phase III CAO/ARO/AIO-94 trial. Following surgical resection with total mesorectal excision (see Surgery above), adjuvant 5-fluorouracil-based therapy (generally with the FOLFOX regimen extrapolating from its benefit in patients with similarly-staged colon cancers) is recommended for a total of approximately 6 months of perioperative therapy inclusive of neoadjuvant chemoradiation.

▶ Follow-Up after Surgery

Patients who have undergone resections for cure are monitored closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. Patients

should be evaluated every 3–6 months for 2 years and then every 6 months for a total of 5 years with history, physical examination, and laboratory surveillance, including serum CEA levels. The NCCN and ASCO guidelines recommend surveillance CT scans of chest, abdomen, and pelvis annually for up to 5 years post-resection in high-risk stage II and all stage III patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively also should undergo colonoscopy within 3–6 months postoperatively to exclude other synchronous colorectal neoplasms. If a colonoscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, proctoscopy surveillance of the low anterior resection anastomotic site may also be performed periodically. New onset of symptoms or a rising CEA warrants investigation with chest, abdominal, and pelvic CT and colonoscopy to look for a new primary tumor or recurrence, or metachronous metastatic disease that may be amenable to curative or palliative therapy. For patients with a rising CEA level with unrevealing CT imaging, a PET scan may be more sensitive for the detection of occult metastatic disease.

▶ Prognosis

The stage of disease at presentation is the most important determinant of long-term survival in colon cancer: stage I, greater than 90%; stage II, 70–85%; stage III with fewer than 4 positive lymph nodes, 67%; stage III with more than 4 positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

▶ Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the US Preventive Services Task Force, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of some kind should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost-effective.

It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs.

Table 39–5. Recommendations for colorectal cancer screening.¹**Average-risk individuals ≥ 50 years old²**

- Annual fecal occult blood testing using higher sensitivity tests (Hemoccult SENSAs)
- Annual fecal immunochemical test (FIT)
- Fecal DNA test (interval uncertain)
- Flexible sigmoidoscopy every 5 years
- Colonoscopy every 10 years
- CT colonography every 5 years

Individuals with a family history of a first-degree member with colorectal neoplasia³

- Single first-degree relative with colorectal cancer diagnosed at age ≥ 60 years:** Begin screening at age 40. Screening guidelines same as average-risk individual; however, preferred method is colonoscopy every 10 years.
- Single first-degree relative with colorectal cancer or advanced adenoma diagnosed at age < 60 years, or two first-degree relatives:** Begin screening at age 40 or at age 10 years younger than age at diagnosis of the youngest affected relative, whichever is first in time. Recommended screening: colonoscopy every 5 years.

¹For recommendations for families with inherited polyposis syndromes or hereditary nonpolyposis colon cancer, see Chapter 15.

²Joint Guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. *Gastroenterology* 2008 May;134(5):1570.

³American College of Gastroenterology. Guidelines for Colorectal Cancer Screening. *Am J Gastroenterol.* 2009 Mar;104(3):739.

Recommendations for screening from the US Multi-Society Task Force are listed in Table 39–5. Screening is recommended for all men and women ages 50 through 75 years of age who are at average risk for cancer. Some guidelines recommend screening for African Americans beginning at age 45. The potential for harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults above age 75, it may be considered on a case-by-case basis in adults age 76 through 85 years who have excellent health and functional status. Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk; earlier and more frequent screening may be recommended (preferably with colonoscopy) for these individuals. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15. For patients at average risk for colorectal cancer, the recommendations of the Task Force are discussed below. Screening tests may be classified into two broad categories: stool-based tests and examinations that visualize the structure of the colon by direct endoscopic inspection or radiographic imaging.

A. Stool-Based Tests

1. Fecal occult blood test—Most colorectal cancers and some large adenomas result in increased chronic blood

loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based tests (Hemoccult I and II and Hemoccult SENSAs) that detect the pseudoperoxidase activity of heme or hemoglobin and fecal immunochemical tests (FITs) that detect human globin.

When fecal occult blood test is administered to the general population as part of a screening program, 2–6% of tests are positive. Of those with positive tests, 5–18% have colorectal cancer that is more likely to be at an earlier stage (stage I or II).

For optimal detection, annual testing is required. In a meta-analysis of four large, prospective, longitudinal studies, annual or biennial screening with Hemoccult I or Hemoccult II reduced mortality from colorectal cancer by 25% among those who were compliant with regular testing.

Several FITs are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. In 19 clinical studies, the pooled sensitivity and specificity of FIT for colorectal cancer in average-risk patients were 79% and 94%, respectively. The optimal interval (yearly or every 2 years) and number of stool samples (one or two) required for optimal FIT testing is as yet undetermined. In clinical trials that compare FIT with guaiac-based tests, FIT had at least comparable sensitivity to Hemoccult SENSAs for detection of cancers (60–85%) with higher specificity. Because FITs are not affected by diet or medications and have superior accuracy, they are increasingly preferred over guaiac-based tests despite a higher cost per test (\$10–20). Randomized controlled trials comparing one-time colonoscopy with FIT testing for colorectal cancer screening are ongoing.

The US Multi-Society Task Force emphasizes that colon cancer prevention should be the primary goal of screening. For that reason, the lower sensitivity of fecal occult blood tests for advanced neoplasia (cancer and advanced adenomatous polyps) makes them a less attractive choice for population-based screening than endoscopic or radiographic tests. Currently, fecal occult blood tests are most suitable in settings where health care resources are limited or in patients who desire a noninvasive method of screening. Regardless of which stool-based test is used, patients should understand that annual testing is required to achieve the maximum screening benefit and that a positive test will require evaluation by colonoscopy accompanied by removal of any polyps identified. If colonoscopy reveals no colorectal neoplasm, further screening for colorectal cancer can be deferred for 10 years. In a meta-analysis of four large, prospective, longitudinal studies, annual or biennial screening with Hemoccult I or Hemoccult II reduced mortality from colorectal cancer by 25% among those who were compliant with regular testing. Long-term studies with more sensitive stool tests (Hemoccult SENSAs or FIT) have not been performed.

2. Multitarget DNA assay—Stool DNA tests measure a variety of mutated genes and methylated gene markers from exfoliated tumor cells. The first-generation commercially

available fecal DNA panel detected only one-half of cancers. In 2014, a newer generation assay (under the proprietary name “Cologuard”) was approved by the FDA, which combines a fecal DNA panel with an immunochemical test for stool hemoglobin. In a prospective comparative trial conducted in persons at average risk for colorectal cancer undergoing colonoscopy, the sensitivity for colorectal cancer for “Cologuard” was 92.3% vs. 73.8% for FIT and the sensitivity for adenomas larger than 1 cm or serrated polyps for “Cologuard” was 42.4% vs. 23.8% for FIT. Although the Multi-Society Task Force concluded that fecal DNA is an acceptable option for colorectal cancer screening, population-based screening may be hampered by its high cost, cumbersome requirements for stool collection and mailing, and high false-positive rate (10.2%).

B. Endoscopic Examinations of the Colon

1. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. A 2012 US study of almost 155,000 participants randomized to sigmoidoscopy screening or usual care between 1993 and 2001 reported a 50% reduction in distal colorectal cancer mortality in the sigmoidoscopy group after 11 years median follow up.

The chief disadvantage of screening with flexible sigmoidoscopy is that it does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in people over age 65 years of age, African Americans, and women. In men, approximately 50% of advanced neoplasms (cancer, adenomas 1 cm or larger, polyps with villous histology, or high-grade dysplasia) are located in the proximal colon, compared with 60–70% in women. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon. Therefore, patients found on screening sigmoidoscopy to have an adenomatous polyp of any size should subsequently undergo colonoscopy to evaluate the proximal colon.

2. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy and a similar decrease in screening sigmoidoscopy due to poor reimbursement and the perceived inferiority of sigmoidoscopy compared with colonoscopy. Almost 62% of US adults have undergone colonoscopy in the past 10 years. Colonoscopy requires aggressive bowel cleansing prior to the examination. To alleviate discomfort, intravenous sedation is used for most patients. The incidence of serious complications after colonoscopy (perforation, bleeding, cardiopulmonary events) is 0.1%. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced neoplasia is 4–11% and of cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it is not infallible. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to adenomatous and serrated polyps and early cancers that were overlooked during colonoscopy. Studies of back-to-back colonoscopies confirm that endoscopists overlook 6–12% of polyps greater than 1 cm in size and up to 25% of smaller adenomas. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon than the proximal colon. This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas. The latter are more common than previously recognized, are more likely to contain advanced pathology, and are more difficult to identify than raised (sessile or pedunculated) polyps. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

C. Radiographic Examinations of the Colon

1. CT colonography—Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy (virtual colonoscopy). CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. It has minimal acute risk although there is controversy about potential long-term risks related to radiation exposure from CT examinations. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is greater than 95% for the detection of cancer and greater than 84–92% for the detection of polyps 10 mm or larger. The sensitivity for polyps 6–9 mm in size ranges from 57% to 84%; for polyps 5 mm or less, the sensitivity is extremely poor.

Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps 10 mm or larger should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps less than 10 mm in size is controversial. The US Multi-Society Task Force currently recommends that colonoscopy with polypectomy be

offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps smaller than 6 mm; however, some radiologists choose not even to report these findings.

2. Barium enema—Double-contrast barium enema was previously used as a screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time-consuming and difficult to perform, less comfortable, and less accurate. Although it continues to be included among recommended screening options, it has been supplanted by CT colonography, where available.

▶ When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests (iron deficiency anemia) suggestive of colorectal neoplasia should be referred for colonoscopy.
- Patients with suspected colorectal cancer or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to medical and radiation oncologists preoperatively for neoadjuvant therapy. Patients with stage III or IV colorectal tumors should be referred to an oncologist.

▶ When to Admit

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with severe complications of chemotherapy.
- Patients with advanced metastatic disease requiring palliative care.

CARCINOMA OF THE ANUS

The anal canal is lined from its proximal to distal extent by columnar, transitional and non-keratinized squamous epithelium, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers make up the majority of anal cancers. Anal cancer is increased among people practicing receptive anal intercourse and those with a history of anorectal warts. In over 80% of cases, HPV may be detected, suggesting that this

virus is a major causal factor. In a large controlled trial, HPV vaccination of healthy men (16- to 26-years-old) who have sex with men decreased the incidence of anal intraepithelial neoplasia by 50%. Women with anal cancer are at increased risk for cervical cancer, which may be due to a field effect of oncogenic HPV infection, and require gynecologic screening and surveillance. Anal cancer is increased in HIV-infected individuals, possibly due to interaction with HPV. Bleeding, pain, and local tumor are the most common symptoms. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes. CT or MRI scans of the abdomen and pelvis are required to identify regional lymphadenopathy or metastatic disease at diagnosis. PET imaging may be used in conjunction.

Treatment depends on the tumor location and histologic stage. Small (less than 3 cm) superficial lesions of the perianal skin may be treated with wide local excision. Adenocarcinoma of the anal canal is treated in similar fashion to rectal cancer (see above), commonly by abdominoperineal resection with neoadjuvant chemoradiotherapy and adjuvant chemotherapy. Squamous cancer of the anal canal and large perianal tumors invading the sphincter or rectum are treated with combined-modality therapy that includes external radiation with simultaneous chemotherapy (5-fluorouracil plus mitomycin). Local control is achieved in approximately 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy. Metastatic disease is generally treated with 5-fluorouracil in combination with cisplatin. The 5-year survival rate is 60–70% for localized tumors and over 25% for metastatic (stage IV) disease.

CANCERS OF THE GENITOURINARY TRACT

Maxwell V. Meng, MD, FACS

PROSTATE CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Prostatic induration on DRE or elevation of PSA.
- ▶ Most often asymptomatic.
- ▶ Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostatic cancer is the most common noncutaneous cancer detected in American men and the second leading cause of cancer-related death in men. In the United States, in 2015 an estimated 220,800 new cases of prostate cancer were diagnosed, and 27,540 deaths resulted. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland; few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men aged 60–69 years will have the disease at autopsy, its incidence increases to 67% in men aged 80–89 years. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (high in North America and European countries, intermediate in South America, and low in the Far East). A 50-year-old American man has a lifetime risk of 40% for latent cancer, 16% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. African American race, family history of prostatic cancer, and history of high dietary fat intake are risk factors for prostate cancer.

Clinical Findings

A. Symptoms and Signs

Prostate cancer may manifest as focal nodules or areas of induration within the prostate at the time of DRE. However, currently most prostate cancers are detected because of elevations in serum PSA (not DRE findings).

Patients rarely present with signs of urinary retention or neurologic symptoms from epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms. Lymph node metastases can lead to lower extremity lymphedema. Because the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the volume of (benign and malignant) prostate tissue. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and detecting recurrence before it becomes clinically evident. As a screening test, PSA will be elevated (greater than 4.0 ng/mL [4.0 mcg/L]) in 10–15% of men. Approximately 18–30% of men with intermediate degrees of elevation (4.1–10 ng/mL [4.1–10 mcg/L]) and between 50% and 70% of men with elevations greater than 10 ng/mL (10 mcg/L) will be found to have prostate cancer. Patients with intermediate levels of PSA usually have localized and therefore potentially curable cancers. Interestingly, approximately 20% of patients who undergo radical prostatectomy for localized prostate cancers have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of the disease. Whereas most organ-confined cancers are associated with PSA levels below 10 ng/mL (10 mcg/L), advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL (40 mcg/L). Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients with urinary retention or with ureteral obstruction due to locally advanced prostate cancers may present with elevations in blood urea nitrogen or serum creatinine. Patients with bony metastases may have elevations in serum alkaline phosphatase or calcium. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portion, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least ten biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Transrectal ultrasonography has primarily been used for the staging of prostate carcinomas, where tumors typically appear as hypoechoic areas. In addition, transrectal ultrasound-guided, rather than digitally-guided, biopsy of the prostate is a more accurate way to evaluate suspicious lesions. Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transrectal ultrasound and associated with modest elevations of PSA (ie, less than 10 ng/mL [10 mcg/L]), need no further imaging.

MRI allows for evaluation of the prostate as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI, although newer multi-parametric MRI techniques may better stage patients considering treatment or, alternatively, active surveillance. MRI-guided biopsy may improve not only overall cancer detection but discovery of clinically relevant disease, and its use in routine clinical practice has increased. CT plays little role because of its inability to accurately identify or stage prostate cancers, but it can be used to detect regional lymphatic metastases and intra-abdominal metastases.

Conventional radionuclide (99-technetium) bone scans are superior to conventional plain skeletal radiographs in detecting bony metastases. Most prostate cancer metastases are multiple and most commonly localized to the axial skeleton. Men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations in PSA greater than 20 ng/mL (20 mcg/L) should undergo radionuclide bone scan. PET (eg, ¹⁸F-sodium fluoride [¹⁸F-NaF] PET) and ¹⁸F-NaF PET/CT hybrid imaging appear to be more sensitive than conventional bone scans. Because of the high frequency of abnormal scans in patients in this age group resulting from degenerative joint disease, plain films are often necessary in evaluating patients with indeterminate findings on bone scan. Cross-sectional imaging either by CT or MRI is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph

node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for FNA.

Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer.

Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

► Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in its mortality rates is controversial. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Prostate cancer detection rates using DRE alone vary from 1.5% to 7%, but unfortunately, most of these cancers are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–6. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone. The Prostate Cancer Prevention Trial provided data demonstrating a significant risk of prostate cancer even in men with PSA less than 4.0 ng/mL (4.0 mcg/L) (Table 39–7) and a web-based calculator has been developed to estimate the risk of harboring both prostate cancer and high-grade cancer (<http://deb.uthscsa.edu>).

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. These include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (percent free PSA), and

Table 39–6. Screening for prostatic cancer: Test performance.

Test	Sensitivity	Specificity	Positive Predictive Value
Abnormal PSA (> 4 ng/mL [mcg/L])	0.67	0.97	0.43
Abnormal DRE	0.50	0.94	0.24
Abnormal PSA or DRE	0.84	0.92	0.28
Abnormal PSA and DRE	0.34	0.995	0.49

DRE, digital rectal examination; PSA, prostate-specific antigen. Modified, with permission, from Kramer BS et al. Prostate cancer screening: what we know and what we need to know. *Ann Intern Med.* 1993 Nov 1;119(9):914–23.

Table 39–7. Risk of prostate cancer in men with PSA \leq 4.0 ng/mL (or mcg/L).

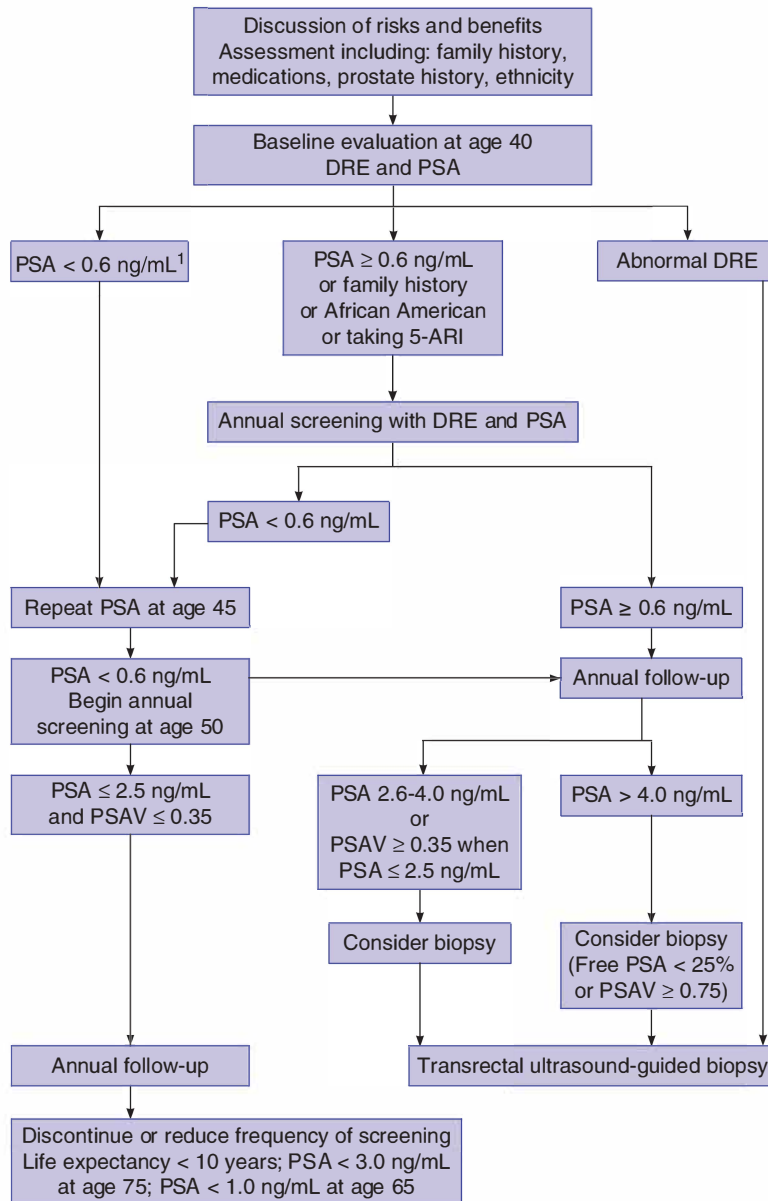

PSA level (ng/mL [or mcg/L])	Percentage with prostate cancer	Percentage with high-grade ¹ prostate cancer
\leq 0.5	6.6	12.5
0.6–1.0	10.1	10.0
1.1–2.0	17.0	11.8
2.1–3.0	23.9	19.1
3.1–4.0	26.9	25.0

¹High-grade cancer was defined as Gleason score \geq 7.

Data from Thompson IM et al. Prevalence of prostate cancer among men with a prostate-specific antigen level \leq 4.0 ng per milliliter. *N Engl J Med.* 2004 May 27;350(22):2239–46.

calculation of changes in PSA over time (PSA velocity). Generally, men with PSA free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions less than 10% have an approximately 50% chance of having prostate cancer. The frequency of PSA testing also remains a matter of debate. The traditional yearly screening approach may not be the most efficient; rather, earlier PSA testing at younger age may allow less frequent testing later as well as provide information regarding PSA velocity. Studies from the Baltimore Longitudinal Study of Aging suggest that men with PSA above the age-based median when tested between 40 and 60 years are at significantly increased risk for subsequent cancer detection over 25 years. Men with lower PSA (0.6 ng/mL [0.6 mcg/L] ages 40–50 and 0.71 ng/mL [0.71 mcg/L] ages 50–60) may require less frequent PSA tests. In addition, men with PSA velocity greater than 0.35 ng/mL (0.35 mcg/L) per year measured 10–15 years before diagnosis had significantly worse cancer-specific survival compared with those with lower PSA velocity. The current NCCN guidelines (http://www.nccn.org/professionals/physician_gls/f_guidelines.asp) for prostate cancer early detection incorporate many of these factors (Figure 39–2). The current European Association of Urology (EAU) recommends offering a baseline serum PSA to all men aged 40–45 years and subsequently initiating a risk-adapted strategy.

Two large, randomized trials question the benefit of screening men for prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and DRE during 13-year follow-up. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (3.7 and 3.4 deaths per 10,000 person-years, respectively). Similarly, in the European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, the benefit of PSA screening was minimal with an absolute reduction of 1.28 prostate cancer deaths per 1000 men screened at 13-year follow-up. Based on these data, the US Preventive Services Task Force has recommended against PSA-based screening for prostate cancer in asymptomatic men (grade D recommendation)

¹NCCN guidelines utilize PSA threshold of 10 ng/mL in men <math>< 50</math> years, the 75th percentile range for this age group; the median PSA value for men 40–49 years is 0.6 ng/mL.

▲ **Figure 39–2.** An algorithm for prostate cancer early detection. DRE, digital rectal examination; 5-ARI, 5-alpha-reductase inhibitor; PSAV, PSA velocity (ng/mL/year) calculated on at least three consecutive values over at least an 18–24 month period. (Based on NCCN guidelines, data from the Baltimore Longitudinal Study on Aging, and Prostate Cancer Prevention Trial.)

and early data already suggest a reduction in screening practice; further studies will reveal whether decreased or delayed detection of higher-grade tumors will impact cancer-specific mortality in the future.

► Staging

The majority of prostate cancers are adenocarcinomas. Most arise in the peripheral zone of the prostate, though a small percentage arise in the central (5–10%) and transition

zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a “primary” grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a “secondary” grade is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five “grades” are possible. Adding the score of the primary and secondary grades gives a Gleason score from 2 to 10. Gleason score correlates with tumor volume, pathologic stage, and prognosis.

Treatment

A. Active Surveillance

The optimal treatment for patients with clinically localized prostate cancers remains controversial. A beneficial impact of treating localized prostate cancer has not been conclusively demonstrated with respect to survival. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. The goal of active surveillance is to avoid treatment in men who never experience disease progression while recognizing and effectively treating men with evidence of progression. Currently, treatment decisions are made based on stage and cancer grade (Gleason score) as well as the age and health of the patient. Given the observed significant migration to lower stage and grade resulting from screening using PSA testing, active surveillance alone may be appropriate management for selected patients. Such patients included are typically older with small volume, well-differentiated cancers. Depending on the age and health of the patient, some of these very low-volume, low-grade cancers may never become clinically relevant and can be monitored with active surveillance, that is, serial PSA levels, DREs, and periodic prostate biopsies to reassess grade and extent of cancer. Endpoints for intervention in patients on active surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain an active area of research; nonetheless, they are increasingly accepted by patients and clinicians. Active surveillance, which is distinguished from mere observation, is featured prominently in the 2015 NCCN guidelines and may be the preferred management in most men with very low risk prostate cancer. This approach is increasingly accepted and incorporated in routine clinical practice.

B. Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy and related to pathologic stage. Organ-confined cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for radical prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although the surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

C. Radiation Therapy

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and

transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and cancer characteristics. The likelihood of a positive prostate biopsy more than 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the cancer may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. Three-dimensional conformal radiation delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of adverse side effects compared with previous techniques. Brachytherapy—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate can be used as monotherapy in those with low-grade or low-volume malignancies or combined with external beam radiation in patients with higher-grade or higher-volume disease. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

D. Cryosurgery

In cryosurgery, liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. The positive biopsy rate after cryoablation ranges between 7% and 23%.

E. Localized Disease

Although selected patients may be candidates for active surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy in excess of 10 years should be considered for treatment. Newly introduced genomic tests may provide novel information to help guide treatment decisions. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared active surveillance with radical prostatectomy in 695 men with clinically localized and well-differentiated to moderately differentiated cancers. Radical prostatectomy significantly reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The relative reduction in the risk of death at 23 years was 0.56 in the prostatectomy group, with the number needed to treat to avert one death (NNT) = 8 patients; the benefit was largest in men younger than age 65 years (relative risk [RR] = 0.45) and with intermediate-risk prostate cancer (RR = 0.38). Surgery also reduced the risk of metastases in older men (RR = 0.68).

F. Locally and Regionally Advanced Disease

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins or androgen deprivation for lymph node metastases). Two randomized clinical trials (EORTC 22911 and SWOG 8794) have demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis of SWOG 8794 showed improved overall survival in men receiving adjuvant radiation therapy. Evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (less than 6 months).

Those with locally extensive cancers, including those with seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy. Currently, a variety of investigational regimens are being tested in an effort to improve cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone.

G. Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. Most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. Androgen deprivation may be affected at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–8). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves androgen deprivation without orchiectomy or administration of diethylstilbestrol and is currently the most common method of reducing testosterone levels. A single LHRH antagonist (degarelix) is FDA approved and has no short-term testosterone “flare” associated with LHRH agonists. Because of its rapid onset of action, ketoconazole should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both testicular and adrenal androgens allows for a better initial and longer response than methods that only inhibit production of testicular androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an

Table 39–8. Androgen deprivation for prostatic cancer.

Level	Agent	Dose	Sequelae
Pituitary, hypothalamus	Diethylstilbestrol	1–3 mg orally daily	Gynecomastia, hot flushes, thromboembolic disease, erectile dysfunction
	LHRH agonists Leuprolide Goserelin Triptorelin Histrelin	Monthly to annual depot injection Subcutaneous implant	Erectile dysfunction, hot flushes, gynecomastia, rarely anemia
	LHRH antagonist Degarelix	240 mg subcutaneously initial dose, then 80 mg subcutaneously monthly	Hot flushes, weight gain, erectile dysfunction, increased liver tests
Adrenal	Ketoconazole	400 mg three times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Aminoglutethimide	250 mg four times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Corticosteroids Prednisone	20–40 mg orally daily 500 mg orally daily	Gastrointestinal bleeding, fluid retention
	CYP17a1 inhibitor Abiraterone		Weight gain, fluid retention, hypokalemia, hypertension
Testis	Orchiectomy		Gynecomastia, hot flushes, erectile dysfunction
Prostate cell	Antiandrogens Flutamide Bicalutamide Enzalutamide	250 mg three times orally daily 50 mg orally daily 160 mg orally daily	No erectile dysfunction when used alone; nausea, diarrhea Seizures, dizziness, asthenia

LHRH, luteinizing hormone-releasing hormone.

LHRH agonist/antagonist or orchiectomy. Nonsteroidal antiandrogen agents appear to act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchiectomy alone or of either in combination with an antiandrogen agent showed little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially. Bisphosphonates can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal-related events. Denosumab, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with hormone-refractory prostate cancer. Current research is underway combining docetaxel with androgen deprivation therapy, radiation therapy, and surgery to determine whether combinations are effective in patients with high-risk prostate cancer. Immune therapies are also under investigation and have shown promise for patients with advanced prostate cancer. Sipuleucel-T, an autologous cellular immunotherapy, is FDA approved in asymptomatic or minimally symptomatic men with metastatic hormone-refractory prostate cancer. Other agents—cabazitaxel, abiraterone, and enzalutamide—are also approved for advanced prostate cancer after clinical trials have demonstrated improvements in survival in men having received prior docetaxel. Both abiraterone and enzalutamide have been FDA approved for use in the pre-chemotherapy, metastatic setting. Radium-223 dichloride is approved for the treatment of men with castration-resistant, symptomatic bone metastases, with significant improvements in both overall survival and time to skeletal-related events (eg, fractures). A recent trial demonstrated the benefit of early combination treatment with chemotherapy and androgen deprivation therapy in men with newly diagnosed metastatic prostate cancer, with an overall survival advantage superior to chemotherapy given at the time of development of castration-resistant disease.

► Prognosis

The likelihood of success of active surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several tools are available on the Internet (eg, <http://www.mskcc.org/nomograms/prostate>). One of the most widely used is the Kattan nomogram; it incorporates cancer stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The University of California San Francisco CAPRA nomogram uses serum PSA, Gleason score, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence

Table 39–9. The UCSF Cancer of the Prostate Risk Assessment (CAPRA).

Variable	Level	Points
PSA (ng/mL [or mcg/L])	0–6	0
	6.1–10	1
	10.1–20	2
	20.1–30	3
	> 30	4
Gleason grade, primary/secondary	1–3/1–3	0
	1–3/4–5	1
	4–5/1–5	3
T-stage	T1 or T2	0
	T3a	1
% positive biopsies (biopsy cores positive divided by the number of biopsies obtained)	< 34%	0
	> 34%	1
Age	< 50 years	0
	> 50 years	1

3 and 5 years after radical prostatectomy (Tables 39–9 and 39–10) as well as metastasis, prostate cancer-specific, and overall survival. The CAPRA nomogram has been validated on large multicenter and international radical prostatectomy and radiation-treated cohorts.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grades 1 and 2) are usually confined within the prostate, whereas large-volume (greater than 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of

Table 39–10. CAPRA: Probability of freedom from PSA recurrence after radical prostatectomy by CAPRA point total.

CAPRA Score	3-Year Recurrence Free Survival (%) (95% CI)	5-Year Recurrence Free Survival (%) (95% CI)

PSA, prostate-specific antigen.

regional or distant disease, and disease recurrence. The most common sites of lymph node metastases are the obturator and internal iliac lymph node chains and of distant metastases, the axial skeleton.

When to Refer

- Refer all patients to a urologist.
- Active surveillance may be appropriate in selected patients with very low volume, low-grade prostate cancer.
- Localized disease may be managed by active surveillance, surgery, or radiation therapy.
- Locally extensive, regionally advanced, and metastatic disease often require multimodal treatment strategies.

BLADDER CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Gross or microscopic hematuria.
- ▶ Irritative voiding symptoms.
- ▶ Positive urinary cytology in most patients.
- ▶ Filling defect within bladder noted on imaging.

General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3.1:1), and the mean age at diagnosis is 73 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. In the United States, almost all primary bladder cancers (98%) are epithelial malignancies, usually urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer. Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities results from locally advanced cancers or metastases to pelvic lymph nodes.

B. Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria is accompanied

by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful to detect the disease initially or to detect its recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%) but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis or response to therapy.

C. Imaging

Bladder cancers may be identified using ultrasound, CT, or MRI as masses within the bladder. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and to stage more advanced lesions.

D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, transurethral prostate biopsies are performed to detect occult disease in the bladder or elsewhere and potentially identify patients at greater risk for cancer recurrence and progression.

▶ Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent (depth) of bladder wall penetration and the presence of regional or distant metastases.

The natural history of bladder cancer is based on two separate but related processes: cancer recurrence within the bladder and progression to higher-stage disease. Both are correlated with cancer grade and stage.

▶ Treatment

Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and selective use of intravesical chemotherapy. The subset of patients with carcinoma in situ and those undergoing resection of large, high-grade, recurrent Ta lesions or T1 cancers are good candidates for adjuvant intravesical therapy.

Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy, irradiation, or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) urothelial cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher stage or bulky tumors in order to improve their surgical resectability.

A. Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, valrubicin, and BCG, the last being the most effective agent in reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancers in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion have been developed that avoid the necessity of an external appliance and can be considered in a significant number of patients.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder, bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and it is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

D. Chemotherapy

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–4).

Combination chemotherapy has been used to decrease recurrence rates with both surgery and radiotherapy and to attempt bladder preservation in those treated with radiation. Neoadjuvant chemotherapy appears to benefit all patients with muscle-invasive disease prior to planned cystectomy. Chemotherapy should also be considered before surgery in those with bulky lesions or those

suspected of having regional disease. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or local invasion.

► Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few low-grade cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in such patients and survival is excellent (81%). Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

► When to Refer

- Refer all patients to a urologist. Hematuria often deserves evaluation with both upper urinary tract imaging and cystoscopy, particularly in a high-risk group (eg, older men).
- Refer when histologic diagnosis and staging require endoscopic resection of cancer.

CANCERS OF THE URETER & RENAL PELVIS

Cancers of the ureter and renal pelvis are rare and occur more commonly in patients with bladder cancer, with Balkan nephropathy, with Lynch syndrome, who smoke, who were exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), and who have a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients, and flank pain secondary to bleeding and obstruction occurs less commonly. Like bladder cancers, urinary cytology is often positive. The most common signs identified at the time of CT or intravenous urography include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of cancers present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers. Similar to urothelial bladder cancers, use of chemotherapy prior to surgery may improve outcomes.

RENAL CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Gross or microscopic hematuria.
- ▶ Flank pain or mass in some patients.
- ▶ Systemic symptoms such as fever, weight loss may be prominent.
- ▶ Solid renal mass on imaging.

▶ General Considerations

Renal cell carcinoma accounts for 2.6% of all adult cancers. In the United States, approximately 63,920 cases of renal cell carcinoma are diagnosed and 13,860 deaths result annually. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with a number of paraneoplastic syndromes.

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial causes of renal cell carcinoma have been identified (von Hippel–Lindau syndrome, hereditary papillary renal cell carcinoma, hereditary leiomyoma-renal cell carcinoma, Birt-Hogg-Dubé syndrome) and there is an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation), but sporadic carcinomas are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and sarcomatoid).

▶ Clinical Findings

A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass was found in only 10–15% of patients, and often a sign of advanced disease. Fever occurs as a paraneoplastic symptom. Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Because of the widespread use of ultrasound and CT scanning, renal tumors are frequently detected incidentally in individuals with no urologic symptoms. There has been profound stage migration toward lower stages of disease over the past 10 years, likely due to the increased use of abdominal imaging. However, population mortality rates remain stable.

B. Laboratory Findings

Hematuria is present in 60% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. **Stauffer syndrome** is a reversible syndrome of hepatic dysfunction (with elevated liver tests) in the absence of metastatic disease.

C. Imaging

Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. These scans confirm the character of the mass and further stage the lesion with respect to regional lymph nodes, renal vein, or liver. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated serum alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing the presence and extent of tumor thrombus within the renal vein or vena cava.

▶ Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include renal angiomyolipomas (fat density usually visible by CT), renal pelvis urothelial cancers (more central location, involvement of the collecting system, positive urinary cytology), renal oncocytomas (indistinguishable from renal cell carcinoma preoperatively), renal abscesses, and adrenal tumors (superoanterior to the kidney).

▶ Treatment

Surgical extirpation is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer are also candidates for partial nephrectomy, while radical nephrectomy is indicated in patients with cancers larger than 7 cm and those in whom partial nephrectomy is not technically feasible. Radiofrequency and cryosurgical ablation are being studied; they likely yield equivalent short-term oncologic outcomes with reduced morbidity.

No effective chemotherapy is available for metastatic renal cell carcinoma. Vinblastine yields short-term partial response rates of 15%. Bevacizumab can prolong time to progression in patients with metastatic disease (see Table 39–4). With biologic response modifiers, such as interferon-alpha and interleukin-2, partial response rates of 15–20% and 15–35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high performance status. Patients with metastatic renal cell carcinoma and good performance status who have resectable primary tumors should undergo cytoreductive nephrectomy. Two randomized trials have shown a survival benefit of surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

Several targeted drugs, specifically VEGF, Raf-kinase, and mTOR inhibitors, are effective (40% response rates) in patients with advanced kidney cancer. These drugs are oral agents, well tolerated, and particularly active for clear cell carcinoma. The appropriate timing and combination of

these agents, with and without surgery and cytokine therapy, remains to be determined. To date, no benefit has been observed in the adjuvant use of these agents after complete surgical resection, even in those with adverse pathologic features. Nivolumab is a recently approved immunotherapy for treating metastatic disease that has progressed despite antiangiogenic therapy.

► Prognosis

After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survival of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50–60% and 0–15% 5-year disease-free survival, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the solitary metastasis results in 5-year disease-free survival rates of 15–30%.

► When to Refer

- Refer patients with solid renal masses or complex cysts to a urologist for further evaluation.
- Refer patients with renal cell carcinoma to a urologic surgeon for surgical excision.
- Refer patients with metastatic disease to an oncologist and urologist.

Motzer RJ et al. Pazopanib versus sunitinib in metastatic renal-cell carcinoma. *N Engl J Med.* 2013 Aug 22;369(8):722–31. [PMID: 23964934]

OTHER PRIMARY TUMORS OF THE KIDNEY

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in

other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions less than 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angioembolization to reduce the risk of bleeding.

SECONDARY CANCERS OF THE KIDNEY

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

TESTICULAR CANCERS (Germ Cell Tumors)

ESSENTIALS OF DIAGNOSIS

- ▶ Most common neoplasm in men aged 20–35 years.
- ▶ Patient typically discovers a painless nodule.
- ▶ Orchiectomy necessary for diagnosis.

► General Considerations

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: **nonseminomas**, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (less than 1%), and mixed cell types (40%); and **seminomas** (35%). The lifetime probability of developing testicular cancer is 0.3% for an American male.

Approximately 5% of testicular cancers develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is higher for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter its malignant potential but does facilitate routine examination and cancer detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of

cryptorchidism on the right side. One to 2 percent of primary testicular cancers are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular cancers may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular cancers, while malignant lymphoma is the most common bilateral testicular tumor overall.

► Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), alpha-fetoprotein, and lactate dehydrogenase. Alpha-fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. Lactate dehydrogenase may be elevated with either type of tumor. Liver tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

C. Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

► Staging

Testicular cancer is staged using the TNM system created based on extent of cancer in the testis, status of regional lymph nodes, the presence of metastases in distant lymph nodes or other viscera, and serum levels of tumor markers. Based on these features, germ cell tumors can be grouped to assign an overall stage: stage I lesion is confined to the testis; stage II demonstrates regional lymph node

involvement in the retroperitoneum; and stage III indicates distant metastasis.

► Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large. Testicular lymphoma is discussed below.

► Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer cannot be excluded by examination of the testis, radical orchiectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Up to 75% of clinical stage I **nonseminomas** are cured by orchiectomy alone. Selected patients who meet specific criteria may be offered surveillance after orchiectomy. These criteria are as follows: (1) cancer is confined within the tunica albuginea; (2) cancer does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen.

Stage I, IIa, and IIb **seminomas** (retroperitoneal disease less than 2 cm diameter in IIa and 2–5 cm in IIb) are treated by radical orchiectomy and retroperitoneal irradiation. Patients with clinical stage I disease may be candidates for surveillance or single-agent carboplatin. Seminomas of stage IIc (greater than 5 cm diameter retroperitoneal nodes) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 39–4). Surgical resection of one or more residual retroperitoneal nodes is warranted if the node is greater than 3 cm in diameter and positive on PET scan, since 40% will harbor residual carcinoma.

Postoperative active surveillance by the clinician and patient means patients are followed up every 1–2 months for the first 2 years and quarterly in the third year. Tumor markers are obtained at each visit, and chest radiographs and CT scans are obtained every 3–4 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. Alternatives to surveillance for clinical stage I nonseminoma include adjuvant chemotherapy (bleomycin,

etoposide, cisplatin) (see Table 39–4) or retroperitoneal lymph node dissection.

Patients with bulky retroperitoneal disease (greater than 5 cm nodes) or metastatic nonseminomas are treated with combination chemotherapy following orchiectomy (cisplatin and etoposide or cisplatin, etoposide, and bleomycin). If tumor markers normalize and a residual mass greater than 1 cm persists on imaging studies, it is resected because 15–20% will harbor residual cancer and 40% will harbor teratomas. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10%, retroperitoneal teratoma. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, and ifosfamide).

► Prognosis

The 5-year disease-free survival rate for patients with stage A **nonseminomas** (includes all treatments) ranges from 96% to 100%. For low-volume stage B disease, 90% 5-year disease-free survival is expected. The 5-year disease-free survival rates for stage I and IIa **seminomas** (retroperitoneal disease less than 2 cm in diameter) treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchiectomy and chemotherapy. Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%.

► When to Refer

Refer all patients with solid masses of the testis to a urologist.

SECONDARY CANCERS OF THE TESTIS

Secondary cancers of the testis are rare. In men over the age of 50 years, lymphoma is the most common. Overall, it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular cancers. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney.

CANCER COMPLICATIONS & EMERGENCIES

SPINAL CORD COMPRESSION

ESSENTIALS OF DIAGNOSIS

- ▶ Complication of metastatic solid tumor, lymphoma, or multiple myeloma.
- ▶ Back pain is most common presenting symptom.
- ▶ Prompt diagnosis is essential because once a severe neurologic deficit develops, it is often irreversible.
- ▶ Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

► General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to the vasculature of the spinal cord. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

► Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in cancer patients.

B. Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. If the back pain symptoms are nonspecific, a whole-body PET scan with ^{18}F -2-deoxyglucose may be useful as a screening procedure. Bone radiographs are neither sensitive nor specific for the evaluation of a cancer patient with back pain. When there are neurologic findings suggesting spinal cord compression, an emergent MRI should be obtained; the MRI should include a survey of the entire spine in order to define all areas of tumor involvement for treatment planning purposes.

Treatment

Patients found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dexamethasone dose is 10–100 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the impingement and obtain a pathologic specimen. Patients with a single area of compression due to solid tumors are best treated with surgical decompression followed by radiation therapy. Better outcomes (ie, improved ability to ambulate and improved bladder and bowel function) are seen in patients who undergo surgery followed by radiation therapy than in those who receive radiation therapy alone. If multiple vertebral body levels are involved with cancer, fractionated radiation therapy is the preferred treatment option. Corticosteroids are generally tapered toward the end of radiation therapy. A scoring system exists for patients presenting with spinal cord metastases to identify those with poor survival times who would be best managed with supportive care or single fraction palliative radiation.

MALIGNANT EFFUSIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Occur in pleural, pericardial, and peritoneal spaces.
- ▶ Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- ▶ Half of undiagnosed effusions in patients not known to have cancer are malignant.

General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

Clinical Findings

A. Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairing both filling and cardiac output can be a life-threatening event. Signs of tamponade include tachycardia, muffled heart sounds, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

B. Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

C. Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

Differential Diagnosis

The differential diagnosis of a malignant exudative pleural or pericardial effusion includes nonmalignant processes, such as infection, pulmonary embolism, heart failure, and trauma.

The differential diagnosis of malignant ascites includes similar benign processes, such as heart failure, cirrhosis, peritonitis, and pancreatic ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

Treatment

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the presence of an effusion is an end-stage manifestation of the disease. In this situation, decisions regarding management are in large part dictated by the patient's symptoms and goals of care.

A. Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a **large volume thoracentesis**. With some patients, the effusion slowly reaccumulates, which allows for periodic thoracentesis when the patient becomes symptomatic. However, in many patients, the effusion reaccumulates quickly, causing rapid return of symptoms of shortness of breath. For those patients, two other options exist for management. **Chest tube drainage followed by pleurodesis** involves placement of a chest tube that is connected to closed water seal drainage. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry or doxycycline) is injected into the catheter. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the drug through the pleural spaces. Pleurodesis will not be successful if the lung cannot be reexpanded. These patients are better managed with the second option of **placement of an indwelling catheter** that can be drained by a family member or a visiting nurse. This procedure may also be preferable for patients with short life expectancies or for those who do not respond to pleurodesis. Chest tube drainage followed by pleurodesis or placement of an indwelling catheter have essentially equivalent outcomes in terms of cost, relief of symptoms, and other measures of quality of life.

B. Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include prolonged catheter drainage for several days until drainage has decreased to 20–30 mL/day or pericardiectomy.

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large volume paracenteses. As the frequency of drainage to maintain comfort can compromise the patient's quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Usually symptomatic and severe (15 mg/dL [3.75 mmol/L] or more).
- ▶ Most common paraneoplastic endocrine syndrome; accounts for most inpatients with hypercalcemia.
- ▶ The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

▶ General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and NSCLC. Hypercalcemia is caused by one of three mechanisms: systemic effects of tumor-released proteins, direct osteolysis of bone by tumor, or vitamin D–mediated osteoabsorption.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapid rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free ionized calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of symptoms or signs of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

C. ECG

Electrocardiography in hypercalcemia often shows a shortening of the QT interval.

Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–300 mL/h to ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, or zoledronic acid, 4 mg intravenously over 15 minutes. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect, but with repeated dosing, it is more often associated with the very uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. Commonly, though, hypercalcemia occurs in patients with cancers that are unresponsive to treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include calcitonin, denosumab, and gallium nitrate; corticosteroids can be useful in patients with myeloma and lymphoma. Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be used in patients with severe, symptomatic hypercalcemia; its onset of action is within hours but its hypocalcemic effect wanes in 2–3 days. Denosumab, 120 mg given subcutaneously weekly for 4 weeks followed by monthly administration, is a choice for long-term management of bisphosphonate-refractory hypercalcemia.

HYPERURICEMIA & TUMOR LYSIS SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Complication of treatment-associated tumor lysis of hematologic and rapidly proliferating malignancies.
- ▶ May be worsened by thiazide diuretics.
- ▶ Rapid increase in serum uric acid can cause acute urate nephropathy from uric acid crystallization.
- ▶ Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired,

hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules further exacerbating the hyperphosphatemia and hyperkalemia.

Clinical Findings

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage, further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

Treatment

Prevention is the most important factor in the management of TLS. Published guidelines for TLS management include aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy. Administration of fluid helps keep urine flowing and facilitates excretion of uric acid and phosphorus. For the patients with moderate risk of developing TLS, for instance, those with intermediate grade lymphomas and acute leukemias, allopurinol should be given before starting chemotherapy at an oral dose of 100 mg/m² every 8 hours (maximum 800 mg/day) with dose reductions for impaired kidney function. For patients at high risk for developing TLS, for instance, patients with high-grade lymphomas or patients with acute leukemias and markedly elevated white blood cell counts (with acute myeloid leukemia, white blood cell count greater than 50,000/mcL [50,000/10⁹/L]; with acute lymphoblastic leukemia, white blood cell count greater than 100,000/mcL [100,000/10⁹/L]) or in whom hyperuricemia develops despite treatment with allopurinol, rasburicase 0.1–0.2 mg/kg/day is given intravenously for 1–7 days. Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. One of the historic mainstays of TLS management, systemic bicarbonate infusions to alkalinize the urine, is no longer routinely recommended. Laboratory values should be monitored following initiation of chemotherapy in addition to the hyperuricemia; elevated potassium or phosphorus levels need to be promptly managed.

When to Refer

Should urinary output drop, creatinine or potassium levels rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.

INFECTIONS

Chapters 30 and 31 provide more detailed discussions of infections in the immunocompromised patient.

ESSENTIALS OF DIAGNOSIS

- ▶ In patients with neutropenia, infection is a medical emergency.
- ▶ Although sometimes attributable to other causes, the presence of fever, defined as a single temperature greater than 38.3°C (101°F) or a temperature of greater than 38°C (100.4°F) for longer than 1 hour, must be assumed to be due to an infection.

▶ General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin lymphoma, multiple myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Complicating impaired defense mechanisms are the frequent presence of indwelling catheters, impaired mucosal surfaces, and colonization with more virulent hospital-acquired pathogens.

The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for the majority of infections in cancer patients include gram-negative bacteria (*Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter*) and gram-positive bacteria (coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Corynebacterium*, and streptococci). There has been a trend over the last few decades of an increasing percentage of gram-positive organisms. The risk of bacterial infections rises when the neutrophil count is below 1000/mcL ($1.0 \times 10^9/L$); the risk dramatically increases when the count falls below 100/mcL ($0.1 \times 10^9/L$).

▶ Clinical Findings

A thorough physical examination should be performed. Routine DREs are generally avoided unless symptoms suggest a rectal abscess or prostatitis. If a DRE is necessary, antibiotics should be administered first. Appropriate cultures (eg, blood, sputum, urine and, if indicated, cerebrospinal fluid) should always be obtained. Two sets of blood cultures should be drawn before starting antibiotics; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

▶ Treatment

Empiric antibiotic therapy needs to be initiated immediately following the collection of blood cultures in the

febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient's clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous beta-lactam with anti-*Pseudomonas* activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an aminoglycoside or fluoroquinolone should be added for "double" gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from *S aureus* catheter infection, vancomycin can be given empirically. In some instances, patients may be treated with oral antibiotics and potentially in the outpatient setting. The Infectious Diseases Society of America (IDSA) has published recommendations for antibiotic use in these low-risk patients. These patients must have an expected neutropenic timeframe of 7 days or less and not have comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary problems (infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease), or liver or kidney disease or impairment. A validated risk index, such as the Multinational Association for Supportive Care in Cancer (MASCC) score, may be used to assess a patient for appropriateness of outpatient management. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens.

Antibiotics should be continued until the neutrophil count is rising and greater than 500/mcL ($0.5 \times 10^9/L$) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

PRIMARY CANCER TREATMENT

SYSTEMIC CANCER THERAPY

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy administered and monitored by a medical oncologist or hematologist. Selection of specific drugs or protocols for various types of cancer is usually based on results of clinical trials. Increasingly, newer agents are being identified that target specific molecular pathways. Yet both initial and acquired drug resistance remains a challenge. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cellular proteins.

TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. The complexity of treating cancer has increased over the last decade as more drugs, including those with novel mechanisms of action, have been approved by the Food and Drug Administration and introduced into general practice. Drug side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities of individual drugs are listed in Tables 39–11 and 39–12. Decisions on dose modifications for toxicities should be guided by the intent of therapy. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible.

A CBC including a differential count, with absolute neutrophil count and platelet count, and liver and kidney tests should be obtained before the initiation of chemotherapy. In patients with normal CBCs as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A CBC with differential may be checked at mid cycle (to determine the nadir of the absolute neutrophil and platelet counts), and liver and kidney function tests should be obtained immediately before the next cycle of chemotherapy.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–13.

1. Bone Marrow Toxicity

A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24 hours after cytotoxic chemotherapy is

completed, has been shown to reduce the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 39–12). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with a G-CSF when there is at least a 20% risk of febrile neutropenia or when the patient's age, medical history, and disease characteristics put the patient at high risk for complications related to myelosuppression.

B. Anemia

Erythropoiesis-stimulating agents (ESAs) ameliorate the anemia and its associated symptoms that are caused by cancer chemotherapy but these drugs have untoward effects, including an increased risk of thromboembolism, and even more concerning, potentially decreased survival due to cancer-related deaths as well as a shortened time to tumor progression. These findings have prompted the US Food and Drug Administration and other organizations (American Society of Hematology, American Society of Clinical Oncology, and NCCN) to issue advisories and guidelines limiting their use. The NCCN recommends that these drugs should not be used when the intent of chemotherapy is curative. Studies done in patients with potentially curable head and neck, breast, and cervical cancers have shown inferior outcomes when ESAs were used. However, the target hemoglobin used in these studies was higher than is currently recommended. Nonetheless, ESAs cannot be currently recommended when the intent of therapy is cure. The alternative to managing symptomatic anemia in these patients receiving curative chemotherapy is administration of red blood cell transfusions.

ESAs can be an option in cancer patients with symptomatic anemia undergoing palliative treatment; patient preference is important in determining when to use ESAs or transfusions. When using ESAs, treatment should not be initiated until the hemoglobin is less than 10 g/dL (100 g/L) with the medication held when the hemoglobin is greater than 12 g/dL (120 g/L). Epoetin alfa can be given subcutaneously at a dose of 40,000 units weekly or 150 units/kg three times weekly with a target hemoglobin of 11–12 g/dL (110–120 g/L). Darbepoetin alfa is given subcutaneously at a dose of 500 mcg every 3 weeks or 2.25 mcg weekly with the same target hemoglobin (see Table 39–12). Patients need to be iron replete to have maximum therapeutic effect. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy. The FDA mandates that prescribing clinicians receive specific education on use of ESAs, and patients receiving ESAs must be provided written material describing the risks and benefits of the drug and sign an acknowledgment form that they talked with their provider about the risks of ESAs.

C. Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving thrombocytopenia associated with chemotherapy; however, it is rarely used due to the side effects of fluid

Table 39–11. Common chemotherapeutic agents.¹

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Alkylating Agents—Nitrogen Mustards		
Bendamustine (Treanda)	100–120 mg/m ² intravenously every 3–4 weeks	Acute: hypersensitivity, nausea, vomiting Delayed: myelosuppression, rash, pyrexia, fatigue
Cyclophosphamide (Cytoxan)	500–1000 mg/m ² intravenously every 3 weeks; 100 mg/m ² /day orally for 14 days every 4 weeks; various doses	Acute: nausea and vomiting Delayed: myelosuppression, alopecia, hemorrhagic cystitis, cardiotoxicity (high dose)
Ifosfamide (Ifex)	1200 mg/m ² intravenously daily for 5 days every 3 weeks; various doses	Acute: nausea and vomiting Delayed: alopecia, myelosuppression, hemorrhagic cystitis, neurotoxicity
Mechlorethamine (Mustargen)	0.4 mg/kg intravenously every 3–6 weeks	Acute: nausea and vomiting Delayed: myelosuppression
Melphalan (Alkeran)	0.25 mg/kg/day or 8–10 mg/m ² /day orally for 4 days every 4–6 weeks; 16 mg/m ² intravenously every 2–4 weeks; various doses	Acute: nausea, vomiting, diarrhea, hypersensitivity (intravenously) Delayed: mucositis (intravenously), myelosuppression, increased risk of secondary malignancies
Alkylating Agents—Platinum Analogs		
Carboplatin (Paraplatin)	Area under the curve (AUC)-based dosing use Calvert equation [Dose (mg) = AUC × (GFR + 25)] AUC = 2–7 mg/mL/min every 2–4 weeks	Acute: nausea and vomiting Delayed: myelosuppression, electrolyte disturbances, peripheral neuropathy, nephrotoxicity, hypersensitivity
Cisplatin (Platinol)	50–100 mg/m ² intravenously every 3–4 weeks; 20 mg/m ² /day intravenously for 5 days every 3 weeks; various doses	Acute: nausea and vomiting Delayed: nephrotoxicity, ototoxicity, neurotoxicity, myelosuppression, electrolyte disturbances
Oxaliplatin (Eloxatin)	85–130 mg/m ² intravenously every 2–3 weeks	Acute: peripheral neuropathy exacerbated by cold, nausea, vomiting, diarrhea Delayed: myelosuppression, elevated transaminases
Alkylating Agents—Triazines		
Dacarbazine (DTIC-Dome)	375 mg/m ² intravenously on day 1 and 15 every 4 weeks; 900–1000 mg/m ² intravenously over 3 to 4 days; various doses	Acute: nausea, vomiting, photosensitivity Delayed: myelosuppression, anorexia, hypotension, flu-like syndrome
Procarbazine (Matulane)	60–100 mg/m ² orally for 14 days every 4 weeks; various doses	Acute: nausea and vomiting Delayed: myelosuppression, disulfiram-like reaction, MAO inhibition, rash
Temozolomide (Temodar)	75 mg/m ² orally daily during radiation for 42 days; 150–200 mg/m ² orally for 5 days every 4 weeks	Acute: nausea, vomiting, constipation Delayed: myelosuppression, fatigue
Alkylating Agents—Miscellaneous		
Busulfan (Myleran)	1–8 mg orally daily; 0.8 mg/kg intravenously every 6 hours for 4 days	Acute: nausea and vomiting Delayed: myelosuppression, mucositis, rash, edema, electrolyte disturbances, hepatic veno-occlusive disease (high dose)
Chlorambucil (Leukeran)	0.1–0.2 mg/kg/day orally for 3–6 weeks; 0.4 mg/kg pulse every 4 weeks	Acute: nausea Delayed: myelosuppression, rash
Antimetabolites—Folate Antagonists		
Methotrexate (MTX; Trexall)	Intrathecal: 12 mg High dose: 1000–12,000 mg/m ² intravenously every 2–3 weeks	Acute: nausea, vomiting, mucositis Delayed: myelosuppression, nephrotoxicity, hepatotoxicity, neurotoxicity, photosensitivity, pulmonary toxicity
Pemetrexed (Alimta)	500 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, rash Delayed: myelosuppression, fatigue, mucositis
Antimetabolites—Purine Analogs		
Cladribine (Leustatin)	0.1 mg/kg/day subcutaneously daily for 5 days or 0.09 mg/kg/day intravenously via continuous infusion for 7 days	Acute: nausea, injection site reaction Delayed: myelosuppression, immunosuppression, fever, fatigue, rash

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Clofarabine (Clolar)	52 mg/m ² intravenously daily for 5 days every 2–6 weeks (for patients < 21 years of age)	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, hepatotoxicity, nephrotoxicity, rash, capillary leak syndrome
Fludarabine (Fludara)	25 mg/m ² intravenously for 5 days every 4 weeks	Acute: fever, nausea, vomiting Delayed: asthenia, myelosuppression, immunosuppression, neurotoxicity, anorexia
Mercaptopurine (6-MP; Purinethol)	Induction: 2.5–5 mg/kg/day orally Maintenance: 1.5–2.5 mg/kg/day orally	Acute: nausea, vomiting, diarrhea, rash Delayed: myelosuppression, immunosuppression, hepatotoxicity, mucositis
Pentostatin (Nipent)	2–4 mg/m ² intravenously every 2–3 weeks	Acute: nausea, vomiting, rash Delayed: myelosuppression, fever, myalgia, immunosuppression, hepatotoxicity, cough
Antimetabolites—Pyrimidine Analogs		
Azacitidine (Vidaza)	75–100 mg/m ² subcutaneously or intravenously for 7 days every 4 weeks	Acute: injection site reaction (subcutaneously), nausea, diarrhea, fever Delayed: myelosuppression, dyspnea, arthralgia
Capecitabine (Xeloda)	1000–1250 mg/m ² orally twice a day for 14 days every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: hand-foot syndrome, mucositis, hyperbilirubinemia, myelosuppression
Cytarabine (Ara-C, Cytosar U)	Standard dose: 100 mg/m ² /day intravenously via continuous infusion for 7 days High dose: 1000–3000 mg/m ² intravenously every 12 hours for 2–6 days	Acute: nausea, vomiting, rash, flu-like syndrome Delayed: myelosuppression High-dose: neurotoxicity, ocular toxicities
Decitabine (Dacogen)	15 mg/m ² intravenously every 8 hours for 3 days every 8 weeks; 20 mg/m ² intravenously daily for 5 days	Acute: nausea, vomiting, hyperglycemia Delayed: myelosuppression, fever, fatigue, cough
Fluorouracil (Aducril)	400 mg/m ² intravenous bolus followed by 2400 mg/m ² intravenously over 46 hours every 2 weeks; 1000 mg/m ² intravenously via continuous infusion for 4–5 days every 3–4 weeks; various doses	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, hand-foot syndrome, mucositis, photosensitivity, cardiotoxicity (rare)
Gemcitabine (Gemzar)	1000–1250 mg/m ² intravenously on days 1 and 8 every 3 weeks or days 1, 8, 15 every 4 weeks	Acute: nausea, vomiting, rash, flu-like symptoms, fever, diarrhea Delayed: myelosuppression, edema, elevated transaminases
Antimicrotubules—Vinca Alkaloids		
Vinblastine (Velban)	6 mg/m ² intravenously on days 1 and 15 every 4 weeks; various doses	Acute: constipation Delayed: myelosuppression, alopecia, bone pain, malaise
Vincristine (Oncovin)	0.5–1.4 mg/m ² intravenously every 3 weeks; various doses; maximum single dose usually limited to 2 mg	Acute: constipation, nausea Delayed: peripheral neuropathy, alopecia
Liposomal Vincristine (Marqibo)	2.25 mg/m ² intravenously every 7 days	Acute: constipation, nausea Delayed: fatigue, neurotoxicity, myelosuppression
Vinorelbine (Navelbine)	25–30 mg/m ² intravenously weekly	Acute: nausea, vomiting Delayed: myelosuppression, peripheral neuropathy, constipation, alopecia, asthenia
Antimicrotubules—Taxanes		
Cabazitaxel (Jevtana)	25 mg/m ² intravenously every 3 weeks	Acute: diarrhea, nausea, vomiting, hypersensitivity Delayed: myelosuppression, peripheral neuropathy, fatigue
Docetaxel (Taxotere)	60–100 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity, rash Delayed: myelosuppression, asthenia, peripheral neuropathy, alopecia, edema, mucositis
Paclitaxel (Taxol)	135–175 mg/m ² intravenously every 3 weeks; 50–80 mg/m ² intravenously weekly; various doses	Acute: diarrhea, nausea, vomiting, hypersensitivity Delayed: myelosuppression, peripheral neuropathy, alopecia, mucositis, arthralgia

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Paclitaxel protein-bound (Abraxane)	100–125 mg/m ² on days 1, 8, 15 every 3–4 weeks; 260 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, peripheral neuropathy, alopecia, asthenia
Antimicrotubules—Epothilone		
Ixabepilone (Ixempra)	40 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity Delayed: peripheral neuropathy, fatigue, alopecia, myelosuppression, mucositis, arthralgia
Enzyme Inhibitors—Anthracyclines		
Daunorubicin (Cerubidine)	30–60 mg/m ² intravenously for 3 days	Acute: nausea, vomiting, diarrhea, red/orange discoloration of urine, infusion-related reactions (liposomal products) Delayed: myelosuppression, mucositis, alopecia, hand-foot syndrome (liposomal doxorubicin), cardiotoxicity (dose related)
Liposomal Daunorubicin (Daunoxome)	40 mg/m ² intravenously every 2 weeks	
Doxorubicin (Adriamycin)	45–75 mg/m ² intravenously every 3 weeks; various doses	
Liposomal Doxorubicin (Lipodox)	20–50 mg/m ² intravenously every 3–4 weeks	
Epirubicin (Ellence)	60–120 mg/m ² intravenously every 3–4 weeks	
Idarubicin (Idamycin)	10–12 mg/m ² intravenously for 3 days	
Enzyme Inhibitors—Topoisomerase Inhibitors		
Etoposide (Vepesid)	50–100 mg/m ² intravenously for 3–5 days every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity, fever, hypotension Delayed: myelosuppression, alopecia, fatigue
Etoposide phosphate (Etopophos)	35–100 mg/m ² intravenously for 3–5 days every 3–4 weeks	
Irinotecan (Camptosar)	180 mg/m ² intravenously every other week; various doses	Acute: diarrhea, cholinergic syndrome, nausea, vomiting Delayed: myelosuppression, alopecia, asthenia
Irinotecan liposome (Onivyde)	70 mg/m ² intravenously over 90 minutes every 2 weeks; prior to leucovorin and fluorouracil	Acute: diarrhea, nausea, vomiting Delayed: myelosuppression, fatigue, decrease in appetite
Topotecan (Hycamtin)	1.5 mg/m ² intravenously for 5 days every 3 weeks; 2.3 mg/m ² orally for 5 days every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, alopecia, asthenia
Immunomodulatory Therapy		
Lenalidomide (Revlimid)	5–25 mg orally once daily on days 1–21 of 28-day cycle; or continuously	Acute: diarrhea, rash Delayed: myelosuppression, fatigue, venous thromboembolism, potential for birth defects
Pomalidomide (Pomalyst)	4 mg orally once daily on days 1–21 of 28-day cycle	Acute: nausea, diarrhea, dizziness Delayed: myelosuppression, fatigue, neuropathy, upper respiratory tract infections, venous thromboembolism, potential for birth defects
Thalidomide (Thalomid)	50–800 mg orally once daily	Acute: sedation, constipation, rash Delayed: edema, peripheral neuropathy, venous thromboembolism, potential for birth defects
Proteasome Inhibitor		
Bortezomib (Velcade)	1.3 mg/m ² intravenous bolus or subcutaneously on days 1, 4, 8, 11 followed by a 10-day rest, or weekly for 4 weeks followed by 13-day rest	Acute: nausea, vomiting, diarrhea Delayed: peripheral neuropathy, fatigue, myelosuppression
Carfilzomib (Kyprolis)	20 mg/m ² or 27 mg/m ² intravenously on days 1, 2, 8, 9, 15, 16 followed by a 12-day rest (28-day cycle)	Acute: nausea, dyspnea, diarrhea, infusion-related reaction Delayed: fatigue, myelosuppression, elevated serum creatinine

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Ixazomib (Ninlaro)	4 mg orally on days 1, 8, 15 of a 28-day treatment cycle	Acute: diarrhea, constipation, nausea, vomiting Delayed: myelosuppression, peripheral neuropathy, peripheral edema, rash, hepatotoxicity (rare)
Targeted Therapy—Monoclonal Antibodies		
Ado-trastuzumab emtansine (Kadcyla)	3.6 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea Delayed: fatigue, musculoskeletal pain, thrombocytopenia, cardiotoxicity, hepatotoxicity
Alemtuzumab (Campath)	3–10 mg intravenously or subcutaneously three times weekly	Acute: infusion-related reaction, nausea, vomiting, hypotension, rash Delayed: myelosuppression, immunosuppression
Bevacizumab (Avastin)	5–15 mg/kg intravenously every 2–3 weeks	Acute: infusion-related reaction Delayed: hypertension, proteinuria, wound healing complications, gastrointestinal perforation, hemorrhage
Blinatumomab (Blinicyto)	9 mcg/day intravenously via continuous infusion on days 1 through 7; 28 mcg/day on days 8 through 28 of the first 42-day cycle; subsequent cycles: 28 mcg/day for 4 weeks followed by at least 2 weeks of no treatment	Acute: infusion-related reaction, nausea, headache, cytokine release syndrome, tumor lysis syndrome Delayed: pyrexia, peripheral edema, myelosuppression, hypokalemia, rash, neurologic toxicity, constipation
Brentuximab vedotin (Adcetris)	1.8 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea, vomiting, diarrhea Delayed: myelosuppression, peripheral neuropathy, fatigue, rash, cough
Cetuximab (Erbixx)	Loading dose 400 mg/m ² intravenously, maintenance dose 250 mg/m ² intravenously weekly	Acute: infusion-related reaction, nausea, diarrhea Delayed: acneiform skin rash, hypomagnesemia, asthenia, paronychia inflammation, dyspnea
Elotuzumab (Empliciti)	10 mg/kg intravenously every week for the first 2 cycles and every 2 weeks thereafter	Acute: infusion-related reaction, diarrhea Delayed: fatigue, peripheral neuropathy, risk for opportunistic infections
Daratumumab (Darzalex)	16 mg/kg intravenously weekly for weeks 1–8, every 2 weeks for weeks 9–24, and every 4 weeks from week 25 until disease progression	Acute: infusion-related reaction, nausea Delayed: myelosuppression, fatigue, upper respiratory tract infection
Ipilimumab (Yervoy)	3 mg/kg intravenously every 3 weeks for a total of four doses	Acute: infusion-related reaction Delayed: immune-related reactions, fatigue
Necitumumab (Portrazza)	800 mg intravenously over 60 mins prior to gemcitabine and cisplatin on days 1 and 8 of 21-day cycle	Acute: infusion-related reaction, vomiting, diarrhea Delayed: electrolyte abnormalities (especially hypomagnesemia), rash, cardiopulmonary arrest (rare)
Nivolumab (Opdivo)	3 mg/kg intravenously over 1 hour every 2 weeks	Acute: vomiting Delayed: fatigue, musculoskeletal pain, rash, pruritus, cough, elevated transaminases
Obinutuzumab (Gazyva)	Cycle 1: 100 mg intravenously on day 1, 900 mg on day 2, 1000 mg on day 8 and 15 of a 28-day cycle; Cycles 2–6: 1000 mg intravenously on day 1	Acute: infusion-related reaction, tumor lysis syndrome Delayed: myelosuppression, pyrexia, cough, musculoskeletal disorder, potential hepatitis B reactivation
Ofatumumab (Arzerra)	300 mg initial dose intravenously, followed 1 week later by 2000 mg intravenously weekly for 7 doses, followed 4 weeks later by 2000 mg intravenously every 4 weeks for four doses; or 300 mg initial dose intravenously, followed 1 week later by 1000 mg intravenously, then 1000 mg intravenously every 4 weeks	Acute: infusion-related reaction, diarrhea, nausea Delayed: neutropenia, infections, pyrexia, rash, fatigue, potential hepatitis B reactivation
Panitumumab (Vectibix)	6 mg/kg intravenously every 2 weeks	Acute: infusion-related reaction, nausea Delayed: acneiform skin rash, hypomagnesemia, asthenia, paronychia, fatigue, dyspnea
Pembrolizumab (Keytruda)	2 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea Delayed: immune-mediated reactions, fatigue, cough

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Pertuzumab (Perjeta)	840 mg intravenously once followed by 420 mg intravenously every 3 weeks	Acute: infusion-related reaction, diarrhea, nausea Delayed: fatigue, alopecia, neutropenia, rash, peripheral neuropathy, cardiomyopathy
Ramucirumab (Cyramza)	8 mg/kg intravenously every 2 weeks or 10 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, hypertension, diarrhea Delayed: fatigue, neutropenia, epistaxis
Rituximab (Rituxan)	375 mg/m ² intravenously weekly for 4 weeks, or every 3–4 weeks	Acute: infusion-related reaction, tumor lysis syndrome Delayed: lymphopenia, asthenia, rash, potential hepatitis B reactivation
Siltuximab (Sylvant)	11 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, hyperuricemia Delayed: pruritus, edema, weight gain, rash, upper respiratory tract infection, diarrhea
Trastuzumab (Herceptin)	Initial dose 4 mg/kg intravenously, then 2 mg/kg intravenously weekly; or initial dose 8 mg/kg then 6 mg/kg, intravenously every 3 weeks	Acute: headache, nausea, diarrhea, infusion-related reaction Delayed: myelosuppression, pyrexia, cardiomyopathy, pulmonary toxicity (rare)
Targeted Therapy—Kinase Inhibitors		
Afatinib (Gilotrif)	40 mg orally once daily without food	Acute: diarrhea Delayed: acneiform rash, stomatitis, paronychia
Alectinib (Alecensa)	600 mg orally twice daily with food	Acute: none Delayed: myelosuppression, fatigue, edema, myalgia, dyspnea, elevated transaminases
Axitinib (Inlyta)	5–10 mg orally twice daily	Acute: diarrhea, nausea, vomiting Delayed: hypertension, fatigue, dysphonia, hand-foot syndrome, elevated transaminases
Bosutinib (Bosulif)	500–600 mg orally once daily with food	Acute: diarrhea, nausea, vomiting Delayed: myelosuppression, rash, abdominal pain, hepatotoxicity, fluid retention
Ceritinib (Zykadia)	740 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: elevated transaminases, abdominal pain, fatigue, decreased appetite
Cobimetinib (Cotellic)	60 mg orally once daily on days 1 to 21 of a 28-day cycle	Acute: diarrhea, photosensitivity reaction, nausea, vomiting Delayed: myelosuppression, hepatotoxicity, rash, cardiomyopathy (with vemurafenib)
Crizotinib (Xalkori)	250 mg orally twice daily	Acute: nausea, vomiting, diarrhea, constipation Delayed: vision disorder, edema, elevated transaminases, fatigue
Dabrafenib (Tafinlar)	150 mg orally twice daily without food	Acute: headache Delayed: hyperkeratosis, fever, hand-foot syndrome, hyperglycemia, hypophosphatemia
Dasatinib (Sprycel)	100–180 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: myelosuppression, fluid retention, fatigue, dyspnea, musculoskeletal pain, rash
Erlotinib (Tarceva)	100 or 150 mg orally once daily without food	Acute: diarrhea, nausea, vomiting Delayed: acneiform skin rash, fatigue, anorexia, dyspnea
Everolimus (Afinitor)	10 mg orally once daily	Acute: mucositis, diarrhea, nausea Delayed: myelosuppression, fatigue, edema, hypercholesterolemia, hypertriglyceridemia, hyperglycemia
Gefitinib (Iressa)	250 mg orally once daily	Acute: diarrhea Delayed: acneiform skin rash
Ibrutinib (Imbruvica)	420 mg or 560 mg orally once daily	Acute: diarrhea, nausea Delayed: myelosuppression, fatigue, edema, rash, elevated serum creatinine, hemorrhage

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Idelalisib (Zydelig)	150 mg orally twice daily	Acute: diarrhea, nausea Delayed: hepatotoxicity, pneumonitis, intestinal perforation, pyrexia, fatigue, neutropenia, hypertriglyceridemia, hyperglycemia
Imatinib (Gleevec)	100–800 mg orally once daily with food	Acute: nausea, vomiting, diarrhea Delayed: edema, muscle cramps, rash, myelosuppression, hepatotoxicity
Lapatinib (Tykerb)	1250 mg or 1500 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: hand-foot syndrome, fatigue, hepatotoxicity (rare)
Lenvatinib (Lenvima)	24 mg orally daily	Acute: hypertension, nausea, vomiting, diarrhea Delayed: fatigue, arthralgia/myalgia, stomatitis, hand-foot syndrome
Nilotinib (Tasigna)	300 or 400 mg orally twice daily without food	Acute: nausea, vomiting, diarrhea Delayed: rash, fatigue, myelosuppression, prolonged QT interval (rare)
Osimertinib (Tagrisso)	80 mg orally once daily	Acute: diarrhea Delayed: myelosuppression, rash, dry skin, nail toxicity, cardiomyopathy (rare), QTc interval prolongation (rare)
Palbociclib (Ibrance)	125 mg orally daily with food for 21 days followed by 7 days off	Acute: nausea, diarrhea, vomiting Delayed: myelosuppression, fatigue, upper respiratory infection, stomatitis, alopecia
Pazopanib (Votrient)	800 mg orally once daily without food	Acute: diarrhea, nausea, vomiting Delayed: hypertension, hair color changes, hepatotoxicity, hemorrhage
Regorafenib (Stivarga)	160 mg orally once daily with food (low-fat breakfast)	Acute: diarrhea Delayed: asthenia, hand-foot syndrome, anorexia, hypertension, mucositis, myelosuppression, hepatotoxicity
Sorafenib (Nexavar)	400 mg orally twice daily without food	Acute: diarrhea and nausea Delayed: fatigue, hand-foot syndrome, rash, hypertension, hemorrhage
Sunitinib (Sutent)	50 mg orally once daily for 4 weeks followed by 2 weeks rest; 37.5 mg orally daily	Acute: diarrhea and nausea Delayed: hypertension, hand-foot syndrome, rash, yellow discoloration of skin, fatigue, hypothyroidism, mucositis, left ventricular dysfunction, bleeding, hepatotoxicity
Temsirolimus (Torisel)	25 mg intravenously weekly	Acute: hypersensitivity, rash Delayed: myelosuppression, asthenia, hyperglycemia, hyperlipidemia, elevated serum creatinine
Trametinib (Mekinist)	2 mg orally once daily without food	Acute: rash, diarrhea Delayed: elevated transaminases, lymphedema, cardiomyopathy
Vandetanib (Caprelsa)	300 mg orally once daily	Acute: diarrhea, nausea Delayed: acneiform skin rash, hypertension, prolonged QT interval
Vemurafenib (Zelboraf)	960 mg orally twice daily	Acute: nausea, hypersensitivity (rare) Delayed: photosensitivity, rash, arthralgia, alopecia, fatigue, prolonged QT interval, cutaneous squamous cell carcinoma
Miscellaneous Agents		
Arsenic trioxide (Trisenox)	0.15 mg/kg intravenously daily	Acute: nausea, dizziness Delayed: acute promyelocytic leukemia differentiation syndrome, prolonged QT interval

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (Continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Asparaginase Erwinia chrysanthemi (Erwinaze)	25,000 international units/m ² intramuscularly three times weekly	Acute: hypersensitivity, nausea, vomiting Delayed: coagulation abnormalities, hepatotoxicity, pancreatitis, neurotoxicity
Belinostat (Beleodaq)	1000 mg/m ² intravenously on days 1 through 5, repeat every 21 days	Acute: nausea, vomiting Delayed: fatigue, pyrexia, anemia
Bleomycin (Blenoxane)	10 units/m ² intravenously on days 1 and 15 every 28 days; 30 units intravenously on day 2, 9, and 16 every 21 days	Acute: hypersensitivity, fever Delayed: skin reaction (rash, hyperpigmentation of skin, striae), mucositis, pneumonitis
Dactinomycin (Cosmegen)	15 mcg/kg or 400–600 mcg/m ² intravenously daily for 5 days	Acute: nausea, vomiting Delayed: myelosuppression, mucositis, rash, diarrhea, hepatoveno-occlusive disease (rare)
Hydroxyurea (Hydrea)	20–30 mg/kg orally daily	Acute: none Delayed: myelosuppression
Mitomycin (Mutamycin)	10–20 mg/m ² intravenously every 4–8 weeks; 20–40 mg intravesically	Acute: cystitis (intravesically), nausea, vomiting Delayed: myelosuppression, mucositis, anorexia
Mitoxantrone (Novantrone)	12–14 mg/m ² intravenously every 3 weeks; 12 mg/m ² intravenously for 2–3 days	Acute: nausea, vomiting, diarrhea, mucositis, blue-green discoloration of urine Delayed: myelosuppression, alopecia, cardiotoxicity
Olaparib (Lynparza)	400 mg orally twice daily	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, elevated serum creatinine, MCV elevation, fatigue, abdominal pain
Omacetaxine mepesuccinate (Synribo)	Induction: 1.25 mg/m ² subcutaneously twice daily for 14 days every 28 days Maintenance: 1.25 mg/m ² subcutaneously twice daily for 7 days every 28 days	Acute: diarrhea, nausea, fatigue, injection site reaction Delayed: myelosuppression, infection
Panobinostat (Farydak)	20 mg orally per day on days 1, 3, 5, 8, 10, 12 of each 21-day cycle	Acute: diarrhea, nausea Delayed: myelosuppression, electrolyte abnormalities, infections
Tretinoin (All-Trans-Retinoic Acid, ATRA, Vesanoid)	45 mg/m ² orally divided twice daily for 45–90 days or 30 days past complete remission	Acute: headache, nausea Delayed: vitamin A toxicity, retinoic acid-acute promyelocytic leukemia syndrome
Trifluridine/tipiracil (Lonsurf)	35 mg/m ² based on trifluridine component orally twice daily within 1 hour of meal on days 1–5 and 8–12 (28-day cycle)	Acute: nausea, diarrhea, vomiting Delayed: myelosuppression, fatigue, anorexia
Ziv-aflibercept (Zaltrap)	4 mg/kg intravenously every 2 weeks	Acute: diarrhea Delayed: myelosuppression, proteinuria, elevated transaminases, stomatitis, fatigue, hypertension
Antiandrogens		
Bicalutamide (Casodex)	50 mg orally once daily	Acute: none Delayed: hot flashes, back pain, asthenia
Enzalutamide (Xtandi)	160 mg orally once daily	Acute: asthenia, diarrhea Delayed: hot flashes, arthralgia, peripheral edema
Flutamide (Eulexin)	250 mg orally every 8 hours	Acute: diarrhea Delayed: hot flashes, hepatotoxicity
Nilutamide (Nilandron)	300 mg orally for 30 days, then 150 mg orally once daily	Acute: none Delayed: visual disturbances (impaired adaptation to dark), hot flashes, disulfiram-like reaction
Selective Estrogen Receptor Modulators		
Tamoxifen (Nolvadex)	20–40 mg orally once daily	Acute: none Delayed: hot flashes, vaginal discharge, menstrual irregularities, arthralgia

(continued)

Table 39–11. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Toremifene (Fareston)	60 mg orally once daily	Acute: nausea Delayed: hot flashes, vaginal discharge
Aromatase Inhibitors		
Anastrozole (Arimidex)	1 mg orally once daily	Acute: nausea Delayed: hot flashes, peripheral edema, asthenia, hypercholesterolemia, arthralgia/myalgia, osteoporosis
Exemestane (Aromasin)	25 mg orally once daily	
Letrozole (Femara)	2.5 mg orally once daily	
Pure Estrogen Receptor Antagonist		
Fulvestrant (Faslodex)	500 mg intramuscularly on days 1, 15, 29, then monthly	Acute: injection site reaction, nausea Delayed: hot flashes, bone pain, elevated transaminases
LHRH Analogs		
Goserelin acetate (Zoladex)	3.6 mg subcutaneously every month; 10.8 mg subcutaneously every 3 months	Acute: injection site discomfort Delayed: hot flashes, tumor flare, edema, decreased libido, erectile dysfunction, osteoporosis
Leuprolide (Lupron)	7.5 mg intramuscularly or subcutaneously every month; 22.5 mg intramuscularly or subcutaneously every 3 months; 30 mg intramuscularly or subcutaneously every 4 months; 45 mg intramuscularly or subcutaneously every 6 months	
Triptorelin pamoate (Trelstar)	3.75 mg intramuscularly every 4 weeks; 11.25 mg intramuscularly every 12 weeks; 22.5 mg every 24 weeks	
LHRH Antagonist		
Degarelix (Firmagon)	240 mg subcutaneously once, then 80 mg subcutaneously every 28 days	Acute: injection site reaction Delayed: hot flashes, weight gain, elevated transaminases, QT prolongation
Adrenocorticosteroids		
Abiraterone (Zytiga)	1000 mg orally once daily	Acute: diarrhea, edema Delayed: adrenal insufficiency, hepatotoxicity, joint pain, hypokalemia
Ketoconazole	400 mg orally three times daily	Acute: nausea and vomiting Delayed: hepatotoxicity, adrenal insufficiency
Biologic Response Modifiers		
Aldesleukin (IL-2, Proleukin)	600,000 international units/kg intravenously every 8 hours for 14 doses, repeat after 9 days rest	Acute: hypotension, nausea, vomiting, diarrhea, flu-like syndrome, capillary leak syndrome Delayed: myelosuppression, confusion, somnolence, oliguria
Interferon-alpha-2b (Intron A)	20 million international units/m ² intravenously 5 days a week for 4 weeks, then 10 million international units/m ² subcutaneously three times a week for 48 weeks	Acute: flu-like syndrome, nausea, vomiting, diarrhea Delayed: myelosuppression, anorexia, alopecia, depression, elevated transaminases
Sipuleucel-T (Provenge)	One dose (minimum of 50 million autologous CD54 cells) intravenously every 2 weeks for three doses	Acute: infusion-related reaction, nausea, vomiting Delayed: fatigue, back pain, arthralgia

¹For altretamine, denileukin diftitox, ibritumomab, lomustine, megestrol, pralatrexate, romidepsin, and vismodegib see Table 39–11 in *CMDT Online* at www.accessmedicine.com.

GFR, glomerular filtration rate; LHRH, luteinizing hormone–releasing hormone; MAO, monoamine oxidase; MCV, mean corpuscular volume.

Table 39–12. Commonly used supportive care agents.¹

Agent	Indication	Usual Dose	Adverse Effects
Allopurinol (Xyloprim)	Prevent hyperuricemia from tumor lysis syndrome	600–800 mg/day orally	Acute: none Delayed: rash
Rasburicase (Elitek)	Prevent hyperuricemia from tumor lysis syndrome	3–6 mg intravenously once	Acute: hypersensitivity, nausea, vomiting, diarrhea, fever, headache Delayed: rash, peripheral edema
Mesna (Mesnex)	Prevent ifosfamide-induced hemorrhagic cystitis	20% of ifosfamide dose intravenously at 0, 4, and 8 hours; various doses	Acute: nausea, vomiting Delayed: fatigue
Leucovorin	Rescue after high-dose methotrexate; in combination with fluorouracil for colon cancer	10 mg/m ² intravenously or orally every 6 hours; 20 mg/m ² or 200–500 mg/m ² intravenously before fluorouracil; various doses	Acute: nausea, vomiting, diarrhea Delayed: stomatitis, fatigue
Levoleucovorin (Fusilev)	Rescue after high-dose methotrexate; in combination with fluorouracil for colon cancer	7.5 mg intravenously every 6 hours for 10 doses; 100 mg/m ² intravenously before fluorouracil	Acute: nausea, vomiting Delayed: stomatitis, diarrhea
Dexrazoxane (Zinecard)	Prevent cardiomyopathy secondary to doxorubicin; anthracycline-induced injection site extravasation	10 times the doxorubicin dose intravenously before doxorubicin; 1000 mg/m ² intravenously on days 1 and 2, then 500 mg/m ² intravenously on day 3	Acute: nausea Delayed: myelosuppression, elevated transaminases
Palifermin (Kepivance)	Prevent mucositis following chemotherapy	60 mcg/kg/day intravenously for 3 days before and 3 days after chemotherapy	Acute: none Delayed: rash, fever, elevated serum amylase, erythema, edema
Pilocarpine (Salagen)	Radiation-induced xerostomia	5–10 mg orally three times a day	Acute: flushing, sweating, nausea, dizziness Delayed: increased urinary frequency, rhinitis
Radium (Ra)-223 dichloride (Xofigo)	Symptomatic bone metastases	50 kilobecquerel/kg (1.35 microCurie/kg) intravenously every 4 weeks for 6 cycles	Acute: nausea, vomiting, diarrhea, peripheral edema Delayed: myelosuppression
Bone-Modifying Agents			
Denosumab (Xgeva)	Osteolytic bone metastasis	120 mg subcutaneously every 4 weeks	Acute: nausea Delayed: hypocalcemia, hypophosphatemia, fatigue, osteonecrosis of the jaw
Pamidronate (Aredia)	Osteolytic bone metastasis, hypercalcemia of malignancy	90 mg intravenously every 3–4 weeks; 60–90 mg intravenously, may repeat after 7 days	Acute: nausea Delayed: dyspnea, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity, hypocalcemia
Zoledronic acid (Zometa)	Osteolytic bone metastasis, hypercalcemia of malignancy	4 mg intravenously every 3–4 weeks; 4 mg intravenously once, may repeat after 7 days	
Growth Factors			
Epoetin alfa (Epogen, Procrit)	Chemotherapy-induced anemia	40,000 units subcutaneously once weekly; 150 units/kg subcutaneously three times a week	Acute: injection site reaction Delayed: hypertension, thromboembolic events, increased risk of tumor progression or recurrence
Darbepoetin alfa (Aranesp)	Chemotherapy-induced anemia	2.25 mcg/kg subcutaneously weekly; 500 mcg subcutaneously every 3 weeks	

(continued)

Table 39–12. Commonly used supportive care agents.¹ (continued)

Agent	Indication	Usual Dose	Adverse Effects
Filgrastim (Neupogen) Filgrastim-sndz (Zarxio)	Febrile neutropenia prophylaxis, mobilization of peripheral stem cells	5–10 mcg/kg/day subcutaneously or intravenously once daily, treat past nadir	Acute: injection site reaction Delayed: bone pain
Pegfilgrastim (Neulasta)	Febrile neutropenia prophylaxis	6 mg subcutaneously once per chemotherapy cycle	
Sargramostim (Leukine)	Myeloid reconstitution following bone marrow transplant, mobilization of peripheral blood stem cells	250 mcg/m ² intravenously daily until the absolute neutrophil count is > 1500 cells/mcL for 3 consecutive days	Acute: fever, rash, pruritus, nausea, vomiting, diarrhea, injection site reaction, dyspnea Delayed: asthenia, bone pain, mucositis, edema, arrhythmia
Tbo-filgrastim (Neuroval)	Severe chemotherapy-induced neutropenia	5 mcg/kg subcutaneously once daily until neutrophil recovery	Acute: none Delayed: bone pain, leukocytosis

¹For amifostine, samarium, and strontium, see Table 39–12 in CMDT Online at www.accessmedicine.com.

retention, heart failure, and arrhythmias (see Table 39–12). Thrombopoietin, the protein that stimulates megakaryopoiesis in vivo, was isolated in 1994. Despite much work attempting to produce a clinically effective thrombopoietin agent for therapeutic use, no such drug is commercially available for this indication. Two drugs that activate the thrombopoietin receptor and are approved for use in idiopathic thrombocytopenia, romiplostim and eltrombopag, have not been shown to be beneficial in patients receiving chemotherapy.

2. Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced nausea and vomiting is mediated in part by the stimulation of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 (5HT₃) and neurokinin subtype 1 (NK₁). Anticipatory nausea and vomiting may even occur before the administration of chemotherapy. Chemotherapy-induced nausea and vomiting can be acute, occurring within minutes to hours of chemotherapy administration, or delayed until the second day and lasting up to 7 days. Chemotherapy drugs or drug regimens are classified into high, moderate, low, and minimal likelihoods of causing

emesis (90%, 30–90%, 10–30%, less than 10%, respectively). Highly emetogenic chemotherapy drugs include cisplatin, carmustine, cyclophosphamide (at doses over 1.5 g/m²), dacarbazine, mechlorethamine, and streptozocin, or a combination of regularly dosed cyclophosphamide and anthracyclines. Chemotherapy drugs that are moderately emetogenic include azacitadine, bendamustine, carboplatin, crizotinib, cyclophosphamide, cytarabine, daunomycin, doxorubicin, epirubicin, idarubicin, ifosfamide, irinotecan, mitotane, oxaliplatin, temozolomide, and vismodegib. Drugs with low emetic potential include bortezomib, brentuximab, capecitabine, cabozantinib, dabrafenib, dasatinib, docetaxel, erlotinib, etoposide, fludarabine, fluorouracil, gemcitabine, hydroxyurea, lenalidomide, methotrexate, mitomycin, mitoxantrone, omacetaxine, paclitaxel, pemetrexed, pomalidomide, ponatinib, temsirolimus, trametinib, and topotecan. Drugs with minimal risk of emesis include bevacizumab, bleomycin, cetuximab, cladribine, decitabine, fludarabine, panitumumab, rituximab, temsirolimus, trastuzumab, vinblastine, vincristine, and vinorelbine.

By understanding the physiology of chemotherapy-induced nausea and vomiting, major advances have occurred with the development of highly effective antiemetic drugs. Antagonists to the 5HT₃-receptor include ondansetron, granisetron, dolasetron, and palonosetron, as well as tropisetron and ramosetron (neither yet available in the United States). Ondansetron can be given either intravenously (8 mg or 0.15 mg/kg) or orally (24 mg for highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given 1.8 mg/kg or a fixed dose of 100 mg intravenously or 100 mg can be given orally. Palonosetron, a long-acting 5HT₃ with high affinity for the 5HT₃-receptor given at a dose of 0.25 mg intravenously, is effective for not only acute but also delayed emesis. Where available, tropisetron is given at a dose of 5 mg either orally or

Table 39–13. A common scheme for dose modification of cancer chemotherapeutic agents.

Granulocyte Count (cells/mcL)	Platelet Count (/mcL)	Suggested Drug Dosage (% of Full Dose)
> 2000	> 100,000	100%
1000–2000	75,000–100,000	50%
< 2000	< 50,000	0%

intravenously. Ramosetron is given as a one time 300 mcg dose intravenously. The efficacy of the 5HT₃-blockers is improved by adding 6–10 mg of either oral or intravenous dexamethasone. As a class of drugs, the 5HT₃-receptor antagonists have the potential to cause electrocardiogram changes including QT prolongation. Before using these agents, any preexisting hypokalemia or hypomagnesemia should be corrected. In addition, clinicians should be cautious when using these agents in elderly patients, patients with preexisting bradyarrhythmias or heart failure, and patients taking medications known to prolong the QT interval.

Aprepitant, fosaprepitant, and rolapitant are antagonists to the NK₁ receptor. Aprepitant is given as a 125-mg oral dose followed by 80 mg on the second and third day with a 5HT₃-receptor antagonist (such as ondansetron or granisetron), the immediate and delayed protective effect for highly emetogenic chemotherapy is increased. Fosaprepitant, the intravenous formulation of aprepitant, can be given at a dose of 115 mg if followed by 2 days of aprepitant or at a dose of 150 mg if given alone. Rolapitant, a potent selective NK₁ receptor antagonist, has a 7-day half-life; it is given as a one-time oral dose of 180 mg 1–2 hours before the start of chemotherapy.

Standard therapy for highly emetogenic chemotherapy includes a 5HT₃-antagonist given on the first day, and both dexamethasone and a neurokinin-1 receptor antagonist (aprepitant, fosaprepitant, or rolapitant) given on the first day as well as (if aprepitant) on the second and third days. Moderately emetogenic chemotherapy regimens are best managed with a two-drug regimen of a 5HT₃-antagonist and dexamethasone. Palonosetron is now a preferred 5HT₃-blocker due to its greater affinity for the 5HT₃-receptor and its longer half-life. For low emetogenic chemotherapy drugs, a single agent such as a 5HT₃-antagonist or prochlorperazine or dexamethasone should be given. A 25-mg suppository form of prochlorperazine may be used for patients unable to swallow oral medications. Another medication that may be helpful is lorazepam, 0.5–1.0 mg given orally every 6–8 hours.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild mouth soreness to frank ulcerations. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from

mild symptoms of loose stools to life-threatening diarrhea leading to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-fluorouracil, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for oral mucositis include a pre-treatment dental examination, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical antifungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Other strategies for prevention of oral mucositis include the use of the recombinant keratinocyte growth factor inhibitor, palifermin. Practice guidelines recommend prophylaxis with intravenous palifermin (60 mcg/kg/day) for patients receiving high-dose chemotherapy in order to reduce the incidence and duration of mucositis (Table 39–12).

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors (sorafenib, sunitinib, regorafenib, imatinib, dasatinib, nilotinib) and epithelial growth factor inhibitors (cetuximab, panitumumab, and erlotinib). Mild to moderate diarrhea can be managed with oral antidiarrheal medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, the diarrhea will be overwhelming causing dehydration, electrolyte imbalances, and acute kidney injury. These patients require inpatient management with aggressive intravenous hydration and replacement of electrolytes. Octreotide, 100–150 mcg subcutaneously three times daily, can be used for severe diarrhea.

4. Skin Toxicity

Dermatologic complications from cancer chemotherapy can include hyperpigmentation (liposomal doxorubicin, busulfan, hydroxyurea), alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema (hand-foot syndrome), most commonly associated with administration of fluorouracil, capecitabine, and liposomal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering, desquamation, and ulceration in its worst forms. Strategies for prevention of acral erythema include oral pyridoxine, 200 mg daily, and applying cold packs to the extremities during chemotherapy administration. Agents targeting the epidermal growth factor pathway can cause an acne-like rash; the development of the rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase

pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

5. Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs are summarized in Tables 39–11 and 39–12; however, several of these warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Metabolic products of cyclophosphamide that retain cytotoxic activity are excreted into the urine. Some patients appear to metabolize more of the drug to these active excretory products; if their urine is concentrated, severe bladder damage may result. Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency of urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented (Table 39–12). Mesna can also be used for patients taking cyclophosphamide in whom cystitis develops.

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these types. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop after vincristine therapy. This may be a form of trigeminal or glossopharyngeal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (paclitaxel and docetaxel) and agents to treat myeloma (thalidomide and bortezomib) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually, though, the development of moderate to severe paresthesias or motor impairment results in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on stool softeners and mild cathartics when therapy is begun; otherwise, severe impaction may result from an atonic bowel.

More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. Methotrexate is almost entirely eliminated by the kidney. Methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m² or more given over 4–36 hours, would be lethal without “rescue” of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (less than 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. The dose used in intrathecal therapy is 12 mg. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot clear the drug normally or with patients who have effusions in whom the drug distributes itself in effusions and leaks out continuously, exposing normal tissue to the drug. In patients with kidney disease or an effusion, prolonged rescue with leucovorin is necessary.

Vigorous hydration and bicarbonate loading can help prevent crystallization of high-dose methotrexate in the renal tubular epithelium and consequent nephrotoxicity. Daily monitoring of the serum creatinine is mandatory. Drugs impairing methotrexate excretion, such as aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa, should be stopped if possible before methotrexate administration.

D. Anthracycline Cardiotoxicity

The anthracycline drugs, including doxorubicin, daunomycin, idarubicin, and epirubicin, are associated with cardiotoxicity. They can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because it is the most commonly

administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated radionuclide cardiac scan (MUGA) to calculate the left ventricular-ejection fraction (LVEF). If the LVEF is greater than 50%, anthracyclines can be administered; if the LVEF is less than 30%, these drugs should not be given. For patients with intermediate cardiac function, anthracyclines should be cautiously given, if necessary, at lower doses with LVEF monitoring between doses. Changes in cardiac dynamics occur in most patients by the time they have received 300 mg/m² of doxorubicin. In general, patients should not receive a total dose of doxorubicin in excess of 450 mg/m²; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at dosage levels above 550 mg/m². At lower doses (eg, 350 mg/m²), the symptoms and signs of cardiac failure generally respond well to medical therapy and discontinuation of the anthracycline. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes in other cancers as a substitute for the conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating testicular, bladder, head and neck, lung, and ovarian cancers. With cisplatin, the serious side effects of nephrotoxicity and neurotoxicity must be anticipated and aggressively managed. Patients must be vigorously hydrated prior to, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low serum magnesium, potassium, and sodium levels can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m². Ototoxicity is a potentially serious

manifestation of neurotoxicity and can progress to deafness. Amifostine, given intravenously at a dose of 910 mg/m² over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not appear to compromise the antineoplastic effect of cisplatin. The second-generation platinum analog, carboplatin, is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

PROGNOSIS

Patients receiving chemotherapy for curative intent will often tolerate side effects with the knowledge that the treatment may result in eradication of their cancer. Patients receiving therapy for palliative intent often have their therapy tailored to improve quality of life while minimizing major side effects. A valuable sign of clinical improvement is the general well-being of the patient. Although general well-being is a combination of subjective (possibly partly a placebo effect) and objective factors, it nonetheless serves as a sign of clinical improvement along with improved appetite and weight gain and increased “performance status” (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5).

40

Inherited Disorders

Reed E. Pyeritz, MD, PhD

ACUTE INTERMITTENT PORPHYRIA

ESSENTIALS OF DIAGNOSIS

- ▶ Unexplained abdominal crisis, generally in young women.
- ▶ Acute peripheral or central nervous system dysfunction; recurrent psychiatric illnesses.
- ▶ Hyponatremia.
- ▶ Porphobilinogen in the urine during an attack.

▶ General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant, though it remains clinically silent in most patients who carry a mutation in *HMBS*. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of hydroxymethylbilane synthase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40-1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

▶ Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute

abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, altered consciousness, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have different mutations in *HMBS* causing AIP. Mutations can be detected in 90% of patients and used for presymptomatic and prenatal diagnosis.

▶ Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40-1 and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

▶ Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose in saline

Table 40–1. Some of the “unsafe” and “probably safe” drugs used in the treatment of acute porphyrias.

Unsafe	Probably Safe
Alcohol	Acetaminophen
Alkylating agents	Beta-adrenergic blockers
Barbiturates	Amitriptyline
Carbamazepine	Aspirin
Chloroquine	Atropine
Chlorpropamide	Chloral hydrate
Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam
Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscyne
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyl dopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spirolactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouราซิล
Theophylline	
Tolazamide	
Tolbutamide	
Valproic acid	

and hematin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

▶ When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

▶ When to Admit

The patient should be hospitalized when he or she has an acute attack accompanied by mental status changes, seizure, or hyponatremia.

ALKAPTONURIA

ESSENTIALS OF DIAGNOSIS

- ▶ Ochronosis (gray-black discoloration of connective tissue, including the sclerae, ears, and cartilage).
- ▶ Characteristic radiologic dense intervertebral disks in the spine.
- ▶ Arthropathy.
- ▶ Urine darkens on standing.

▶ Clinical Findings

A. Symptoms and Signs

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient’s life. A dark oxidation product accumulates slowly in cartilage and other connective tissues throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called **ochronosis**. In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Kidney, biliary, and salivary stones can occur. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. Although the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria. The disorder is uncommon in most populations (less than 1 per 100,000) but much more common in Slovakia and the Dominican Republic.

B. Laboratory Findings

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy

if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene (*HGD*) is available but not necessary for diagnosis.

▶ Prevention

Carrier screening and prenatal diagnosis are possible by testing for genetic mutations.

▶ Treatment

Treatment of the arthritis is similar to that for other arthropathies and joint replacement can be effective. Although, in theory, rigid dietary restriction or medications might reduce accumulation of the pigment, this has not proved to be of practical benefit. Since the aortic valve becomes involved by the fifth decade, screening echocardiography of affected adults is indicated. Nitisinone, a drug that inhibits the formation of homogentisic acid, reduces urinary homogentisic acid and shows clinical promise.

Ranganath LR et al. Suitability of nitisinone in alkaptonuria 1 (SONIA 1): an international, multicenter, randomized, open-label, no-treatment controlled, parallel-group, dose-response study to investigate the effect of once daily nitisinone on 24-h urinary homogentisic acid excretion in patients with alkaptonuria after 4 weeks of treatment. *Ann Rheum Dis*. 2016 Feb;75(2):362–7. [PMID: 25475116]

DOWN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- ▶ Intellectual disability.
- ▶ Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- ▶ Dementia of the Alzheimer type in early-to-mid adulthood.
- ▶ Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

▶ General Considerations

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700 but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for alpha-fetoprotein and other biomarkers (“multiple marker screening”) and by detecting increased nuchal thickness and underdevelopment of the nasal bone on ultrasonography. Prenatal

diagnosis with high sensitivity and specificity can be achieved by assaying fetal DNA that is circulating in maternal blood. The chance of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. Because there are so many distinct conditions, though, the chance of fathering an offspring with any given one is extremely small.

▶ Clinical Findings

A. Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, frequent infections due to immune deficiency, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

B. Laboratory Findings

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent’s relatives.

▶ Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. As yet, no medical treatment has been proven to affect the neurodevelopmental or the neurodegenerative aspects. Based on the glutamatergic hypothesis for Alzheimer disease, studies have been initiated examining the potential benefit of the *N*-methyl-D-aspartate receptor antagonist memantine.

▶ When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

▶ When to Admit

An affected young patient should be hospitalized when he or she has failure to thrive, regurgitation, breathlessness, or easy bruising.

FRAGILE X MENTAL RETARDATION

ESSENTIALS OF DIAGNOSIS

- ▶ Expanded trinucleotide repeat (more than 200) in the *FMR1* gene.
- ▶ Mental retardation and autism in males; large testes after puberty.
- ▶ Learning disabilities or mental retardation in females; premature ovarian failure.
- ▶ Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat (55–200) expansion (premutation carriers).

▶ Clinical Findings

A. Symptoms and Signs

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 4000 males is affected. The central nervous system phenotype includes autism spectrum, impulsivity and aggressiveness, and repetitive behaviors. The condition also affects intellectual function in females, although less severely and about 50% less frequently than in males. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties, anxiety, sensory issues, or frank

retardation. Affected males show macro-orchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive abnormalities. Male and female premutation carriers are at risk for mood and anxiety disorders and the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter may be evident on MRI before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population (1/130–1/600), older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

B. Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

▶ Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation. Newborn screening based on hypermethylation of the *FMR1* gene is being considered as a means of early detection and intervention.

▶ Treatment

Several treatments that address the imbalances in neurotransmission have been developed based on the mouse model and are in clinical trials. Valproic acid may reduce symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

▶ When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

GAUCHER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Deficiency of beta-glucocerebrosidase.
- ▶ Anemia and thrombocytopenia; hypersplenism.
- ▶ Pathologic fractures.

Clinical Findings

A. Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of beta-glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed “crises”) are reminiscent of those in sickle cell disease. A hip fracture in a patient of any age with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease. Peripheral neuropathy may develop in patients.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

B. Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity

in leukocytes. Hundreds of mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

Prevention

Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible. Because of an increased risk of malignancy, especially multiple myeloma and other hematologic cancers, regular screening of adults with Gaucher disease is warranted.

Treatment

A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis reduces total body stores of glycolipid and improves orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed \$300,000 per year for a severely affected adult patient. More recently, an oral therapy that reduces substrate has been approved, but the annual cost is about the same. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. In adults with thrombocytopenia due to splenic sequestration, enzyme replacement often obviates the need for splenectomy. Alternative or complementary therapies, including methods to reduce substrate and to provide a chaperone for a defective enzyme, are being developed. One approved medication, miglustat, does reduce the production of glucocerebroside in some patients, but can be poorly tolerated because of adverse effects.

DISORDERS OF HOMOCYSTEINE METABOLISM

ESSENTIALS OF DIAGNOSIS

- ▶ For homocystinuria, dislocated ocular lenses.
- ▶ Elevated homocysteine in the urine or plasma.

General Considerations

Considerable evidence has accumulated to support the observation that patients with clinical and angiographic evidence of coronary artery disease tend to have higher levels of plasma homocysteine than persons without coronary artery disease. The relationship has been extended to cerebrovascular and peripheral vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine beta-synthase deficiency (see below), there is little supporting evidence. Rather, an important factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B₆) and vitamin B₁₂ are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copies of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B₆ and B₁₂. In the United States, cereal grains are fortified with folic acid. However, therapy with B vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for cardiovascular disease has received modest direct support in clinical trials. Hyperhomocysteinemia occurs with end-stage chronic kidney disease.

Clinical Findings

A. Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine beta-synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Thus, the diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors. Bone

mineral density is reduced in untreated patients. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. In addition, homozygotes for a common mutant allele, p.I278T, show marked clinical variability, with some unaffected as adults.

B. Laboratory Findings

Although many mutations have been identified in the cystathionine beta-synthase gene (*CBS*), amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

Prevention

About 50% of patients have a form of cystathionine beta-synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine (50–500 mg/d) and folate (5–10 mg/d). For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine nonresponders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

KLINFELTER SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Males with hypergonadotropic hypogonadism and small testes.
- ▶ 47,XXY karyotype.

Clinical Findings

A. Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, sparse body hair, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The incidence is 1 in 660 newborn males, but the diagnosis is often not made until a man is evaluated for inability to conceive. Intellectual disability is somewhat more common than in the general population. Many men with Klinefelter syndrome have language-based learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of osteoporosis, breast cancer and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

B. Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY, but other sex chromosome anomalies cause variations of Klinefelter syndrome.

Prevention

Screening for cancer (especially of the breast), deep venous thrombosis, and glucose intolerance are indicated.

Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. However, men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore genomic analysis of a blastocyst should be considered before implantation.

MARFAN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- ▶ Ectopia lentis and myopia.
- ▶ Aortic root dilation and dissection; mitral valve prolapse.
- ▶ Mutation in *FBN1*, the gene encoding fibrillin-1.

General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often with elongated chordae tendineae, which on occasion may rupture.

Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine beta-synthase deficiency also have dislocated lenses, tall, disproportionate stature, and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

B. Laboratory Findings

Mutations in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the *FBN1* mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF)-beta activity. Mutations in either of two receptors for TGF-beta (*TGFBR1* and *TGFBR2*) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance. Mutations in more than one dozen other genes can predispose adults to thoracic aortic aneurysm and dissection.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in *FBN1* has been found.

Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic root diameter and mitral valve function. Long-term beta-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily) retards the rate of aortic dilation. A dozen clinical trials comparing the effectiveness of atenolol and losartan or other angiotensin receptor blockers (ARBs), drugs that reduce activity of TGF-beta, are underway or recently completed. Several trials suggested a benefit of an ARB over beta-blockade, but the largest found no difference in benefit when young subjects were treated with optimally titrated doses of atenolol or losartan. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: less than 40 mm) prolongs life. A procedure to resuspend the patient's native aortic valve and replace just the aneurysmal sinuses of Valsalva and ascending aorta avoids the need for lifelong anticoagulation. Women with Marfan syndrome are at heightened risk for aortic dissection in the peripartum and postpartum periods. Having an aortic root dimension greater than 40 mm should prompt consideration for prophylactic, valve-sparing aortic repair before undertaking a pregnancy.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic

dissection or heart failure secondary to aortic or mitral regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic and mitral valve surgery, life expectancy has increased by several decades.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent epistaxis.
- ▶ Mucocutaneous telangiectases.
- ▶ Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

A. Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed “Osler-Weber-Rendu syndrome,” is an autosomal dominant disorder of development of the vasculature.

Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

B. Laboratory Findings

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified, and molecular analysis to identify them is available; these mutations in *ENG*, *ALK1*, and *SMAD4* account for about 87% of families with HHT. When the familial mutation is known, molecular testing is far more cost effective than repeated clinical screening of relatives who are at risk.

▶ Prevention

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis (see Table 33–6). All intravenous lines (except those for transfusion of red blood cells and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

▶ Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when “bubbles” appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1–2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 6 months and 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years. Several recent studies suggest that treatment with anti-estrogenic agents (eg, tamoxifen), thalidomide or its relatives, or anti-vascular endothelial growth factor agents (eg, bevacizumab) can reduce epistaxis and gastrointestinal bleeding and improve hepatic shunting. Randomized, controlled clinical trials of these various therapies are ongoing.

Sports Medicine & Outpatient Orthopedics

Anthony Luke, MD, MPH
C. Benjamin Ma, MD

41

Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as traumatic (ie, injury-related) or atraumatic (ie, degenerative or overuse syndromes) as well as acute or chronic. The mechanism of injury is usually the most helpful part of the history in determining the diagnosis.

SHOULDER

1. Subacromial Impingement Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Shoulder pain with overhead motion.
- ▶ Night pain with sleeping on shoulder.
- ▶ Pain with internal rotation.
- ▶ Numbness and pain radiation below the elbow are usually due to cervical spine disease.

▶ General Considerations

The subacromial impingement syndrome describes a collection of diagnoses that cause mechanical inflammation in the subacromial space. Causes of impingement syndrome can be related to muscle strength imbalances, poor scapula control, rotator cuff tears, and subacromial bone spurs.

The chief complaints for shoulder problems are usually pain, instability, weakness, or loss of range of motion. With any shoulder problem, it is important to establish the patient's hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint. For example, baseball pitchers with impingement syndrome may complain of pain while throwing. Alternatively, elders with even full thickness rotator cuff tears may not complain of any pain because the demands on the joint are low.

▶ Clinical Findings

A. Symptoms and Signs

Shoulder problems classically present with one or more of the following: pain with overhead activities, nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). On inspection, there may be appreciable atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or “dyskinesis.” The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, the patient can have tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion (Table 41–1) but should have preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 41–1).

B. Imaging

The following four radiographic views should be ordered to evaluate subacromial impingement syndrome: the anteroposterior (AP) scapula, the AP acromioclavicular joint, the lateral scapula (scapular Y), and the axillary lateral. The AP scapula view can rule out glenohumeral joint arthritis. The AP acromioclavicular view evaluates the acromioclavicular joint for inferior spurs. The scapula Y view evaluates the acromial shape, and the axillary lateral view visualizes the glenohumeral joint as well and for the presence of os acromiale.

MRI of the shoulder may demonstrate full or partial thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized on ultrasound, although it is more difficult to identify partial tears from small full thickness than on MRI.

▶ Treatment

A. Conservative

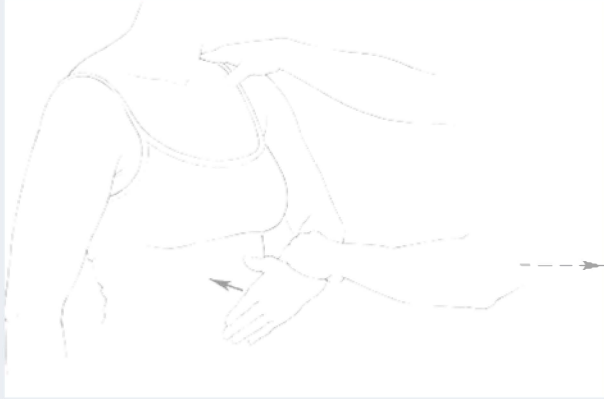

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity

Table 41-1. Shoulder examination.

Maneuver	Description
<p data-bbox="76 253 323 277">Rotator cuff strength testing</p> <p data-bbox="76 287 334 312">Supraspinatus (open can) test</p> 	<p data-bbox="810 287 1211 439">Perform resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees to test for supraspinatus tendon strength ("open can" test), or with shoulder abduction at 30 degrees and flexion to 30 degrees ("empty can" test).</p>
<p data-bbox="76 691 225 715">External rotation</p> 	<p data-bbox="810 691 1174 744">The patient resists by externally rotating the arms with elbows at his or her side.</p>
<p data-bbox="76 1235 326 1260">Internal rotation (lift off test)</p> 	<p data-bbox="810 1235 1211 1410">A positive "lift-off" test is the inability of the patient to hold his or her hand away from the body when reaching toward the small of the back. The clinician pushes the patient's hand toward the back while the patient resists. A positive lift-off indicates subscapularis tendon insufficiency.</p>

Maneuver	Description
<p data-bbox="156 253 444 276">Internal rotation (belly press test)</p> 	<p data-bbox="889 253 1292 376">A positive “belly-press” test is the inability to hold the elbow in front of the trunk while pressing down with the hand on the belly. A positive belly press test indicates subscapularis tendon insufficiency.</p>
Impingement tests	
<p data-bbox="156 748 362 771">Neer impingement sign</p> 	<p data-bbox="889 748 1292 872">Perform by having the clinician flex the shoulder maximally in an overhead position. The test is positive when pain is reproduced with full passive shoulder flexion. Sensitivity is 79%; specificity is 53%.</p>
<p data-bbox="156 1357 389 1380">Hawkins impingement sign</p> 	<p data-bbox="889 1357 1292 1557">Perform with the shoulder forward flexed 90 degrees and the elbow flexed at 90 degrees. The shoulder is then maximally internally rotated to impinge the greater tuberosity on the undersurface of the acromion. The test is considered positive when the patient’s pain is reproduced by this maneuver. Sensitivity is 79%; specificity is 59%.</p>

(continued)

Table 41–1. Shoulder examination. (continued)

Maneuver	Description
<p data-bbox="79 257 196 281">Stability tests</p> <p data-bbox="79 291 238 316">Apprehension test</p> 	<p data-bbox="810 291 1222 468">With persistent anterior instability or a recent dislocation, the patient feels pain or guards when the shoulder is abducted and externally rotated at 90 degrees. With posterior instability, the patient is apprehensive with the shoulder forward flexed and internally rotated to 90 degrees with a posteriorly directed force.</p>
<p data-bbox="79 609 238 634">Load and shift test</p> 	<p data-bbox="810 609 1199 734">Perform to determine shoulder instability by manually translating the humeral head anteriorly and posteriorly in relation to the glenoid. However, this test can be difficult to perform when the patient is not relaxed.</p>
<p data-bbox="79 1062 182 1087">O'Brien test</p> 	<p data-bbox="810 1062 1222 1490">Performed to rule out labral cartilage tears that often occur following a shoulder subluxation or dislocation. The test involves flexing the patient's arm to 90 degrees, fully internally rotating the arm so the thumb is facing down (palm down) and adducting the arm to 10 degrees. Once positioned properly, the clinician applies downward force and asks the patient to resist. The test is then repeated in the same position except that the patient has his arm fully supinated (palm up). A positive O'Brien test for labral tear is pain deep in the shoulder with palm down more than the palm up. The O'Brien test can also be used to identify AC joint pathology. The patient would typically complain equally of pain directly over the AC joint with the palm down or up.</p>

modification, and physical therapy exercises. Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, which may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong evidence supporting the effectiveness of ice and NSAIDs as a prolonged therapy. In a Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short-term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears.

▶ When to Refer

- Failure of conservative treatment over 3 months.
- Young and active patients with impingement due to full thickness rotator cuff tears.

Hermans J et al. Does this patient with shoulder pain have rotator cuff disease? The Rational Clinical Examination systematic review. JAMA. 2013 Aug 28;310(8):837-47. [PMID: 23982370]

2. Rotator Cuff Tears

- ▶ A common cause of shoulder impingement syndrome after age 40.
- ▶ Difficulty lifting the arm with limited active range of motion.
- ▶ Weakness with resisted strength testing suggests full thickness tears.

▶ General Considerations

Rotator cuff tears can be caused by acute injuries related to falls on an outstretched arm or to pulling on the shoulder. It can also be related to chronic repetitive injuries with overhead movement and lifting. **Partial rotator cuff tears are one of the most common reasons for impingement syndrome.** Full thickness rotator cuff tears are usually more symptomatic and may require surgical treatment. The most commonly torn tendon is the supraspinatus.

▶ Clinical Findings

A. Symptoms and Signs

Most patients complain of weakness or pain with overhead movement. Night pain is also a common complaint. The

clinical findings with rotator cuff tears include those of the impingement syndrome except that with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Supraspinatus tendon strength is tested with resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees (“open can” test) (Table 41-1). Infraspinatus/teres minor strength is tested with resisted shoulder external rotation with shoulder at 0 degrees abduction, elbow by side (Table 41-1). Subscapularis strength is tested with the “lift-off” or “belly-press” tests (Table 41-1). The affected patient usually also has positive Neer and Hawkins impingement tests.

B. Imaging

Recommended radiographs are very similar to impingement syndrome: AP scapula (glenohumeral), axillary lateral, supraspinatus outlet, and AP acromioclavicular joint views. The AP scapula view is useful in visualizing rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder. Axillary lateral views show superior elevation of the humeral head in relation to the center of the glenoid. Supraspinatus outlet views allow evaluation of the shape of the acromion. High-grade acromial spurs are associated with a higher incidence of rotator cuff tears. The AP acromioclavicular joint view evaluates for the presence of acromioclavicular joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff injuries.

MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (less than 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

▶ Treatment

Partial rotator cuff tears may heal with scarring. Most partial rotator cuff tears can be treated with physical therapy and scapular and rotator cuff muscle strengthening. However, research suggests that 40% of the partial thickness tears progress to full thickness tears in 2 years. Physical therapy can strengthen the remaining muscles to compensate for loss of strength and can have high rate of success for chronic tears. Physical therapy is also an option for older sedentary patients. On the contrary, full-thickness rotator cuff tears do not heal well and also have a tendency to increase in size with time. Forty-nine percent of the full thickness tears get bigger on an average of 2.8 years. When tears get larger, they are also associated with worsening pain. Fatty infiltration progresses in full thickness rotator cuff tears and it is a negative prognostic factor for successful surgical treatment. Fatty infiltration is an irreversible process so operative interventions are usually performed when the degree of infiltration is low. **Most young active patients with acute, full-thickness tears should be treated with operative fixation.** Full-thickness subscapularis tendon tears should undergo surgical repair as untreated tears usually lead to premature osteoarthritis (OA) of the shoulder.

▶ When to Refer

- Young and active patients with full thickness rotator cuff tears.
- Partial tears with greater than 50% involvement and with significant pain.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full thickness subscapularis tears.

3. Shoulder Dislocation & Instability

ESSENTIALS OF DIAGNOSIS

- ▶ Most dislocations (95%) are in the anterior direction.
- ▶ Pain and apprehension with an unstable shoulder that is abducted and externally rotated.
- ▶ Acute shoulder dislocations should be reduced as quickly as possible, using manual relocation techniques if necessary.

▶ General Considerations

The shoulder is a ball and socket joint, similar to the hip. However, the bony contours of the shoulder bones are much different than the hip. Overall, the joint has much less stability than the hip, allowing greater movement and action. Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. If patients have poor scapular control or weak rotator cuff tendons or tears, their shoulders are more likely to have instability. Ninety-five percent of the shoulder dislocations/instability occur in the anterior direction. Dislocations usually are caused by a fall on an outstretched and abducted arm. Patients complain of pain and feeling of instability when the arm is in the abducted and externally rotated position. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to instability. The rate of repeated dislocation is directly related to the patient's age: patients age 21 years or younger have a 70–90% risk of redislocation, whereas patients age 40 years or older have a much lower rate (20–30%). Ninety percent of young active individuals who had traumatic shoulder

dislocation have labral injuries often described as Bankart lesions when the anterior inferior labrum is torn, which can lead to continued instability. Older patients (over age 55 years) are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in swimmers, gymnasts, and pitchers as well as other athletes involved in overhead and throwing sports.

▶ Clinical Findings

A. Symptoms and Signs

For acute traumatic dislocations, patients usually have an obvious deformity with the humeral head dislocated anteriorly. The patient holds the shoulder and arm in an externally rotated position. The patient complains of acute pain and deformity that are improved with manual relocation of the shoulder. Reductions are usually performed in the emergency department. Even after reduction, the patient will continue to have limited range of motion and pain for 4–6 weeks, especially following a first-time shoulder dislocation.

Patients with recurrent dislocations can have less pain with subsequent dislocations. Posterior dislocations can be easily missed because the patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. Patients complain of difficulty pushing open a door.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually complain of a “sliding” sensation during exercises or strenuous activities such as throwing. Such dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test (Table 41–1), the load and shift test (Table 41–1) and the O'Brien test (Table 41–1). Most patients with persistent shoulder instability have preserved range of motion.

B. Imaging

Radiographs for acute dislocations should include a standard trauma series of AP and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed easily with one AP view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a patient with a painful shoulder dislocation. For chronic injuries or symptomatic instability, these recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indented compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation). MRI is commonly used to show soft tissue injuries to the labrum and to

visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures. Three-dimensional CT scans are being used to determine the significance of bone loss.

► Treatment

For **acute dislocations**, the shoulder should be reduced as soon as possible. The Stimson procedure is the least traumatic method and is quite effective. The patient lies prone with the dislocated arm hanging off the examination table with a weight applied to the wrist to provide traction for 20–30 minutes. Afterward, gentle medial mobilization can be applied manually to assist the reduction. The shoulder can also be reduced with axial “traction” on the arm with “counter-traction” along the trunk. The patient should be sedated and relaxed. The shoulder can then be gently internally and externally rotated to guide it back into the socket.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. For patients with a traumatic incident and unilateral shoulder dislocation, a Bankart lesion is commonly present. The risk of recurrence is dependent on the age of first shoulder dislocation. Young patients (less than 27 years of age) can have recurrence up to 70% whereas patients older than 40 years old have recurrences as low as 10%. However, once the patient has a second dislocation, the recurrence rate is extremely high, up to 95%. Operative intervention is the only treatment that has been shown to decrease recurrence. Open and arthroscopic stabilization can have very similar outcomes.

The treatment of **atraumatic shoulder instability** is different than traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. Surgical reconstructions are less successful for atraumatic shoulder instability than for traumatic shoulder instability.

► When to Refer

- Patients who are at risk for second dislocation, such as young patients, certain job holders (eg, police officers, fire fighters, and rock climbers) to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to conservative approach or who have chronic instability.

Chahal J et al. Anatomic Bankart repair compared with nonoperative treatment and/or arthroscopic lavage for first-time traumatic shoulder dislocation. *Arthroscopy*. 2012 Apr; 28(4):565–75. [PMID: 22336435]

4. Adhesive Capsulitis (“Frozen Shoulder”)

ESSENTIALS OF DIAGNOSIS

- Very painful shoulder triggered by minimal or no trauma.
- Pain out of proportion to clinical findings during the inflammatory phase.
- Stiffness during the “freezing” phase and resolution during the “thawing” phase.

► General Considerations

Adhesive capsulitis (“frozen shoulder”) is seen commonly in patients 40 to 65 years old. It is more commonly seen in women than men, especially in perimenopausal women or in patients with endocrine disorders, such as diabetes mellitus or thyroid disease. Adhesive capsulitis is a self-limiting but very debilitating disease.

► Clinical Findings

A. Symptoms and Signs

Patients usually present with a painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk (Table 41–1). Strength is usually normal but it can appear diminished when the patient is in pain.

There are three phases: the inflammatory phase, the “freezing” phase, and the “thawing” phase. During the **inflammatory phase**, which usually lasts 4–6 months, patients complain of a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the **“freezing” phase**, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The **“thawing” phase** can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

B. Imaging

Standard AP, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic work-up.

► Treatment

Adhesive capsulitis is caused by acute inflammation of the capsule followed by scarring and remodeling. During the acute “freezing” phase, NSAIDs and physical therapy are recommended to maintain motion. There is also evidence of short-term benefit from intra-articular corticosteroid injection or oral prednisone. One study demonstrated

improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the “freezing” phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the “thawing” phase as it is during the “freezing” phase, and the shoulder symptoms usually resolve with time. Surgical treatments include manipulation under anesthesia and arthroscopic release.

▶ When to Refer

- When the patient does not respond after more than 6 months of conservative treatment.
- When there is no progress or worsening range of motion over 3 months.

Robinson CM et al. Frozen shoulder. *J Bone Joint Surg Br.* 2012 Jan;94(1):1–9. [PMID: 22219239]

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- ▶ Alarming signs for serious spinal disease include unexplained weight loss, failure to improve with treatment, severe pain for more than 6 weeks, and night or rest pain.
- ▶ The cauda equina syndrome often presents with bowel or bladder symptoms (or both) and is an emergency.

▶ General Considerations

Low back pain remains the most common cause of disability for patients under the age of 45 and is the second most common cause for primary care visits. The annual prevalence of low back pain is 15–45%, and the annual cost in the United States is over \$50 billion. Low back pain is the condition associated with the highest years lived with disability. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. The exact cause of the low back pain is often difficult to diagnose; its cause is often multifactorial, although there are usually degenerative changes in the lumbar spine.

Alarming symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for more than 6 weeks, and pain at night or rest. History of cancer and age older than 50 years are other risk factors for malignancy. Alarming symptoms for infection include fever, rest pain, recent infection (urinary tract infection, cellulitis, pneumonia), or history of immunocompromise or injection drug use. The **cauda equina**

syndrome is suggested by urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits. Risk factors for back pain due to vertebral fracture include use of corticosteroids, age over 70 years, history of osteoporosis, severe trauma, and presence of a contusion or abrasion. Back pain may also be the presenting symptom in other serious medical problems, including abdominal aortic aneurysm, peptic ulcer disease, kidney stones, or pancreatitis.

▶ Clinical Findings

A. Symptoms and Signs

The physical examination can be conducted with the patient in the standing, sitting, supine, and finally prone positions to avoid frequent repositioning of the patient. In the standing position, the patient's posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed while standing. The common directions include flexion, extension, rotation and lateral bending. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis.

With the patient sitting, motor strength, reflexes, and sensation can be tested (Table 41–2). The major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for approximately 5 seconds.

Table 41–2. Neurologic testing of lumbosacral nerve disorders.

Nerve Root	Motor	Reflex	Sensory Area
L1	Hip flexion	None	Groin
L2	Hip flexion	None	Thigh
L3	Extension of knee	Knee jerk	Knee
L4	Dorsiflexion of ankle	Knee jerk	Medial calf
L5	Dorsiflexion of first toe	Babinski reflex	First dorsal web space between first and second toes
S1	Plantar flexion of foot, knee flexors or hamstrings	Ankle jerk	Lateral foot
S2	Knee flexors or hamstrings	Knee flexor	Back of the thigh
S2–S4	External anal sphincter	Anal reflex, rectal tone	Perianal area

It is important to compare the strength bilaterally to detect subtle muscle weakness. Similarly, sensory testing to light touch can be checked in specific dermatomes for corresponding nerve root function. Knee (femoral nerve L2–4), ankle (deep peroneal nerve L4–L5), and Babinski (sciatic nerve L5–S1) reflexes can be checked with the patient sitting.

In the supine position, the hip should be evaluated for range of motion, particularly internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots.

Finally, in the prone position, the clinician can carefully palpate each vertebral level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering.

B. Imaging

In the absence of alarming “red flag” symptoms suggesting infection, malignancy, or cauda equina syndrome, most patients do not need diagnostic imaging, including radiographs, in the first 6 weeks. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 41–3. Most clinicians obtain radiographs for new back pain in patients older than 50 years. If done, radiographs of the lumbar spine should include AP and lateral views. Oblique views can be useful if the neuroforamina or bone lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms

Table 41–3. AHRQ criteria for lumbar radiographs in patients with acute low back pain.

Possible fracture

- Major trauma
- Minor trauma in patients > 50 years
- Long-term corticosteroid use
- Osteoporosis
- > 70 years

Possible tumor or infection

- > 50 years
- < 20 years
- History of cancer
- Constitutional symptoms
- Recent bacterial infection
- Injection drug use
- Immunosuppression
- Supine pain
- Nocturnal pain

AHRQ, Agency for Healthcare Research and Quality. Reproduced, with permission, from Suarez-Almazor et al. Use of lumbar radiographs for the early diagnosis of low back pain. Proposed guidelines would increase utilization. *JAMA*. 1997 Jun; 277:1782–6.

not responding to conservative treatment or in the presence of red flags of serious conditions.

C. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

► Treatment

A. Conservative

Nonpharmacologic treatments are key in the management of low back pain. Education alone improves patient satisfaction with recovery and recurrence. Patients require information and reassurance, especially when diagnostic procedures are not necessary. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening, weight loss, and smoking cessation.

Physical therapy exercise programs can be tailored to the patient's symptoms and pathology. Strengthening and stabilization exercises effectively reduce pain and functional limitation compared with usual care. Neither spinal manipulation nor traction have shown benefits for low back pain; however, the studies so far are low quality and limited by small sample sizes. Heat and cold treatments have not shown any long-term benefits but may be used for symptomatic treatment. The efficacy of transcutaneous electrical nerve stimulation (TENS), back braces, physical agents, and acupuncture is unproven. Improvements in posture, core stability strengthening, physical conditioning, and modifications of activities to decrease physical strain are keys for ongoing management.

NSAIDs are effective in the early treatment of low back pain (see Chapter 20). There is limited evidence that muscle relaxants provide short-term relief; since these medications have addictive potential, they should be used with care. Muscle relaxants are best used if there is true muscle spasm that is painful rather than simply a protective response. Opioids alleviate pain in the short term but have the usual side effects and concerns of long-term opioid use. Treatment of more chronic neuropathic pain with alpha-2-delta ligands (eg, gabapentin), serotonin-norepinephrine reuptake inhibitors (eg, duloxetine) or tricyclic antidepressants (eg, nortriptyline) may be helpful. Epidural injections may reduce pain in the short term, and appear to reduce the need for surgery in some patients within a 1-year period but not longer.

B. Surgical

Surgical indications for back surgery include cauda equina syndrome, ongoing morbidity with no response to more than 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and

symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important and the specific surgery recommended should have very clear indications. Patients should understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is relatively asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; deep venous thrombosis; and death.

▶ When to Refer

- Patients with the cauda equina syndrome.
- Patients with cancer, infection, fracture, or severe spinal deformity.
- Patients who have not responded to conservative treatment.

2. Spinal Stenosis

ESSENTIALS OF DIAGNOSIS

- ▶ Pain is usually worse with back extension and relieved by sitting.
- ▶ Occurs in older patients.
- ▶ May present with neurogenic claudication symptoms with walking.

▶ General Considerations

OA in the lumbar spine can cause narrowing of the spinal canal. A large disk herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in “claudication” symptoms with ambulation. The condition usually affects patients aged 50 years or older.

▶ Clinical Findings

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting (“neurogenic claudication”). On examination, patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating

down the legs. A thorough neurovascular examination is recommended (Table 41–2).

▶ Treatment

Exercises, usually flexion-based as demonstrated by a physical therapist, can help relieve symptoms. Physical therapy showed similar results as surgical decompression in a randomized trial, though there was a 57% crossover rate from physical therapy to surgery. Facet joint corticosteroid injections can also reduce pain symptoms. A 2014 randomized trial found a benefit overall from epidural injection at 6 weeks but did not find a difference when patients received injections of corticosteroids plus lidocaine compared to lidocaine alone. The extended benefit of epidural lidocaine injection alone is not well studied, so present practice most likely will continue to include corticosteroids. Epidural corticosteroid injections similarly showed only modest but significant improvement compared to gabapentin in patients with worse leg symptoms.

Surgical treatments for spinal stenosis include spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebra to eliminate motion and diminish pain from the arthritic joints). In an ongoing multicenter randomized trial, subgroups initially improved significantly more with surgery than with nonoperative treatment. Variables associated with greater treatment effects included lower baseline disability scores, not smoking, neuroforaminal stenosis, predominant leg pain rather than back pain, not lifting at work, and the presence of a neurologic deficit. However, long-term follow-up of the patients with symptomatic spinal stenosis who received surgery in the multicenter randomized trial showed less benefit of surgery between 4 and 8 years, suggesting that the advantage of surgery for spinal stenosis likely does diminish over time.

▶ When to Refer

- If a patient exhibits radicular or claudication symptoms for longer than 12 weeks.
- MRI or CT confirmation of significant, symptomatic spinal stenosis.

3. Lumbar Disk Herniation

ESSENTIALS OF DIAGNOSIS

- ▶ Pain with back flexion or prolonged sitting.
- ▶ Radicular pain into the leg due to compression of neural structures.
- ▶ Lower extremity numbness.
- ▶ Lower extremity weakness.

▶ General Considerations

Lumbar disk herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disk contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disk herniations usually occur from degenerative disk disease (desiccation of the annulus fibrosus) in patients between 30 and 50 years old. The L5–S1 disk is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency.

▶ Clinical Findings

A. Symptoms and Signs

Discogenic pain typically is localized in the low back at the level of the affected disk and is worse with activity. “Sciatica” causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disk herniation can cause numbness and weakness, including weakness with plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient complains of perianal numbness or bowel or bladder incontinence.

B. Imaging

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disk space narrowing, and OA changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned.

▶ Treatment

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs and other analgesics; and physical therapy, including core stabilization and McKenzie exercises. Following nonsurgical treatment for a lumbar disk for over 1 year, the incidence of low back

pain recurrence is at least 40% and is predicted by longer time to initial resolution of pain. In a randomized trial, oral prednisone caused a modest improvement in function at 3 weeks but there was no significant improvement in pain in patients with acute radiculopathy who were monitored for 1 year. The initial dose for oral prednisone is approximately 1 mg/kg once daily with tapering doses over 10–15 days. Analgesics for neuropathic pain, such as the calcium channel alpha-2-delta ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (see Chapter 5). Epidural and transforaminal corticosteroid injections can be beneficial. A systemic review demonstrated strong evidence that fluoroscopic-guided epidural injections gave short-term benefit (less than 6 months) in acute radicular pain for individuals. However, epidural injections have not shown any change in long-term surgery rates for disk herniations.

A large, ongoing trial has shown that patients who underwent surgery for a lumbar disk herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return to work status after 4-year follow-up. Patients with sequestered fragments, symptom duration greater than 6 months, higher levels of low back pain, or who were neither working nor disabled at baseline showed greater surgical treatment effects. Microdiscectomy is the standard method of treatment with a low rate of complications and satisfactory results over 90% in the largest series. Minimally invasive techniques include percutaneous endoscopic discectomy, which involves using an endoscope to remove fragments of disk herniation fragments (interlaminar or transforaminal approaches) under local anesthesia, although results are less successful than microdiscectomy. So far, disk replacement surgery has not shown benefits beyond generally accepted clinically important differences in short-term pain relief, disability, and quality of life compared with spine fusion surgery.

▶ When to Refer

- Cauda equina syndrome.
- Progressive worsening of neurologic symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

4. Neck Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Most chronic neck pain is caused by degenerative joint disease and responds to conservative treatment.
- ▶ Cervical radiculopathy symptoms can be referred to the shoulder, arm, or upper back.
- ▶ Whiplash is the most common type of traumatic injury to the neck.
- ▶ Poor posture is often a factor for persistent neck pain.

General Considerations

Most neck pain, especially in older patients, is due to mechanical degeneration involving the cervical disks, facet joints, and ligamentous structures and may occur in the setting of degenerative changes at other sites. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. **Posture is a very important factor, especially in younger patients.** Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. Whiplash occurs from rapid flexion and extension of the neck and affects 15–40% of people in motor vehicle accidents; chronic pain develops in 5–7%. Neck fractures are serious traumatic injuries acutely and can lead to OA in the long term. Ultimately, many degenerative conditions of the neck result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures.

Cervical radiculopathy can cause neurologic symptoms in the upper extremities usually involving the C5–C7 disks. Patients with neck pain may report associated headaches and shoulder pain. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain. Other causes of neck pain include rheumatoid arthritis, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and tropical spastic paresis from HTLV-1 infection can mimic myelopathy from cervical arthritis.

Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder

girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity.

The patient's posture should be assessed, checking for shoulder rolled forward or head forward posture as well as scoliosis in the thoracolumbar spine. Patients with discogenic neck pain often complain of pain with flexion, which causes cervical disks to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. Limitation of cervical movements is the most common objective finding.

A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C6], opponens strength (thumb to pinky) [C7], and finger abductors and adductors strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The **Spurling test** involves asking the patient to rotate and extend the neck to one side (Table 41–4). The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed.

Table 41–4. Spine: neck examination.

Maneuver	Description
Inspection	Check the patient's posture in the standing position. Assess for cervical hyperlordosis, head forward posture, kyphosis, scoliosis, torticollis.
Palpation	Include important landmarks: spinous process, facet joints, paracervical muscles (sternocleidomastoid, scalene muscles).
Range of motion testing	Check range of motion in the cervical spine, especially with flexion and extension. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions. Pain and radicular symptoms can be exacerbated by range of motion testing.
Neurologic examination	Check motor strength, reflexes and dermatomal sensation in the upper (and lower if necessary) extremities.
Spurling test	Involves asking the patient to rotate and extend the neck to one side. The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression.

B. Imaging

Radiographs of the cervical spine include the AP and lateral view of the cervical spine. The odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can provide further information about arthritis changes and assess the neural foramina for narrowing. Plain radiographs can be completely normal in patients who have suffered an acute cervical strain. Comparative reduction in height of the involved disk space and osteophytes are frequent findings when there are degenerative changes in the cervical spine. Loss of cervical lordosis is commonly seen but is nonspecific.

MRI is the best method to assess the cervical spine since the soft tissue structures (such as the disks, spinal cord, and nerve roots) can be evaluated. If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently. CT scanning is the most useful method if bony abnormalities, such as fractures, are suspected.

Treatment

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. More frequent observation of individuals in whom very severe symptoms are present early on after an injury is recommended because high pain-related disability is a predictor of poor outcome at 1 year even if individuals decline care. Ergonomics should be assessed at work and home. A course of neck stretching, strengthening and postural exercises in physical therapy have demonstrated benefit in relieving symptoms. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10/million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. NSAIDs are commonly used and opioids may be needed in cases of severe neck pain. Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short-term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course of oral prednisone (5–10 days) can be considered (starting at 1 mg/kg). Cervical foraminal or facet joint injections can also reduce symptoms. Cervical spine surgery does not have clear evidence of benefit over conservative treatment. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases but are still considered as treatments of last resort.

When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

UPPER EXTREMITY

1. Lateral & Medial Epicondylitis

ESSENTIALS OF DIAGNOSIS

- ▶ Tenderness over the lateral or medial epicondyle.
- ▶ Diagnosis of tendinopathy is confirmed by pain with resisted strength testing and passive stretching of the affected tendon and muscle unit.
- ▶ Physical therapy and activity modification are more successful than anti-inflammatory treatments.

General Considerations

Tendinopathy involving the wrist extensors, flexors, and pronators are very common complaints. The underlying mechanism is chronic repetitive overuse causing micro-trauma at the tendon insertion, although acute injuries can occur as well if the tendon is strained due to excessive loading. The traditional term “epicondylitis” is a misnomer because histologically tendinosis or degeneration in the tendon is seen rather than acute inflammation. Therefore, these entities should be referred to as “tendinopathy” or “tendinosis.” Lateral epicondylitis involves the wrist extensors, especially the extensor carpi radialis brevis. This is usually caused by lifting with the wrist and the elbow extended. Medial epicondylitis involves the wrist flexors and most commonly the pronator teres tendon. Ulnar neuropathy and cervical radiculopathy should be considered in the differential diagnosis.

Clinical Findings

A. Symptoms and Signs

For lateral epicondylitis, the patient describes pain with the arm and wrist extended. For example, common complaints include pain while shaking hands, lifting objects, using a computer mouse, or hitting a backhand in tennis (“tennis elbow”). Medial epicondylitis presents with pain during motions in which the arm is repetitively pronated or the wrist is flexed. This is also known as “golfer’s elbow” due to the motion of turning the hands over during the golf swing. On examination, tenderness directly over the

epicondyle is present, especially over the posterior aspect where the tendon insertion occurs. The proximal tendon and musculotendinous junction can also be sore. To confirm that the pain is due to tendinopathy, pain can be reproduced over the epicondyle with resisted wrist extension and third digit extension for lateral epicondylitis and resisted wrist pronation and wrist flexion for medial epicondylitis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy.

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

▶ Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain. The most important steps are to begin a good stretching program followed by strengthening exercises, particularly eccentric ones. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or longstanding symptoms, the mainstay of treatment is a course of physical therapy. A randomized trial showed no differences with platelet-rich plasma, corticosteroid, or saline (placebo) injections at 3 months. Corticosteroid injection had improvement at 1 month as well as evidence of decreased tendon thickness and Doppler changes. Treatments such as extracorporeal shock wave therapy and other injections have not shown clear long-term benefit. A systematic review found strong evidence that platelet-rich plasma injections showed no effects for lateral epicondylitis. Unfortunately, pooled data from randomized controlled trials assessing the nonsurgical treatments of lateral epicondylitis lack evidence of intermediate- to long-term clinical benefit compared with observation only or placebo.

▶ When to Refer

Patients not responding to 6 months of conservative treatment should be referred for surgical debridement or repair of the tendon.

2. Carpal Tunnel Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Pain, burning, and tingling in the distribution of the median nerve.
- ▶ Initially, most bothersome during sleep.
- ▶ Late weakness or atrophy, especially of the thenar eminence.
- ▶ Can be caused by repetitive activities using the wrist.
- ▶ Commonly seen during pregnancy and in patients with diabetes mellitus or rheumatoid arthritis.

▶ General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the overlying carpal ligament. The disorder may occur in fluid retention of pregnancy, in individuals with a history of repetitive use of the hands, or following injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified. Carpal tunnel syndrome can also be a feature of many systemic diseases, such as rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis), myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly, and hyperparathyroidism.

▶ Clinical Findings

A. Symptoms and Signs

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between

Table 41–5. Wrist examination.

Maneuver	Description
Inspection	Examine for the alignment of the wrist and fingers SEADS.
Palpation	Include important landmarks: scaphoid “snuff box,” distal radius, scapholunate ligament, hook of hamate, ulnar joint line, distal radioulnar joint.
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs) especially with flexion and extension of the wrist. Ulnar and radial deviation and circumduction of the wrist can be screened.
Neurovascular examination	Check motor strength and dermatomal sensation in the fingers in the radial (thumb), median (3rd finger) and ulnar distribution (5th finger). Check capillary refill to digits as well as radial pulse.
Tinel sign	Tingling or shock-like pain on volar wrist percussion. The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests.
Phalen sign	Pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds.
Carpel compression test	Performed by applying direct application of pressure over the carpal tunnel.

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. A Tinel or Phalen sign may be positive. A **Tinel sign** is tingling or shock-like pain on volar wrist percussion (Table 41–5). The **Phalen sign** is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds (Table 41–5). The **carpal compression test**, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests (Table 41–5). Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens.

B. Imaging

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but estimated between 54% and 98%.

C. Special Tests

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which can occur in severe cases.

► Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it should be treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities. The affected wrist can be splinted in the neutral position for up to 3 months, but a series of Cochrane reviews show limited evidence for splinting, therapeutic ultrasound, exercises, and ergonomic positioning. Oral corticosteroids or NSAIDs can also be tried. Methylprednisolone injections were found to have more effect at 10 weeks than placebo but the benefits diminished by 1 year. A randomized, controlled trial showed both corticosteroid injection and surgery resolved symptoms but only decompressive surgery led to resolution of neurophysiologic changes.

Compared to trigger finger management, which usually includes injections, as many as 71% of patients with carpal tunnel directly undergo surgery without first getting injections. Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting longer than 12 months. Surgery can be done with an open approach or endoscopically, both yielding similar good improvements.

► When to Refer

- If symptoms persist more than 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

Andreu JL et al. Local injection versus surgery in carpal tunnel syndrome: neurophysiologic outcomes of a randomized clinical trial. *Clin Neurophysiol*. 2014 Jul;125(7):1479–84. [PMID: 24321619]

3. Dupuytren Contracture

ESSENTIALS OF DIAGNOSIS

- Benign fibrosing disorder of the palmar fascia.
- Contracture of one or more fingers can lead to limited hand function.

► General Considerations

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures,

with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50 years of age, particularly in those of Celtic descent. The incidence is higher among alcoholic patients and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes plantar fibromatosis (10% of patients), Peyronie disease (1–2%), mediastinal and retroperitoneal fibrosis, and Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

▶ Clinical Findings

Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand.

▶ Treatment

If the palmar nodule is growing rapidly, injections of triamcinolone or collagenase into the nodule may be of benefit. The injection of collagenase *Clostridium histolyticum* is a nonoperative treatment option that lyses collagen disrupting the contracted cords. Surgical options include open fasciectomy, partial fasciectomy, or percutaneous needle aponeurotomy and are indicated in patients with significant flexion contractures. Recurrence is possible and there are more adverse events compared to nonoperative treatments. A multicenter study showed that collagenase injection and limited fasciectomy had similar improvements with contractures at the metacarpophalangeal joints, while surgery had better results for contractures involving the proximal interphalangeal joints.

▶ When to Refer

Referral can be considered when one or more digits are affected by severe contractures, which interfere with everyday activities and result in functional limitations.

Coleman S et al. Efficacy and safety of concurrent collagenase *Clostridium histolyticum* injections for multiple Dupuytren contractures. *J Hand Surg Am.* 2014 Jan;39(1):57–64. [PMID: 24315486]

Zhou C et al. Collagenase *Clostridium histolyticum* versus limited fasciectomy for Dupuytren's contracture: outcomes from a multicenter propensity score matched study. *Plast Reconstr Surg.* 2015 Jul;136(1):87–97. [PMID: 25829153]

4. Bursitis

ESSENTIALS OF DIAGNOSIS

- ▶ Often occurs around bony prominences where it is important to reduce friction.
- ▶ Typically presents with local swelling that is painful acutely.
- ▶ Septic bursitis can present without fever or systemic signs.

▶ General Considerations

Inflammation of bursae—the synovium-like cellular membranes overlying bony prominences—may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or OA. Bursitis can result from infection. The two common sites are the olecranon (Figure 41–1) and prepatellar bursae; however, others include subdeltoid, ischial, trochanteric, and semimembranous-gastrocnemius (Baker cyst) bursae. The bursitis can be septic. Aseptic bursitis is usually afebrile.

▶ Clinical Findings

A. Symptoms and Signs

Bursitis presents with focal tenderness and swelling and is less likely to affect range of motion of the adjacent joint. Olecranon or prepatellar bursitis, for example, causes an oval (or, if chronic, bulbous) swelling at the tip of the elbow

▲ **Figure 41–1.** Aseptic olecranon bursitis secondary to repetitive trauma. (Reproduced, with permission, from Richard P. Usatine, MD.)

or knee and does not affect joint motion. Tenderness, erythema and warmth, cellulitis, a report of trauma, or evidence of a skin lesion are more common in septic bursitis but can be present in aseptic bursitis as well. Patients with septic bursitis can be febrile but the absence of fever does not exclude infection; **one-third of those with septic olecranon bursitis are afebrile**. A bursa can also become symptomatic when it ruptures. This is particularly true for Baker cyst, whose rupture can cause calf pain and swelling that mimic thrombophlebitis.

B. Imaging

Imaging is unnecessary unless there is concern for osteomyelitis, trauma or other underlying pathology. Ruptured Baker cysts are imaged easily by sonography or MRI. It may be important to exclude a deep venous thrombosis, which can be mimicked by a ruptured Baker cyst.

C. Special Tests

Acute swelling and redness at a bursal site calls for aspiration to rule out infection especially if the patient is either febrile (temperature more than 37.8°C) or has prebursal warmth (temperature difference greater than 2.2°C) or both. A bursal fluid white blood cell count of greater than 1000/mcL indicates inflammation from infection, rheumatoid arthritis, or gout. The bursal fluid of septic bursitis characteristically contains a purulent aspirate, fluid-to-serum glucose ratio less than 50%, white cell count more than 3000 cells/mcL, polymorphonuclear cells more than 50%, and a positive Gram stain for bacteria. Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds.

▶ Treatment

Bursitis caused by trauma responds to local heat, rest, NSAIDs, and local corticosteroid injections. Chronic, stable olecranon bursa swelling usually does not require aspiration. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad. For chronic aseptic bursitis or when there are athletic or occupational demands, aspiration with intrabursal steroid injection can be performed. Aspiration of the olecranon bursa runs the risk of creating a chronic drainage site, which can be reduced by using a “zig-zag” approach with a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Ultrasound-guided aspiration and injection can improve the accuracy of the procedures. Treatment of a ruptured Baker cyst includes rest, leg elevation, and possibly injection of triamcinolone, 20–40 mg into the knee anteriorly (the knee compartment communicates with the cyst). However, corticosteroid injections in nonseptic bursitis have more complications and skin atrophy than simple symptomatic treatment.

Treatment for septic bursitis involves incision and drainage and antibiotics usually delivered intravenously.

▶ When to Refer

- Surgical removal of the bursa is indicated only for cases in which repeated infections occur.
- Elective removal for persistent symptoms affecting activities of daily living can be considered.

HIP

1. Hip Fractures

ESSENTIALS OF DIAGNOSIS

- ▶ Internal rotation of the hip is the best provocative diagnostic maneuver.
- ▶ Hip fractures should be surgically repaired as soon as possible (within 24 hours).
- ▶ Delayed treatment of hip fractures in the elderly leads to increased complications and mortality.

▶ General Considerations

Approximately 4% of the 7.9 million fractures that occur each year in the United States are hip fractures. There is a high mortality rate among elderly patients following hip fracture, with death occurring in 8–9% within 30 days and in approximately 25–30% within 1 year. Osteoporosis, female sex, height greater than 5-foot 8-inches, and age over 50 years are risk factors for hip fracture. Hip fractures usually occur after a fall. High velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with poor bone mineral density following repetitive loading activities.

▶ Clinical Findings

A. Symptoms and Signs

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee can also commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, the clinician can, with the patient supine, flex the hip to 90 degrees with the knee flexed to 90 degrees. The leg can then be internally and externally rotated to assess the range of motion on both sides. **Pain with internal rotation of the hip is the most sensitive test**

Table 41–6. Hip examination.

Maneuver	Description
Inspection	Examine for the alignment of the lower extremity, consider lumbar spine exam.
Palpation	Include important landmarks: ASIS and AIIS (proximal quadriceps muscle insertions), greater trochanter (gluteal tendon insertions and bursa), anterior femoral triangle (hip joint and hip flexion insertion), ischial tuberosity (hamstring tendon insertion), sacroiliac joints.
Range of motion testing	Check range of motion passively (clinician performs) especially internal and external rotation of the hip.
Hip strength testing	Test resisted hip flexion, extension, abduction and adduction strength manually.
Trendelenburg test	The patient balances first on one leg, raising the non-standing knee toward the chest. The clinician can stand behind the patient and observe for dropping of the pelvis and buttock on the non-stance side.

AIIS, anterior inferior iliac spine; ASIS, anterior superior iliac spine.

to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle (Table 41–6). Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in patients with hip complaints, including examining for signs for sciatica.

Following displaced hip fractures, a thorough medical evaluation and treatment should be pursued to maximize the patients' ability to undergo operative intervention. Patients who are unable to get up by themselves may have been immobile for hours or even days following their falls. Thus, clinicians must exclude rhabdomyolysis, hypothermia, deep venous thrombosis, pulmonary embolism, and other conditions that can occur with prolonged immobilization. Delay of operative intervention leads to an increased risk of perioperative morbidity and mortality.

B. Imaging

Useful radiographic views of the hip include AP views of the pelvis and bilateral hips and frog-leg-lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to evaluate non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

► Treatment

Almost all patients with a hip fracture will require surgery and may need to be admitted to hospital for pain control while they await surgery. **Surgery is recommended within the first 24 hours** because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, pressure ulcers, and deep venous thrombosis. High-volume centers have developed multidisciplinary teams (including orthopedic surgeons, internists, social workers, and specialized physical therapists) to comanage these patients, which improves perioperative medical care and expedites preoperative evaluation leading to reduced costs.

Stress fractures in active patients require a period of protected weight-bearing and a gradual return to activities, although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight-bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight-bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are common complications after surgery. The surgical trends for treating femoral neck fractures show a rise in use of arthroplasty, which was possibly reflecting a rising trend toward specialty care (more arthroplasty surgeon care).

Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and decubitus ulcers. Supervised physical therapy and rehabilitation are important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence.

► Prevention

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly. There is strong evidence that bisphosphonates, denosumab, and teriparatide reduce fractures compared with placebo, with relative risk reductions of 0.60–0.80 for nonvertebral fractures. Nutrition (calcium and vitamin D intake) and bone health (bone densitometry, serum calcium and 25-OH vitamin D levels) should be reviewed with the patient (see Chapter 26). For patients with decreased mobility, systemic anticoagulation should be considered to avoid deep venous thrombosis (see Table 14–14). Fall prevention exercise programs are available for elderly patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

► When to Refer

- All patients in whom hip fracture is suspected.
- All patients with hip fracture or in whom the diagnosis is uncertain after radiographs.

2. Hip Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- ▶ Pain deep in the groin on the affected side.
- ▶ Swelling.
- ▶ Degeneration of joint cartilage.
- ▶ Loss of active and passive range of motion in severe OA.

▶ General Considerations

In the United States, the prevalence of OA will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. Cartilage loss and OA symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of OA is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions. Femoroacetabular impingement, which affects younger active patients, is considered an early development of hip OA.

▶ Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients complain of pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up from a chair. They may limp and develop a lurch during their gait, leaning toward the unaffected side as they walk to reduce pressure on the hip.

B. Imaging

An anterior-posterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip are preferred

views for evaluation of hip OA. Joint space narrowing and sclerosis suggest early OA, while osteophytes near the femoral head or acetabulum and subchondral bone cysts are more advanced changes. The sensitivity of radiographic hip OA for hip pain localized to the groin was 36.7%, specificity 90.5%, positive predictive value 6.0%, and negative predictive value 98.9%. However, not all patient with radiographic hip OA had hip or groin pain; the converse is also true because of the low sensitivity of the radiographs. After age 35, MRI of the hips already show labral changes in almost 70% of asymptomatic patients.

▶ Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for patients with OA includes activity modification, proper footwear, therapeutic exercises, weight loss, and use of assistive devices (such as a cane). A 2014 randomized study found that physical therapy did not lead to greater improvement in pain or function compared with sham treatment in patients with hip OA. Analgesics may be effective in some cases. Corticosteroid injections can be considered for short-term relief of pain; however, hip injections are best performed under fluoroscopic, ultrasound, or CT guidance to ensure accurate injection in the joint.

B. Surgical

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms and functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Hip resurfacing surgery is a newer joint replacement technique. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Evidence to date suggests that hip resurfacing is comparable to total hip replacement and is a viable alternative for younger patients. The cumulative survival rate of this implant at 10 years is estimated to be 94%. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. In a systematic review of national databases, the average time to revision was 3.0 years for metal-on-metal hip resurfacing versus 7.8 years for total hip arthroplasty. Dislocations were more frequent with total hip arthroplasty than metal-on-metal hip resurfacing: 4.4 versus 0.9 per 1000 person-years, respectively.

Guidelines recommend prophylaxis for venous thromboembolic disease for a minimum of 14 days after arthroplasty of the hip or knee using warfarin, low-molecular-weight heparin, fondaparinux, aspirin, rivaroxaban, dabigatran, apixaban, or portable mechanical compression (see Table 14–14).

When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

KNEE

1. Knee Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Effusion can occur with intra-articular pathology, such as OA, and meniscus and cruciate ligament tears.
- ▶ Acute knee swelling (due to hemarthrosis) within 2 hours may indicate ligament injuries or patellar dislocation or fracture.

General Considerations

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation, infection, and degenerative changes. The knee is a hinge joint. The joint line exists between the femoral condyles and tibial plateaus. Separating and cushioning these bony surfaces is the lateral and medial meniscal cartilage, which functions as a shock absorber during weight bearing, protecting the articular cartilage. The patella is a large sesamoid bone anterior to the joint. It is embedded in the quadriceps tendon, and it articulates with the trochlear groove of the femur. Poor patellar tracking in the trochlear groove is a common source of knee pain especially when the cause is atraumatic in nature. The knee is stabilized by the collateral ligaments against varus (lateral collateral ligament) and valgus (medial collateral ligament) stresses. The tibia is limited in its anterior movement by the anterior cruciate ligament (ACL) and in its posterior movement by the posterior cruciate ligament (PCL). The bursae of the knee are located between the skin and bony prominences. They are sac-like structures with a synovial lining. They act to decrease friction of tendons and muscles as they move over adjacent

bony structures. Excessive external pressure or friction can lead to swelling and pain of the bursae. The **prepatellar bursae** (located between the skin and patella), and the **pes anserine bursa** (which is medial and inferior to the patella, just below the tibial plateau) are most commonly affected. Joint fluid, when excessive due to synovitis or trauma, can track posteriorly through a potential space, resulting in a popliteal cyst (also called a **Baker cyst**). Other structures that are susceptible to overuse injury and may cause knee pain following repetitive activity include the patellofemoral joint and the iliotibial band. OA of the knees is common after 50 years of age and can develop due to previous trauma, aging, activities, alignment issues, and genetic predisposition.

Clinical Findings

A. Symptoms and Signs

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma, previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptom complaints include the following:

1. Presence of grinding, clicking, or popping with bending, may be indicative of OA or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture or patellar dislocation, especially if trauma is involved.
4. Lateral “snapping” with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened with bending and walking downstairs suggests issues with the patellofemoral joint, usually degenerative such as chondromalacia of the patella or OA.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A careful history coupled with a physical examination that includes observation, palpation, and range of motion testing, as well as specific tests for particular anatomic structures is frequently sufficient to establish a diagnosis. When there is a knee joint effusion caused by increased fluid in the intra-articular space, physical examination will demonstrate swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

Table 41–7. Differential diagnosis of knee pain.

Mechanical dysfunction or disruption
Internal derangement of the knee: injury to the menisci or ligaments
Degenerative changes caused by osteoarthritis
Dynamic dysfunction or misalignment of the patella
Fracture as a result of trauma
Intra-articular inflammation or increased pressure
Internal derangement of the knee: injury to the menisci or ligaments
Inflammation or infection of the knee joint
Ruptured popliteal (Baker) cyst
Peri-articular inflammation
Internal derangement of the knee: injury to the menisci or ligaments
Prepatellar or anserine bursitis
Ligamentous sprain

Table 41–7 shows the differential diagnosis of knee pain, and Table 41–8 outlines possible diagnoses based on the location of pain.

B. Laboratory Findings

Laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients (see Tables 20–2 and 20–3).

C. Imaging

Knee pain is evaluated with plain (weight-bearing) radiographs and MRI most commonly, but CT and ultrasound are sometimes useful.

Table 41–8. Location of common causes of knee pain.

Medial knee pain
Medial compartment osteoarthritis
Medial collateral ligament strain
Medial meniscal injury
Anserine bursitis (pain over the proximal medial tibial plateau)
Anterior knee pain
Patellofemoral syndrome (often bilateral)
Osteoarthritis
Prepatellar bursitis (associated with swelling anterior to the patella)
“Jumper’s knee” (pain at the inferior pole of the patella)
Septic arthritis
Gout or other inflammatory disorder
Lateral knee pain
Lateral meniscal injury
Iliotibial band syndrome (pain superficially along the distal iliotibial band near lateral femoral condyle or lateral tibial insertion)
Lateral collateral ligament sprain (rare)
Posterior knee pain
Popliteal (Baker) cyst
Osteoarthritis
Meniscal tears
Hamstring or calf tendinopathy

An acute hemarthrosis represents bloody swelling that usually occurs within the first 1–2 hours following trauma. In situations where the trauma may be activity-related and not a result of a fall or collision, the differential diagnosis most commonly includes ACL tear (responsible for almost 50% of hemarthrosis in children and more than 70% in adults), fracture (patella, tibial plateau, femoral supracondylar, growth plate [physeal]), and patellar dislocation. Meniscal tears are unlikely to cause large hemarthrosis.

2. Anterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ An injury involving an audible pop when the knee buckles.
- ▶ Acute swelling immediately (or within 2 hours).
- ▶ Instability occurs with lateral movement activities and going down stairs.

▶ General Considerations

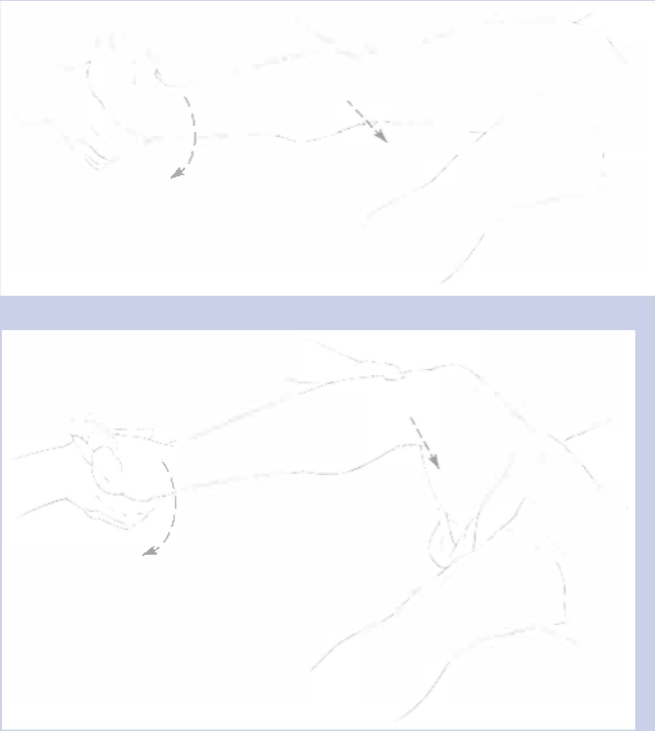

The anterior cruciate ligament (ACL) connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. Its main function is to control anterior translation of the tibia on the femur. It also provides rotational stability of the tibia on the femur. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury, has acute swelling and difficulty with weight-bearing, and complains of instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-age patients. Prepubertal and older patients usually sustain fractures instead of ligamentous injuries.

▶ Clinical Findings

A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a “stiff-knee” gait or quadriceps avoidance gait because of the instability. More importantly, patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing side-to-side maneuvers or descending stairs. The **Lachman test** (84–87% sensitivity and 93% specificity) is performed with the patient lying supine and the knee flexed to 20–30 degrees (Table 41–9). The clinician grasps the distal femur from the lateral side and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a

Table 41–9. Knee examination.

Maneuver	Description
Ligament stress tests	
<p data-bbox="79 291 207 312">Lachman test</p>  <p>The diagram shows a lateral view of the knee joint. A dashed line and arrow labeled 'Fix femur' indicate the femur is held stationary. Another dashed line and arrow show the tibia being pulled forward (anteriorly) from its normal position.</p>	<p data-bbox="793 291 1226 540">Performed with the patient lying supine, and the knee flexed to 20–30 degrees. The examiner grasps the distal femur from the lateral side, and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10–15 pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the anterior cruciate ligament.</p>
<p data-bbox="79 658 230 679">Anterior drawer</p>  <p>The diagram shows a lateral view of the knee joint. A dashed line and arrow indicate the tibia being pulled forward (anteriorly) from its normal position.</p>	<p data-bbox="793 658 1226 833">Performed with the patient lying supine and the knee flexed to 90 degrees. The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds anterior cruciate ligament laxity compared with the unaffected side.</p>
<p data-bbox="79 1026 179 1047">Pivot shift</p>  <p>The top diagram shows the knee in a flexed position with the tibia subluxated (partially dislocated) posteriorly. A dashed arrow indicates the direction of movement.</p>	<p data-bbox="793 1026 1226 1220">Used to determine the amount of rotational laxity of the knee. The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.</p>

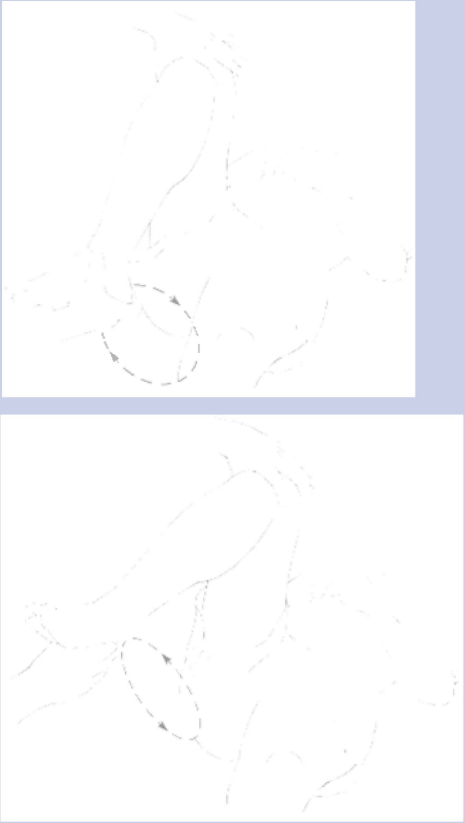

(continued)

Table 41–9. Knee examination. (continued)

Maneuver	Description
<p>Valgus stress</p> 	<p>Performed with the patient supine. The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the medial collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee extension.</p>
<p>Varus stress</p> 	<p>The patient is again placed supine. For the right knee, the clinician should be standing on the right side of the patient. The left hand of the examiner should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the lateral collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.</p>

(continued)

Table 41–9. Knee examination. (continued)

Maneuver	Description
The sag sign	The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia that is “sagging” posteriorly.
Posterior drawer	The patient is placed supine with the knee flexed at 90 degrees (see Anterior drawer figure above). In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the posterior cruciate ligament, is compared with the uninjured knee.
Meniscal signs	
McMurray test	Performed with the patient lying supine. The clinician flexes the knee until the patient reports pain. For this test to be valid, it must be flexed pain-free beyond 90 degrees. The clinician externally rotates the patient’s foot and then extends the knee while palpating the medial knee for “click” in the medial compartment of the knee or pain reproducing pain from a meniscus injury. To test the lateral meniscus, the same maneuver is repeated while rotating the foot internally (53% sensitivity and 59–97% specificity).
<p data-bbox="79 953 248 972">Modified McMurray</p> 	Performed with the hip flexed to 90 degrees. The knee is then flexed maximally with internal or external rotation of the lower leg. The knee can then be rotated with the lower leg in internal or external rotation to capture the torn meniscus underneath the condyles. A positive test is pain over the joint line while the knee is being flexed and internally or externally rotated.

(continued)

Table 41–9. Knee examination. (continued)

Maneuver	Description
<p>Thessaly test</p> 	<p>Performed with the patient standing on one leg with knee slightly flexed. The patient is asked to twist the knee while standing on one leg. Pain can be elicited during twisting motion.</p>
<p>Patellofemoral joint test</p> <p>Apprehension sign</p>	<p>Suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally.</p>

10- to 15-pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the ACL. The **anterior drawer test** (48% sensitivity and 87% specificity) is performed with the patient lying supine and the knee flexed to 90 degrees (Table 41–9). The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds ACL laxity compared with the unaffected side. The **pivot shift** test is used to determine the amount of rotational laxity of the knee (Table 41–9). The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.

B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee. This is called a “Segond” fracture and is pathognomonic of an ACL injury. MRI is the best method to

diagnose ACL tears and associated articular and meniscal cartilage issues. It has greater than 95% sensitivity and specificity for ACL tears.

► Treatment

Most young and active patients will require surgical reconstruction of the ACL. Some data suggest reconstruction within 5 months has better outcomes. However, a small randomized trial suggested that acute ACL injuries can be treated nonoperatively and delayed ACL reconstruction had similar outcomes to acute ACL reconstructions. Common surgical techniques use the patient's own tissues, usually the patellar or hamstring tendons (autograft) or a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL. Different patient groups experienced improved results with specific surgical graft choices. However, allografts do have a higher failure rate when compared with autografts. Recovery from surgery usually requires 6 months.

Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core

stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears.

▶ When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (greater than 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

Shea KG et al. The American Academy of Orthopaedic Surgeons evidence-based guideline on management of anterior cruciate ligament injuries. *J Bone Joint Surg Am*. 2015 Apr 15; 97(8):672–4. [PMID: 25878313]

3. Collateral Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Caused by a valgus or varus blow or stress to the knee.
- ▶ Pain and instability in the affected area.
- ▶ Limited range of motion.

▶ General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

▶ Clinical Findings

A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The

patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests. The sensitivity of the tests is as high as 86–96%.

The **valgus stress test** is performed with the patient supine (Table 41–9). The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the MCL. The test should be performed at both 30 degrees and at 0 degrees of knee extension.

For the **varus stress test**, the patient is again placed supine (Table 41–9). For the right knee, the clinician should be standing on the right side of the patient. The clinician's left hand should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the LCL. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

The test results can be graded from 1–3. Grade 1 is when the patient has pain with varus/valgus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain. The knee is often unstable at both 30 degrees and 0 degrees of knee flexion.

B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out fractures that can occur with collateral ligament injuries. Isolated MCL injuries usually do not require evaluation by MRI, but MRI should be used to evaluate possible associated cruciate ligament injuries. LCL or posterolateral corner injuries should have MRI evaluation to exclude associated injuries and to determine their significance.

▶ Treatment

The majority of MCL injuries can be treated with protected weight-bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion. A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear but only with the knee locked in extension with a brace. The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. LCL injuries usually require surgical repair or reconstruction.

▶ When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.

- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).

Pacheco RJ et al. Posterolateral corner injuries of the knee: a serious injury commonly missed. *J Bone Joint Surg Br.* 2011 Feb;93(2):194–7. [PMID: 21282758]

4. Posterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Usually follows an anterior trauma to the tibia, such as a dashboard injury during a motor vehicle accident.
- ▶ The knee may freely dislocate and reduce.
- ▶ One-third of multi-ligament injuries involving the PCL have neurovascular injuries.

▶ General Considerations

The posterior cruciate ligament (PCL) is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL injuries have associated injuries to the posterolateral corner, MCL, and ACL. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries. **There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed.**

▶ Clinical Findings

A. Symptoms and Signs

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may complain of subjective “looseness” and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the “**sag sign**” (Table 41–9). The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the PCL-injured knee will have an obvious set-off at the anterior tibia that is “sagging” posteriorly. The PCL ligament can also be examined using the **posterior drawer test** (90% sensitivity and 99% specificity) (Table 41–9). The patient is placed supine with the knee flexed at 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee. A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a

false-positive test for an ACL injury. Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery.

B. Imaging

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

▶ Treatment

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction.

▶ When to Refer

- The patient should be seen urgently within 1–2 weeks.
- If the lateral knee is also unstable with varus stress testing, the patient should be assessed for a posterolateral corner injury, which may require an urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.

5. Meniscus Injuries

ESSENTIALS OF DIAGNOSIS

- ▶ Patient may or may not report an injury.
- ▶ Joint line pain and pain with deep squatting are the most sensitive signs.
- ▶ Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

▶ General Considerations

The menisci act as shock absorbers within the knee. Injuries to a meniscus can lead to pain, clicking, and locking sensation. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).

▶ Clinical Findings

A. Symptoms and Signs

The patient may have an antalgic (painful) gait and difficulty with squatting. He or she may complain of catching or locking of the meniscal fragment. Physical findings can include effusion or joint line tenderness. Patients can

usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Provocative tests, including the **McMurray** test, the **modified McMurray test**, and the **Thessaly test**, can be performed to confirm the diagnosis (Table 41–9). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a “duck walk”).

B. Imaging

Radiographs are usually normal but may show joint space narrowing, early OA changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity). High signal through the meniscus (bright on T2 images) represents a meniscal tear.

▶ Treatment

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar for patients with mild knee OA, including analgesics and physical therapy for strengthening and core stability. A randomized controlled trial showed that physical therapy compared to arthroscopic partial meniscectomy had similar outcomes at 6 months. However, 30% of the patients who were assigned to physical therapy alone underwent surgery within 6 months. Another randomized study has shown that arthroscopic surgery has no benefit over sham operation for patients who have meniscus tears in osteoarthritic knees. A 2013 randomized controlled study has further demonstrated no benefit for arthroscopic meniscectomy with sham operation for patients with degenerative meniscal tears.

Acute tears in young and active patients with signs of internal derangement and without signs of arthritis on imaging can be best treated arthroscopically with meniscus repair or debridement.

▶ When to Refer

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears, are amenable to meniscal repair surgery.

Sihvonen R et al; Finnish Degenerative Meniscal Lesion Study (FIDELITY) Group. Arthroscopic partial meniscectomy versus sham surgery for a degenerative meniscal tear. *N Engl J Med.* 2013 Dec 26;369(26):2515–24. [PMID: 24369076]

6. Patellofemoral Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Pain experienced with bending activities (kneeling, squatting, climbing stairs).
- ▶ Lateral deviation or tilting of the patella in relation to the femoral groove.

▶ General Considerations

Patellofemoral pain, also known as anterior knee pain, chondromalacia, or “runner’s knee,” describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. The patella engages the femoral trochlear groove with approximately 30 degrees of knee flexion. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually complain of pain in the anterior knee with bending movements and less commonly in full extension. Pain from this condition is localized under the kneecap but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after a trauma or after repetitive physical activity, such as running and jumping. When maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless there are articular cartilage defects or if OA changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. For example, the clinician can use one hand to move the patella laterally, and use the fingertips of the other hand to palpate the lateral undersurface of patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the kneecap is consider normal; greater than one-half the diameter suggests excessive mobility). The **apprehension sign** suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally

Katz JN et al. Surgery versus physical therapy for a meniscal tear and osteoarthritis. *N Engl J Med.* 2013 May 2;368(18):1675–84. Erratum in: *N Engl J Med.* 2013 Aug 15;369(7):683. [PMID: 23506518]

Khan M et al. Arthroscopic surgery for degenerative tears of the meniscus: a systematic review and meta-analysis. *CMAJ.* 2014 Oct 7;186(14):1057–64. [PMID: 25157057]

(Table 41–9). The **patellar grind test** is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) Patients whose ligaments and patella are too loose (hypermobility); (2) and patients who have soft tissues that are too tight leading to excessive pressure on the joint.

Evaluation of the quadriceps strength and hip stabilizers can be accomplished by having the patient perform a one-leg squat without support. Patients who are weak may display poor balance, with dropping of the pelvis (similar to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for OA or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

▶ Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking. There is consistent evidence that exercise therapy for **patellofemoral pain syndrome** may result in clinically important reduction in pain and improvement in functional ability. Lower quality research supports that hip and knee exercises are better than knee exercises alone. Strengthening the quadriceps and the posterolateral hip muscles such as the hip abductors that control rotation at the knee should be recommended. Support for the patellofemoral joint can be provided by use of a patellar stabilizer brace or special taping techniques (McConnell taping). Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves and hip flexors.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery.

▶ When to Refer

Patients with persistent symptoms despite a course of conservative therapy.

7. Knee Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- ▶ Degeneration of joint cartilage.
- ▶ Pain with bending or twisting activities.
- ▶ Swelling.
- ▶ Loss of active and passive range of motion in severe OA.

▶ General Considerations

In the United States, the prevalence of OA will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. The incidence of knee OA in the United States is 240 per 100,000 person-years.

Cartilage loss and OA symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of OA is often multifactorial including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

▶ Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee OA have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities, and going up and down stairs. Swelling, limping, and pain while sleeping are common complaints with OA, especially as it progresses.

B. Imaging

The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, including ischemic osteonecrosis of the knee.

▶ Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with OA includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high impact activities. Optimal exercise programs for knee OA should focus on improving aerobic capacity, quadriceps muscle strength, or lower extremity performance. Ideally, the program should be supervised and carried out three times a week.

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartamental OA in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

There are several oral and intra-articular pharmacologic options. Treatments that have been shown to have small but robust differences include oral acetaminophen, diclofenac, ibuprofen, naproxen, celecoxib, and intra-articular corticosteroids and hyaluronic acid. All treatments except acetaminophen showed clinically significant improvement in pain. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and adherence. The cyclooxygenase (COX)-2 inhibitor celecoxib is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential cardiovascular risk, celecoxib should be reserved for carefully selected patients. Topical NSAIDs or capsaicin can be effective in the treatment of OA, since they avoid many of the traditional NSAID complications. Opioids can be used appropriately in patients with severe OA (see Chapter 5). Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for OA. Evidence for their effectiveness in slowing or reversing cartilage loss is limited and any effect present appears to be small. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in OA. However, they have minimal side

effects and may be appropriate if the patient experiences subjective benefit.

Knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. Viscosupplementation by injections of hyaluronic acid–based products is controversial. Because reviews suggest that viscosupplementation has a questionably clinically relevant effect size, and has an increased risk of adverse events, the American Academy of Orthopedic Surgeons has recommended that viscosupplementation should not be used in the treatment of knee OA. However, the American College of Rheumatology's 2012 OA guidelines recommend the use of intra-articular hyaluronic acid injection for the treatment of OA of the knee in adults. Platelet-rich plasma injections contain high concentration of platelet-derived growth factors, which regulate some biologic processes in tissue repair. A meta-analysis of 10 studies demonstrated that platelet-rich plasma injections reduced pain in patients with knee OA more efficiently than placebo and hyaluronic acid injections. However, 9 of the 10 studies had a high risk of bias, and the underlying mechanism of biologic healing is unknown. The authors recommend further studies before recommending platelet-rich plasma for routine management of knee OA.

B. Surgical

Two randomized trials demonstrated that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of OA. **Joint replacement surgeries are effective and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life.** The number of total knee arthroplasty procedures jumped 162% from 1991 to 2010, along with an increase in complications and hospital readmissions. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates; however, major improvements have yet to be demonstrated.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartamental OA, who would benefit from delaying total knee replacement. Knee joint replacement surgery has been very successful in improving outcomes for patient with end-stage OA. Long-term series describe more than 95% survival rate of the implant at 15 years.

▶ When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

ANKLE INJURIES

1. Inversion Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- ▶ Localized pain and swelling.
- ▶ The majority of ankle injuries involve inversion injuries affecting the lateral ligaments.
- ▶ Consider chronic ankle instability or associated injuries if pain persists for longer than 3 months following an ankle sprain.

General Considerations

Ankle sprains are the most common sports injuries seen in outpatient clinics. Patients usually report “turning the ankle” during a fall or after landing on an irregular surface such as a hole or an opponent’s foot. The most common mechanism of injury is an inversion and plantar flexion sprain, which injures the anterior talofibular ligament (ATF) ligament rather than the calcaneofibular ligament (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in Table 41–10. Women appear to sustain an inversion injury more frequently than men.

Table 41–10. Injuries associated with ankle sprains.

Ligaments	
Subtalar joint sprain	
Sinus tarsi syndrome	
Syndesmotic sprain	
Deltoid sprain	
Lisfranc injury	
Tendons	
Posterior tibial tendon strain	
Peroneal tendon subluxation	
Bones	
Osteochondral talus injury	
Lateral talar process fracture	
Posterior impingement (os trigonum)	
Fracture at the base of the fifth metatarsal	
Jones fracture	
Salter fracture (fibula)	
Ankle fractures	

Clinical Findings

A. Symptoms and Signs

The usual symptoms following a sprain include localized pain and swelling over the lateral aspect of the ankle, difficulty weight bearing, and limping. The patient’s ankle may feel unstable. On examination, there may be swelling or bruising over the lateral aspect of the ankle. The anterior, inferior aspect below the lateral malleolus is most often the point of maximal tenderness consistent with ATF and CF ligament injuries. The swelling may limit motion of the ankle. Special stress tests for the ankle include the **anterior drawer test** (Table 41–11) and **subtalar tilt test**

Table 41–11. Ankle examination.

Maneuver	Description
Inspection	Examine for the alignment of the ankle (SEADS).
Palpation	Include important landmarks: Ottawa Ankle Rules (medial and lateral malleolus, base of fifth metatarsal and navicular area), anterior tibiofibular ligament, posterior talus; tendons (Achilles, peroneals, posterior tibialis, flexor hallucis longus).
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs), especially with flexion and extension of the spine. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions.
Ankle strength testing	Test resisted ankle dorsiflexion, plantarflexion, inversion and eversion strength manually.
Ankle anterior drawer	The clinician keeps the foot and ankle in the neutral position with the patient sitting, then uses one hand to fix the tibia and the other to hold the patient’s heel and draw the ankle forward. Normally, there may be approximately 3 mm of translation until an endpoint is felt. A positive test includes increased translation of one foot compared to the other with loss of the endpoint of the anterior talofibular ligament.
Subtalar tilt test	Performed with the foot in the neutral position with the patient sitting. The clinician uses one hand to fix the tibia and the other to hold and invert the calcaneus. Normal inversion at the subtalar joint is approximately 30 degrees. A positive test consists of increased subtalar joint inversion greater than 10 degrees on the affected side with loss of endpoint for the calcaneofibular ligament.
External rotation stress test	Performed when the clinician fixes the tibia with one hand and grasps the foot in the other with the ankle in the neutral position and then dorsiflexes and externally rotates the ankle, reproducing the patient’s pain.

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

(Table 41–11). In order to grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury.

B. Imaging

Routine ankle radiographic views include the AP, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. **Ottawa Ankle Rules** are clinical prediction rules to guide the need for radiographs and have a 97% sensitivity and 99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleoli demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

▶ Treatment

Immediate treatment of an ankle sprain follows the MICE mnemonic: *modified activities, ice, compression, and elevation*. Subsequent treatment involves protected weight bearing with crutches and use of an ankle stabilizer brace, especially for grade 2 and 3 injuries. **Early motion is essential, and patients should be encouraged to do home exercises or physical therapy.** Proprioception and balance exercises (eg, “wobble board”) are useful to restore function to the ankle and prevent future ankle sprains. Regular use of an ankle support with activities can reduce the risk of lateral ankle sprains. Chronic instability can develop after acute ankle sprain in 10–20% of people and may require surgical stabilization with ligament reconstruction surgery.

▶ When to Refer

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.
- No response after more than 3 months of conservative treatment.
- Suspicion of associated injuries.

2. Eversion (“High”) Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- ▶ Severe and prolonged pain.
- ▶ Limited range of motion.
- ▶ Mild swelling.
- ▶ Difficulty with weight bearing.

▶ General Considerations

A syndesmotic injury or “high ankle” sprain involves the anterior *tibiofibular* ligament in the anterolateral aspect of the ankle, superior to the anterior *talofibular* (ATF) ligament. The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiofibular ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiofibular ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotic ligament injury and associated fracture known as a “maisonneuve fracture.” There is often some mild swelling in this area, and the patient may or may not have an ankle effusion. The patient usually has limited range of motion in all directions. The **external rotation stress test** reproduces the mechanism of injury (Table 41–11). (**Note:** The patient’s foot should have an intact neurovascular examination before undertaking this test.)

B. Imaging

Radiographs of the ankle should include the AP, mortise, and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotic ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an AP and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. Radiographs during an external rotation stress test may visualize instability at the distal tibiofibular joint. MRI is the best method to visualize injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

▶ Treatment

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight-bearing initially.

▶ When to Refer

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a

foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint. Screw fixation remains the gold standard, although newer techniques with bioabsorbable constructs are emerging.
