Annotation of the OY-M phytoplasma genome has been followed by three other phytoplasma genome annotations. Aster yellows witches'-broom phytoplasma ("*Candidatus* Phytoplasma asteris"-related strain AY-WB) possesses a circular 706,569 nucleotide chromosome and plasmids AYWB-pI (3872 bp), -pII (4009 bp), -pIII (5104 bp), and -pIV (4316 bp) (Bai et al., 2006). Australian tomato big bud phytoplasma ("*Candidatus* Phytoplasma australiense"-related strain TBB) has a circular 879,324 bp chromosome and a 3700 bp plasmid (Tran-Nguyen et al., 2008), whereas apple proliferation phytoplasma ("*Candidatus* Phytoplasma mali"-related strain AT) has a linear 601,943 bp chromosome (Kube et al., 2008).

The chromosome of "*Candidatus* Phytoplasma mali" is characterized by large terminal inverted repeats and covalently closed hairpin ends. Analysis of protein-coding genes revealed that glycolysis, the major energy-yielding pathway supposed for OY-M phytoplasma, is incomplete in AT phytoplasma. It also differs from OY-M and AY-WB phytoplasmas by a lower G+C content (21.4 mol%), fewer paralogous genes, a strongly reduced number of ABC transporters for amino acids, and an extended set of genes for homologous recombination, excision repair, and SOS response.

Comparative genomics have also recently identified ORFs shared by AY-WB phytoplasma and the distantly-related corn stunt pathogen *Spiroplasma kunkelii* that are absent from obligate animal and human pathogenic mollicutes. These proteins were identified as polynucleotide phosphorylase (PNPase), cmp-binding factor (CBF), cytosine deaminase, and Y1xR protein and could be important for insect transmission or plant pathogenicity. Also identified were four additional proteins, ppGpp synthetase, HAD hydrolase, AtA (AAA type ATPase), and P-type Mg²⁺ transport ATPase, that seemed to be more closely related between AY-WB and *Spiroplasma kunkelii* than to their mycoplasmal counterparts (Bai et al., 2004).

Phytoplasmas possess a unique genome architecture that is characterized by multiple, nonrandomly distributed sequence-variable mosaics (SVMs) of clustered genes, originally recognized in a study of closely related "*Candidatus* Phytoplasma asteris"-related strains CPh and OY-M (Jomantiene and Davis, 2006). Targeted genome sequencing and comparative genomics indicated that this genome architecture is a common characteristic among phytoplasmas, leading to the proposal that the origin of SVMs was an ancient event in the evolution of the phytoplasma clade (Jomantiene et al., 2007), perhaps as a result of recurrent targeted attacks by mobile elements such as phages (Wei et al., 2008a). Jomantiene and Davis (2006) proposed that sizes and numbers of SVMs could account in part for the known variation in genome size among phytoplasma strains; this concept was independently suggested by Bai et al. (2006) on the basis of results from a comparative study of two completely sequenced phytoplasma genomes. Nucleotide sequences within SVMs included full length or pseudogene forms of *fliA*, an ATP-dependent Zn protease gene, *tra5*, *smc*, *himA*, *tmk*, and *ssb* (encoding single-stranded DNA-binding protein), genes potentially encoding hypothetical proteins of unknown function, genes exhibiting similarities to transposase, and a phage-related gene (Jomantiene et al., 2007). A similar set of nucleotide sequences occurs in AY-WB genomic regions termed potential mobile units (PMUs) by Bai et al. (2006). The presence of sequences encoding putatively secreted and/or transmembrane, cell surface-interacting proteins indicates that these genomic features are likely to be significant for phytoplasma/host interactions (Bai et al., 2006; Jomantiene and Davis, 2006; Jomantiene et al., 2007).

Short (17–35 bases) conserved, imperfect palindromic DNA sequences (PhREPs) that are present in SVMs possibly play a role in phytoplasma genome plasticity and targeting of mobile genetic elements. SVMs can be viewed as composites formed by the acquisition of genes through horizontal transfer, recombination, and rearrangement, and capture of mobile elements recurrently targeted to SVMs, leading Jomantiene et al. (2007) to suggest that SVMs provide loci for acquisition of new genes

and targeting of mobile genetic elements to specific regions in phytoplasma chromosomes.

The chromosomes of avirulent, mildly, moderately, and highly virulent strains of "*Candidatus Phytoplasma mali*" (Seemüller and Schneider, 2007) differ from one another in size and exhibit distinct restriction endonuclease patterns when cleaved with rare cutting enzymes. PCR-based DNA amplifications, primed separately by eight primer pairs, revealed target sequence heterogeneity among all "*Candidatus Phytoplasma mali*"-related strains tested, but no correlations linked molecular markers with strain virulence or the maximum titer obtained upon infection of apple trees. In a separate study, a comparison of mild (OY-M) and severe (OY-W) strains of onion yellows (OY) phytoplasma indicated that severe symptoms were associated with higher populations of OY-W in infected host plants (Oshima et al., 2001b). A cluster of eight genes, considered essential for glycolysis, were subsequently identified within a similar 30 kb genomic region of both strains (Oshima et al., 2007). Of these, five genes (*smtA*, *greA*, *osmC*, *eno*, and *pfkA*) were randomly duplicated in OY-W, possibly influencing glycolytic activity. A higher consumption of metabolites such as sugars in the intracellular environment of the phloem may explain differences between OY-W and OY-M in growth rate, which in turn may be linked, directly or indirectly, to symptom severity.

Cloned fragments of phytoplasma DNA have been widely employed as probes in dot and Southern blot hybridization assays to identify and characterize phytoplasmas (reviewed by Lee and Davis, 1992; Lee et al., 2000). Southern blot restriction fragment length polymorphism (RFLP) analysis has enabled investigations of genetic relationships among phytoplasmas associated with similar hosts or with symptomatologically similar diseases (Kison et al., 1997, 1994; Kuske et al., 1991; Schneider and Seemüller, 1994b). Several discrete phytoplasma groups, each comprising strains that shared extensive sequence homology and little or no apparent homology with other phytoplasmas, were identified by this type of analysis. Lee and co-workers (1992) coined the term "genomic strain cluster" to denote each of seven discrete genotypic groups resolved by employing a selection of phytoplasma genomic DNA probes (reviewed by Lee and Davis, 1992). Of these, aster yellows (AY) was the largest group, represented by 15 genetically variable strains that were further delineated into three distinct genomic types (types I, II, and III) or subclusters (Lee et al., 1992). Significantly, major groupings later revealed by RFLP analysis of 16S rRNA genes were consistent with those defined by monoclonal antibody typing (Lee et al., 1993a) and other molecular methods (Lee et al., 1998b), but differed from distinctions made in traditional classification based solely on biological properties such as plant host range, symptomatology, and insect vector specificity (Chiykowski and Sinha, 1990).

Polyclonal antibodies (PABs) have been produced against phytoplasma-enriched extracts (intact organisms or membrane fractions) partially purified from plants (reviewed by Chen et al., 1989) and against vector leafhopper-derived immunogens (Errampelli and Fletcher, 1993; Kirkpatrick et al., 1987). Most PABs exhibit relatively high background reactions with healthy host antigens; thus, generation of useful polyclonal antisera has been limited so far to a few phytoplasmas maintained at high titer in host tissues. Phytoplasmas can be differentiated on the basis of their antigenic properties through the use of PABs in

enzyme-linked immunosorbent (ELISA), immunofluorescence, or Western blot assays. Antigenic similarity revealed among phytoplasmas by these assays is often in agreement with relationships demonstrated by vector transmission studies. Detection of antigenically distinct phytoplasmas in plants exhibiting very similar disease symptoms attests to the unreliability of symptom expression alone as a means of differentiating phytoplasmas.

Improvements in phytoplasma extraction methods have provided a source of immunogens for monoclonal antibody (MAb) production (Chang et al., 1995; Hsu et al., 1990; Jiang et al., 1989; Loi et al., 2002, 1998; Shen and Lin, 1993; Tanne et al., 2001). Used in ELISA, dot or tissue blot immunoassay, immunocapture PCR (Rajan et al., 1995), immunofluorescence microscopy, or immunosorbent electron microscopy (ISEM) (Clark, 1992; Shen and Lin, 1994), MAbs have demonstrated considerable promise for detection and differentiation of phytoplasmas infecting a broad range of host plants, including woody perennials (Guo et al., 1998). Due to their high degree of specificity, monoclonals seem most suited for differentiating very closely related strains (Lee et al., 1993a).

Isolation, cloning, and expression of immunodominant protein genes have identified putative proteins that account for a major portion of the membrane proteins of several phytoplasmas (Arashida et al., 2008; Barbara et al., 2002; Berg et al., 1999; Blomquist et al., 2001; Galetto et al., 2008; Kakizawa et al., 2004, 2009; Morton et al., 2003; Suzuki et al., 2006; Yu et al., 1998). When these purified proteins were used as immunogens, the resulting polyclonal antisera exhibited high specific titers and low background reactions in ELISA and Western blot analyses that were designed to detect phytoplasma proteins in infected hosts. Similarly, the *secA* gene was cloned from an onion yellows (OY-M) strain of aster yellows phytoplasma (Kakizawa et al., 2001) and used to raise an anti-SecA rabbit antibody against a purified partial SecA protein expressed in *Escherichia coli*. Light microscopy of thin sections of garland chrysanthemum (*Chrysanthemum coronarium*) treated by immunohistochemical staining revealed that the SecA protein was present in phloem of OY-M-infected but not healthy host plants. In addition, antisera against both OY-M phytoplasma SecA protein and GyrA protein of *Acholeplasma laidlawii* reacted with proteins of several unrelated phytoplasmas extracted from plant tissues (Koui et al., 2002; Wei et al., 2004a).

Phytoplasmas are the apparent etiological agents of diseases of at least 1000 plant species worldwide (McCoy et al., 1989; Seemüller et al., 1998). Although they can be transmitted from infected to healthy plants by scion or root grafts, most plant to plant spread occurs naturally via phloem-feeding insect vectors primarily of the family *Cicadellidae* (leafhoppers) and, less commonly, by planthoppers (*Fulgoroidea*) of the family *Cixiidae* and psyllids (*Psylloidea*) (D'Arcy and Nault, 1982; Tsai, 1979; Weintraub and Beanland, 2006). Phytoplasmas are transmitted in a circulative-propagative manner that typically involves a transmission latent period from 2 to 8 weeks (Carraro et al., 2001; Webb et al., 1999). The insect vector becomes infected upon ingesting phytoplasmas in phloem sap of infected plants. After an incubation period of one to several weeks, the phytoplasma multiplies to high titer in the salivary glands and the insect becomes capable of infecting the phloem of the healthy plants on which it feeds (Kunkel, 1926; Lee et al., 1998a; Nasu et al., 1970). Generally, phytoplasma infection does not appear to significantly affect the activity, weight, longevity, or fecundity

of vector insects (Garnier et al., 2001). Some phytoplasmas can be vectored by many species of leafhoppers (McCoy et al., 1989; Nielson, 1979) and different insect species may serve as vectors in different geographic regions. Several vectors also have the ability to transmit more than one type of phytoplasma, whereas other phytoplasmas are transmitted by one or a few vector species to a narrow range of plant species (Lee et al., 1998a). There is mounting evidence also for transovarial transmission of some phytoplasmas (Alma et al., 1997; Hanboonsong et al., 2002; Kawakita et al., 2000; Tedeschi et al., 2006).

Plants may serve as both natural and experimental hosts to several different phytoplasmas. Dual or mixed infections involving related or unrelated phytoplasmas are known to occur naturally in plants and appear to be more common in perennial than annual plants (Bianco et al., 1993; Lee et al., 1995). Also, closely related phytoplasma strains are capable of inducing dissimilar symptoms on the same plant species (White et al., 1998), whereas similar symptoms on the same host plant may be induced by unrelated phytoplasmas (Harrison et al., 2003). The ability to accurately identify phytoplasmas by using DNA-based methods has shown that these organisms are more genetically diverse than was once thought (Davis and Sinclair, 1998). The geographic occurrence of phytoplasmas is determined largely by geographic ranges and feeding behavior (mono-, oligo-, or polyphagous) of the vector species, the relative susceptibility of the preferred host plant species, and the native host ranges of plant and insect hosts (Lee et al., 1998a). Phytoplasmas can be introduced into new geographic regions by long-distance dispersal of infectious vectors (Lee et al., 2003) and by movement of infected plants or vegetative plant parts. Most recently, phytoplasma DNA has been detected in embryos of aborted seed from diseased plants (Cordova et al., 2003; Nipah et al., 2007) and seed transmission of phytoplasmas infecting alfalfa (*Medicago sativa* L.) has been demonstrated (Khan et al., 2002).

An array of characteristic symptoms is associated with phytoplasma infection of several hundred plant species worldwide. Symptoms vary according to the particular host species, stage of host infection and the associated phytoplasma strain (reviewed by Davis and Lee, 1992; Hogenhout et al., 2008; Kirkpatrick, 1989, 1992; Lee et al., 2000; McCoy et al., 1989; Seemüller et al., 2002; Sinclair et al., 1994). Some symptoms indicative of profound disturbances in the normal balance of growth regulators in plants include virescence (greening of petals), phyllody (conversion of floral organs into leafy structures), big bud, floral proliferation, sterility of flowers, proliferation of adventitious or axillary shoots, internode elongation and etiolation, generalized stunting (small flowers, leaves and fruits or shortened internodes), unseasonal discoloration of leaves or shoots (yellow to purple discoloration), leaf curling, cupping or crinkling, witches'-brooms (bunchy growth at stem apices), vein clearing, vein enlargement, phloem discoloration, and general plant decline such as die-back of twigs, branches and trunks (Lee and Davis, 1992; Lee et al., 2000; McCoy et al., 1989).

Infection of herbaceous host plants is followed by rapid intraphloemic spread of phytoplasma from leaves to roots, often accompanied by six-fold increases in phytoplasma populations in these tissues between 14 and 28 d post-inoculation (Kuske and Kirkpatrick, 1992a; Wei et al., 2004b). Phytoplasma concentrations ranging from 2.2×10^8 to 1.5×10^9 cells per gram of tissue have been measured in high titer herbaceous hosts such

asperiwinkle (*Catharanthus roseus*) and in certain woody perennial hosts such as alder (*Alnus*) and most poplar (*Populus*) species. Lowest phytoplasma concentrations, from 370 to 34,000 cells per gram of tissue, were detected in apple trees that were grafted on resistant rootstocks and in oak (*Quercus robur*) or hornbeam (*Carpinus betulus*) trees exhibiting nonspecific leaf yellowing symptoms (Berg and Seemüller, 1999).

Colonization is usually marked by phloem dysfunction and a reduction in photosynthetic capacity. Alterations in phloem function have been correlated with structural degeneration of sieve elements due possibly to physical blockage by colonizing phytoplasma or the action of a phytotoxin (Guthrie et al., 2001; Siddique et al., 1998). The onset of symptoms may be accompanied by substantial impairment of the photosynthetic rate of mature leaves and by fluctuations in carbohydrate and amino acid levels in source versus sink leaves (Lepka et al., 1999; Tan and Whitlow, 2001). Leaf yellowing is associated with: decreases in chlorophyll content, carotenoids, and soluble proteins (Bertamini and Nedunchezian, 2001); abnormal stomatal function (Martinez et al., 2000); histopathological changes such the amount of total polyphenols; loss of cellular integrity (Musetti et al., 2000); fluctuations in hydrogen peroxide; peroxidase activity and glutathione content in diseased versus healthy plant tissues (Musetti et al., 2004); and increases in calcium (Ca^{2+}) ions in cells (Musetti and Favali, 2003; Rudzinska-Langwald and Kaminska, 2003). Such adverse changes are accompanied by differential regulation of genes encoding proteins involved in floral development (Pracros et al., 2006), photosynthesis, sugar transport, and response to stress or in pathways of lipid and phenylpropanoid or phytosterol synthesis (Albertazzi et al., 2009; Carginale et al., 2004; Hren et al., 2009; Jagoueix-Eveillard et al., 2001).

The organisms degenerate and lose their cellular contents following treatment of infected plants with tetracycline antibiotics (Kamińska and Śliwa, 2003; Sinha and Peterson, 1972). Tetracycline sensitivity and the lack of sensitivity to cell wall-inhibiting antibiotics such as penicillin (Davis and Whitcomb, 1970; Ishii et al., 1967) also support their inclusion in the *Mollicutes*. Protective or therapeutic treatments with tetracycline antibiotics for phytoplasma disease control have been extended to a few high-value crop plants such as coconut for control of palm lethal yellowing, and to cherries and peaches for control of X-disease (McCoy, 1982; Nyland, 1971; Raju and Nyland, 1988). Administered by trunk injection, treatment of each tree with 1.0 g (protective dose) or 3.0 g (therapeutic dose) three times per year was sufficient for control of coconut lethal yellowing disease (McCoy, 1982).

Enrichment and isolation procedures

Isolation of phytoplasma-enriched fractions from plant and insect host tissues is possible by differential centrifugation and filtration after first disrupting tissues in osmotically-augmented buffers (Kirkpatrick et al., 1995; Lee et al., 1988; Sinha, 1979; Thomas and Balasundaran, 2001). Further purification of phytoplasmas is possible by centrifugation of enriched preparations in discontinuous Percoll density gradients (Davis et al., 1988; Gomez et al., 1996; Jiang and Chen, 1987) or by affinity chromatography using phytoplasma-specific antibodies coupled to Protein A-Sepharose columns (Jiang et al., 1988; Seddas et al., 1995). Viability of these enriched preparations may be assessed

by infectivity tests in which aliquots of the phytoplasma preparations are micro-injected into vector insects, which are then fed on healthy indicator plants (Nasu et al., 1974; Sinha, 1979; Whitcomb et al., 1966a, b). Separation of enriched phytoplasma DNA from mixtures with host DNA is also possible by use of cesium chloride-bisbenzimidazole buoyant density gradient centrifugation (Kollar and Seemüller, 1989). Present as an uppermost band in final gradients, phytoplasma DNA fractionated by this means was suitable for endonuclease digestion and cloning for DNA probe development (Harrison et al., 1992, 1991; Kollar and Seemüller, 1990).

Maintenance procedures

Viable phytoplasmas have been maintained for at least 6 years in intact vector insects frozen at -70°C (Chiykowski, 1983). Viable X-disease phytoplasmas have been maintained for 2 weeks in salivary glands suspended in a tissue culture medium (Nasu et al., 1974). Extracts of phytoplasma-infected insects prepared in a MgCl_2 /glycine buffer, osmotically adjusted to 800 milliosmoles/kg with sucrose, retained their infectivity for up to 3 d (Smith et al., 1981). Phytoplasma strains have been routinely maintained in diseased plants kept in an insect-proof greenhouse or in plantlets grown in tissue culture (Bertaccini et al., 1992; Davis and Lee, 1992; Jarausch et al., 1996; Sears and Klomparens, 1989; Wongkaew and Fletcher, 2004). While plant to plant transmission is accomplished naturally by vector insects and, in some cases, through grafts, experimental transmissions commonly include the use of plant parasitic dodders (*Cuscuta* sp.) (Marcone et al., 1999a). Although phytoplasma strains are commonly maintained in plants by periodic graft inoculation, maintenance of phytoplasmas exclusively in plants can result in strain attenuation over time and an associated loss of transmissibility by vector insects (Chiykowski, 1988; Denes and Sinha, 1992).

Differentiation of the genus "Candidatus Phytoplasma" from other genera

Phytoplasma-specific nucleic acid probes and PCR technology have largely supplanted traditional methods of electron microscopy and biological criteria for sensitive detection, identification, and genetic characterization of phytoplasmas. Molecular-based analyses have shown phytoplasma genomes to be A+T rich (Kollar and Seemüller, 1989; Oshima et al., 2004) and to range from 530 to 1350 kbp in size (Marcone et al., 1999b, 2001; Neimark and Kirkpatrick, 1993). Before any phytoplasma genomes were sequenced, phytoplasmas were shown to contain two rRNA operons (Davis, 2003a; Harrison et al., 2002; Ho et al., 2001; Jomantiene et al., 2002; Jung et al., 2003a; Lee et al., 1998b; Liefting et al., 1996; Marcone et al., 2000; Schneider and Seemüller, 1994a). Other genes that have been identified include ribosomal protein genes (Gundersen et al., 1994; Lee et al., 1998b; Lim and Sears, 1992; Martini et al., 2007; Miyata et al., 2002a; Toth et al., 1994) of the S10-*spc* operon (Miyata et al., 2002a), a nitroreductase gene (Jarausch et al., 1994), DNA gyrase genes (Chuang and Lin, 2000), genes encoding elongation factors G and Tu (An et al., 2006; Berg and Seemüller, 1999; Kouji et al., 2003; Marcone et al., 2000; Miyata et al., 2002b; Schneider et al., 1997), *secA*, *secY*, and *secE* genes of a functional Sec protein translocation system (Kakizawa et al., 2001, 2004), *gidA*, *potB*, *potC*, and *potD* (Mounsey et al., 2006),

a gene encoding an RNase P ribozyme (Wagner et al., 2001), *recA* (Chu et al., 2006), *rpoC* (Lin et al., 2006), *polC* (Chi and Lin., 2005), and insertion sequence (IS)-like elements (Lee et al., 2005). Numerous other putative genes or pseudogenes have been identified recently after partially or fully sequencing random fragments of genomic DNA cloned from phytoplasmas by various methods (Bai et al., 2004; Cimerman et al., 2006, 2009; Davis et al., 2003b, 2005; Garcia-Chapa et al., 2004; Liefting and Kirkpatrick, 2003; Melamed et al., 2003; Miyata et al., 2003; Streten and Gibb, 2003).

Development of phytoplasma-specific rRNA gene primers has permitted PCR-mediated amplification of various regions of the rRNA operons (Ahrens and Seemüller, 1992; Baric and Dalla-Via, 2004; Davis and Lee, 1993; Deng and Hiruki, 1991; Gundersen and Lee, 1996; Lee et al., 1993b) (Namba et al., 1993; Smart et al., 1996). RFLP analysis of PCR-amplified rDNA provided a practical solution to the problem of phytoplasma identification and classification (Lee et al., 2000, 1998b). Pairwise comparisons of disparate strains were marked by considerable differences in RFLP patterns, whereas strains that were considered closely related on the basis of similar biological properties were often, although not always, indistinguishable on the basis of RFLP patterns. Alternatively, heteroduplex mobility analysis has demonstrated greater sensitivity than RFLP analysis for detecting minor variability in 16S rRNA genes of closely related phytoplasma strains (Cousin et al., 1998; Wang and Hiruki, 2000), since RFLP analysis is limited to detection of recognition sites for restriction endonucleases. Cluster analysis of rDNA RFLP patterns provided the first means to differentiate between known and unknown phytoplasmas from a wide range of plant hosts and geographic locations, and to resolve phytoplasmas into well-defined phylogenetic groups and subgroups (Ahrens and Seemüller, 1992; Lee et al., 1993b; Schneider et al., 1993, 1995).

Taxonomic comments

The inability to cultivate phytoplasmas outside of their plant and insect hosts has thus far rendered traditional methods impractical as aids for taxonomy of these organisms. Unlike their culturable *Mollicute* relatives, which were originally classified based only upon biological and phenotypic properties in pure culture, phytoplasmas cannot be classified by these criteria. Through application of DNA-based methods, it is now possible to accurately identify and characterize phytoplasmas and to assess their genetic interrelationships. These capabilities have assisted development of classification systems, first based on hybridization data, later based on 16S rDNA RFLPs, and ultimately on phylogenetic analysis of 16S rRNA genes and other conserved gene sequences. Classification schemes founded upon these molecular criteria have been refined and expanded upon over time, with the goal of defining a taxonomy for these unique organisms. In a phytoplasma classification scheme proposed by Lee et al. (1993b), based on analyses of rDNA RFLPs, a total of nine primary 16S rDNA groups (termed 16Sr groups) and 14 subgroups were initially recognized. Phytoplasma groups delineated by these analyses were consistent with genomic strain clusters previously identified by DNA hybridization analysis (Lee et al., 1992), although a greater diversity among strains comprising group 16SrI (aster yellows and related strains) was indicated by the earlier hybridization data. Subgroups within a

given 16Sr group were distinguished by the presence of one or more restriction sites in a phytoplasma strain that differed from those in all existing members of a given subgroup. For those strains in which intra-rRNA operon heterogeneity was detected, subgroup designations were assigned according to the combined patterns of both 16S rRNA genes.

RFLP analysis of more variable ribosomal protein genes (Gundersen et al., 1994; Lee et al., 2004a, b) or *tuf* genes (Marcone et al., 2000; Schneider et al., 1997) has provided a means for more detailed subdivision of phytoplasma primary groups delineated by 16S rDNA RFLP data. This strategy for finer subgroup differentiation has been used to modify and expand upon earlier classifications and to incorporate many newly identified phytoplasma strains. Based on RFLP analysis of nearly full-length 16S rRNAs, at least 15 primary 16Sr groups have been recognized (Lee et al., 1998b; Montano et al., 2001): 16SrI, Aster yellows; 16SrII, Peanut witches'-broom; 16SrIII, X-disease; 16SrIV, Coconut lethal yellows; 16SrV, Elm yellows; 16SrVI, Clover proliferation; 16SrVII, Ash yellows; 16SrVIII, Loofah witches'-broom; 16SrIX, Pigeonpea witches'-broom; 16SrX, Apple proliferation; 16SrXI, Rice yellow dwarf; 16SrXII, Stolbur; 16SrXIII, Mexican periwinkle virescence; 16SrXIV, Bermuda grass white leaf; and 16SrXV Hibiscus witches'-broom. A total of 45 subgroups were identified when ribosomal protein gene RFLP data was also considered in the analyses.

Sequencing of 30 nearly full-length amplified 16S rRNA genes was undertaken by Namba et al. (1993), Gundersen et al. (1994), and Seemüller et al. (1994) from a diversity of strains previously characterized by rDNA RFLP analysis. These collective efforts, combined with earlier studies (Kuske and Kirkpatrick, 1992b; Lim and Sears, 1989), provided the first comprehensive phytoplasma phylogeny. In recognition of their unique phylogenetic status, the trivial name "phytoplasma" was initially proposed (Sears and Kirkpatrick, 1994) and has since been adopted formally (IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004) to collectively name these fastidious, phytopathogenic mollicutes previously known as mycoplasma-like organisms. Within the phytoplasma clade, major subclades (primary groups representing "*Candidatus*" species) include: (1) Stolbur; (2) Aster yellows; (3) Apple proliferation; (4) Coconut lethal yellowing; (5) Pigeonpea witches'-broom; (6) X-disease; (7) Rice yellow dwarf; (8) Elm yellows; (9) Ash yellows; (10) Sunnhemp witches'-broom; (11) Loofah witches'-broom; (12) Clover proliferation; and (13) Peanut witches'-broom (Kirkpatrick et al., 1995; Schneider et al., 1995; White et al., 1998). Primary phytoplasma groups including 19 novel groups, namely Australian grapevine yellows (AUSGY), Italian bindweed stolbur (IBS), Buckthorn witches'-broom (BWB), *Spartium* witches'-broom (SpaWB), *Galactia* little leaf (GaLL), *Vigna* little leaf (ViLL), Clover yellow edge (CYE), Hibiscus witches'-broom (HibWB), Pear decline (PD), European stone fruit yellows (ESFY), Japanese hydrangea phyllody (JHP), *Psammotettix cephalotes*-borne (BVK), Italian alfalfa witches'-broom (IAWB), *Cirsium* phyllody (CirP), Bermuda grass white leaf (BGWL), Sugarcane white leaf (SCWL), Tanzanian lethal decline (TLD), *Stylosanthes* little leaf (StLL), and *Pinus sylvestris* yellows (PinP), that were absent from previous classification schemes have been subsequently defined. These new taxonomic entities were delineated on the basis of phylogenetic tree branching patterns, differences in 16S rRNA

gene sequence similarities that were 1.2–2.3% or greater and, in some instances, by additional considerations such as plant host and vector specificity, primer specificity, and RFLP comparisons of ribosomal and nonribosomal DNA, as well as serological comparisons (Seemüller et al., 2002, 1998).

Most recently, Wei et al. (2007) applied computer-simulated RFLP analysis for classification of phytoplasma strains. Through comparisons of virtual RFLP patterns of 16S rRNA genes and calculations of coefficients of RFLP similarity, the authors classified all available 16S rRNA gene sequences, including sequences from 250 previously unclassified phytoplasma strains, into a total of 28 16Sr RFLP groups. These included ten new groups and dozens of new subgroup lineages (Cai et al., 2008; Wei et al., 2008b). Each new group represents a potential "*Candidatus* Phytoplasma" species level taxon. This information was used to augment the 16Sr RFLP classification system (Lee et al., 2000, 1998b, 1993b) with the following additional groups: 16SrXVI, Sugarcane yellow leaf syndrome; 16SrXVII, Papaya bunchy top group; 16SrXVIII, American potato purple top wilt group; 16SrXIX, Japanese chestnut witches'-broom group; 16SrXX, Buckthorn witches'-broom group; 16SrXXI, Pine shoot proliferation group; 16SrXXII, Nigerian coconut lethal decline (LDN) group; 16SrXXIII, Buckland valley grapevine yellows group; 16SrXXIV, Sorghum bunchy shoot group; 16SrXXV, Weeping tea witches'-broom group; 16SrXXVI, Mauritius sugarcane yellow D3T1 group; 16SrXXVII, Mauritius sugarcane yellow D3T2 group; and 16SrXXVIII, Havana derbid phytoplasma group. The virtual RFLP patterns are available for online use as reference patterns at <http://www.ba.ars.usda.gov/data/mppl/virtualgel.html>.

The spacer region (SR) separating the 16S from the 23S rRNA gene of phytoplasmas was also shown to be a reliable phylogenetic marker. Phylogenetic trees derived from the entire 16S–23S SR (Gibb et al., 1998; Kenyon et al., 1998) or variable regions flanking the tRNA^{leu} gene (Kirkpatrick et al., 1995; Schneider et al., 1995) differentiated phytoplasmas into groups that were concordant with the major groups established previously from analyses of 16S rRNA genes. Phytoplasmas collectively differ in their 16S rRNA gene sequence by no more than 14%, whereas their respective 16S–23S SR sequences differ by as much as 22%. This added variation has contributed to improved accuracy of phytoplasma classification at the subgroup level. Similarly, phylogenetic analysis of ribosomal protein genes, *secY*, *secA*, or 23S rRNA genes has been employed to differentiate closely related phytoplasma strains, as well as to aid the group and subgroup classification of diverse phytoplasmas (Daire, 1993; Hodgetts et al., 2008; Lee et al., 1998b, 2004a, 2006b; Martini et al., 2007; Reinert, 1999). Such studies have led to finer differentiation among phytoplasma subgroups and to enriched descriptions of "*Candidatus* Phytoplasma" species (Lee et al., 2004a, 2006a, b).

A polyphasic system for taxonomy based on integration of genotypic, phenotypic, and phylogenetic information employed for bacterial classification (Murray et al., 1990; Stackebrandt and Goebel, 1994) has proved problematic for nonculturable phytoplasmas. In response to a rapidly growing database of phylogenetic markers, even in the absence of species-defining biological or phenotypic characters, the Working Team on Phytoplasmas of the International Research Programme of Comparative Mycoplasmaology (IRPCM Phytoplasma/Spiroplasma

Working Team – Phytoplasma Taxonomy Group, 2004) proposed that taxonomy of phytoplasmas be based primarily upon phylogenetic analyses. This proposal was agreed to and adopted as policy by the ICSB Subcommittee on the Taxonomy of *Mollicutes* (1993, 1997), which also recommended that the provisional taxonomic status of "Candidatus", originally proposed by Murray and Schleifer (1994), be used for assigning genera names as follows: "Candidatus Phytoplasma" (from *phytos*, Greek for plant; *plasma*, Greek for thing molded) [(*Mollicutes*) NC; NA; O; NAS (GenBank no. M30790); oligonucleotide sequence of unique region of the 16S rRNA gene is CAA GAY BAT KAT GTK TAG CYG GDC T; P (Plant, phloem; Insect, salivary gland); M]. (IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004). By this same approach, major groups within the genus also delineated by phylogenetic analysis of near full-length 16S rRNA gene sequences were considered to represent one or more distinct species.

Current guidelines for "Candidatus Phytoplasma" species descriptions (Anonymous, 2000; Firrao et al., 2005; IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004) are based upon identification of a significantly unique 16S rRNA gene sequence >1200 bp in length. The strain from which the sequence is obtained should be designated as the reference strain. Strains with minimal differences in the 16S rRNA sequence, relative to the reference strain, should be referred to as related strains. In general, a strain can be described as a new "Candidatus Phytoplasma" species if its 16S rRNA gene sequence has less than 97% identity to any previously described "Candidatus Phytoplasma" species (ICSB Subcommittee on the Taxonomy of *Mollicutes*, 2001). There are cases in which phytoplasmas may share more than 97% of their 16S rRNA gene sequence, but clearly represent ecologically distinct populations and, thus, they may warrant description as

separate species. In such cases, the description of two different species is recommended when all of the following conditions apply: (1) the two phytoplasmas are transmitted by different vector species; (2) the two phytoplasmas have a different natural plant host, or at least their symptomatology is significantly different in the same plant host; (3) there is evidence of significant molecular diversity between phytoplasmas as determined by DNA hybridization assays with cloned nonribosomal DNA markers, serological reactions, or by PCR-based assays. The taxonomic rank of subspecies should not be used. Reference strains should be available to the scientific community in graft-inoculated or *in vitro* micropropagated host plants or as DNA if perpetuation of strains in infected host plants is not feasible. Descriptions of "Candidatus Phytoplasma" species should be preferably submitted to the International Journal of Systematic and Evolutionary Microbiology (<http://ijs.sgmjournals.org/>).

Recent phylogenetic investigations, including the present analyses (Figure 116), suggest 97.5% 16S rRNA gene sequence similarity may represent a more suitable upper threshold for "Candidatus Phytoplasma" species separation, in that taxonomic subgroups designated based on 16S rRNA gene sequence similarities of $\leq 97.5\%$ more consistently define species that are phylogenetically distinct from nearest related species. Regardless of homology criteria, a taxonomy is emerging for the phytoplasmas in the absence of cultivability where species and related strains of a species are clearly recognized with due consideration of the genetic, ecological, and environmental constraints unique to this group of plant- and insect-associated *Mollicutes*. To a large extent, the present taxonomy employs vernacular names based on associated diseases, but is constantly shifting towards a traditional taxonomy as more and more "Candidatus Phytoplasma" species continue to be recognized and proposed.

List of species of the genus "Candidatus Phytoplasma"

In accordance with the current guidelines for "Candidatus Phytoplasma" species descriptions, the following species have been designated. Proposed assignments to the class *Mollicutes* are based on nucleic acid sequences. None of these species have been cultivated independently of their host, and their metabolism and growth temperatures are unknown.

1. "Candidatus Phytoplasma allocasuarinae" Marcone, Gibb, Stretten and Schneider 2004a, 1028
Vernacular epithet: Allocasuarina yellows phytoplasma, strain AlloY^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AY135523.
Unique region of 16S rRNA gene: 5'-TTTATTCGAGAG-GGCCG-3'.
Habitat, association, or host: phloem of *Allocasuarina muel-leriana* (Slaty she-oak).
2. "Candidatus Phytoplasma americanum" Lee, Bottner, Secor and Rivera-Varas 2006a, 1596
Vernacular epithet: Potato purple top, strain APPTW12-NE^R.
Gram reaction: not applicable.
3. "Candidatus Phytoplasma asteris" Lee, Gundersen-Rindal, Davis, Bottner, Marcone and Seemüller 2004a, 1046
Vernacular epithet: Aster yellows (AY) phytoplasma, strain OAY^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): M30790.
Unique regions of 16S rRNA gene: 5'-GGGAGGA-3', 5'-CTGACGGTACC-3', and 5'-CACAGTGGAGGTTAT-CAGTTG-3'.
Habitat, association, or host: phloem of *Oenothera hookeri* (Evening primrose).
4. "Candidatus Phytoplasma aurantifolia" Zreik, Carle, Bové and Garnier 1995, 452
Vernacular epithet: Witches'-broom disease of lime phytoplasma, strain WBDL^R.
Morphology: other.
Sequence accession no. (16S rRNA gene): DQ174122.
Unique regions of 16S rRNA gene: 5'-GTTTCTTCGAAA-3' (68–80), 5'-GTTAGAAATGACT-3' (142–153), 5'-GCTGGT-GGCTT-3' (1438–1448).
Habitat, association, or host: *Solanum tuberosum* phloem.

FIGURE 116. Phylogenetic analysis of the phytoplasmas. Phylogenetic trees were constructed by parsimony analyses of phytoplasma 16S rRNA gene sequences using the computer program PAUP (Swofford, 1998). The closely related culturable *Acholeplasma palmae* was employed as the outgroup. Because phytoplasma taxa are too numerous to present in a single inclusive tree, a global phylogeny of representative phytoplasmas is first presented. The global tree is divided into lower (a) and upper (b) regions. Each region of the global phylogeny is then expanded into inclusive trees, a and b, which collectively include 145 phytoplasmas from diverse geographic origins. Taxonomic subgroups, representing phytoplasmas sharing at least 97.5% 16S rRNA gene sequence similarity, are identified on each inclusive tree. Each phylogenetically distinct subgroup is equivalent to a subclade (or putative species) within the genus “*Candidatus* Phytoplasma”. In all trees, branch lengths are proportional to the number of inferred character state transformations. Bootstrap (confidence) values greater than or equal to 50 are shown on the branches. Phytoplasmas for which 16S rRNA gene sequences of at least 1200 bp in length have been determined (312 total) are listed by subgroup in Table 144 along with their sequence accession numbers.

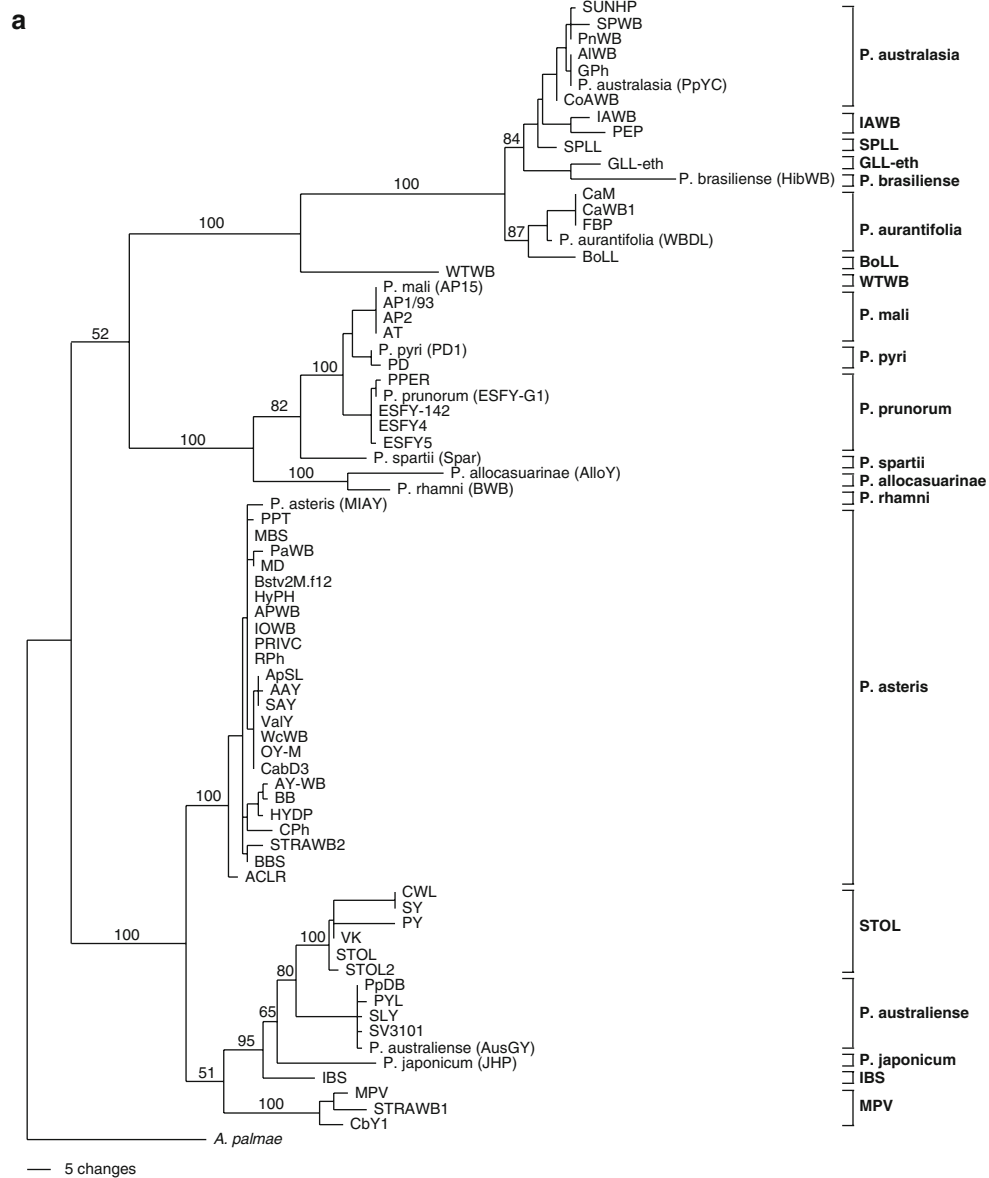

FIGURE 116. (Continued)

Gram reaction: not applicable.

Morphology: other.

Sequence accession no. (16S rRNA gene): U15442.

Unique region of 16S rRNA gene: 5'-GCAAGTGGTGAAC-CATTTGTTT-3'.

Habitat, association, or host: phloem of *Citrus*; hemolymph and salivary glands of *Hishimonus phycitis* (Cicadellidae).

5. "**Candidatus Phytoplasma australasia**" White, Blackall, Scott and Walsh 1998, 949

Vernacular epithet: Papaya yellow crinkle phytoplasma, strain PpYC^R.

Gram reaction: not applicable.

Morphology: other.

Sequence accession no. (16S rRNA gene): Y10097.

Unique regions of 16S rRNA gene: 5'-TAAAAGGCATCTTT-TATC-3' and 5'-CAAGGAAGAAAAGCAAATGGCGAAC-CATTTGTTT-3'.

Habitat, association, or host: phloem of *Carica papaya* and *Lycopersicon esculentum*.

6. "**Candidatus Phytoplasma australiense**" Davis, Dally, Gundersen, Lee and Habili 1997, 268

Vernacular epithet: Australian grapevine yellows phytoplasma, strain AUSGY^R.

Gram reaction: not applicable.

Morphology: other.

Sequence accession no. (16S rRNA gene): L76865.

Unique regions of 16S rRNA gene: 5'-CGGTAGAAATAT-CGT-3' and 5'-TTTATCTTTAAAGACCTCGCAAGA-3'.

Habitat, association, or host: *Vitis* phloem.

7. "**Candidatus Phytoplasma brasiliense**" Montano, Davis, Dally, Hogenhout, Pimentel and Brioso 2001, 1117

Vernacular epithet: Hibiscus witches'-broom (HibWB) phytoplasma, strain HibWB26^R.

Gram reaction: not applicable.

Morphology: other.

Sequence accession no. (16S rRNA gene): AF147708.

Unique regions of 16S rRNA gene: 5'-GAAAAAGAAAAG-3', 5'-TCTTTCTTT-3', 5'-CAG-3', 5'-ACTTTG-3', and 5'-GTCAA AAC-3'.

Habitat, association, or host: *Hibiscus* phloem.

8. "*Candidatus Phytoplasma caricae*" Arocha, López, Piñol, Fernández, Picornell, Almeida, Palenzuela, Wilson and Jones 2005, 2462

Vernacular epithet: Cuban papaya phytoplasma, strain PAY^R.

Gram reaction: not applicable.

Morphology: other.

Sequence accession no. (16S rRNA gene): AY725234.

Vernacular epithet: Bermuda grass white leaf (BGWL) phytoplasma, strain BGWL-C1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ550984.
Unique region of 16S rRNA gene: 5'-AATTAGAAGGCAT-CTTTAAT-3'.
Habitat, association, or host: phloem of *Cynodon dactylon* (Bermuda grass).
11. “**Candidatus Phytoplasma fragariae**” Valiunas, Staniulis and Davis 2006, 280
Vernacular epithet: Strawberry yellows phytoplasma, strain StrawY^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): DQ086423.
Unique regions of 16S rRNA gene: 5'-GTGCAATGCT-CAACGTTGTGAT-3', 5'-AATTGCA-3', and 5'-TGAGTAAT-CAAGAGGGAG-3'.
Habitat, association, or host: phloem of *Fragaria x ananassa*.
12. “**Candidatus Phytoplasma fraxini**” Griffiths, Sinclair, Smart and Davis 1999, 1613
Vernacular epithet: Ash yellows phytoplasma, strain AshY^R and lilac witches’-broom (LWB) phytoplasma.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AF092209.
Unique regions of 16S rRNA gene: 5'-CGGAAACCCCT-CAAAAGGTTT-3' and 5'-AGGAAAGTC-3'.
Habitat, association, or host: phloem of *Fraxinus* and *Syringa*.
13. “**Candidatus Phytoplasma graminis**” Arocha, López, Piñol, Fernández, Picornell, Almeida, Palenzuela, Wilson and Jones 2005, 2462
Vernacular epithet: Sugarcane yellow leaf phytoplasma, strain SCYP^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AY725228.
Unique regions of 16S rRNA gene: 5'-TTTG-3' (465–468), 5'-TTG-3' (478–480), 5'-GGG-3' (1552–1554), 5'-TAA-3' (1381–1383), and 5'-ATTTACGTTTCTG-3' (1392–1404).
Habitat, association, or host: *Saccharum officinarum* phloem.
14. “**Candidatus Phytoplasma japonicum**” Sawayanagi, Horikoshi, Kanehira, Shinohara, Bertaccini, Cousin, Hiruki and Namba 1999, 1284
Vernacular epithet: Japanese *Hydrangea* phyllody phytoplasma, strain JHP^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AB010425.
Unique regions of 16S rRNA gene: 5'-GTGTAGCCG-GGCTGAGAGGTCA-3' and 5'-TCCAACCTAGCTAAA-CAGTTTCTG-3'.
Habitat, association, or host: *Hydrangea* phloem.
15. “**Candidatus Phytoplasma lycopersici**” Arocha, Antesana, Montellano, Franco, Plata and Jones 2007, 1709
Vernacular epithet: Tomato “hoja de perejil” phytoplasma, strain THP^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AY787136.
Unique regions of 16S rRNA gene: 5'-CTTA-3' (positions 175–178), 5'-AATGGT-3' (198–203), 5'-ATA-3' (229–231), 5'-TGGAGGAA-3' (234–242), 5'-CACG-3' (302–305), 5'-TCT-3' (315–317), 5'-GCT-3' (334–336), 5'-TAT-3' (336–338), 5'-TAC-3' (413–415), and 5'-AGC-3' (434–436).
Habitat, association, or host: *Lycopersicon esculentum* phloem.
16. “**Candidatus Phytoplasma mali**” Seemüller and Schneider 2004, 1224
Vernacular epithet: Apple proliferation (AP) phytoplasma, strain AP15^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ542541.
Unique region of 16S rRNA gene: 5'-AATACTCGAAACCA-GTA-3'.
Habitat, association, or host: *Malus* phloem.
17. “**Candidatus Phytoplasma omanense**” Al-Saady, Khan, Calari, Al-Subhi and Bertaccini 2008, 464
Vernacular epithet: Cassia witches’-broom (CWB) phytoplasma, strain IM-1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): EF666051.
Unique regions of 16S rRNA gene: 5'-AAAAAACAGT-3' (467–474), 5'-TTGC-3' (642–645), 5'-GTTAAAAG-3' (853–861), 5'-TAATT-3' (1010–1014), and 5'-AAATT-3' (1052–1056).
Habitat, association, or host: *Cassia italica* phloem.
18. “**Candidatus Phytoplasma oryzae**” Jung, Sawayanagi, Wongkaew, Kakizawa, Nishigawa, Wei, Oshima, Miyata, Ugaki, Hibi and Namba 2003c, 1928
Vernacular epithet: Rice yellow dwarf (RYD) phytoplasma, strain RYD-Th^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession nos (16S rRNA gene): D12581, AB052873 (RYD-Th).

- Unique regions of 16S rRNA gene:* 5'-AACTGGATAGGAAAT-TAAAAGGT-3' and 5'-ATGAGACTGCCAATA-3'.
Habitat, association, or host: *Oryza sativa* phloem.
19. "**Candidatus Phytoplasma phoenicium**" Verdin, Salar, Danet, Choueiri, Jreijiri, El Zammar, Gélie, Bové and Garnier 2003, 837
Vernacular epithet: Almond witches'-broom (AlmWB) phytoplasma, strain AlmWB-A4^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AF515636.
Unique region of 16S rRNA gene: 5'-CCTTTTTTCGGAAGG-TATG-3'.
Habitat, association, or host: *Prunus amygdalus* phloem.
20. "**Candidatus Phytoplasma pini**" Schneider, Torres, Martín, Schröder, Behnke and Seemüller 2005, 306
Vernacular epithet: *Pinus halepensis* yellows (Pin) phytoplasma, strain Pin127S^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ632155.
Unique regions of 16S rRNA gene: 5'-GGAAATCTTTCGGATTTTAGT-3' and 5'-TCTCAGTGCTTAACGCTGT-TCT-3'.
Habitat, association, or host: *Pinus* phloem.
21. "**Candidatus Phytoplasma prunorum**" Seemüller and Schneider 2004, 1224
Vernacular epithet: European stone fruit yellows (ESFY) phytoplasma, strain ESFY-G1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ542544.
Unique regions of 16S rRNA gene: 5'-AATACCCGAAACCA-GTA-3' and 5'-TGAAGTTTTGAGGCATCTCGAA-3'.
Habitat, association, or host: *Prunus* phloem.
22. "**Candidatus Phytoplasma pyri**" Seemüller and Schneider 2004, 1224
Vernacular epithet: Pear decline (PD) phytoplasma, strain PD1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ542543.
Unique regions of 16S rRNA gene: 5'-AATACTCAAAACCA-GTA-3' and 5'-ATACGGCCCCAACTCATACGGA-3'.
Habitat, association, or host: *Pyrus* phloem.
23. "**Candidatus Phytoplasma rhamni**" Marcone, Gibb, Stretten and Schneider 2004a, 1028
Vernacular epithet: Buckthorn witches'-broom phytoplasma, strain BWB^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession nos (16S rRNA gene): X76431, AJ583009.
Unique regions of 16S rRNA gene: 5'-CGAAGTATTTCGA-TAC-3'.
Habitat, association, or host: phloem of *Rhamnus catharticus* (buckthorn).
24. "**Candidatus Phytoplasma solani**" Firrao, Gibb and Stretten 2005, 251
Vernacular epithet: Stolbur phytoplasma; subgroup A reference type of the stolbur phytoplasma taxonomic group 16SrXII (Lee et al., 2000).
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AJ970609 (strain PO; Cimerman et al., 2006).
Unique region of 16S rRNA gene: not reported.
Habitat, association, or host: many species of *Solanaceae* plus several species in other plant families, and *Fulguromorpha* spp. planthopper vectors.
25. "**Candidatus Phytoplasma spartii**" Marcone, Gibb, Stretten and Schneider 2004a, 1028
Vernacular epithet: Spartium witches'-broom phytoplasma, strain SpaWB^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): X92869.
Unique region of 16S rRNA gene: 5'-TTATCCGCGTTAC-3'.
Habitat, association, or host: phloem of *Spartium junceum* (Spanish broom).
26. "**Candidatus Phytoplasma tamaricis**" Zhao, Sun, Wei, Davis, Wu and Liu 2009, 2496
Vernacular epithet: Salt cedar witches'-broom phytoplasma, strain SCWB1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): FJ432664.
Unique regions of 16S rRNA gene: 5'-ATTAGGCATCTAG-TAACTTTG-3', 5'-TGCTCAACATTGTTGC-3', 5'-AGCTTT-GCAAAGTTG-3', and 5'-TAACAGAGGTTATCAGAGTT-3'.
Habitat, association, or host: phloem of *Tamarix chinensis* (salt cedar).
27. "**Candidatus Phytoplasma trifolii**" Hiruki and Wang 2004, 1352
Vernacular epithet: Clover proliferation phytoplasma, strain CP^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession no. (16S rRNA gene): AY390261.
Unique regions of 16S rRNA gene: 5'-TTCTTACGA-3' and 5'-TAGAGTTAAAAGCC-3'.
Habitat, association, or host: *Trifolium* phloem.
28. "**Candidatus Phytoplasma ulmi**" Lee, Martini, Marcone and Zhu 2004b, 345
Vernacular epithet: Elm yellows phytoplasma (EY) phytoplasma, strain EY1^R.
Gram reaction: not applicable.
Morphology: other.
Sequence accession nos (16S rRNA gene): AY197655, AY197675, and AY197690.
Unique regions of 16S rRNA gene: 5'-GGAAA-3' and 5'-CGT-TAGTTGCC-3'.
Habitat, association, or host: *Ulmus americana* phloem.
29. "**Candidatus Phytoplasma vitis**" Firrao, Gibb and Stretten 2005, 251
Vernacular epithet: Flavescence dorée phytoplasma; strains are genetically heterogenous and vary in degree of virulence, but all are referable to subgroups C or D of the elm yellows

phytoplasma taxonomic group 16SrV (Lee et al., 2000).

Gram reaction: not applicable.

Morphology: other.

Sequence accession nos (16S rRNA gene): AY197645 (16SrV subgroup C), AY197644 (16SrV subgroup D1).

Unique regions of 16S rRNA gene: not reported.

Habitat, association, or host: grapevines (*Vitis vinifera*) and the leafhopper vector *Scaphoideus titanus*.

30. “*Candidatus Phytoplasma ziziphi*” Jung, Sawayanagi, Kakizawa, Nishigawa, Wei, Oshima, Miyata, Ugaki, Hiibi and Namba 2003b, 1041

Vernacular epithet: Jujube witches'-broom phytoplasma, strain JWB^R.

Gram reaction: not applicable.

Morphology: other.

Sequence accession nos (16S rRNA gene): AB052875–AB052879.

Unique regions of 16S rRNA gene: 5'-TAAAAAGGCATCTT-TTTGTT-3' and 5'-AATCCGGACTAAGACTGT-3'.

Habitat, association, or host: *Ziziphus jujube* phloem.

Order IV. Anaeroplasmatales Robinson and Freundt 1987, 81^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.n.a.e.ro.plas.ma.ta'les. N.L. neut. n. *Anaeroplasma*, -atos type genus of the order; -ales ending to denote an order; N.L. fem. pl. n. *Anaeroplasmatales* the *Anaeroplasma* order.

This order in the class *Mollicutes* represents a unique group of strictly anaerobic, wall-less prokaryotes (trivial name, anaeroplasmas) first isolated from the bovine and ovine rumen. Other than their anaerobiosis, the description of organisms in the order is essentially the same as for the class. A single family, *Anaeroplasmataceae*, with two genera, was proposed to recognize the two most prominent characteristics of the organisms: a requirement of sterol supplements for growth by those strictly anaerobic organisms now assigned to the genus *Anaeroplasma*; and strictly anaerobic growth in the absence of sterol supplements by those now assigned to the genus *Asteroleplasma*. Genome sizes range from 1542 to 1794 kbp as estimated by renaturation kinetics. The DNA G+C content ranges from 29 to 40 mol%. All species examined utilize the universal genetic code in which UGA is a stop codon. Phylogenetic studies indicate that members of the *Anaeroplasmatales* are much more closely related to the *Acholeplasmatales* than to the *Mycoplasmatales* or *Entomoplasmatales* (Weisburg et al., 1989).

Type genus: *Anaeroplasma* Robinson, Allison and Hartman 1975, 179^{AL}.

Further descriptive information

The initial proposal for elevation of the anaeroplasmas to an order of the class *Mollicutes* (Robinson and Freundt, 1987) was based upon the description of three novel species and the observation that some anaeroplasmas did not have a sterol requirement for growth.

The obligate requirement for anaerobic growth conditions is the single most important property in distinguishing members of the *Anaeroplasmatales* from other mollicutes. The

anaeroplasmas exist in a natural environment where the oxidation potential is maintained at a low level by the metabolism of associated micro-organisms. Anaerobic methods for preparing media and culture techniques for the organisms are essentially those described by Hungate (1969), with media and inocula maintained in closed vessels and exposure to air avoided during inoculation and incubation. A primary isolation medium and clarified rumen fluid broth have been described (Bryant and Robinson, 1961; Robinson, 1983; Robinson et al., 1975).

Family I. **Anaeroplasmataceae** Robinson and Freundt 1987, 80^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.n.a.e.ro.plas.ma.ta.ce'ae. N.L. neut. n. *Anaeroplasma*, -atos type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Anaeroplasmataceae* the *Anaeroplasma* family.

All members have an obligate requirement for anaerobiosis. Organisms assigned to the genus *Anaeroplasma* require sterol supplements for growth. Organisms assigned to the genus *Asteroleplasma* grow in the absence of sterol supplements. Other characteristics are as described for the type genus.

Type genus: Anaeroplasma Robinson, Allison and Hartman 1975, 179^{AL}.

Further descriptive information

The obligate requirement for anaerobic growth conditions and for growth only in media containing cholesterol is established with the methods described by Hungate (1969), with media and inocula maintained in closed vessels and exposure to air avoided during inoculation and incubation. The primary isolation medium and the clarified rumen fluid broth supplemented with cholesterol have been described (Robinson, 1983).

Genus I. **Anaeroplasma** Robinson, Allison and Hartman 1975, 179^{AL}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.n.a.e.ro.plas'ma. Gr. prefix *an* without; Gr. masc. n. *aer* air; Gr. neut. n. *plasma* a form; N.L. neut. n. *Anaeroplasma* intended to denote "anaerobic mycoplasma".

Cells are predominantly **coccoid**, about 500 nm in diameter; clusters of up to ten coccoid cells may be joined by short filaments. Older cells have a variety of pleomorphic forms. **Cells lack a cell wall** and are bound by a single plasma membrane. Gram-stain-negative due to absence of cell wall. **Obligately anaerobic**; the inhibitory effect of oxygen on growth is not alleviated during repeated subcultures. **Require sterol** supplements for growth. **Nonmotile**. Optimal temperature, 37°C; no growth at 26 or 47°C. Optimal pH, 6.5–7.0. Surface colonies have a dense center with a translucent periphery, or "fried-egg" appearance. Subsurface colonies are golden, irregular, and often multilobed. Strains **vary in their ability to ferment various carbohydrates**. The products of carbohydrate fermentation include acids (generally acetic, formic, propionic, lactic, and succinic), ethanol, and gases (primarily CO₂, but some strains also produce H₂). Bacteriolytic and nonbacteriolytic strains have been described. **Commensals** in the bovine and ovine rumen.

DNA G+C content (mol%): 29–34 (T_m, Bd).

Type species: Anaeroplasma abactoclasticum Robinson, Allison and Hartman 1975, 179^{AL}.

Further descriptive information

Cells of *Anaeroplasma* examined by phase-contrast microscopy appear as single cells, clumps, dumbbell forms, and clusters of coccoid forms joined by short filaments. In electron micrographs of negatively stained preparations, pleomorphic forms are observed; these include filamentous cells, budding cells, and cells with bleb-like structures.

All species examined have similar fermentation products of acetate, formate, lactate, ethanol, and carbon dioxide (Robinson et al., 1975). *Anaeroplasma abactoclasticum* is the only species known not to digest casein. *Anaeroplasma abactoclasticum* strains are the only ones known to produce succinate through fermentation. *Anaeroplasma bactoclasticum*, *Anaeroplasma intermedium*, and *Anaeroplasma varium* are the only species known to produce hydrogen and propionate during their fermentation.

The roll-tube anaerobic culture technique (Hungate, 1969), with pre-reduced medium maintained in a system for exclusion of oxygen, is used to culture the organisms (Robinson, 1983; Robinson and Allison, 1975; Robinson et al., 1975;

Robinson and Hungate, 1973). Anaerobic mollicutes in a sewage sludge digester were cultured in an anaerobic cabinet (Rose and Pirt, 1981). Although it is possible that other types of anaerobic culture techniques might be acceptable (anaerobic culture jar or GasPak system), the effective use of such equipment has not been demonstrated (Robinson, 1983). Strains with bacteriolytic activity are detected with the addition of autoclaved *Escherichia coli* cells to the Primary Isolation Medium (PIM) described below. Clear zones around colonies of anaeroplasmata, when viewed by a stereoscopic microscope, are suggestive of bacteriolytic anaeroplasmata. Colonies can be subcultured to clarified rumen fluid broth (CRFB) medium described below.

A slide agglutination test was first used to show that the antigens of anaerobic mollicutes were not related to established *Mycoplasma* or *Acholeplasma* species found in cattle (Robinson and Hungate, 1973). Later, the agglutination test was adapted to either a plate or tube test and combined with an agar gel diffusion test and a modified growth inhibition procedure to examine the antigenic interrelationships among the anaerobic mollicutes (Robinson and Rhoades, 1977). On the basis of these tests, a serological grouping of anaerobic mollicutes appeared compatible with the group separations based upon cultural, biochemical, and biophysical properties of the organisms (Robinson, 1979; Robinson and Rhoades, 1977).

There is no current evidence for the pathogenicity of any of the *Anaeroplasma* species described so far. Obligately anaerobic mollicutes appear to be a heterogeneous group that has been found so far only in the rumen of cattle and sheep (Robinson, 1979; Robinson et al., 1975). Each new isolated group of these organisms seems to have different properties, suggesting that additional undescribed species are likely to exist. The ecological role of these organisms in the rumen has not been determined. Although the titer of these organisms in the rumen appears to be low when compared to titers of other rumen organisms, the mollicutes probably contribute to the pool of microbial fermentation products at that site. Growth of anaeroplasmata is inhibited by thallium acetate (0.2%), bacitracin (1000 mg/ml), streptomycin (200 mg/ml), and D-cycloserine (500 mg/ml), but not by benzylpenicillic acid (1000 U/ml).

Enrichment and isolation procedures

The PIM medium used to grow and detect anaerobic mycoplasmas (Robinson, 1983; Robinson et al., 1975; Robinson and Hungate, 1973) contains: 40% (v/v) rumen fluid strained through cheesecloth, autoclaved, and clarified by centrifugation; 0.05% (w/v) glucose; 0.05% (w/v) cellobiose; 0.05% (w/v) starch; 3.75% (v/v) of a mineral solution consisting of 1.7×10^{-3} M K_2HPO_4 , 1.3×10^{-3} M KH_2PO_4 , 7.6×10^{-4} M NaCl, 3.4×10^{-3} M $(NH_4)_2SO_4$, 4.1×10^{-4} M $CaCl_2$, and 3.8×10^{-4} M $MgSO_4 \cdot 7H_2O$; 0.2% (w/v) trypticase; 0.1% (w/v) yeast extract; 0.0001% (w/v) resazurin; 0.5% (w/v) autoclaved *Escherichia coli* cells; 0.4% (w/v) Na_2CO_3 ; 0.05% (w/v) cysteine hydrochloride; 1.5% (w/v) agar; and 0.0006% (w/v) benzylpenicillic acid. Pure cultures are established by picking individual colonies from PIM roll tubes and subculturing into CRFB medium. CRFB medium contains the same ingredients and concentrations as PIM, except: glucose, cellobiose, and starch concentrations are 0.2% (w/v), and autoclaved *Escherichia coli* cells, agar, and benzylpenicillic acid are omitted. Growth also occurs in a rumen fluid-free medium (Medium D) in which growth factors supplied in rumen fluid are replaced by lipopolysaccharide (Boivin; Difco) and cholesterol (Robinson, 1983; Robinson et al., 1975), or in a completely defined medium in which the trypticase, yeast extract, and lipopolysaccharide of Medium D are replaced by amino acids, vitamins, and phosphatidylcholine esterified with unsaturated fatty acids (Robinson, 1979, 1983). An agar-overlay plating technique carried out in an anaerobic hood has also been reported to be an effective isolation procedure (Robinson, 1979). Anaerobic mollicutes grow only in a prereduced medium maintained in a system for exclusion of oxygen. When resazurin is used in the test medium and becomes oxidized, mollicutes will fail to grow.

Maintenance procedures

Cultures are viable after storage for as long as 5 years at -40°C in CRFB medium. They may also be preserved by lyophilization using standard techniques for other mollicutes (Leach, 1983). However, the type strains of several species of *Anaeroplasmata* are no longer available from the American Type Culture Collection because it was impossible to revive the cultures sent by the depositors.

Differentiation of the genus *Anaeroplasmata* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. The obligately anaerobic nature of *Anaeroplasmata* species is a distinctive and stable characteristic among these organisms. Strictly anaerobic growth plus the requirement for sterol supplements for growth exclude assignment to any other taxon in the class. Moreover, the bacteriolytic capability possessed by some of the anaeroplasmata has not been reported for other mycoplasmas. Plasmalogens (alkenyl-glycerol ethers), which are found in various anaerobic bacteria but not in aerobic bacteria, are major components of polar lipids from anaeroplasmata (Langworthy et al., 1975); this further supports the contention that anaeroplasmata are distinct from other mollicutes.

Taxonomic comments

The first organism in the group to be described was referred to as *Acholeplasma bactoclasticum* (type strain JR^T = ATCC 27112^T; Robinson and Hungate, 1973) because the organism was

thought to lack a sterol requirement for growth. Later, when other obligately anaerobic mollicutes were isolated, these and the JR^T strain were found to require sterol for growth. A proposal was then made to form the new genus *Anaeroplasmata* to accommodate strain JR^T (as *Anaeroplasmata bactoclasticum*; Robinson and Allison, 1975) and a second anaerobic mollicute designated *Anaeroplasmata abactoclasticum* (Robinson et al., 1975). These developments prompted a proposal for an amended classification of anaerobic mollicutes, which included descriptions of *Anaeroplasmata varium* and *Anaeroplasmata intermedium*, the family *Anaeroplasmataceae*, and the order *Anaeroplasmatales* within the class *Mollicutes* (Robinson and Freundt, 1987).

Early serological studies suggested the existence of several distinct species of anaeroplasmata. Subsequent reports on DNA–DNA hybridization, DNA base composition, and genome size comparisons of organisms in the group also indicated the existence of a number of species in two distinct genera of anaerobic mollicutes (Christiansen et al., 1986; Stephens et al., 1985). Strains initially assigned to *Acholeplasma abactoclasticum* [serovar 3, type strain 6-1^T (=ATCC 27879^T)] were found to be a single species with about 80% interstrain DNA–DNA hybridization. However, strains A-2^T (serovar 1) and 7LA^T (serovar 2), previously included in the description of *Acholeplasma bactoclasticum*, are the type strains of separate species designated *Anaeroplasmata varium* and *Anaeroplasmata intermedium*, respectively (Robinson and Freundt, 1987). Strains of *Anaeroplasmata* all have DNA G+C contents in the range 29.3–33.7 mol%, whereas the base composition of serovar 4 strains 161^T, 162, and 163 clustered above 40 mol%. These were assigned to the new genus *Asteroleplasma* [type strain 161^T (=ATCC 27880^T)] whose members are anaerobic, but do not require sterol for growth. Genome sizes ranged from 1542 to 1715 kbp for *Anaeroplasmata* species, as determined by renaturation kinetics (Christiansen et al., 1986). Although the genome sizes reported were in the expected range for members of the class *Mollicutes*, no data are currently available on genome sizes estimated by the more accurate pulsed-field gel electrophoresis technique. A phylogenetic analysis of members of the *Anaeroplasmatales*, based upon 16S rRNA gene sequence comparison, was carried out by Weisburg et al. (1989). *Anaeroplasmata* and *Acholeplasma* are sister genera basal on the mollicute tree.

Further reading

Johansson, K.-E. 2002. Taxonomy of *Mollicutes*. In *Molecular Biology and Pathogenicity of Mycoplasmas* (edited by Razin and Herrmann). Kluwer Academic/Plenum Publishers, New York, pp. 1–29.

Differentiation of the species of the genus *Anaeroplasmata*

The technical challenges of cultivating these anaerobic mollicutes have led to a current reliance principally on the combination of 16S rRNA gene sequencing and reciprocal serology for species differentiation. Serological characterization of anaeroplasmata has been performed with agglutination, modified metabolism inhibition, and immunodiffusion tests (Robinson and Rhoades, 1977). Failure to cross-react with antisera against previously recognized species provides substantial evidence for species novelty. DNA–DNA hybridization values between species

examined are less than 5%. Bacteriolytic and nonbacteriolytic organisms occur within the genus. When grown on agar media containing a suspension of autoclaved *Escherichia coli* cells, bacteriolytic strains form colonies surrounded by a clear zone

due to lysis of the suspended cells by a diffusible enzyme(s). On media lacking suspended cells, bacteriolytic and nonbacteriolytic strains of *Anaeroplasmataceae* cannot be distinguished from each other on the basis of colonial or cellular morphology.

List of species of the genus *Anaeroplasmataceae*

1. *Anaeroplasmataceae abactoclasticum* Robinson, Allison and Hartman 1975, 179^{AL}

a.bac.to.clas'ti.cum. Gr. pref. *a* without; Gr. *bakt-* (L. transliteration *bact-*) part of the stem of the Gr. dim. n. *bakterion* (L. transliteration *bacterium*) a small rod; N.L. adj. *clasticus*, *-a*, *um* (from Gr. adj. *klastos*, *-ê*, *-on* broken in pieces) breaking; N.L. neut. adj. *abactoclasticum* intended to denote "not bacteriolytic".

This is the type species of the genus *Anaeroplasmataceae*. Cells are coccoid, about 500 nm in diameter, sometimes joined into short chains by filaments. Colonies on solid medium are subsurface, but nevertheless present a typical fried-egg appearance. Growth is inhibited by 20 mg/ml digitonin. A major distinguishing factor is the lack of the extracellular bacteriolytic and proteolytic enzymes that characterize the lytic species.

No evidence of a role in pathogenicity.

Source: occurs primarily in the bovine and ovine rumen.

DNA G+C content (mol%): 29.3 (Bd).

Type strain: 6-1, ATCC 27879.

Sequence accession no. (16S rRNA gene): M25050.

2. *Anaeroplasmataceae bactoclasticum* (Robinson and Hungate 1973) Robinson and Allison 1975, 186^{AL} (*Acholeplasmataceae bactoclasticum* Robinson and Hungate 1973, 180)

bac.to.clas'ti.cum. Gr. *bakt-* (L. transliteration *bact-*) part of the stem of the Gr. dim. n. *bakterion* (L. transliteration *bacterium*) a small rod; N.L. adj. *clasticus*, *-a*, *um* (from Gr. adj. *klastos*, *-ê*, *-on* broken in pieces) breaking; N.L. neut. adj. *bactoclasticum* bacteria-breaking.

Pleomorphic and coccoid cells ranging in size from 550 to 2000 nm in diameter. Cells cluster and sometimes form short chains. Colonies on solid medium have a typical fried-egg appearance. Optimal temperature for growth is between 30 and 47°C. Growth is inhibited by 20 mg/ml digitonin. Skim milk is cleared by a proteolytic, extracellular enzyme and certain bacteria are lysed by an extracellular enzyme

that attacks the peptidoglycan layer of the cell wall. Shares some serological relationship to other established species in the genus, but can be distinguished by agglutination, modified metabolism inhibition, and agar gel immunodiffusion precipitation tests.

No evidence of pathogenicity.

Source: occurs in the bovine and ovine rumen.

DNA G+C content (mol%): 32.5 to 33.7 (T_m , Bd).

Type strain: JR, ATCC 27112.

Sequence accession no. (16S rRNA gene): M25049.

3. *Anaeroplasmataceae intermedium* Robinson and Freundt 1987, 79^{VP} in.ter.me'di.um. L. neut. adj. *intermedium* intermediate.

Cellular morphology and colonial features are similar to those of *Acholeplasmataceae bactoclasticum*. Serologically distinct from other species in the genus by agglutination, metabolism inhibition, and agar gel immunodiffusion precipitation tests (Robinson and Rhoades, 1977).

No evidence of pathogenicity.

Source: occurs in the bovine and ovine rumen.

DNA G+C content (mol%): 32.5 (Bd).

Type strain: 7LA, ATCC 43166.

Sequence accession no. (16S rRNA gene): not available.

4. *Anaeroplasmataceae varium* Robinson and Freundt 1987, 79^{VP}

va'ri.um. L. neut. adj. *varium* diverse, varied, intended to mean different from *Anaeroplasmataceae bactoclasticum*.

Cellular morphology and colonial features are similar to those of *Acholeplasmataceae bactoclasticum*. Serologically distinct from other species in the genus by agglutination, metabolism inhibition, and agar gel immunodiffusion precipitation tests (Robinson and Rhoades, 1977).

No evidence of pathogenicity.

Source: occurs in the bovine and ovine rumen.

DNA G+C content (mol%): 33.4 (T_m).

Type strain: A-2, ATCC 43167.

Sequence accession no. (16S rRNA gene): M23934.

Genus II. *Asteroleplasmataceae* Robinson and Freundt 1987, 79^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.ste.rol.e.plas'ma. Gr. pref. *a* not; N.L. neut. n. *sterolum* sterol; *e* combining vowel; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Asteroleplasmataceae* name intended to indicate that sterol is not required for growth.

Cellular and colonial morphology **similar to species of the genus *Anaeroplasmataceae***. Nonmotile. The three strains that form the new genus and species are **obligately anaerobic** and **capable of growth in the absence of cholesterol or serum supplements**. Temperature optimum for growth is 37°C. No evidence of bacteriolytic activity. The organisms are serologically distinct from other members in the family *Anaeroplasmataceae*. Occur in the ovine rumen.

DNA G+C content (mol%): about 40 (T_m , Bd).

Type species: Asteroleplasmataceae anaerobium Robinson and Freundt 1987, 79^{VP}.

Further descriptive information

The most prominent characteristics of the organisms are strictly anaerobic growth and growth in the absence of sterol supplements. The G+C contents of strains analyzed to date are higher than the values for *Anaeroplasmataceae* species (Stephens et al., 1985). DNA-DNA reassociation values clearly show that strains 161^T,

162, and 163 of *Asteroleplasma anaerobium* are genetically related and distinct from established species in the genera *Acholeplasma* or *Anaeroplasmatales* (Stephens et al., 1985). Tube agglutination tests and gel diffusion precipitation tests showed that strains assigned to *Asteroleplasma anaerobium* are serologically distinct from *Anaeroplasmatales* species (Robinson and Rhoades, 1977). No data have been reported on antibiotic sensitivity or pathogenicity of asteroleplasmas. Strains have been isolated only from sheep rumen. Isolation and maintenance techniques are similar to those reported for *Anaeroplasmatales* species.

Differentiation of the genus *Asteroleplasma* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. The obligately anaerobic nature of *Asteroleplasma* is a distinctive and stable characteristic. Strictly anaerobic growth plus growth in the absence of sterol supplements exclude assignment to any other taxon in the class. Extracellular bacteriolytic and proteolytic enzymes are absent. Growth is not inhibited by 20 mg/ml digitonin.

Taxonomic comments

The taxonomic position of strains 161^T, 162, and 163 of obligately anaerobic mollicute serovar 4 was delineated through observations that they did not require sterol for growth (Robinson

et al., 1975), were serologically distinct (Robinson and Rhoades, 1977), and had G+C contents that were much higher than those of *Anaeroplasmatales* species (Christiansen et al., 1986). Less than 5% DNA–DNA relatedness existed between these strains and species assigned to the genus *Anaeroplasmatales* (Stephens et al., 1985). Lastly, the significance of the group and the need to clarify its taxonomic status was emphasized when it was demonstrated that a significant proportion of the anaerobic mollicute population in the bovine and ovine rumen does not require sterol for growth (Robinson and Rhoades, 1982). The phylogenetic analysis of Weisburg et al. (1989) indicated that *Asteroleplasma anaerobium* had branched from the *Firmicutes* lineage independently of *Acholeplasma* and *Anaeroplasmatales*. Further, *Asteroleplasma* shared two of three important synapomorphies that united the *Mycoplasma* and *Spiroplasma* lineages. Thus, the question of possible monophyly and the true phylogenetic position of *Asteroleplasma* with respect to other mollicutes remains open.

Phylum XVII. Acidobacteria phyl. nov.

J. CAMERON THRASH AND JOHN D. COATES

A.ci'do.bac.ter'i.a. *Acidobacteriales* type order of the phylum; removing the *-ales* ending and inserting *-a* to denote phylum; N.L. neut. n. *Acidobacteria* the phylum of *Acidobacteriales*.

The phylum currently contains two classes, three orders, three families, and six described genera. The phylum is identified on the basis of phylogenetic analysis of 16S rRNA gene sequences (Figure 117).

Culture-independent methods have identified significant diversity within the phylum based on 16S rRNA gene sequences (Barns et al., 1999; Hugenholtz et al., 1998; Kuske et al., 1997; Ludwig et al., 1997; Meisinger et al., 2007; Quaiser et al., 2003; Zimmermann et al., 2005). Currently, more than 3000 *Acidobacteria* sequences exist in public databases making up 26 coherent groups within the phylum (Barns et al., 2007). *Acidobacteria* sequences have been detected in a wide variety of habitats including soils, sediments, hot springs, marine

snow, feces (Barns et al., 1999), a variety of cave environments (Meisinger et al., (2007), and references therein), and metal-contaminated soils (Barns et al., 2007). Although few of these representatives have been cultivated, many new isolates have recently been reported (Janssen et al., 2002; Joseph et al., 2003; McCaig et al., 2001; Sait et al., 2006, 2002; Stevenson et al., 2004). Future analysis of these additional isolates should improve understanding of the various functional roles played by members of this phylum, supplementing that for the six genera already described.

Table 145 provides characteristics that can be used to distinguish the six genera.

Type order: Acidobacteriales ord. nov.

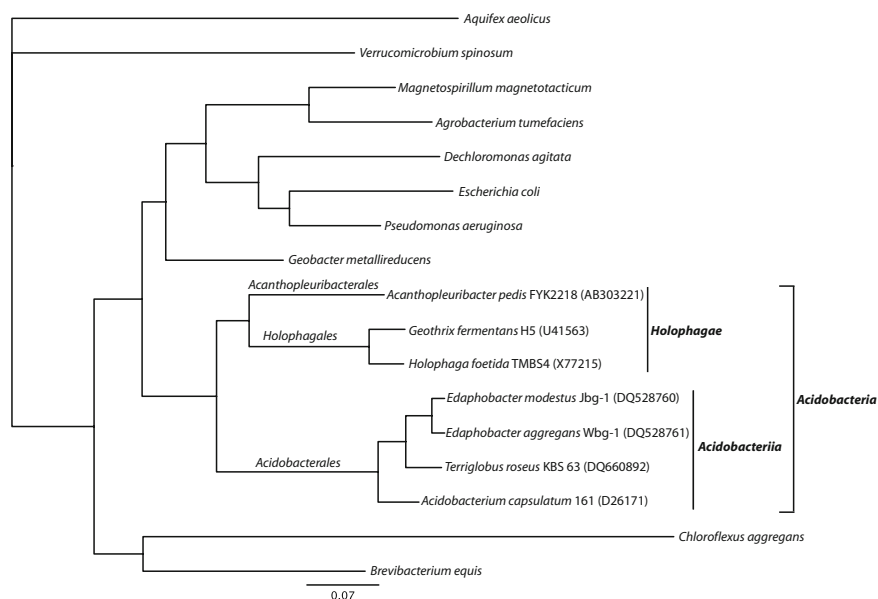

FIGURE 117. Phylogenetic tree of the *Acidobacteria* based on the 16S rRNA gene. The phylum contains six described genera in two classes, three orders, and three families. The class *Acidobacteriia* contains the genera *Acidobacterium*, *Edaphobacter*, and *Terriglobus* in a single family, *Acidobacteriaceae*, in the order *Acidobacteriales*. The class *Holophagae* contains the genera *Holophaga*, and *Geothrix* in the family *Holophagaceae* in the order *Holophagales*, and the genus *Acanthopleuribacter* in the family *Acanthopleuribacteraceae* in the order *Acanthopleuribacteriales*. Bar = 0.07 substitutions per site. Tree was constructed using Bayesian analysis (Huelsenbeck and Ronquist, 2001; Ronquist and Huelsenbeck, 2003).

TABLE 145. Differential characteristics of the genera of the phylum Acidobacteria^a

	<i>Acidobacterium</i>	<i>Edaphobacter</i>	<i>Terriglobus</i>	<i>Holophaga</i>	<i>Geothrix</i>	<i>Acanthopleuribacter</i>
Size (µm)	0.3–0.8 × 1.1–2.3	0.5–0.9 × 1–2.1	0.5–0.7 × 0.9–1.4	0.5–0.7 × 1–3	0.1 × 1–2	0.7–1.0 × 2.4–4.7

The family *Acidobacteriaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences; the family contains the genera *Acidobacterium* (type genus), *Edaphobacter*, and *Terriglobus*. All known species grow as **chemoorganotrophs**.

Type genus: Acidobacterium Kishimoto, Kosako and Tano 1991b, 456 (Effective publication: Kishimoto, Kosako and Tano 1991c, 6.).

Genus I. **Acidobacterium** Kishimoto, Kosako and Tano 1991b, 456^{VP} (Effective publication: Kishimoto, Kosako and Tano 1991c, 6)

J. CAMERON THRASH AND JOHN D. COATES

A.ci'do.bac.ter'i.um. N.L. n. *acidum* an acid; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Acidobacterium* an acid-loving rod.

Rod-shaped cells, 0.3–0.8 µm × 1.1–2.3 µm. Gram-stain-negative. Nonphotosynthetic. Nonsporeforming. **Cells occur singly, in pairs, or in short chains**. **Capsule** produced. **Aerobic**, having an obligately aerobic metabolism. **Acidophilic**. Growth at pH 3.0–6.0, but not at 6.5. No growth at 3.5% NaCl. Do not denitrify. Catalase-positive. Chemoorganotrophic. Growth on a variety of sugars including glucose as the sole carbon source. No growth on alcohols including methanol. Growth is inhibited by 0.25 mM acetate, 2 mM lactate, and 4 mM succinate. Growth at 25–37°C but not at 42°C. **Motile by peritrichous flagella**. The major quinone is menaquinone with eight isoprene units (MK-8). The major fatty acid is C_{15:0}. 2- and 3-Hydroxy fatty acids are absent except for trace amounts of C_{12:0}.

Source: acid mine drainage in the Yanahaya mine, Okayama, Japan.

DNA G+C content (mol%): 59.7–60.8.

Type species: Acidobacterium capsulatum Kishimoto, Kosako and Tano 1991b, 456^{VP} (Effective publication: Kishimoto, Kosako and Tano 1991c, 6.).

Further descriptive information

As seen by electron microscopy, cells have peritrichous flagella. A capsule can be visualized by India ink staining.

The only species in the genus was isolated from a mine in Okayama, Japan by plating acid mine drainage samples on glucose-yeast extract (GYE) plates (Kishimoto and Tano, 1987). Many closely related organisms identified by both culture and culture-independent techniques have been reported from a variety of ecosystems including acid mine drainage (Kishimoto

et al., 1991c), mine mud and soil (Kishimoto et al., 1991c), and other acidic soils (Sait et al., 2006). *Acidobacterium* contains the following major fatty acids: C_{14:0}, C_{15:1}, C_{16:1}, C_{16:0}, C_{17:1}, C_{17:0}, C_{18:1}, C_{18:0}, C_{15:0} iso, C_{17:1} iso, C_{17:0} iso, and C_{19:0} cyclo.

Enrichment and isolation procedures

The type strain was isolated on GYE plates from an acid mine drainage community obtained from the Yanahaya mine in Okayama, Japan. Samples were collected and plated within 8 h (Kishimoto et al., 1991c; Kishimoto and Tano, 1987). GYE media is composed of (g/l distilled water): (NH₄)₂SO₄, 2.0; KCl, 0.1; K₂HPO₄, 0.1; MgSO₄·7H₂O, 0.5; glucose, 1.0, yeast extract (Difco Laboratories), 0.1. pH adjusted to 3.0 with H₂SO₄. Cells are grown at 30°C.

Maintenance procedures

The type strain is maintained as a lyophilized culture at the DSMZ.

Differentiation of the genus *Acidobacterium* from other genera

Acidobacterium is strictly aerobic whereas *Geothrix* and *Holophaga* are strictly anaerobic. *Acidobacterium* is acidophilic, but *Geothrix* and *Holophaga* grow preferentially at about neutral pH. *Acidobacterium* has 79% 16S rRNA gene sequence identity with *Geothrix* and *Holophaga*, 91% identity with *Edaphobacter*, and 92% identity with *Terriglobus*. *Terriglobus* does not contain the fatty acid C_{18:1} ω9c.

List of species of the genus *Acidobacterium*

1. **Acidobacterium capsulatum** Kishimoto, Kosako and Tano 1991b, 456^{VP} (Effective publication: Kishimoto, Kosako and Tano 1991c, 6.)

cap.su.la'tum. N.L. neut. adj. *capsulatum* capsuled.

Colonies on GYE gellan gum plates are pale orange to orange.

The characteristics are as described for the genus with the following additional information. The cells are positive for β-galactosidase, β-glucuronidase, α-fucosidase,

N-acetyl-β-glucosaminidase, and α-glucosidase activity (Kishimoto et al., 1991a). Additionally, cells produce β-glucosidase and secrete it extracellularly (Kishimoto et al., 1991a, c). Cells also have cellulase, xylanase, and trehalase activity (Inagaki et al., 1998, 2001).

DNA G+C content (mol%): 60.8 (HPLC).

Type strain: 161, ATCC 51196, DSM 11244, JCM 7670, NCIMB 13165, NRBC 15755.

Sequence accession no. (16S rRNA gene): D26171.

Genus II. **Edaphobacter** Koch, Gich, Dunfield and Overmann 2008, 1119^{VP}

J. CAMERON THRASH AND JOHN D. COATES

E.da'pho.bac'ter. Gr. neut. n. *edaphos* soil; N.L. masc. n. *bacter* a short rod; N.L. masc. n. *Edaphobacter* rod of the soil.

Rod-shaped cells, 1.0–2.1 μm \times 0.5–0.9 μm . Gram-stain-negative. Nonsporeforming. **Cells occur singly or in clumps**. Do not form capsule. **Aerobic**, having an obligately aerobic metabolism with oxygen as the terminal electron acceptor. **Acidophilic**. Growth at pH 4.0–7.0, with a pH optimum of 5.5. Catalase-positive. Chemoorganotrophic. Growth on a variety of sugars, some amino acids, yeast extract, and peptone as the sole carbon source. Growth between 15 and 37°C, with a temperature optimum of 30°C. May be motile or nonmotile. Major fatty acids include C_{16:1} ω 7c/C_{15:0} iso 2-OH and C_{17:1} ω 8c. Isolated from mollisol on Jochberg in southern Germany and leptosol in a forest near Würzburg, Germany.

DNA G+C content (mol%): 55.8–56.9.

Type species: **Edaphobacter modestus** Koch, Gich, Dunfield and Overmann 2008, 1121^{VP}.

Further descriptive information

Cells form round beige colonies when grown on agar or gellan gum. *Edaphobacter* are positive for the following enzyme activities: alkaline phosphatase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, esterase, esterase lipase, leucyl arylamidase, α -chymotrypsin, α -galactosidase, β -galactosidase, β -glucuronidase, α -glucosidase, β -glucosidase, and α -fucosidase.

Edaphobacter contain the following major fatty acids in common between both species: C_{16:0}, C_{15:0} iso, C_{17:0} iso, and may contain the following additional fatty acids: C_{14:0}, C_{15:0}, C_{17:0}, C_{18:0}, C_{19:0}, C_{14:1} ω 5c, C_{15:1} ω 6c, C_{16:1} iso H, C_{17:1} ω 6c, C_{17:1} ω 8c, C_{18:1} ω 9c, C_{18:1} iso H, C_{14:0} iso, C_{16:0} iso, C_{17:1} iso ω 9c, C_{17:0} 10-methyl, C_{18:0} iso, C_{16:1} ω 7c/C_{15:0} iso 2-OH, and C_{19:1} ω 11c/C_{19:1} ω 9c.

Species in the genus were isolated from mollisol on Jochberg in southern Germany and leptosol in forest near Würzburg, Germany.

Enrichment and isolation procedures

Edaphobacter modestus Jbg-1 was isolated from mollisol at 1400 m on Jochberg, Germany. Enrichments were inoculated from soil sampled within the top 3 cm into pH 6.3 HEPES-buffered (10 mM) media containing pectin, chitin, starch, cellulose, xylan, and curdlan (1% each), and included cAMP, *N*-(oxohexanoyl)-DL-homoserine lactone, *N*-(butyryl)-DL-homoserine lactone at 10 μM each. Incubations were carried out at

15°C. An enrichment positive for acidobacteria-specific PCR products was streaked on agar plates containing casein peptone (0.05%), glucose (0.01%), and yeast extract (0.025%) (Koch et al., 2008).

Edaphobacter aggregans Wbg-1 was isolated from forest leptosol in a deciduous forest near Würzburg, Germany. Agar plates containing defined pH 7.0 phosphate-buffered (100 mM) media, as described by Koch et al. (2008), were sprinkled with soil sampled within the top 8–13 cm and incubated at 20°C in a sealed, 20% methane (in air) headspace. After successive transfers on this media, colonies were transferred to R2A agar plates.

Maintenance procedures

Both strains are maintained as lyophilized culture at the DSMZ.

Differentiation of the genus *Edaphobacter* from other genera

While both *Acidobacterium* and *Terriglobus* can utilize cellobiose, D-galactose, maltose, and D-mannose, *Edaphobacter* species cannot. Likewise, *Edaphobacter* can make use of amino acids, such as L-glutamate and L-glutamine, which the other genera cannot. Additionally, 16S rRNA gene sequence identity between the type species and the other genera distinguishes *Edaphobacter* as a unique genus: 95% identity with *Terriglobus*, 91% identity with *Acidobacterium*.

Differentiation of species of the genus *Edaphobacter*

The two species of the genus *Edaphobacter* are distinguished physiologically by differential substrate utilization. Additionally, *Edaphobacter modestus* and *Edaphobacter aggregans* contain very different fatty acid profiles. The dominant fatty acid for *Edaphobacter modestus* is C_{16:1} ω 7c/C_{15:0} iso 2-OH, with C_{15:0} iso and C_{16:0} as secondary fatty acids. In contrast, the dominant fatty acid for *Edaphobacter aggregans* is C_{17:1} ω 8c, with C_{16:0} iso and C_{17:0} as secondary fatty acids. *Edaphobacter modestus* can be motile, *Edaphobacter aggregans* is nonmotile, and each have slightly different growth ranges for temperature and pH. Also, by DNA–DNA hybridization, these two species share only 11.5–13.6% similarity (Koch et al., 2008).

List of species of the genus *Edaphobacter***1. *Edaphobacter modestus* Koch, Gich, Dunfield and Overmann 2008, 1121^{VP}**

mo.des'tus. L. masc. adj. *modestus* moderate, referring to the adaptation of the type strain to low substrate concentrations.

The type strain is adapted to low substrate concentrations.

The characteristics are as described for the genus with the following additional information. Rods are 1.0–1.8 μm \times 0.5–0.7 μm . Motile. Positive for cytochrome oxidase. Growth

at pH 4.5–7.0 with an optimum of pH 5.5. Growth at 15–30°C with an optimum of 30°C. Differential to Wbg-1, Jbg-1 can utilize L-arabinose, D-fructose, D-glucosamine, D-lyxose, trehalose, D-xylose, L-rhamnose, D-sorbitol, L-lyxitol, D-mannitol, *myo*-inositol, and xylitol. Contains the following fatty acids: C_{16:0}, C_{15:0} iso, C_{17:0} iso, C_{14:0}, C_{18:0}, C_{14:1} ω 5c, C_{17:1} iso ω 9c, and C_{16:1} ω 7c/C_{15:0} iso 2-OH.

DNA G+C content (mol%): 55.8 (HPLC).

Type strain: Jbg-1, ATCC BAA-1329, DSM 18101.

Sequence accession no. (16S rRNA gene): DQ528760.

2. **Edaphobacter aggregans** Koch, Gich, Dunfield and Overmann 2008, 1121^{VP}

ag'gre.gans. L. part. adj. *aggregans* assembling, aggregating.

The type strain may grow in clumps.

The characteristics are as described for the genus with the following additional information. Rods are 1.5–2.1 μm \times 0.7–0.9 μm . Nonmotile. Growth at pH 4.0–7.0 with an optimum of pH 5.5. Growth at 15–37°C with an optimum of 30°C.

Differential to Jbg-1, Wbg-1 can utilize L-aspartate, L-ornithine, and D-glucuronic acid. Contains the following fatty acids: C_{16:0}^o, C_{15:0} iso, C_{17:0} iso, C_{15:0}^o, C_{17:0}^o, C_{19:0}^o, C_{15:1} ω 6c, C_{16:1} iso H, C_{17:1} ω 6c, C_{17:1} ω 8c, C_{18:1} ω 9c, C_{18:1} iso H, C_{14:0} iso, C_{16:0} iso, C_{17:0} 10-methyl, C_{18:0} iso, C_{16:1} ω 7c/C_{15:0} iso 2-OH, and C_{19:1} ω 11c/C_{19:1} ω 9c.

DNA G+C content (mol%): 56.9 (HPLC).

Type strain: Wbg-1, ATCC BAA-1497, DSM 19364.

Sequence accession no. (16S rRNA gene): DQ528761.

Genus III. **Terriglobus** Eichorst, Breznak and Schmidt 2007b, 1933^{VP} (Effective publication: Eichorst, Breznak and Schmidt 2007a, 2715.)

J. CAMERON THRASH AND JOHN D. COATES

Ter.ri.glo'bus. L. fem. n. *terra* earth; L. masc. n. *globus* ball, clump; N.L. masc. n. *Terriglobus* clump of earth.

Rod-shaped cells, 0.5–0.7 μm \times 0.9–1.4 μm . Gram-stain-negative. **Cells occur singly or in clumps**. Extracellular matrix produced. **Aerobic**, having an obligately aerobic metabolism. **Acidophilic**. Growth at pH 4.5–7.0, with optimum between pH 5–6. Catalase-positive. Negative for oxidase activity. Chemooorganotrophic. Growth on a variety of sugars as well as succinate as the sole carbon source. Growth at 12–23°C, but not at 4 or 37°C. Nonmotile. The major fatty acid is C_{16:1} ω 7c/C_{15:0} iso 2-OH.

Source: never-tilled soils at the Michigan State University W. K. Kellogg Biological Station Long-Term Ecological Research (KBS LTER) site in Michigan, USA.

DNA G+C content (mol%): 59.8.

Type species: **Terriglobus roseus** Eichorst, Breznak and Schmidt 2007b, 1933^{VP} (Effective publication: Eichorst, Breznak and Schmidt 2007a, 2716.).

Further descriptive information

Cells contain carotenoids with absorption maxima in chloroform at 473, 505, and 539 nm. *Terriglobus* can grow at oxygen content from 2 to 20%.

Terriglobus contains the following major fatty acids: C_{14:0}^o, C_{15:0}^o, C_{16:0}^o, C_{16:0} N OH, C_{17:0}^o, C_{18:0}^o, C_{20:0}^o, C_{14:1} ω 5c, C_{15:1} ω 6c, C_{16:1} ω 5c, C_{18:1} ω 7c, C_{18:1} ω 5c, C_{20:2} ω 6,9c, C_{13:0} iso, C_{15:0} iso, C_{15:0} anteiso, C_{17:1} iso ω 5c, C_{17:0} iso, C_{17:0} anteiso, C_{19:0} anteiso, C_{15:1} iso H/C_{13:0} 3-OH, and C_{16:1} ω 7c/C_{15:0} iso 2-OH.

The only species in the genus was isolated from never-tilled soils at the Michigan State University KBS LTER site in Michigan, USA.

Enrichment and isolation procedures

Approximately 30 g from 2.5 cm \times 10.0 cm cores of never-tilled soil from the Michigan State University Kellogg Biological Station LTER site was added to 100 ml phosphate-buffered solution containing 137 mM NaCl, 2.7 mM KCl, 10 mM Na₂HPO₄, and 2 mM KH₂PO₄, adjusted to pH 7.0, supplemented with 2.24 mM Na₄P₂O₇ decahydrate and 1 mM dithiothreitol, and stirred vigorously for 30 min. The slurry was allowed to settle for 30 min. Aliquots of supernatant were then used to inoculate serial dilutions in isolation media and plated as described in Eichorst et al. (2007a).

Maintenance procedures

The type strain is maintained as lyophilized culture at the DSMZ.

Differentiation of the genus *Terriglobus* from other genera

Terriglobus can be distinguished from *Acidobacterium* and *Edaphobacter* by 16S rRNA gene sequence identity (92 and 95%, respectively) and fatty acid composition, as *Terriglobus* does not contain the fatty acid C_{18:1} ω 9c, which is present in *Acidobacterium* and *Edaphobacter*.

List of species of the genus *Terriglobus*

1. **Terriglobus roseus** Eichorst, Breznak and Schmidt 2007b, 1933^{VP} (Effective publication: Eichorst, Breznak and Schmidt 2007a, 2716.)

ro'se.us. L. masc. adj. *roseus* rose-colored, pink.

Colonies on R2A medium are round and pink.

The characteristics are as described for the genus with the following additional information. Carotenoid concentration increases with increasing oxygen partial pressures.

DNA G+C content (mol%): 59.8 (HPLC).

Type strain: KBS 63, DSM 18391, NRRL B-41598.

Sequence accession no. (16S rRNA gene): DQ660892.

Family I. **Holophagaceae** Fukunaga, Kurahashi, Yanagi, Yokota and Harayama 2008, 2600^{VP}

J. CAMERON THRASH AND JOHN D. COATES

Ho.lo.pha.ga'ce.ae. N.L. fem. n. *Holophaga* type genus of the family; suff. *-aceae* denoting family; N.L. fem. pl. n. *Holophagaceae* the *Holophaga* family.

The family *Holophagaceae* was designated by Fukunaga et al. (2008) on the basis of phylogenetic analysis of 16S rRNA gene sequences; the family contains the genera *Holophaga* (type genus) and *Geothrix*. All known species grow as **chemoorganotrophs**.

Type genus: Holophaga Liesack, Bak, Kreft and Stackebrandt 1995, 197^{VP} (Effective publication: Liesack, Bak, Kreft and Stackebrandt 1994, 85–90.).

Genus I. **Holophaga** Liesack, Bak, Kreft and Stackebrandt 1995, 197^{VP} (Effective publication: Liesack, Bak, Kreft and Stackebrandt 1994, 88.)

J. CAMERON THRASH AND JOHN D. COATES

Ho.lo'pha.ga. Gr. adj. *holos* entire; Gr. v. *phagein* to eat; N.L. fem. n. *Holophaga* eating it all.

Rod-shaped cells, 0.5–0.7 µm × 1–3 µm. Gram-stain-negative. Nonphotosynthetic. Nonsporeforming. Anaerobic, having **strictly anaerobic** metabolism that is **obligately fermentative**. Ferments trimethoxybenzoate and syringate to dimethylsulfide and methanediol. Ferments pyruvate and trihydroxybenzenes such as pyrogallol and gallate, as well as methylated derivatives of hydroxybenzene including 3,4,5-trimethoxybenzoate (TMB). Aromatics are fermented to acetate. Optimal growth is at 28–32°C. No growth below 10°C or above 35°C. Optimum growth from pH 6.8 to 7.5. No growth below pH 5.5 or above pH 8.0. Growth with NaCl from 0.1 to 1.5%. Nonmotile. Contains ϵ -type cytochromes.

Source: anoxic mud near Konstanz, Germany.

DNA G+C content (mol%): 62.5.

Type species: Holophaga foetida Liesack, Bak, Kreft and Stackebrandt 1995, 197^{VP} (Effective publication: Liesack, Bak, Kreft and Stackebrandt 1994, 89.).

Further descriptive information

Only the following compounds are known to support growth: TMB, syringate, 5-hydroxyvanillate, phloroglucinolmonomethylether, sinapate, ferulate, caffeate, gallate, 2,4,6-trihydroxybenzoate, pyrogallol, phloroglucinol, and pyruvate. Cells also utilize the methyl substituents of methylated aromatic compounds. Methyl substituents are subject to simultaneous or

alternative homoacetogenic metabolism. If sulfide is present in the media, methylated sulfides are formed. Trihydroxybenzenes are degraded through the phloroglucinol pathway.

The only species in the genus was isolated from black anoxic mud near Konstanz, Germany.

Enrichment and isolation procedures

The type strain was isolated with deep-agar dilutions from black anoxic ditch mud near Konstanz, Germany. Mud was added to liquid media dilution series supplemented with 3 mM TMB or syringate (Bak et al., 1992). Dilutions of 10⁻⁴ and higher showed positive growth and were successfully subcultured and transferred to deep-agar tubes for isolation. All enrichment procedures were carried out under anoxic conditions at 28°C in the dark.

Maintenance procedures

The type strain is maintained as lyophilized culture at the DSMZ.

Differentiation of the genus *Holophaga* from other genera

Holophaga is anaerobic and obligately fermentative, distinguishing it from the respiratory *Acanthopleuribacter*, and *Geothrix*. *Holophaga* can complete methyl-transfer reactions to sulfide generating methanethiol and dimethylsulfide. 16S rRNA gene sequence divergence also distinguishes *Holophaga* from *Geothrix* (94%), and *Acanthopleuribacter* (84%).

List of species of the genus *Holophaga*

1. ***Holophaga foetida*** Liesack, Bak, Kreft and Stackebrandt 1995, 197^{VP} (Effective publication: Liesack, Bak, Kreft and Stackebrandt 1994, 89.)

foe.ti'da. L. fem. adj. *foetida* stinking, here referring to the production of malodorous methanethiol and dimethylsulfide.

Colonies on agar are lens-shaped, translucent, beige. The characteristics are as described for the genus with the following additional information.

DNA G+C content (mol%): 62.5 (HPLC).

Type strain: TMBS4, DSM 6591.

Sequence accession no. (16S rRNA gene): X77215.

Genus II. **Geothrix** Coates, Ellis, Gaw and Lovley 1999, 1620^{VP}

J. CAMERON THRASH AND JOHN D. COATES

Ge'o.thrix. Gr. n. *gê* earth; Gr. fem. n. *thrix* hair; N.L. fem. n. *Geothrix* hair of earth, refers to the cell morphology under fumarate-reducing conditions.

Rod-shaped cells 0.1 µm × 1–2 µm. Nonphotosynthetic. Nonsporeforming. Cells occur singly and in chains. Anaerobic,

having an **obligately anaerobic metabolism** that can be either fermentative or respiratory using nitrate, Mn(IV),

anthraquinone-2,6-disulfonate (AQDS), poorly crystalline iron(III) oxide, and iron(III) chelated with nitrilotriacetic acid [Fe(III)-NTA] or citrate as alternative electron acceptors. Chemolithoautotrophic. Growth on yeast extract and organic acids including acetate and lactate, but not on alcohols including ethanol. Capable of fermenting organic acids including citrate and fumarate. End products of citrate fermentation are acetate and succinate. Optimal growth is 35–40°C. No growth at or below 25°C. Nonmotile. Contains ϵ -type cytochromes.

Source: petroleum-contaminated aquifer in Hanahan, South Carolina, USA.

DNA G+C content (mol%): unknown.

Type species: ***Geothrix fermentans*** Coates, Ellis, Gaw and Lovley 1999, 1620^{VP}.

Further descriptive information

When growing with fumarate as the sole electron acceptor in liquid medium, cells form long intertwined chains of hundreds of cells. In contrast, when growing on iron(III) as the sole electron acceptor, cells grow singly or in short chains of two to three cells.

The only species in the genus was isolated from petroleum-contaminated aquifer sediment in South Carolina, USA, by enrichment first with toluene and iron(III) NTA and then with acetate and iron(III) NTA.

Enrichment and isolation procedures

The type strain was isolated on iron(III) pyrophosphate/acetate plates from a contaminated aquifer enrichment culture growing on toluene and iron(III) NTA. The original inoculum was from petroleum-contaminated aquifer sediment from the

Defense Fuel Supply Center in Hanahan, South Carolina, USA. The enrichment sediments were amended with 2 mmol kg NTA and 10 μ M toluene. After sediments were adapted to consistent oxidation of toluene coupled to iron(III) reduction, 1 g of this enrichment sediment was used to inoculate liquid enrichment cultures growing on iron(III) NTA and acetate (Coates et al., 1999). After enrichment, the organism was isolated on iron(III) pyrophosphate/acetate plates where growth resulted in clearing zones in the green-colored iron(III) pyrophosphate around the colonies. All incubations were carried out at 30°C under strictly anaerobic conditions with a N₂/CO₂ (80:20) headspace.

Maintenance procedures

Cultures of *Geothrix* can be maintained on plates or liquid culture with weekly transfers. Long term storage can be done with lyophilization or freezing at –80°C. Cryoprotective agents like 50% glycerol should be added before freezing and must be made anaerobic prior to addition of cells.

Differentiation of the genus *Geothrix* from other genera

Terminal electron-accepting processes distinguish *Geothrix* from *Holophaga* and *Acanthopleuribacter*. *Geothrix* is an obligate anaerobe whereas *Acanthopleuribacter* is an obligate aerobe and *Holophaga* is non-respiratory. Additionally, *Geothrix* can also ferment, *Acanthopleuribacter* does not. Low (94% and 84%) 16S rRNA gene sequence homology distinguishes *Geothrix* from *Holophaga* and *Acanthopleuribacter*, respectively. *Holophaga* is obligately fermentative, whereas *Geothrix* is capable of fermentation and anaerobic respiration of a variety of alternative electron acceptors including iron(III) and nitrate.

List of species of the genus *Geothrix*

1. ***Geothrix fermentans*** Coates, Ellis, Gaw and Lovley 1999, 1620^{VP}

fer.men'tans. L. part. adj. *fermentans* fermenting.

Colonies on iron(III) pyrophosphate are white, less than 1 mm in diameter. Colonies are red when grown on fumarate medium.

The characteristics are as described for the genus with the following additional information. Optimum growth temper-

ature is 35°C. Contact is not required for reduction of insoluble iron(III) oxide (Nevin and Lovley, 2002). Both chelating and electron shuttling properties are identified in soluble fractions of insoluble iron(III) oxide-reducing cultures of *Geothrix fermentans* (Nevin and Lovley, 2002).

DNA G+C content (mol%): unknown.

Type strain: H-5, ATCC 700665, DSM 14018.

Sequence accession no. (16S rRNA gene): U41563.

Rod-shaped cells, 0.7–1.0 µm × 2.4–4.7 µm. Gram-negative by TEM inspection. **Aerobic**, having an obligately aerobic metabolism. **Mesophilic**. Growth at pH 5.0–9.0, optimally at pH 7.0–8.0. Do not reduce nitrate or nitrite. Chemoorganotrophic. Growth on a variety of amino acids including L-serine, as well as α-D-glucose as the sole carbon source. Growth on marine agar from 15 to 30°C with optimum growth at 30°C. **Motile by peritrichous flagella**. The major quinones are menaquinone with six and seven isoprene units (MK-6, MK-8). The major fatty acids are C_{15:0} iso, C_{17:0} iso, C_{16:0}; major hydroxy fatty acids are C_{13:0} iso 3-OH and C_{17:0} iso 3-OH.

Source: *Acanthopleura japonica* chiton from the Boso peninsula, Chiba, Japan.

DNA G+C content (mol%): 56.7.

Type species: **Acanthopleuribacter pedis** Fukunaga, Kurahashi, Yanagi, Yokota and Harayama 2008, 2600^{VP}.

Further descriptive information

As seen by electron microscopy, cells have peritrichous flagella and gram-negative cell wall structure.

The only species in the genus was isolated from foot tissue of a *Acanthopleura japonica* chiton taken from a beach near the

Natural History Museum and Institute at Katsuura, Boso peninsula, Chiba, Japan.

Enrichment and isolation procedures

The type strain was isolated from a *Acanthopleura japonica* chiton. The chiton was washed in sterile artificial seawater (ASW, Naigai Chemical Products), dissected, and tissues homogenized to serve as inoculum for serial dilutions in sterile ASW. Dilutions yielding cells were plated on 1:5 dilution marine agar 2216 (Difco) and incubated at 20°C for 8 d.

Maintenance procedures

The type strain is maintained as a lyophilized culture at the NBRC.

Differentiation of the genus *Acanthopleuribacter* from other genera

Acanthopleuribacter is obligately aerobic whereas *Geothrix* and *Holophaga* are obligately anaerobic. *Acanthopleuribacter* is strictly respiratory, whereas *Geothrix* is respiratory and fermentative and *Holophaga* is strictly fermentative. *Acanthopleuribacter* has 84% 16S rRNA gene sequence identity with *Geothrix* and *Holophaga*.

List of species of the genus *Acanthopleuribacter*

1. ***Acanthopleuribacter pedis*** Fukunaga, Kurahashi, Yanagi, Yokota and Harayama 2008, 2600^{VP}

pe'dis. L. gen. n. *pedis* of the foot, referring to the chiton foot from which the type strain was isolated.

Colonies on marine agar plates are smooth circular, and yellow.

The characteristics are as described for the genus with the following additional information. Cells contain the following major fatty acids: C_{11:0} iso, C_{13:0} iso, C_{14:0}, C_{15:0} iso, C_{16:0},

C_{16:0} N alcohol, C_{17:0} iso, C_{16:1} ω9c, C_{17:1} ω10c iso, C_{20:5} ω3c, C_{13:0} iso 3-OH and C_{17:0} iso 3-OH. Cells also have catalase, oxidase, protease, β-glucosidase, alkaline phosphatase, leucine arylamidase, valine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, N-acetyl-β-glucosaminidase, esterase C4, ester lipase C8, and cystine arylamidase activity.

DNA G+C content (mol%): 56.7 (HPLC).

Type strain: FYK2218, NRBC 101209, KCTC = 12899.

Sequence accession no. (16S rRNA gene): AB303221.

Phylum XVIII. Fibrobacteres Garrity and Holt 2001

ANNE M. SPAIN, CECIL W. FORSBERG AND LEE R. KRUMHOLZ

Fī'bro.bac.ter'es. N.L. masc. n. *Fibrobacter* type genus of the type order; -es ending to denote phylum N.L. fem. pl. n. *Fibrobacteres* the *Fibrobacter* phylum.

The phylum *Fibrobacteres* currently consists of three classes circumscribed on the basis of phylogenetic analysis of 16S rRNA gene sequences, including one cultivated class, *Fibrobacteria* class. nov. *Fibrobacterales* is the type order, and contains a single family and genus.

The phylum *Fibrobacteres* is most closely related to the *Bacteroidetes* [*Cytophaga-Flavobacterium-Bacteroides* (CFB)] phylum based on signature sequences of proteins (Griffiths and Gupta, 2001; Gupta, 2004; Gupta and Lorenzini, 2007). Phylogenetic analyses based on 16S rRNA gene sequences support the relatedness of *Fibrobacteres* to this phylum, but indicate it is even more closely related to a candidate division TG3 (Hongoh et al., 2005, 2006a), and also shares a common ancestor with *Gemmatimonadetes* (Figure 118). The phylum contains three classes (Table 146, Figure 118), only one of which contains cultivated isolates and is formally named and described herein.

Although all of the currently extant species were isolated from the rumen or other locations of the gastrointestinal tract, 16S rRNA

genes related to the *Fibrobacteres* have been observed in a number of environments (Table 146, Figure 119). It is therefore likely that this phylum is much more broadly distributed in the environment than indicated on the basis of the habitat of the pure culture representatives. Clones within the class *Fibrobacteria* (but not belonging to *Fibrobacterales*) were detected in an acid-impacted lake and a sulfidic cave stream biofilm (Figure 119), as well as within the termite species *Macrotermes gilvus* (Hongoh et al., 2006b). The class-level lineage *Fibrobacteria*-2 was originally named a subphylum of *Fibrobacteres* and is solely composed of clone sequences derived from the gut of different species of termites (Hongoh et al., 2006a). The third class-level lineage of *Fibrobacteria*, denoted here as "Environmental clones", consists of clones detected in both soil and water downstream of manure (Figure 119). Although only three sequences are shown in Figure 119, unpublished sequences of <1000 bp belonging to this class-level lineage have been deposited in GenBank and also come from soil and water sources.

Type order: **Fibrobacterales** ord. nov.

FIGURE 118. Maximum-likelihood tree of the phylum *Fibrobacteres* in relation to closely related phyla. The tree was constructed from two or more aligned nearly full-length (>1300 bp) 16S rRNA gene sequences from each phylum-level lineage using the fastDNAMl method. Bootstrap values >50 are shown on the left or above corresponding branches and are based on 1000 replicates.

Family I. **Fibrobacteraceae** fam. nov.

ANNE M. SPAIN, CECIL W. FORSBERG AND LEE R. KRUMHOLZ

Fi.bro.bac.ter.a'ceae. N.L. masc. n. *Fibrobacter* type genus of the family, -aceae ending to denote family; N.L. fem. pl. n. *Fibrobacteraceae* the *Fibrobacter* family.

Cells are Gram-stain-negative obligately anaerobic and rod-to-ovoid in shape depending on the strain and the culture conditions. Older cultures form sphaeroplasts. Motility appears to occur by gliding, but cannot be observed microscopically. Flagella have not been detected. Membranes are composed of straight-chain fatty acids and phospholipids are predominantly ethanolamine plasmalogens.

All of the strains grow by degrading cellulose and cellulose containing plant compounds. Cells will also grow on the soluble sugars, glucose, or cellobiose. The major fermentation products are succinate and acetate. Although bacteria will grow on soluble forms of cellulose, they are thought to exist primarily as cells that are directly attached to decomposing plant material.

Type genus: **Fibrobacter** Montgomery, Flesher and Stahl 1988, 434^{VP}.

Genus I. *Fibrobacter* Montgomery, Flesher and Stahl 1988, 434^{VP}

ANNE M. SPAIN, CECIL W. FORSBERG AND LEE R. KRUMHOLZ

Fi'bro.bac'ter. L. fem. n. *fibra* fiber or filament in plants or animals; N.L. masc. n. *bacter* rod or staff; N.L. masc n. *Fibrobacter* bacterial rod that subsists on fiber.

Cells are rod-shaped (0.3–0.5 $\mu\text{m} \times$ 0.8–1.6 μm) or ovoid (0.8–1.6 $\mu\text{m} \times$ 0.8–1.6 μm). Obligately anaerobic non-sporing and not detectably motile by microscopy. They are able to migrate through agar when growing on cellulose, suggesting a gliding form of motility. Ferment a narrow range of carbohydrates including glucose, cellobiose, and cellulose. Other sugars including lactose or maltose are fermented by a few species. The fermentation products are acetate and succinate, and sometimes formate at low levels. Cells require CO_2 , straight-chain and branched-chain fatty acids in the media as well as ammonia as the N source. Membranes are composed of straight-chain fatty acids, and phospholipids are predominantly ethanolamine plasmalogens. Habitat is the mammalian gastrointestinal tract.

DNA G+C content (mol%): 45–51.

Type species: *Fibrobacter succinogenes* Montgomery, Flesher and Stahl 1988, 434^{VP}.

Taxonomic comments and further descriptive information

The first pure culture of *Fibrobacter* was described as *Bacteroides succinogenes* by (Hungate, 1950). Prévot (1966) considered *Bacteroides succinogenes* to belong in the genus *Ruminobacter*, but the name *Ruminobacter succinogenes* was not validly published. More recently, phylogenetic analysis showed that strains of *Bacteroides succinogenes* were phylogenetically distinct from other species of *Bacteroides* necessitating the formation of a new genus (Montgomery et al., 1988). Sequences of small-subunit rRNA of several strains were shown to have less than 72% similarity with *Bacteroides fragilis* providing evidence that these organisms constituted a distinct evolutionary line of descent at the phylum level.

There are currently no phenotypic characteristics that are useful for distinguishing the two species *Fibrobacter intestinalis* and *Fibrobacter succinogenes*. Small-subunit rRNA analysis must be used. *Fibrobacter succinogenes* subsp. *succinogenes* can be distinguished from *Fibrobacter succinogenes* subsp. *elongatus* based on cell morphology, the former being ovoid and the latter more slender and rod-shaped.

Within the genus, strains of *Fibrobacter succinogenes* subsp. *succinogenes* and *Fibrobacter succinogenes* subsp. *elongatus* have a 16S rRNA sequence similarity of 95.3–98.1% (Amann et al., 1992) and DNA hybridization of less than 20%. Between the two species, the 16S rRNA similarity is 91.8–92.9%, with a DNA hybridization of less than 10%.

Enrichment and isolation procedures

All of the isolates to date have been obtained from the gastrointestinal (GI) tract and have been described as two species within *Fibrobacter*. These organisms were isolated by directly diluting GI tract contents into roll tubes containing media with milled filter paper as substrate. Hungate originally isolated *Fibrobacter succinogenes* using an agar mineral medium containing clarified rumen fluid (a source of nutrients) and acid treated milled cotton (Hungate, 1950) in a mineral solution containing bicarbonate and a reducing agent. This original medium contained 1–2% agar and involved shake or roll tubes. Bryant and Doetsch (1954) later isolated a variety of strains from the rumen, most

likely using similar techniques. Much more recently, an effective technique was described by Macy et al. (1982), which involves diluting the contents of the rat cecum using a mineral solution buffered with 0.5% NaHCO_3 and reduced with cysteine and sulfide. Dilutions were then used as inoculum for a similar agar medium containing 0.5% agar and 0.5% pebble-milled Whatman no. 1 filter paper. Each serum tube (1.6 \times 15 cm) contained a low volume (3 ml) of agar medium. Tubes were then cooled on a tube roller producing an extremely thin agar layer. Tubes were then incubated at 39°C for several days. Cells do not form colonies under these conditions, but the clearings due to cellulose hydrolysis can be easily visualized in this soft thin agar. Cells were picked from the cleared areas and transferred to a rich sugar based medium.

Alternatively, *Fibrobacter succinogenes* can be isolated from enrichment cultures (Stewart et al., 1981). The enrichment media contained minerals, vitamins, fatty acids, and dewaxed cotton (0.25%). After approximately five transfers in the enrichment media, colonies of *Fibrobacter succinogenes* are isolated by diluting into roll tubes containing a cellobiose-based medium.

The above isolation techniques are tedious and also technically challenging. As such, they have not been used commonly outside of the rumen microbiology field. It is likely that this is the main reason why there are no isolates from any environment other than the GI tract.

Miscellaneous comments

Accessibility to cellulose digestion sites in the cell-wall matrix has been suggested as the rate-limiting factor in cellulose digestion (Dehority and Tirabasso, 1998). It has been proposed that access to cell-wall polymers is limited by the small pore size between polymers, which is on the order of 2–4 nm. This size is not sufficient to allow free diffusion of simple globular enzymes with masses greater than 20 kDa into the wall matrix (Gardner et al., 1999). Since the plant cell wall is a matrix of different polymers, a combination of cellulase and hemicellulase enzymes acting simultaneously is therefore essential. It was originally assumed that *Fibrobacter succinogenes* cells contained an array of the key enzymes for plant cell-wall biodegradation because it can burrow into the plant cell-wall matrix (Cheng et al., 1983). Insight into this conclusion was clearly documented (Matulova et al., 2005) by growth of *Fibrobacter succinogenes* strain S85 on ^{13}C enriched wheat straw and by assessment of the products of hydrolysis using a combination of nuclear magnetic resonance spectroscopy, and sugar linkage and compositional analysis. They observed the absence of acetylated xylooligosaccharides among the hydrolysis products despite the highly acetylated state of wheat straw cell-wall materials (Bourquin and Fahey, 1994), thereby documenting extensive enzymic deacetylation. Free sugars and polymers that accumulated in the culture fluid were xylose, arabinose, and arabinoglucuronoxylan oligosaccharides indicating extensive hemicellulase action. They also observed simultaneous degradation of hemicellulose and cellulose, and furthermore, amorphous and crystalline regions of cellulose were degraded at the same rate, which supported the

concept of the concerted action of numerous enzymes in the surface degradation of the cell walls. Glucose did not accumulate in the medium, indicating rapid utilization of plant cell oligosaccharides with minimal cellodextrin export and recycling as previously suggested (Wells et al., 1995). The accumulation of xylose and arabinose occurred as was expected since they are not used as a carbon source (Matte and Forsberg, 1992; Matte et al., 1992). However, 4-OMe- α -glucuronic acid was not detected despite the presence of α -glucuronidase (Smith and Forsberg, 1991), which may be explained by low activity of the enzyme. This research clearly documented that digestion of the cell-wall matrix by *Fibrobacter succinogenes* involves the interaction of a complex array of fibrolytic enzymes.

Enzymology and cloning studies prior to sequencing the genome of *Fibrobacter succinogenes* S85 documented the presence of seven endoglucanases, as well as a cellodextrinase, a chloride-stimulated cellobiosidase, a lichenase, and a α -glucuronidase (Forsberg et al., 2000). Added to this array of enzymes were at least three xylanases (Jun et al., 2003), an arabinose debranching xylanase (Matte and Forsberg, 1992), three acetyl xylan esterases (Kam et al., 2005; McDermid et al., 1990a), an arabinofuranosidase, and a ferulic acid esterase (McDermid et al., 1990b). The debranching nature of both the acetylxylan esterase and the xylanase clearly have very important roles in plant cell-wall biodegradation because they improve access of other enzymes to previously unavailable substrate.

Bera-Maillet et al. (2004) conducted experiments to determine whether ten glycosyl hydrolase genes, previously cloned from *Fibrobacter succinogenes* S85, were present in other strains of *Fibrobacter succinogenes* and in *Fibrobacter intestinalis* strain NR9. Almost all of the glycosyl hydrolase genes were detected in strains of *Fibrobacter succinogenes* closely related to strain S85, and a few were present in *Fibrobacter intestinalis* NR9. Only *celF*, a member of glycosyl hydrolase family 51, a 118-kDa endoglucanase of carbohydrate binding module families 11 and 30, was detected in all strains of *Fibrobacter succinogenes* and in *Fibrobacter intestinalis* NR9. A concluding remark from this study was that *Fibrobacter succinogenes* strain S85 is a representative model of the species for studying the mechanism of cellulose and plant cell-wall digestion.

To elucidate the role of adhesion of *Fibrobacter* cells to microcrystalline cellulose in the digestion of cellulose, adhesion defective mutants were isolated from both *Fibrobacter succinogenes* S85 (Gong and Forsberg, 1989) and *Fibrobacter intestinalis* DR7 (Miron and Forsberg, 1998). In both studies it was observed that the mutants either grew more slowly on cellulose or not at all, but their growth on glucose was unaffected, which suggested that adhesion was essential for cellulose digestion.

Sequencing of the genome of *Fibrobacter succinogenes* strain S85 has dramatically modified the approach to studies on the mechanism of plant cell-wall digestion. The genome of *Fibrobacter succinogenes* S85 is 3.8 Mbp and contains 3252 open reading frames putatively encoding proteins. Of these, 120 appear to encode enzymes involved in plant cell-wall biodegradation on the basis of amino acid sequence similarity to plant cell-wall-degrading enzymes of other bacteria and fungi. The degradative enzymes include 91 glycosyl hydrolases, 14 carbohydrate esterases, and nine pectate hydrolases (Morrison et al., 2003). The glycosyl hydrolases include 33 cellulases (in families 5, 8, 9, 10, 44, 45, 51, and 74), and 27 xylanases (mainly in families 8, 10, 11, 30,

39, and 43). Only five of these cellulases have cellulose binding modules (CBMs) while 13 of the xylanases have CBMs. Hemicellulose debranching enzymes include 14 cinnamoyl esterases (ten containing CBMs) and nine pectate lyases (four containing CBMs). From a count of putative plant cell-wall-degrading enzymes, the number present in *Fibrobacter succinogenes* exceeds those present in *Thermobifida fusca*, *Clostridium thermocellum*, and *Cytophaga hutchinsonii*. However, no proteins were found with similarity to scaffoldin, cohesin, or dockerin proteins characteristic of cellulosomal cellulase complexes present in the ruminal bacteria *Ruminococcus albus* and *Ruminococcus flavefaciens* and the cellulolytic ruminal fungi (Doi and Kosugi, 2004; Lynd et al., 2002). Furthermore, there were no genes encoding cellulases from families 6 and 48, which typically contain exoglucanases found in both cellulosomal and non-cellulosomal cellulase systems that degrade crystalline cellulose, for example, those of *Thermobifida fusca* and *Clostridium thermocellum*. Furthermore, in contrast to the cellulase systems of *Thermobifida fusca* and *Clostridium thermocellum*, which once synthesized remain active, that of *Fibrobacter succinogenes* is inactivated upon suspension of growth (Maglione et al., 1997). This further supports the conclusion that the mechanism of cellulose digestion by *Fibrobacter succinogenes* is very different from that of other organisms in nature.

The availability of the genome has not led to an immediate solution of the mechanism of cellulose digestion by *Fibrobacter succinogenes*. Nonetheless, it has greatly enhanced our ability to dissect the cellulase system through the application of one- and two-dimensional electrophoresis and mass spectroscopy of tryptic digests of nanogram quantities of proteins. A total of 11 novel cellulose binding proteins were identified as important candidates for roles in adhesion of cells to cellulose as all were absent from the outer membrane of a mutant strain of *Fibrobacter succinogenes* S85 incapable of binding to cellulose. None of these proteins contained a classic CBM (Jun et al., 2007). Some of these proteins have affinity specifically for amorphous cellulose, as documented, with a second non-adherent mutant that bound to amorphous cellulose, but not to crystalline cellulose, while others are specific for crystalline cellulose. The binding properties of the proteins were determined by mixing detergent-solubilized outer membranes from the two mutants and the wild-type bacterium with amorphous and crystalline cellulose, and analysis of the bound proteins by SDS-PAGE and mass spectrometry. One of these proteins was a pilin, and a role for pili in binding of *Ruminococcus albus* to cellulose has been documented (Pegden et al., 1998). In the same study, 16 proteins induced by growth of *Fibrobacter succinogenes* on cellulose were also identified, and this included Cel10A (FSU0257) a previously characterized chloride-stimulated cellobiosidase (Huang et al., 1988; Jun et al., 2007). A critical question is whether all of the putative glycosyl hydrolases are expressed at a level sufficiently high to have a role in plant cell-wall digestion, or whether only selected hydrolase enzymes are responsible for this phenotype. Several published studies (Jun et al., 2007; Qi et al., 2007, 2008a) and unpublished data have led to the identification of a short list of glycoside hydrolases that are expressed by *Fibrobacter succinogenes* S85 (Table 147). However, this is not the complete list since the nucleotide sequences of several biochemically characterized xylanases (Matte and Forsberg, 1992), acetyl xylan esterases (McDermid et al., 1990a), feruloyl

^aSymbols: +, present; -, absent.^bAbbreviations: FSU, *Fibrobacter succinogenes*; Mw, molecular weight; IP, isoelectric point; SP, signal peptide; CD, catalytic domain; CBM, carbohydrate-binding module; Fd, fibronectin-like domain; Ig, immunoglobulin-like domain; BTD, basic terminal domain, number of residues (r) in the domain is in parentheses.

esterase(s) (McDermid et al., 1990b), and an α -glucuronidase (Smith and Forsberg, 1991) have not been determined. It will be important to obtain the sequences of these genes, because of their potentially important roles in hemicellulose digestion.

Beginning with highly expressed cellulases, the synergistic interaction of the enzymes was studied (Qi et al., 2007). These experiments led to the conclusion that the two predominant endoglucanases Cel51A (FSU0382) and Cel9B (FSU2361) formerly characterized as endoglucanases 1 and 2, respectively (McGavin and Forsberg, 1988), probably play central roles in cellulose digestion. However, one of the most interesting enzymes recently identified is a glucan glucohydrolase Cel9D (FSU2558) that preferentially cleaves glucose residues from the non-reducing ends of long chains of glucose residues, but does not readily hydrolyze cellobiose (Qi et al., 2008a). It exhibits a strong synergistic interaction with Cel51A (FSU0382) and Cel8B (FSU2303), both of which produce a mixture of cellobiosaccharides as their cellulose hydrolysis products.

Based on our knowledge of the *Fibrobacter succinogenes* cellulase system, a schematic diagram illustrating the cellulases and CBMs involved in cellulose digestion is presented in Figure 120.

Although information about the proteins involved in cellulose digestion is extensive, precise knowledge of the mechanism of decrystallization of highly crystalline cellulose, and the proteins involved in the process, is still lacking. *Fibrobacter succinogenes* S85 obviously has a very efficient mechanism for the initial amorphization of crystalline cellulose, since it grows as rapidly as any other cellulolytic bacterium with crystalline cellulose as the sole source of carbon and energy.

Fibrobacter intestinalis strains are known for their capacity to degrade and utilize cellulose as a source of carbon. The availability of the *Fibrobacter succinogenes* genome sequence has been valuable in the identification of numerous *Fibrobacter intestinalis* glycosyl hydrolases with similarity to those in *Fibrobacter succinogenes*. Application of both forward and reverse suppressive subtractive hybridization (Qi et al., 2005, 2008b) found 37 glycosyl hydrolases in *Fibrobacter intestinalis* strain DR7 that, on the basis of low stringency hybridization, were similar to those in *Fibrobacter succinogenes*. In addition, five other cellulase similarities were already known. This genome sequence provides information that will enable the cloning and subsequent enzymic characterization of many *Fibrobacter intestinalis* cellulases.

List of species of the genus *Fibrobacter*

1. ***Fibrobacter succinogenes*** (*Bacteroides succinogenes* Hungate 1950, 13^{AL}) Montgomery, Flesher and Stahl 1988, 434^{VP}
 suc.ci.no'ge.nes. N.L. n. *acidum succinum* succinic acid; N.L. suff. *-genes* (from Gr. v. *gennaô* to produce), producing; N.L. adj. *succinogenes* succinic-acid-producing.
 Cellulose is also used by all strains. Soluble substrates include cellobiose, D-glucose, and sometimes lactose. Other compounds such as starch, pectin, maltose, and trehalose have been used, but consistent results have not been obtained. Habitats include the mammalian GI tract. Several studies have addressed the question of distribution of *Fibrobacter* within the intestine of cattle, sheep, goats, and horses (Koike et al., 2004; Lin et al., 1994; Lin and Stahl, 1995). *Fibrobacter succinogenes* subsp. *succinogenes* was present in roughly equal levels in comparison to *Fibrobacter succinogenes* subsp. *elongatus* in the rumina of sheep and hay fed cattle. *Fibrobacter succinogenes* subsp. *succinogenes* was the dominant *Fibrobacter* subspecies in rumina of goats. However, this subspecies was only a minor component if observed at all in the lower GI tract of horses and goats and in the rumina of commercial (non-hay fed) steers. These data in conjunction with earlier results support the conjecture that *Fibrobacter succinogenes* subsp. *succinogenes* is a critical component of the rumen microbial community during feeding of hay.
Source: bovine rumen.
DNA G+C content (mol%): 48–49 (Bd).
Type strain: S85, ATCC 19169.
Sequence accession no. (16S rRNA gene): AJ496032.
- 1a. ***Fibrobacter succinogenes* subsp. *succinogenes*** (*Bacteroides succinogenes* Hungate 1950, 13^{AL}) Montgomery, Flesher and Stahl 1988, 434^{VP}
 suc.ci.no'ge.nes. N.L. n. *acidum succinum* succinic acid; N.L. suff. *-genes* (from Gr. v. *gennaô* to produce), producing; N.L. adj. *succinogenes* succinic-acid-producing.
 Cells are ovoid to lemon shaped (0.8–1.6 μm \times 0.9–1.6 μm). Sphaeroplasts form after growth ceases. Colonies on
- cellobiose agar are lenticular, translucent, and light brown when examined by transmitted light. Individual colonies poorly clear cellulose contained in agar unless they are cultured with *Treponema bryanti* (Kudo et al., 1987). Optimal clearing occurs in roll tubes containing 0.5% each of milled cellulose and purified agar (Montgomery and Macy, 1982). Broth cultures are evenly turbid and produce a smooth sediment. All of the strains tested require biotin, and para-aminobenzoic acid (PABA) is stimulatory.
Source: bovine rumen.
DNA G+C content (mol%): 48–49 (Bd).
Type strain: S85, ATCC 19169
Sequence accession no. (16S rRNA gene): AJ496032.
- 1b. ***Fibrobacter succinogenes* subsp. *elongatus*** corrig. Montgomery, Flesher and Stahl 1988, 434^{VP}
 e'lon.ga'tus. L. masc. part. adj. *elongatus* elongated, stretched out.
 Cells are rod-shaped (0.3–0.5 μm \times 0.8–2.0 μm). Sphaeroplasts form after growth ceases. Colonies on cellobiose agar are lenticular, translucent, and light brown when examined by transmitted light. Some strains produce a yellow pigment. Clear zones are formed in cellulose agar, but colonies are indistinct and transient in the absence of fermentable sugars. Clearing is best at 0.5% each of agar and cellulose. Broth cultures are evenly turbid and produce a smooth sediment; some strains produce a yellow pigment. Vitamin requirements are biotin and sometimes cyanocobalamin (B₁₂) and PABA. Habitats include the mammalian intestines, rumina, and ceca. In studies characterizing the distribution of *Fibrobacter* species in the GI tracts of cattle, sheep, goats, and horses (Koike et al., 2004; Lin et al., 1994; Lin and Stahl, 1995), *Fibrobacter succinogenes* subsp. *elongatus* was shown to make up the majority of *Fibrobacter* cells in commercial (grain fed) steers and in the lower GI tract and cecum of one of three goats and in the rumina of the other two goats. It was present at roughly equal levels relative to

FIGURE 120. Putative strategy for cellulose degradation by *Fibrobacter succinogenes*. This figure shows the cellulases produced by *Fibrobacter succinogenes*. Degradation of cellulose could be divided into three steps. In STEP 1, cellulases Cel9B, Cel9C, Cel51A, Cel8B, and Cel5G cleave the cellulose chains probably at amorphous regions and degrade the strand(s) into cellodextrins; STEP 2, cellodextrinases Cel5C and Cl-stimulated cellobiosidase Cel10A degrade the cellodextrins produced in STEP 1 to cellobiose; STEP 2', cellodextrins and single glycan chains on cellulose are degraded to glucose by Cel9D; STEP 3, cellobiose is degraded by cell associated β -glucosidase to glucose intra- or extracellularly. Glucose and cellobiose produced from STEP 2 and 3 can be transported into cells by unknown permeases (Maas and Glass, 1991) and metabolized. Cellulases Cel5G, Cel5H, Cel8B, and Cel9D, which contain the BTDII (amino acid Basic C-Terminal Domain), are cell associated. Cel9H, Cel10A, and Cel51A were also known to be cell associated. Adhesion of *Fibrobacter succinogenes* was shown to be mediated by both catalytic and non-catalytic proteins. Cel5H, Cel51A, Cel10A, and Cel5G contain CBMs (cellulose-binding modules), which are cell associated, and may mediate the attachment of cells to cellulose. Cel9H was known as a cellulose-binding cellulase, but its catalytic properties remain to be studied. Three other cellulases, Cel45C, Cel5B, and Cel9G are also produced by this bacterium. However, since the distribution of these enzymes has not been studied and no CBM or other non-catalytic domains (CDs) could be predicted, the role of these enzymes is unknown (contributed by Dr Meng Qi, University of Guelph).

Phylum XIX. Fusobacteria Garrity and Holt 2001, 140

JAMES T. STALEY AND WILLIAM B. WHITMAN

Fu.so.bac.te'ri.a. N.L. neut. n. *Fusobacterium* genus of the phylum with ending *-ia* to denote phylum; N.L. neut. pl. n. *Fusobacteriia* the phylum of *Fusobacterium*.

The phylum *Fusobacteria* is described in part on the basis of phylogenetic analyses of the 16S rRNA gene sequences of its members. The phylum contains rod-shaped bacteria that stain Gram-negative. Described species are fermentative and produce a variety of organic acids when grown on carbohydrates, amino acids or peptides. Some species are pathogenic to humans.

Type order: **Fusobacteriales** Staley and Whitman, this volume.

Class I. Fusobacteriia class. nov.

JAMES T. STALEY AND WILLIAM B. WHITMAN

Fu.so.bac.te'ri.ia. N.L. neut. n. *Fusobacterium* type genus of the order *Fusobacteriales*; suff. *-ia* ending proposed by Gibbons and Murray and by Stackebrandt et al. to denote class; N.L. neut. pl. n. *Fusobacteriia* the *Fusobacterium* class.

The class *Fusobacteria* is described in part on the basis of phylogenetic analyses of the 16S rRNA gene sequences of its members. The class contains facultative aerobic to obligately anaerobic organisms that stain as Gram-negative rods and ferment carbohydrates or amino acids and peptides to produce various

organic acids including acetic, propionic, butyric, formic or succinic, depending on the substrate and species. Species occur in sediments as well as the oral or intestinal habitats of animals. Some species are human pathogens.

Type order: **Fusobacteriales** Staley and Whitman, this volume.

Order I. Fusobacteriales ord. nov.

JAMES T. STALEY AND WILLIAM B. WHITMAN

Fu.so.bac.te.ri.a'les. N.L. neut. n. *Fusobacterium* type genus of the order; suff. *-ales* ending denoting order; N.L. fem. pl. n. *Fusobacteriales* the *Fusobacterium* order.

The order *Fusobacteriales* is described in part on the basis of phylogenetic analyses of the 16S rRNA gene sequences of its members. The order contains facultative aerobic to obligately anaerobic organisms that stain as Gram-negative rods. All described species are nonmotile and fermentative. Organisms ferment carbohydrates or amino acids and peptides to produce various organic acids including acetic, propionic, butyric, formic or succinic depending on the substrate and species. Species occur in anoxic environments including sediments as well as the oral or intestinal habitats

of animals, including mammals. Some species are pathogenic to humans.

Type genus: **Fusobacterium** Knorr 1922, 4^{AL}.

Family I. **Fusobacteriaceae** fam. nov.

JAMES T. STALEY AND WILLIAM B. WHITMAN

Fu.so.bac.te.ri.a.ce'a.e. N. L. neut. n. *Fusobacterium* type genus of the family; suff. *-aceae* ending denoting family; N.L. fem. pl. n. *Fusobacteriaceae* the *Fusobacterium* family.

The family *Fusobacteriaceae* is described in part on the basis of phylogenetic analyses of the 16S rRNA gene sequences of its members. Micro-aerotolerant to obligately anaerobic organisms that stain as Gram-stain-negative rods. All named species are nonmotile and fermentative. Ferment carbohydrates or amino acids and peptides to produce various organic acids including acetic, propionic, butyric, formic or succinic depending on the

substrate and species. Occur in anoxic environments including sediments as well as the oral and intestinal habitats of animals including mammals.

Comprises the genera *Cetobacterium*, *Fusobacterium*, *Ilyobacter*, and *Propionigenium*.

Type genus: Fusobacterium Knorr 1922, 4^{AL}.

Genus I. **Fusobacterium** Knorr 1922, 4^{AL}

SAHEER E. GHARBIA, HAROUN N. SHAH AND KIRSTIN J. EDWARDS

Fu.so.bac.te'ri.um. L. n. *fusus* a spindle; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Fusobacterium* a small spindle-shaped rod.

Nonsporeforming rods that are **Gram-stain-negative** and **obligately anaerobic**. Metabolize peptone or carbohydrates in PY-glucose to **produce butyrate**, often with acetate and lower levels of lactate, propionate, succinate, and formate.

DNA G+C content (mol%): 26–34.

Type species: Fusobacterium nucleatum Knorr 1922, 17^{AL} [*Bacillus fusiformis* Veillon and Zuber 1898, 540 and other combinations using “*Fusiformis*” except the organism described as *Fusobacterium fusiforme* by Hoffman in the 7th edition of the *Manual*; Group I, Spaulding and Rettger 1937, 535; Group III (and probably *Fusobacterium polymorphum*) Baird-Parker 1960, 458; not *Fusobacterium plauti-vincentii* Knorr 1922, 5.].

Further descriptive information

The genus *Fusobacterium* includes species that do not ferment adonitol, arabinose, dulcitol, glycerol, glycogen, inositol, inulin, mannitol, melezitose, rhamnose, ribose, sorbitol, or sorbose. Cellobiose is not fermented and esculin is not hydrolyzed except by *Fusobacterium mortiferum* and *Fusobacterium necrogenes*; does not reduce nitrate (except for *Fusobacterium ulcerans*); and does not produce catalase, lecithinase, or acetylmethylcarbinol. In addition to butyric, propionic, and acetic acids, species produce variable amounts of butanol from PY medium. Small amounts of formate, lactate, succinate, and ethanol may be produced. Some species convert threonine or lactate to propionate. Pyruvate is converted to acetate and butyrate and sometimes also to formate, succinate, and lactate. H₂S is produced. All species, except *Fusobacterium naviforme* and *Fusobacterium russii*, produce propionate from threonine. Lactate is converted to propionate by *Fusobacterium necrophorum* and *Fusobacterium equinum*. *Fusobacterium* form volatile sulfur compounds from cysteine and methionine (Claesson et al., 1990; Pianotti et al., 1986). All species produce indole except for *Fusobacterium mortiferum*, *Fusobacterium necrogenes*, *Fusobacterium russii*, *Fusobacterium ulcerans*, and some strains of *Fusobacterium varium*. Apart from a weak reaction by *Fusobacterium necrophorum*, only *Fusobacterium equinum* produces esterases, while *Fusobacterium canifelinum* is the only fluoroquinolone resistant species of the genus. Additional features are described in Table 148.

Cell morphology. The cells are pleomorphic, some are arranged into filaments, and are spindle-shaped with pointed ends (fusiform) in a few species, while others are coccobacilli. Width is variable. The cells may be single, in pairs end-to-end, or form long coiled filaments. Staining may be irregular and spheroplasts are common in some species. The cells of *Fusobacterium nucleatum* are slender, spindle-shaped with tapered or pointed ends 0.4–0.7 µm thick and 4–10 µm long, and appear singly, in tandem pairs, or in bundles of roughly parallel bacilli. Filaments are often seen in old cultures of *Fusobacterium periodonticum* and *Fusobacterium simiae* which have similar cellular morphology to *Fusobacterium nucleatum*. The cells of *Fusobacterium necrophorum* are pleomorphic, often curved, with rounded and sometimes tapered ends, and they may have spherical enlargements. Free coccoid bodies and especially filaments are common. Cell length may vary from coccobacilli to long threads in clinical samples. *Fusobacterium naviforme* strains have boat-shaped cells. Gonidial forms may be seen in old cultures of *Fusobacterium gonidiaformans*. *Fusobacterium varium* is a small bacillus that does not form filaments. Strains of *Fusobacterium mortiferum* are extremely pleomorphic with globular forms, swellings, and threads. Short rods are predominant in cultures of *Fusobacterium equinum*. The other fusobacteria are pleomorphic filamentous organisms.

Cell-wall composition. Fusobacteria have a cell-wall structure based on two membranes separated by a periplasmic space containing a peptidoglycan layer. Meso-lanthionine replaces diaminopimelic acid in *Fusobacterium nucleatum*, *Fusobacterium gonidiaformans*, *Fusobacterium necrophorum*, *Fusobacterium russii*, *Fusobacterium necrogenes*, *Fusobacterium simiae*, and *Fusobacterium periodonticum* (Gharbia and Shah, 1990; Kato et al., 1981; Vasstrand et al., 1982), while *Fusobacterium varium*, *Fusobacterium naviforme*, and *Fusobacterium ulcerans* retain meso-diaminopimelic acid and *Fusobacterium mortiferum* contain both versions. *Fusobacterium equinum* and *Fusobacterium canifelinum* have not been tested. Information on the fatty acid content and cell-wall composition of various *Fusobacterium* species can be found in Hofstad (1979), Kato et al. (1981, 1979), Miyagawa et al. (1979), Hofstad and Skaug (1980), Jantzen and Hofstad

^aSymbols: w, weakly positive; w⁻, most strains weakly positive, some negative; -^w, most strains negative, some weakly positive; a^w, strongly acid with some weakly acid reactions; w⁺, usually weakly acid with occasional strong acid reactions; nt, not tested. (Adapted from Conrads et al., 2004a.)

(1981), and Vasstrand (1981). LPS exhibits O-antigenic specificity linked to lipid A through 2-keto-3-deoxyoctonate. The lipid A of *Fusobacterium nucleatum* is structurally similar to that of *Enterobacteriaceae* and cross-reacts serologically with antibodies to *Escherichia coli* lipid A (Dahlen and Mattsby-Baltzer, 1983). *Fusobacterium necrophorum* isolates have a rough-type LPS, whereas that of *Fusobacterium necrophorum* subsp. *necrophorum* is of a smooth type (Brown et al., 1997). The repeat unit of the O-antigenic polysaccharide of *Fusobacterium necrophorum* LPS is an acid identified as a 2-amino-2-deoxy-2-C-methyl-pentonic acid (2-amino-2-methyl-3,4,5-trihydroxypentanoic acid), a novel structure not found before in nature (Hermansson et al., 1993). The main protein of the outer membrane of *Fusobacterium nucleatum*, designated FomA, has a molecular mass of 40 kDa (Bakken et al., 1989b). It is a nonspecific porin present in the outer membrane as a trimer (Kleivdal et al., 1995). The gene encoding the FomA porin has been sequenced (Bolstad et al., 1994). The deduced topology is similar to that of porin structures from other bacteria. *fomA* has been cloned and expressed in *Escherichia coli* (Haake and Wang, 1997; Jensen et al., 1996). Several other outer-membrane proteins have been predicted from the genome sequence, among them some very-high-molecular-mass-proteins (Kapatral et al., 2002). FomA and outer-membrane proteins with molecular masses of 55, 60 and 70 kDa are the major antigens in *Fusobacterium nucleatum* (Bakken et al., 1989a).

The cellular fatty acids in the *Fusobacterium* species examined are straight-chain saturated and monoenoic acids of chain lengths C₁₂-C₁₈ and *O*-3-hydroxy-tetradecanoate is distinctive to the oral species *Fusobacterium nucleatum*, *Fusobacterium simiae*, and *Fusobacterium periodonticum* (Jantzen and Hofstad, 1981).

Comparison of small-subunit rRNA sequences has revealed levels of sequence similarity that are consistent with the single genus, but intragenetic heterogeneity is evident (Lawson et al., 1991; Tanner et al., 1994). *Fusobacterium nucleatum*, the species isolated most frequently from humans, is divided into five subspecies; *Fusobacterium nucleatum* subsp. *nucleatum*, subsp. *polymorphum*, subsp. *vincetii*, subsp. *fusiforme*, and subsp. *animalis*, described on the basis of electrophoretic patterns of whole-cell proteins and DNA homology (Dzink et al., 1990) and electrophoretic mobility of two enzymes and DNA homology (Gharbia and Shah, 1992). Recent evidence to support the heterogeneity within *Fusobacterium nucleatum* and the existence of distinct subspecies within *Fusobacterium nucleatum* was obtained by comparison of their 16S-23S internal transcribed spacer regions (Conrads et al., 2002).

Fusobacterium periodonticum is phylogenetically similar to *Fusobacterium nucleatum* (Jousimies-Somer and Summanen, 2002). *Fusobacterium nucleatum*-like isolates from cats and dogs were found to be distinct from *Fusobacterium nucleatum* both in their 16S rRNA and DNA-DNA hybridization. These have been reclassified as *Fusobacterium canifelinum* which are resistant to levofloxacin (MIC >4 µg/ml) and other fluoroquinolones. The resistance is due to two substitutions in the quinolone resistance determining region of *gyrA* relative to *Fusobacterium nucleatum*. The first replacement is of Ser79 with leucine and the second is Gly83 is replaced with arginine (Conrads et al., 2005).

Animal isolates of *Fusobacterium necrophorum* form two subspecies: *Fusobacterium necrophorum* subsp. *necrophorum* and *Fusobacterium necrophorum* subsp. *funduliforme* (Shinjo et al., 1991)

corresponding to biovars A and B. A distinctive feature separating the subspecies genetically is the presence of isoleucine and alanine tRNA gene in *Fusobacterium necrophorum* subsp. *necrophorum*, while *Fusobacterium necrophorum* subsp. *funduliforme* contains the isoleucine tRNA gene (Jin et al., 2002).

Genetic differences between the species have been reported in leukotoxin A (*lktA*) between both subspecies (Narayanan et al., 2001). Subspecies *necrophorum* is more frequently isolated, often in pure culture, from liver abscesses than subsp. *funduliforme*. Leukotoxin, an exotoxin, is a major virulence factor. In *Fusobacterium necrophorum* subsp. *necrophorum*, Lkt is a high-molecular-mass protein that is encoded by a tricistronic leukotoxin operon (*lktBAC*) and induces apoptosis and necrosis of bovine leukocytes in a dose-dependent manner. The subsp. *funduliforme* produces lower concentration of leukotoxin and hence is less virulent than subsp. *necrophorum*. The low toxicity associated with subsp. *funduliforme* leukotoxin, a less virulent subspecies, may in part be due to the differences in the *lktA* gene and reduced transcription (Tadepalli et al., 2008).

Fusobacterium mortiferum, *Fusobacterium varium*, and *Fusobacterium ulcerans* share several phenotypic properties similar to *Fusobacterium varium*, but *Fusobacterium ulcerans* reduces nitrate to nitrite (Citron, 2002). It also contains unique fragments of 1000 and 550 bp not present in *Fusobacterium varium* and *Fusobacterium mortiferum* (Claros et al., 1999). *Fusobacterium necrogenes* is distantly related to the other *Fusobacterium* species. Based on 16S-23S rDNA spacer region sequences (Conrads et al., 2002) *Fusobacterium gonidiaformans* is genealogically related to *Fusobacterium necrophorum* (Nicholson et al., 1994).

Metabolism. The core metabolism of *Fusobacterium nucleatum* is similar to that of *Clostridium*, *Lactococcus*, and *Enterococcus* species (Kapatral et al., 2002). More than 137 transporters for the uptake of substrates such as peptides, sugars, metal ions, and cofactors have been detected. Amino acids and small peptides comprise the major sources of energy for all *Fusobacterium* species (Gharbia and H.N. Shah, 1989), however, peptides influence the uptake of amino acids enhancing the utilization of histidine and glutamate while threonine, methionine, and asparagine were repressed (Gharbia et al., 1989). Acidic and cationic amino acids are the main acids incorporated. Glutamate, histidine, lysine, and serine appear to be key amino acids in *Fusobacterium nucleatum* (Gharbia and Shah, 1991a; Rogers et al., 1992). Biosynthetic pathways exist for glutamate, aspartate, and glutamylglutamate to be used as growth substrates for *Fusobacterium nucleatum* (Takahashi and Sato, 2002). Glutamate is a key catabolic substrate in *Fusobacterium* species (Gharbia and Shah, 1991b). It is catabolized via the 2-oxoglutarate pathway with the production of acetate and butyrate as end products (Gharbia and Shah, 1991b). Glutamate may also be degraded by the methylaspartate pathway in *Fusobacterium varium* (Gharbia and Shah, 1991b). Enzymes representative for the mesaconate pathway for catabolism of glutamate have been detected in *Fusobacterium varium*, *Fusobacterium mortiferum*, and *Fusobacterium ulcerans* (Gharbia and Shah, 1991b). *Fusobacterium varium* and *Fusobacterium mortiferum* also possess enzymes representative of the 4-aminobutyrate pathway.

Amino acids are imported as monomers, di-, or oligopeptides, and an active transport of the dipeptide L-cysteinglycine has been detected in *Fusobacterium nucleatum* (Carlsson et al., 1994).

Fusobacterium species differ in their ability to use fermentable carbohydrates as energy sources for growth (Robrish et al., 1991). *Fusobacterium nucleatum* and other species utilize glucose for biosynthesis of intracellular glycopolymers that can be degraded to produce energy under conditions of amino-acid deprivation (Robrish et al., 1987). The accumulation of glucose is dependent on energy generated by the fermentation of amino acids (Robrish et al., 1987). *Fusobacterium mortiferum* is an exception in that accumulation of sugars is independent of a fermentable amino acid. Significantly, *Fusobacterium mortiferum* has the ability to metabolize various sugars as energy sources for growth (Robrish et al., 1991). Sugars utilized include α - and β -glycosides, which are transported by the phosphoenolpyruvate-dependent sugar: phosphotransferase system. Thus, it utilizes sucrose and its isomeric α -D-glucosyl-D-fructoses as energy sources for growth (Pikis et al., 2002).

The genes encoding phospho- β -glucosidase (P- β -glucosidase; EC 3.22.1.86) and 6-phospho- α -D-glucosidase (maltose-6-phosphate hydrolase; EC 3.2.1.122) known as *phgA* and *malH*, respectively, have been expressed in *Escherichia coli* (Bouma et al., 1997; Thompson et al., 1997).

Genetics. The genome of *Fusobacterium nucleatum* subsp. *nucleatum* (strain ATCC 25586^T) contains 2.17 Mb encoding 2067 open reading frames (ORFs) organized on a single circular chromosome (Kapatral et al., 2002). About 2.3% of the ORFs are unique to *Fusobacterium nucleatum*. The genome analysis has revealed several key aspects of the pathways of organic acid, amino acid, carbohydrate, and lipid metabolism. Nine very-high-molecular-mass outer-membrane proteins are predicted from the sequence, none of which has been reported in the literature. More than 137 transporters for the uptake of a variety of substrates such as peptides, sugars, metal ions, and cofactors have been identified. Biosynthetic pathways exist for only three amino acids: glutamate, aspartate, and asparagine. The remaining amino acids are imported as such or as di- or oligopeptides that are subsequently degraded in the cytoplasm. A principal source of energy appears to be the fermentation of glutamate to butyrate. Additionally, desulfuration of cysteine and methionine yields ammonia, H₂S, methyl mercaptan, and butyrate, which are capable of arresting fibroblast growth, thus preventing wound healing and aiding penetration of the gingival epithelium.

Analysis of the draft genome sequence of *Fusobacterium nucleatum* subsp. *vincentii* (ATCC 49256), and comparison of this sequence to the genome ATCC 25586 sequence resolved that 441 ORFs have no orthologs in strain ATCC 25586. Of these, 118 ORFs have no known function and are unique, whereas 323 ORFs have functional orthologs in other organisms. Genes for eukaryotic serine/threonine kinase and phosphatase, transpeptidase E-transglycosylase Pbp1A were also identified among the ATCC 49256-specific ORFs. Unique ABC transporters, cryptic phages, and three types of restriction-modification systems have been identified in ATCC 49256. ORFs for ethanolamine utilization, thermostable carboxypeptidase, glutamyl-transpeptidase, and deblocking aminopeptidases are absent from ATCC 49256. Both strains lack a catalase-peroxidase system, but possess thioredoxin/glutaredoxin enzymes. Genes for resistance to antibiotics such as acriflavin, bacitracin, bleomycin, daunorubicin, florfenicol, and other general multidrug resistance are present (Kapatral et al., 2003)

The genome of *Fusobacterium nucleatum* subsp. *polymorphum* ATCC 10953 contains a chromosome of approximately 2.4 Mbp and a plasmid (pFN3) of 11.9 kbp, and there are 2361 proteins encoded in the genome. Plasmid pFN3 from the strain was also sequenced and analyzed. When compared to the other two available fusobacterial genomes (*Fusobacterium nucleatum* subsp. *nucleatum* and *Fusobacterium nucleatum* subsp. *vincentii*) 627 ORFs unique to *Fusobacterium nucleatum* subsp. *polymorphum* ATCC 10953 were identified. A large percentage of these mapped within one of 28 regions or islands containing five or more genes. Seventeen percent of the clustered proteins that demonstrated similarity were most similar to proteins from the clostridia, with others being most similar to proteins from other Gram-stain-positive organisms such as *Bacillus* and *Streptococcus*. A 10 kb region homologous to the *Salmonella typhimurium* propanediol utilization locus was identified, as was a prophage and integrated conjugal plasmid. The genome contains five composite ribozyme/transposons similar to the CdIst IStrons described in *Clostridium difficile*.

Additionally, three plasmids isolated from *Fusobacterium nucleatum* strains were sequenced. These are designated pFN1, pPA52, and pKH9 (Bachrach et al., 2004; Haake et al., 2000; McKay et al., 1995).

Ecology. *Fusobacterium* are normal inhabitants of the mucous membrane of humans and animals. The habitat of *Fusobacterium nucleatum* and *Fusobacterium periodonticum* is the human oral cavity; the gingival crevice is the niche of both. Strains are isolated from the oral microflora of adults and children and are also found in edentulous infants. The vagina is likely to be the primary endogenous site for *Fusobacterium naviforme* and *Fusobacterium gonidiaformans* (Hill, 1993). The habitat of *Fusobacterium mortiferum* and *Fusobacterium varium* is the gastrointestinal tract, where they are present in small numbers. *Fusobacterium necrogenes*, which was originally isolated from a chicken abscess and from cecal contents of ducks, is very rarely isolated from humans. The habitat of *Fusobacterium ulcerans*, isolated from tropical ulcers, is unknown.

Fusobacterium necrophorum is a normal inhabitant of the alimentary tract of cattle, horses, sheep, and pigs and is frequently isolated from cats and dogs. Reports, mainly from the first part of the twentieth century, indicate its presence in a range of wild animals including reptiles. However, the relatively frequent isolation of *Fusobacterium necrophorum* from soft-tissue infections of the oral cavity and the upper respiratory tract compared to elsewhere in the body, suggest that these sites are the principal human habitat of this organism.

Fusobacterium russii is normally found in the canine and feline oral flora (Love et al., 1987), but it has also been isolated from human feces. The oral cavity of horses and the stump-tailed macaque (*Macaca arctoides*) are the habitat of *Fusobacterium equinum* and *Fusobacterium simiae*, respectively. *Fusobacterium canifelinum* was isolated from the microflora of infected cat and dog bite wounds in humans (Conrads et al., 2005).

Maintenance procedures

Fusobacteria are not particularly demanding with regard to a low oxidation-reduction potential. They are, however, killed fairly readily by exposure to oxygen. This is possibly due to their susceptibility to peroxides. Growth is best at 35–37°C and at a pH near 7.

All *Fusobacterium* species grow on blood agar based on proteose-peptone, tryptone, or trypticase. Good growth is usually obtained in a rich semifluid medium such as brain heart medium supplemented with yeast extract. Batch cultivation is best performed in a fluid medium containing a reducing agent.

Laboratory isolation and identification

Fusobacterium species can be separated from other related taxa based on their phylogenetic relatedness and distinctive phenotypic characteristics (Table 149).

The isolation of fusobacteria from an aerobic infection requires proper collection of the specimen, the use of an anaerobic transport vial, optimal anaerobiosis (an anaerobic chamber is not necessary), and a rich medium for optimal growth. Fastidious Anaerobe Agar Base (FAA, Lab M) supplemented with 5% sheep or horse blood is recommended for culture.

The use of a selective medium is necessary for the enumeration of viable fusobacteria in specimens of normal flora. The addition of josamycin, vancomycin, and norfloxacin plus 5% defibrinated horse blood to FAA supports the growth of *Fusobacterium* species while completely inhibiting most other obligate anaerobes and facultative bacteria (Brazier et al., 1991). Rifampin blood agar (Sutter et al., 1971) is useful for the selective isolation of *Fusobacterium varium* and *Fusobacterium mortiferum*. Diagnostic tables are convenient for the examination of bile resistance, production of alkaline phosphatase, and orthonitrophenol- β -D-galactopyranoside (ONPG)-test. Commercially available kits based on the detection of preformed enzymes and designed for identification of anaerobes may be of help in supporting a suspected identity of a *Fusobacterium* isolate.

Surface colonies of *Fusobacterium nucleatum* are 1–2 mm in diameter after incubation for 2 d. They are white to yellow-gray in color, speckled, smooth or breadcrumb-like. The colonies are usually nonhemolytic. Cultures of *Fusobacterium nucleatum* produce an unpleasant, but not fetid, smell. After incubation for 2 d, colonies of animal isolates of *Fusobacterium necrophorum* produce a foul, putrid odor. Fluid or semifluid cultures are characterized by abundant production of gas, and colonies are about 2 mm in diameter, flat, circular with scalloped to erose edge, opaque, and white to gray (subsp. *necrophorum*); or 1 mm wide, circular with entire margins, gray, translucent, and with smooth surfaces (subsp. *funduliforme*) (Shinjo et al., 1991).

The colonial morphology of *Fusobacterium necrophorum* isolated from human infections is similar to that of *Fusobacterium necrophorum* subsp. *funduliforme*. The colonies are small and have been described as creamy, opaque, smooth, umbonate or raised, and with entire edges (Hall et al., 1997). The colonial morphology of most other *Fusobacterium* species is similar to that of *Fusobacterium necrophorum* subsp. *funduliforme*.

All *Fusobacterium* species produce butyric acid. They are catalase and nitrate negative, sensitive to kanamycin (1000 μ g disk) and colistin (10 μ g disk), resistant to vancomycin (5 μ g disk), and produce a rancid odor.

Determination of the electrophoretic migration of glutamate dehydrogenase and 2-oxoglutarate reductase provides a rapid method for the identification of most *Fusobacterium* species (Gharbia and Shah, 1990). Identification based on gas-liquid chromatography of cellular fatty acids may be of value in reference laboratories, provided a database is used as a basis for comparison. A DNA probe has been used successfully to detect

Fusobacterium nucleatum directly in samples of subgingival plaque (Lippke et al., 1991), and checkerboard DNA–DNA hybridization has been used successfully to detect *Fusobacterium nucleatum* and subspecies in periodontal and endodontic infections (Socransky et al., 1998; Sunde et al., 2000). A PCR-detection of part of the

major 40 kDa outer-membrane protein, the FomA porin of *Fusobacterium nucleatum*, is specific for *Fusobacterium nucleatum* when used under condition of high stringency (Bolstad and Jensen, 1993). Sequencing of 16S rRNA from clinical isolates provides a discriminatory tool for separating all species (Figure 121).

List of species of the genus *Fusobacterium*

1. ***Fusobacterium nucleatum*** Knorr 1922, 17^{AL}. [*Bacillus fusiformis* Veillon and Zuber 1898, 540 and other combinations using “*Fusiformis*” except the organism described as *Fusobacterium fusiforme* by Hoffman in the 7th edition of the *Manual*; Group I, Spaulding and Rettger 1937, 535; Group III (and probably *Fusobacterium polymorphum*) Baird-Parker 1960, 458; not *Fusobacterium plauti-vincentii* Knorr 1922, 5.]

nu.cle.a'tum. L. neut. adj. *nucleatum* having a kernel, intended to mean nucleated.

Cells from glucose broth cultures are 0.4–0.7 × 3 μm, have tapered to pointed ends, and often have central swellings and intracellular granules. Cell length is variable but is usually fairly uniform within actively growing cultures. Cells do not possess pili or flagella (Dahlen et al., 1978; Falkler and Hawley, 1977). Surface colonies on blood agar are 1–2 mm in diameter, circular to slightly irregular, convex to pulvinate, translucent often with a “flecked” appearance, usually nonhemolytic (horse or rabbit blood), but may be slightly hemolytic under the area of confluent growth or may produce greenish discoloration of the blood agar upon exposure to oxygen. Glucose broth cultures have a flocculent or granular sediment with or without turbidity, a final pH of 5.6–6.2, and a foul “bad breath” odor. Produces DNase (Porschen and Sonntag, 1974). No phosphatase detected (Porschen and Sonntag, 1974). Most strains produce H₂S. Capable of hemagglutinating human and animal erythrocytes. Contains the diamino acid lantionine in cell-wall peptidoglycan as a major component;

no lysine, diaminopimelic acid, or ornithine (Gharbia and Shah, 1990; Kato et al., 1979; Vasstrand, 1981). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974). Grows in the presence of up to 6% oxygen; survives exposure to air for 100 min (Loesche, 1969).

Strains are resistant to 3 μg/ml of erythromycin (broth disc test). Some *Fusobacterium nucleatum* isolates produce β-lactamase, an activity not reported for other *Fusobacterium* species. A penicillin-hydrolyzing β-lactamase inhibited by clavulanic acid has been isolated from *Fusobacterium nucleatum* (Turner et al., 1985). *Fusobacterium nucleatum*, similar to other species of the genus, are susceptible to amoxicillin/clavulanate, carbapenems, chloramphenicol, quinolone clinafloxacin, linezolid, and nitroimidazoles (Goldstein et al., 1999). Resistance to cefoxitin and clindamycin is very low. Resistance to tetracyclines is common in *Fusobacterium nucleatum* since a high percentage of strains harbor a chromosomal *tetM* locus. Alternatively, a *tetM* determinant on a conjugal transposon (Roberts and Lansciardi, 1990) was also detected. Resistance to glycyglycines has not been observed (Downes et al., 1999). *Fusobacterium nucleatum* is sensitive to the bactericidal action of protegrins and other antibacterial peptides (Miyasaki et al., 1998). Other characteristics of the species are given in Table 148.

DNA G+C content (mol %): 26–28 (*T_m*).

Type strain: ATCC 25586, CCUG 32989, CCUG 33059, CIP 101130, JCM 8532, LMG 13131.

Sequence accession no. (16S rRNA gene): AJ133496.

Further comments: *Fusobacterium nucleatum* is divided into

FIGURE 121. Unrooted neighbor-joining tree of the 16S rRNA gene sequences of *Fusobacterium*. GenBank accession numbers are given after species names. The numbers above branches are bootstrap percentages from 1000 resampled datasets. Bar = 0.1 difference per nucleotide.

five subspecies: *Fusobacterium nucleatum* subsp. *nucleatum*, subsp. *animalis*, subsp. *fusiforme*, subsp. *polymorphum*, and subsp. *vincentii*, described on the basis of electrophoretic patterns of whole-cell proteins and DNA homology (Dzink et al., 1990) and electrophoretic mobility of glutamate dehydrogenase and 2-oxoglutarate dehydrogenases and DNA homology (Gharbia and Shah, 1992). The five subspecies differed from each other and from other closely related species by comparisons of their 16S–23S internal transcribed spacer regions (Conrads et al., 2002).

1a. ***Fusobacterium nucleatum* subsp. *nucleatum*** (Knorr 1922) Dzink, Sheenan and Socransky 1990, 77^{VP} (*Fusobacterium nucleatum* Knorr 1922, 17)

nu.cle.a'tum. L. neut. adj. *nucleatum* having a kernel, intended to mean nucleated.

DNA G+C content (mol%): 26–28 (T_m).

Type strain: ATCC 25586, CCUG 32989, CCUG 33059, CIP 101130, JCM 8532, LMG 13131.

Sequence accession no. (16S rRNA gene): AJ133496.

Further information: the subspecies name *Fusobacterium nucleatum* subsp. *nucleatum* Knorr (1922) is automatically created by the valid publication of *Fusobacterium nucleatum* subsp. *polymorphum* (ex Knorr (1922) Dzink (1990)), and the valid publication of *Fusobacterium nucleatum* subsp. *vincentii* (ex Knorr (1922) Dzink (1990)) [Rule 40d (formerly Rule 46)].

1b. ***Fusobacterium nucleatum* subsp. *animalis*** Gharbia and Shah 1992, 297^{VP}

a.ni.ma'lis. L. n. *animal*, -*alis* an animal; L. gen. n. *animalis* of an animal.

Type strain: ATCC 51191, CCUG 32879, CIP 104879, JCM 11025, NCTC 12276.

Sequence accession no. (16S rRNA gene): X55404.

1c. ***Fusobacterium nucleatum* subsp. *fusiforme*** (ex Veillon and Zuber 1898) Gharbia and Shah 1992, 297^{VP} (*Sphaerophorus fusiformis* Veillon and Zuber 1898; Sebald 1962)

fu.si.for'me. L.n. *fusus* a spindle; L. neut. suff. *forme* in shape of; N.L. neut. adj. *fusiforme* spindle-shaped.

Type strain: ATCC 51190, CCUG 32880, CIP 104878, DSM 19508, JCM 11024, NCTC 11326.

Sequence accession no. (16S rRNA gene): AM849219.

1d. ***Fusobacterium nucleatum* subsp. *polymorphum*** (Knorr 1922) Dzink, Sheenan and Socransky 1990, 77^{VP} (*Fusobacterium polymorphum* Knorr 1922)

po.ly.mor'phum. N.L. neut. adj. *polymorphum* (from Gr. adj. *polumorphos* -on) multiform, polymorphic.

Type strain: ATCC 10953, CCUG 9126, DSM 20482, JCM 12990, NCTC 10562.

Sequence accession no. (16S rRNA gene): AF287812.

1e. ***Fusobacterium nucleatum* subsp. *vincentii*** (Knorr 1922) Dzink, Sheenan and Socransky 1990, 77^{VP} (*Fusobacterium plauti-vincentii* Knorr 1922)

vin.cen'ti.i. N.L. masc. gen. n. *vincentii* of Vincent, referring to Henri Vincent who studied the organism originally isolated from Vincent's angina and necrotizing ulcerative gingivitis.

Type strain: ATCC 49256, CCUG 37843, CIP 104988, DSM 19507, JCM 11023.

Sequence accession no. (16S rRNA gene): AJ006964, AM887529.

2. ***Fusobacterium canifelinum*** Conrads, Citron, Mutters, Jang and Goldstein 2004b, 1909^{VP} (Effective publication: Conrads, Citron, Mutters, Jang and Goldstein 2004a, 412.)

ca.ni.fel'i num. L. gen. pl. n. *canum* of dogs; L. neut. adj. *felinum* of or belonging to a cat; N.L. neut. adj. *canifelinum* of dogs and cats.

Strains grown on supplemented Brucella blood-agar for 2 d; colonies are convex, 1–2 mm in diameter with a slightly lobate margin, white, opaque with a granular internal appearance. Cells are slender Gram-stain-negative rods with pointed ends. Glucose and fructose are fermented weakly with a terminal pH 5.7–6.0. End product analysis of PY-glucose by gas-liquid chromatography reveals acetic and butyric acids. Threonine, but not lactate, is converted to propionate. The isolates produce indole, fail to grow in bile, do not hydrolyze esculin, and do not produce acid from lactose, maltose, mannose, raffinose, and sucrose. On agar dilution sensitivity tests, all isolates tested were susceptible to penicillin G, and metronidazole. All strains were resistant (MIC >4 µg/ml) to levofloxacin, moxifloxacin, gemifloxacin, and other fluoroquinolones. *Fusobacterium canifelinum* can be distinguished phenotypically from other species of the genus *Fusobacterium* by the resistance to fluoroquinolones.

Source: a purulent dog-bite wound in a human patient.

DNA G+C content (mol%): 26–28 (T_m).

Type strain: RMA 1036, ATCC BAA-689, CCUG 49733, DSM 15542.

Sequence accession no. (16S rRNA gene): AY162221.

3. ***Fusobacterium equinum*** Dorsch, Love and Bailey 2001, 1962^{VP}

e.quin'um. L. neut. adj. *equinum* of horses.

On sheep-blood agar after 2 d, colonies are circular with an entire undulate margin, convex to umbonate, 1–2 mm in diameter, and creamish in color. Gram staining of single colonies on primary plates reveals pleomorphic Gram-stain-negative rods (coccobacilli to rods, with rounded ends, and curved rods often with irregular staining), but on subculture, coccobacilli and short rods predominate. The terminal pH in glucose liquid medium ranges from pH 6.8–7.0. On GLC analysis, acetic, propionic, and butyric acids are produced and lactate and threonine are converted to propionate. The isolates produce indole and grow in bile and are nonmotile and fail to hydrolyze esculin and starch. The isolates do not ferment esculin, fructose, glucose, lactose, maltose, mannose, starch, and sucrose. They do not hemagglutinate chicken erythrocytes. They are lipase and lecithinase positive. On broth disc sensitivity tests, all isolates are sensitive to penicillin G, amoxicillin, chloramphenicol, doxycycline, and metronidazole; all strains except VPB 4076 and VPB 4014 are sensitive to erythromycin.

Source: pus obtained from a discharged sinus associated with the purulent para-oral lesion in a horse.

DNA G+C content (mol%): 29–31 (T_m).

Type strain: JCM 11174, NCTC 13176, VPB 4027.

Sequence accession no. (16S rRNA gene): AJ295750.

4. **Fusobacterium gonidiaformans** (Tunncliffe and Jackson 1925) Moore and Holdeman 1970, 45^{AL} [*Bacillus gonidiaformans* Tunncliffe and Jackson 1925, 430; *Sphaerophorus gonidiaformans* (Tunncliffe and Jackson 1925) Prévot 1938, 299] go.ni.di.a.for'mans. Gr. n. *gone* offspring, seed; N.L. n. *gonidium* gonidium; N.L. pl. n. *gonidia* gonidia; L. part. adj. *formans* forming; N.L. part. adj. *gonidiaformans* gonidia forming.

Cells from glucose broth cultures are pleomorphic and vacuolated, 0.4–0.7 × 0.7–3.0 µm, often with degenerate filaments or long strands. The spheroid or gonidial forms implied by the name of this organism are seen most often in old cultures or in media that are not highly reduced. Surface colonies on horse blood agar plates are punctiform to 1 mm in diameter, circular entire, low convex, translucent, and smooth. Glucose broth cultures are turbid with smooth sediment and a final pH of 5.6–6.2. Produces DNase (Porschen and Sonntag, 1974). No phosphatase is detected (Porschen and Spaulding, 1974). Hippurate is hydrolyzed. Other characteristics of the species are given in Table 148.

Source: the intestinal and urogenital tracts of humans, various types of human infections and from a lamb with pneumonia.

DNA G+C content (mol%): 33 (T_m) (Gharbia and Shah, 1990).

Type strain: ATCC 25563, CCUG 16790.

Sequence accession no. (16S rRNA gene): X55410.

5. **Fusobacterium mortiferum** (Harris 1901) Moore and Holdeman 1970, 45^{AL} [*Bacillus mortiferus* Harris 1901, 546; *Sphaerophorus mortiferus (sic)* (Harris 1901) Prévot 1938, 299] mor.ti'fer.um. L. neut. adj. *mortiferum* death-bringing, death-bearing.

Cells from glucose broth cultures are 0.8–1.0 × 1.5–10 µm occurring singly and in pairs and short chains. Cells stain irregularly and may be extremely pleomorphic. Surface colonies on horse blood agar are 1–2 mm in diameter, circular with entire, diffuse, or slightly scalloped edge; convex; translucent; smooth. Glucose broth cultures are uniformly turbid with smooth or semiviscous sediment. No superoxide dismutase is detected (Gregory et al., 1978). Lysine decarboxylase is not produced (Werner, 1974). Produces DNase and phosphatase (Porschen and Sonntag, 1974; Porschen and Spaulding, 1974). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974). *Fusobacterium mortiferum* is the only member of the genus *Fusobacterium* to have a mixture of mesolanthionine and diaminopimelic acids at an equimolar ration in its cell wall. Some strains are susceptible to cephalothin, cefazolin, cefoxitin, and lincomycin (Finegold, 1977). Resistant to 3 µg/ml erythromycin; susceptible to 12 µg/ml chloramphenicol, 2 U/ml penicillin G, and 6 µg/ml tetracycline (broth disk method).

Source: blood and various human clinical specimens, intestinal tract and feces; and one from irradiated mice.

DNA G+C content (mol%): 26–28 (T_m).

Type strain: ATCC 25557, CCUG 14475.

Sequence accession no. (16S rRNA gene): AJ867032.

6. **Fusobacterium naviforme** (Jungano 1909) Moore and Holdeman 1970, 45^{AL} [*Bacillus naviformis* Jungano 1909, 123; *Ristella naviformis* (Jungano 1909) Prévot 1938, 291] na.vi.for'me. L. n. *navis* ship; L. neut. suff. *forme* in shape of; N.L. neut. adj. *naviforme* in the shape of a ship.

Cells from glucose broth cultures are 4–10 µm that are often concave. Cells in old cultures have a beaded appearance. Surface colonies are punctiform to 2.0 mm in diameter, circular entire, low convex, gray-white, translucent with mottled appearance when viewed by obliquely transmitted light. Glucose broth cultures are lightly turbid with smooth to clumpy sediment and final pH of 5.5–6.4. Produces DNase (Porschen and Sonntag, 1974). No phosphatase is detected (Porschen and Spaulding, 1974). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974). All strains produce indole from glucose-peptone medium (Gharbia and H.N. Shah, 1989) The cell walls contain *meso*-lanthionine as the major diaminopimelic acid. Some strains are resistant to 3 µg/ml erythromycin. Susceptible to 12 µg/ml chloramphenicol, 1.6 µg/ml clindamycin, 2 U/ml penicillin G, and 6 µg/ml tetracycline.

Source: the large intestine of a laboratory rat. Other strains have been isolated from the human gingival sulcus, from various human clinical specimens, and the bovine rumen.

DNA G+C content (mol%): 32–33 (T_m).

Type strain: ATCC 25832, CCUG 50052, NCTC 13121.

Sequence accession no. (16S rRNA gene): not available.

7. **Fusobacterium necrogenes** (Weinberg, Nativelle and Prévot 1937) Moore and Holdeman 1970, 45^{AL} [*Bacillus necrogenes* Weinberg, Nativelle and Prévot 1937, 681; *Sphaerophorus necrogenes (sic)* (Weinberg, Nativelle and Prévot 1937) Prévot 1938, 298]

ne.cro'ge.nes. Gr. n. *necros* the dead; N.L. suff. *-genes* (from Gr. v. *gennaō* to produce) producing; N.L. adj. *necrogenes* dead-producing, here necrosis-producing.

This description is based on our study of the type and three phenotypically similar strains. Cells from 1-d-old glucose broth cultures are extremely pleomorphic with coccoid cells about 0.3–0.8 µm and thin filamentous forms 0.2–0.8 µm in diameter and up to 20 µm in length. Cells in older cultures are somewhat more uniform, irregularly staining rods 0.7–0.8 × 1.5–4.0 µm. Surface colonies on horse blood agar are minute to 0.5 mm in diameter, circular, flat to low convex, entire, translucent, white, smooth, and shiny, and colonies are surrounded by zones of β-hemolysis. Glucose broth cultures are moderately turbid with pH of 5.7–6.0. Glutamine decarboxylase negative (Terada et al., 1976). Heptose and KDO present in the lipopolysaccharide (Hofstad, 1974).

Source: isolated by Kawamura (1926) from necrotic abscess of a chicken. Barnes strain EB/D/1/4a was isolated from cecal contents of a duck (Barnes and Impy, 1968). Other strains have been isolated from human feces.

DNA G+C content (mol%): 27–28 (T_m).

Type strain: ATCC 25556, CCUG 4949, NCTC 10723.

Sequence accession no. (16S rRNA gene): AJ867034.

8. **Fusobacterium necrophorum** (Flügge 1886) Moore and Holdeman 1969, 12^{AL} [*Bacillus necrophorus* Flügge 1886, 273;

Fusiformis necrophorus (Flügge) Topley and Wilson 1929, 299; *Sphaerophorus necrophorus* (Flügge) Prévot 1938, 298]

ne.cro'pho.rum. Gr. n. *necros* the dead; Gr. v. *phoreô* to bear; N.L. neut. adj. *necrophorum* dead producing, here necrosis producing.

Cells in glucose broth cultures are 0.5–0.7 µm in diameter with swellings up to 1.8 µm. The ends of the cells may be round or tapered. Cell length ranges from coccoid bodies to filaments over 1.00 µm. Filamentous forms with granular inclusions are more common in broth, while bacilli are more common in older cultures and growth on agar. Surface colonies on blood agar are 1–2 mm in diameter; circular with scalloped to erose edges, convex to umbonate, often with bumpy, ridged, or uneven surface; translucent to opaque, often with mosaic internal structure when viewed by transmitted light. Most strains produce either α- or β-hemolysis on rabbit blood agar. In general, the β-hemolytic strains are lipase positive (on egg yolk agar), and the α-hemolytic or nonhemolytic strains are lipase negative. No lecithinase is produced. Glucose broth cultures have a smooth, flocculent, granular, or stringy sediment and usually are turbid. The final pH of fructose and glucose cultures is 5.6–6.3. A few strains produce a pH of 5.8–5.9 in maltose medium.

Human rabbit and guinea pig red blood cells are agglutinated; bovine and ovine red blood cells are not (Simon, 1975). Dextran is not hydrolyzed (Holbrook and McMillan, 1977). No superoxide dismutase (Gregory et al., 1978) or lysine decarboxylase (Werner, 1974) is detected. Produce DNase (Porschen and Sonntag, 1974). No phosphatase is detected (Porschen and Spaulding, 1974). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974).

Source: the natural cavities of humans and other animals and from clinical specimens (necrotic lesions, abscesses, and blood) of humans and other animals particularly liver abscesses and foot rot of cattle. For a review of natural and experimental pathogenicity, see Prévot et al. (1967) and Langworth (1977).

Source: bovine liver abscess; Fievez strain 2358.

DNA G+C content (mol%): 31–34 (T_m) [chromatographic separation (Sebald, 1962)].

Type strain: ATCC 25286, CCUG 9994, CIP 104559, JCM 3718, VPI 2891.

Sequence accession no. (16S rRNA gene): AJ867039.

Further comments: two subspecies have been described among isolates of *Fusobacterium necrophorum*. These correspond to Biovar A and B.

- 8a. ***Fusobacterium necrophorum* subsp. *necrophorum*** (Flügge 1886) Shinjo, Fujisawa and Mitsuoka 1991, 396^{VP} (*Fusobacterium necrophorum* Moore and Holdeman 1969, 12)

9. ***Fusobacterium perfoetens*** (Tissier 1905) Moore and Holdeman 1973, 72^{AL} [*Coccobacillus perfoetens* Tissier 1905, 110; *Ristella perfoetens* (Tissier 1905) Prévot 1938, 291; *Sphaerophorus perfoetens* (Tissier, 1905) Sebald 1962, 149]

per.foe'tens. L. prep. *per* very; L. part. adj. *foetens* stinking; N.L. part. adj. *perfoetens* very stinking.

Description is from Prévot et al. (1967), Weinberg et al. (1937), van Assche and Wilssens (1977). Cells from glucose cultures are 0.6–0.8 × 0.8–1.0 µm, oval, never elongated, occurring singly, in pairs, in chains of no more than three cells, or in masses. No flagella or capsule. Colonies in deep agar (2 d) are 1 mm in diameter and lenticular. Surface colonies on blood agar are 1–2 mm in diameter, circular with an entire edge, convex to raised, grayish white, translucent, smooth, and nonhemolytic on horse blood. Colonies of some strains are slightly umbonate with diffuse edges and a slightly mottled or granular appearance.

Growth in glucose broth is rapid. Cultures are turbid with a fine to ropy sediment and a pH of 5.6. Gas and a fetid odor are produced. Galactose is weakly fermented (Van Assche and Wilssens, 1977). Growth is enhanced in media containing fructose, glucose, mannose, sucrose, and trehalose. The pH of cultures in these media ranges from 5.6 to 5.95. Produces CO₂ and NH₃. Major amounts of lactic acid produced from PYG cultures (Van Assche and Wilssens, 1977) no lactic acid detected in PYG cultures of the type strain.

Inhibited by 0.001% polymyxin. Resistant to 0.001% brilliant green. Optimum temperature is 37°C; good growth occurs at 45°C, poor growth at 25–30°C. Survives up to 24 h of exposure to air.

Source: isolated by Tissier in 1900 from an infant with diarrhea and in 1905 from nursing infants. Strain CC1 isolated in 1947 by Prévot from the cecum of a horse and studied by Sebald (1962) has been lost. Van Assche and Wilssens (1977) studied 6 isolates from the feces of a 2-week-old pig, one of which has been designated the neotype strain.

DNA G+C content (mol%): 28–30 (T_m) (Sebald, 1962; Van Assche and Wilssens, 1977).

Type strain: ATCC 29250.

Sequence accession no. (16S rRNA gene): M58684.

10. ***Fusobacterium peridonticum*** Slots, Potts and Mashimo 1984, 270^{VP} (Effective publication: Slots, Potts and Mashimo 1983, 963.)

pe.ri.o'don.ti.cum. Gr. prep. *peri* around; Gr. n. *odous*, *ontos* tooth; L. neut. suff. *-icum* suffix used with the sense of pertaining to; N.L. neutr. adj. *peridonticum* pertaining to periodontic.

Description is from Slots et al. (1982). Obligately anaerobic, nonmotile, nonsporeforming, Gram-stain-negative rod. Mean cell size on blood agar is $0.5\text{--}1.0 \times 4.0\text{--}7.0 \mu\text{m}$, but filaments longer than $100 \mu\text{m}$ are often present. Cells had pointed to slightly rounded ends and generally occurred singly or in pairs lying end to end. After anaerobic incubation for 2–3 d on blood agar, the colonies measured from 2.0 to 3.0 mm in diameter, were circular, convex, entire or slightly scalloped at the edge, slightly rough, and granular and opaque. Glucose broths were turbid, with flocculent or stringy sediment. Indole is produced, hydrogen sulfide formed from cysteine, litmus milk reduced, hippurate hydrolyzed, and fructose, galactose, and glucose fermented. Growth is inhibited by $1 \mu\text{g}/\text{ml}$ chloramphenicol, penicillin G, and tetracycline and was unaffected by $5 \mu\text{g}/\text{ml}$ erythromycin and vancomycin. Addition of 2% oxgall inhibited the growth.

DNA G+C content (mol%): 28 (T_m).

Type strain: EK1-15, ATCC 33693, CCUG 14345, JCM 12991.

Sequence accession no. (16S rRNA gene): X55405.

11. **Fusobacterium russii** (Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937) Moore and Holdeman 1970, 45^{AL} (*Bacteroides russii* Hauduroy, Ehringer, Urbain, Guillot and Magrou 1937, 73)

rus'si.i. N.L. masc. gen. n. *russii* of Russ, named after V. Russ, the bacteriologist who first cultured this organism.

Cells in glucose broth are $1.5\text{--}4.0 \mu\text{m}$ in length and may form thin filaments $10\text{--}15 \mu\text{m}$ in length. Surface colonies on horse blood agar are $0.5\text{--}1 \text{ mm}$ in diameter, circular, smooth, shiny, entire, convex, and translucent. The type strain is β -hemolytic on horse blood agar. Glucose-peptone broth cultures are turbid, often with stringy sediment and have a final pH of 5.9–6.1. Produces DNase and phosphatase (Porschen and Sonntag, 1974; Porschen and Spaulding, 1974). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974). The major dibasic amino acid is meso-lanthionine. Strains do not ferment any carbohydrates nor produce lactate threonine, but phosphatase activities were reported (Table 148). Susceptible to $12 \mu\text{g}/\text{ml}$ chloramphenicol, $1.6 \mu\text{g}/\text{ml}$ clindamycin, and $2 \text{ U}/\text{ml}$ penicillin G. Some strains are resistant to $6 \mu\text{g}/\text{ml}$ tetracycline.

Source: isolated by Russ (1905) from perianal abscess. Also isolated from infections of cats, including actinomycosis of cats and from human and animal feces.

DNA G+C content (mol%): 31 (T_m).

Type strain: ATCC 25533.

Sequence accession no. (16S rRNA gene): X55409.

12. **Fusobacterium simiae** Slots and Potts 1982, 193^{VP}

sim'i.ae. L. fem. n. *simia* monkey; L. gen. n. *simiae* of the monkey.

Cellular morphology resembles that of *Fusobacterium nucleatum* (q.v., species 1). Fructose and glucose are fermented (pH of 5.5–5.6). Twenty-seven other substrates tested are not fermented. Indole and lipase are produced; hippurate is hydrolyzed. Grows in media containing 2% oxgall. From glucose, butyrate is the major fermentation product; major amounts of acetate and small amounts or

propionate, lactate, and succinate also are produced. Neither hydrogen nor gas is detected. Lactate and threonine are converted to propionate. The type strain has 48% DNA homology with the type and one other strain of *Fusobacterium nucleatum* and 9% homology with the type strain of *Fusobacterium necrophorum*.

Source: the mouth of the stump-tailed macaque (*Macaca arctoides*).

DNA G+C content (mol%): 27–28 (T_m).

Type strain: 7511 R2-13, ATCC 33568, CCUG 16798 (Slots and Potts 7511 R2-13).

Sequence accession no. (16S rRNA gene): X55407.

13. **Fusobacterium ulcerans** Adriaans and Shah 1988, 447^{VP}

ul'ce. rans. L. part. adj. *ulcerans* making sore, causing to ulcerate, referring to the source of isolation.

Gram-stain-negative, nonsporeforming, obligately anaerobic, rod-shaped $0.5\text{--}4.5 \mu\text{m}$ long. Most strains consist of long cells with pointed ends. Surface colonies on anaerobic blood agar plates are 2–3 mm in diameter, circular, entire, domed to low convex, cream colored, and nonhemolytic. A second morphological type consists of rod-shaped organisms that are $0.8\text{--}4.5 \times 0.2 \mu\text{m}$ and have a large round swelling (diameter $0.5 \mu\text{m}$) in the center of the cell. Surface colonies on blood agar plates are 1–2 mm in diameter, circular, entire, and low convex. They are translucent or white in color, butyrous, and nonhemolytic. The optimal temperature for growth is 37°C with colonies appearing in 36–48 h. Culture in brain heart infusion broth produce generalized turbidity after incubation for 3–4 d.

Fermentation of peptone-yeast-glucose broth produces large amounts of butyric acid and small to moderate amounts of acetic, propionic, lactic, and succinic acids. All strains convert threonine to propionic acid. Both colonial types produce gas when grown in deep culture. No H_2S is detected. Acid is produced from glucose, and some strains ferment glucose and mannose. No acid is produced from fructose, lactose, sucrose, maltose, arabinose, raffinose, or rhamnose. Indole, catalase, lecithinase, urease, lipase, and oxidase are not produced. Esculin and starch are not hydrolyzed. Nitrate is reduced by all strains.

All strains are susceptible to penicillin and phosphamycin and are resistant to rifampin.

DNA G+C content (mol%): 29.2–29.5 (T_m).

Type strain: ATCC 49185, CCUG 50053, NCTC 12111.

Sequence accession no. (16S rRNA gene): AJ867037.

14. **Fusobacterium varium** (Eggerth and Gagnon 1933) Moore and Holdeman 1969, 12^{AL} [*Bacteroides varius* Eggerth and Gagnon 1933, 409; *Sphaerophorus varius* (Eggerth and Gagnon 1933) Prévot 1938, 299]

va'ri.um. L. neut. adj. *varium* diverse, different, various.

Cells from glucose broth cultures are pleomorphic, coccoid and rod-shaped, and stain unevenly. Cells are $0.3\text{--}0.7 \times 0.7\text{--}2.0 \mu\text{m}$ and occur singly and in pairs. Surface colonies on blood agar are punctiform to 1 mm in diameter, circular with entire edges, flat to low convex, translucent, usually with gray-white centers, and colorless edges. Glucose broth cultures are turbid with smooth sediment and a final pH of 5.3–5.7. Dextran is not hydrolyzed (Holbrook and

McMillan., 1977). Produces lysine decarboxylase (Werner, 1974). Produces DNase (Porschen and Sonntag, 1974). No phosphate detected (Porschen and Spaulding, 1974). Heptose and KDO are present in the lipopolysaccharide (Hofstad, 1974).

A temperate lysogenic bacteriophage is harbored by the reference ATCC 27725 which causes a lytic response in other strains of *Fusobacterium varium* including the reference strain ATCC 8501. The phage is activated by incubation at

45°C and UV exposure (Gharbia, personal observation)

Source: human feces, purulent infections of humans (upper respiratory tract, surgical wounds, peritonitis), cecal contents of mice, intestinal contents of *Blatta orientalis* (roach), posterior intestinal tract of *Reticulitermes lucifugus* (termite) and vaginal swab of chinchilla.

DNA G+C content (mol%): 29 (T_m) (Sebald, 1962).

Type strain: ATCC 8501, CCUG 4858, NCTC 10560.

Sequence accession no. (16S rRNA gene): AJ867036.

Genus II. *Cetobacterium* Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1996, 362^{VP} (Effective publication: Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1995, 206.)

KIRSTIN J. EDWARDS, JULIE M. J. LOGAN AND SAHEER E. GHARBIA

Ce.to.bac.te'ri.um. Gr. n. *kétos* whale; L. neut. n. *bacterium* a rod; N.L. neut. n. *Cetobacterium* a bacterium found in association with whales.

Short pleomorphic, nonsporeforming, rod-shaped cells.

Central swelling and filaments may be present. Gram-stain-negative. Nonmotile. Microaerotolerant. Catalase negative. **Fermentative. Acetic acid is the major end product from peptones or carbohydrates**; butyric, propionic, lactic, and succinic acids may or may not be formed in small amounts. Indole produced and ONPG hydrolyzed. Alkaline phosphatase, and acid phosphatase positive. Produces small to moderate amounts of phosphohydrolase. May or may not produce α - or β -galactosidase and α -glucosidase. Urease may or may not be produced. Lecithinase and lipase negative. Gelatin is not hydrolyzed. Nitrate may or may not be reduced to nitrite. Resistant to 20% bile. Resistant to vancomycin. Sensitive to kanamycin and colistin sulfate discs. Susceptible to cefoxitin, clindamycin, imipenem, and metronidazole. Isolated from mammalian intestinal tract and oral cavity.

DNA G+C content (mol%): 29–31.

Type species: *Cetobacterium ceti* Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1996, 362^{VP} (Effective publication: Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1995, 206.).

Further descriptive information

Cetobacterium was first isolated from the intestinal contents of a porpoise and from a mouth lesion of a minke whale (Foster

et al., 1995). *Cetobacterium somerae* has subsequently been isolated from human feces (Finegold et al., 2003a). Colonies are gray, waxy, circular with scalloped to erose edges, slightly-raised, smooth, dull, and opaque with a diameter of 2–4 mm. Weak hemolysis was observed with both sheep and horse blood. No growth was observed for *Cetobacterium ceti* following subculture in an atmosphere of 10% CO₂ or in air, whereas *Cetobacterium somerae* grows in 2% but not 6% oxygen (Finegold et al., 2003a).

Differentiation of the genus *Cetobacterium* from other genera

Cetobacterium differs from *Fusobacterium* species in producing acetic and propionic acids, whereas members of the genus *Fusobacterium* produce butyric acid (Foster et al., 1995). Sequencing the 16S rRNA gene demonstrates the highest sequence similarities with *Fusobacterium* (91–94%) and 92% similarity with *Propionigenium modestum*. Significant sequence similarity was also observed with *Leptotrichia* and *Sebedella* (86%) (Foster et al., 1995). A large amount of acetic acid with lesser amounts of propionic, lactic, and succinic acids permits differentiation from *Propionigenium modestum* which does not ferment carbohydrates, but produces large amounts propionic and lesser amounts of acetic acid only from succinate and other substrates (Schink and Pfennig, 1982). A positive indole reaction allows further separation from *Propionigenium modestum*.

List of species of the genus *Cetobacterium*

1. *Cetobacterium ceti* Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1996, 362^{VP} (Effective publication: Foster, Ross, Naylor, Collins, Ramos, Fernández-Garayzábal and Reid 1995, 206.)

ce.ti. L. gen. n. *ceti* of a whale.

Description is from Foster et al. (1995). Surface colonies on blood agar are 2–4 mm in diameter after 48 h at 37°C, gray, waxy, circular, with scalloped to erose edges, slightly raised, smooth, dull, opaque, and weakly hemolytic on sheep and horse blood. No growth at 25°C or 45°C. Catalase-negative. Indole, ONPG and phosphatase positive. Lecithinase, lipase, DNase, nitrate, urea, esculin, gelatin, and starch negative. Resistant to 20% bile. Resistant

to vancomycin. Sensitive to colistin sulfate and kanamycin. Sensitivity to penicillin varies. The major volatile fatty acids produced are acetic, propionic, lactic, and succinic. Butyric acid is not produced.

DNA G+C content (mol%): 29 (T_m).

Type strain: M-3333, ATCC 700028, NCIMB 703026.

Sequence accession no. (16S rRNA gene): X78419.

2. *Cetobacterium somerae* Finegold, Vaisanen, Molitoris, Tomzynski, Song, Liu, Collins and Lawson 2003b, 1219^{VP} (Effective publication: Finegold, Vaisanen, Molitoris, Tomzynski, Song, Liu, Collins and Lawson 2003a, 180.)

so'me.rae. N.L. gen. fem. n. *somerae* of Somer, to honor Hannele Jousimies-Somer, a contemporary Finish

microbiologist, in recognition of her important contributions to anaerobic microbiology.

Description is from Finegold et al. (2003a). Rod-shaped. Gram-stain-negative. Microaerotolerant. After 48 h incubation anaerobically at 37°C on brucella blood agar, colonies are 2–3 mm in diameter, smooth, circular, entire, and gray in color. Colonies do not fluoresce under UV light. Catalase negative. Indole positive after 48 h incubation. Acetic acid is the major end product in peptone yeast broth; small amounts of propionic and butyric acids may be formed; a trace of succinic acid was produced by all strains. Nitrate is reduced to nitrite. Resistant to 20% ox bile. Esculin may or may not be hydrolyzed. Gelatin is not hydrolyzed. By traditional tests, ONPG is hydrolyzed, but

lecithinase, lipase, and β -lactamase are not produced. Urease may or may not be detected. Using the API ZYM system, α - and β -galactosidase and alkaline phosphatase are produced; phosphohydrolase is produced in lesser amounts, and α -glucosidase may or may not be produced. Susceptible to kanamycin, colistin sulfate, cefoxitin, clindamycin, imipenem, and metronidazole. Resistant to ampicillin, penicillin G, ramoplanin, trimethoprim/sulfamethoxazole, and vancomycin. Predominant long-chain cellular fatty acids are C_{14:0}, C_{16:0}, and C_{16:1} ω 9c.

Source: human fecal material.

DNA G+C content (mol %): 31 (HPLC).

Type strain: WAL 14325, ATCC BAA-474, CCUG 46254.

Sequence accession no. (16S rRNA gene): AJ438155.

Genus III. *Ilyobacter* Stieb and Schink 1985, 375^{VP} (Effective publication: Stieb and Schink 1984, 145.)

BERNHARD SCHINK, PETER H. JANSSEN AND ANDREAS BRUNE

I.ly.o.bac'ter. Gr. fem. n. *ily*s mud; N.L. masc. n. *bacter* rod; N.L. masc. n. *Ilyobacter* a mud-inhabiting rod.

Strictly anaerobic chemoorganotrophic bacteria with fermentative metabolism, nonphotosynthetic, inorganic electron acceptors not used. Nonsporeforming.

Chemoorganotrophic, fermentative type of metabolism. Media containing a reductant are necessary for growth. Catalase negative. Isolated from anoxic environments.

DNA G+C content (mol %): 31.7–36.7.

Type species: *Ilyobacter polytropus* Stieb and Schink 1985, 375^{VP} (Effective publication: Stieb and Schink 1984, 145.).

Further descriptive information

The genus *Ilyobacter* consists so far of four species, *Ilyobacter polytropus*, *Ilyobacter delafieldii*, *Ilyobacter insuetus*, and *Ilyobacter tartaricus*. The genus was created to house Gram-stain-negative, obligately anaerobic, nonsporeforming bacteria that do not contain cytochromes and use unusual substrates for growth. Its members differ from those of most other genera of strictly anaerobic bacteria by their unusual patterns of substrate utilization and product formation. Fermentation products include acetate, butyrate, and (on some substrates) also formate and ethanol. Malate and fumarate are fermented to acetate, formate, and propionate. The DNA base ratio of *Ilyobacter* species ranges from 32 to 36 mol% G+C, and so is clearly lower than that of any *Bacteroides*, *Selenomonas*, or *Pelobacter* species. With the exception of *Ilyobacter delafieldii* (see below), all *Ilyobacter* species are short to coccoid rods, often in pairs or short chains.

Ilyobacter polytropus was enriched and isolated from marine sediment with 3-hydroxybutyrate, which was fermented to acetate and butyrate. Glycerol was fermented to 1,3-propanediol and 3-hydroxypropionate. Acetate and formate were the only products of pyruvate or citrate fermentation. Glucose and fructose were fermented to acetate, formate, and ethanol. Malate and fumarate were fermented to acetate, formate, and propionate.

Ilyobacter tartaricus was enriched and isolated from marine sediment with L-tartrate as sole source of carbon and energy. Tartrate, citrate, pyruvate, and oxaloacetate are fermented to acetate, formate, and CO₂. In addition, ethanol is formed from fructose and glucose.

Ilyobacter insuetus was isolated from marine sediment with quinic acid (1,3,4,5-tetrahydroxy-cyclohexane-1-carboxylic acid, sodium salt) as the sole source of carbon and energy. This

bacterium is restricted to the fermentation of hydroaromatic substrates. Of more than 30 different substrates tested, only quinic acid and shikimic acid (3,4,5-trihydroxy-1-cyclohexene-1-carboxylic acid) are utilized. Neither sugars, alcohols, other carboxylic acids, amino acids, nor aromatic compounds are fermented. Thus, this species represents an extreme case of specialization in substrate utilization.

Ilyobacter delafieldii (Janssen and Harfoot, 1991) was enriched and isolated from estuarine sediment with crotonate as substrate. It ferments crotonate, 3-hydroxybutyrate, lactate, pyruvate, and poly- β -hydroxybutyrate to acetate, propionate, butyrate, CO₂, and H₂. Poly- β -hydroxybutyrate is hydrolyzed outside the cell without cell contact, by a PHB depolymerase that is excreted into the growth medium (Janssen and Harfoot, 1990). So far, this bacterium is unique in its capacity to degrade extracellular PHB anaerobically (Schink et al., 1992).

The taxonomic status of *Ilyobacter delafieldii* is unclear. Since it stains Gram-negative and resembles *Ilyobacter polytropus* in many of its metabolic capacities, it was originally assigned to the genus *Ilyobacter*. However, sequence analysis of its 16S rRNA gene later revealed that it should be grouped within the genus *Clostridium* (Janssen, unpublished), even though spore formation could not be demonstrated (Janssen and Harfoot, 1990). The cell-wall architecture of *Ilyobacter delafieldii* strain 10cr1 (Janssen and Harfoot, 1990) is not typical of Gram-stain-negative bacteria but resembles that of a Gram-stain-positive bacterium with a complex cell-wall structure. For this reason, we do not include *Ilyobacter delafieldii* any further in this genus.

Ilyobacter tartaricus has generated major interest because of its Na⁺-translocating ATP-synthase system. Tartrate and oxaloacetate are metabolized via pyruvate; the oxaloacetate decarboxylase is a Na⁺-translocating, membrane-bound enzyme. The Na⁺-gradient established this way is used for ATP-synthesis via a membrane-bound Na⁺-translocating ATP-synthase enzyme, and contributes to the overall energy balance of the cell. Together with a similar enzyme in *Propionigenium modestum* (Hilpert et al., 1984), this Na⁺-ATPase has become one of the model systems to study the architecture of this type of F₁F₀-ATPases and especially the linkage between Na⁺-ion transport and ATP synthesis (Neumann et al., 1998). The three-dimensional structure of this Na⁺-ATPase was recently resolved in detail (Meier et al., 2005).

The study of Na⁺-translocating ATPases has also contributed significantly to a better understanding of proton transport in the more common H⁺-translocating F₁F₀-ATPases (Gemperli et al., 2003).

It appears that anoxic marine sediments are the typical habitats of these bacteria. At least with *Ilyobacter tartaricus*, the energy metabolism is based on sodium ions as coupling ions in energy conservation.

Enrichment and isolation procedures

A strictly anoxic, sulfide-reduced mineral medium with 10 mM of either 3-hydroxybutyrate, shikimate, or L-tartrate as the sole organic carbon and energy source, and incubation at 27–30°C has proven to be highly selective for the enrichment of *Ilyobacter polytropus*, *Ilyobacter insuetus*, or *Ilyobacter tartaricus*, respectively. The carbonate-buffered standard medium used for enrichment and isolation has been described in detail (Schink and Pfennig, 1982; Widdel and Pfennig, 1981).

After two to three transfers, the bacteria can be isolated in anoxic agar deep dilution series (Pfennig, 1978) or in roll tubes (Balch et al., 1979). Streaking on Petri dishes in an anoxic glove box has not yet been tried with these bacteria.

Maintenance procedures

Cultures are maintained either by repeated transfer at intervals of 2–3 months or by freezing in liquid nitrogen using techniques common for strictly anaerobic bacteria.

Differentiation of the genus *Ilyobacter* from other genera

The three species remaining in the genus *Ilyobacter* differ from most other strictly anaerobic bacteria in their unusual patterns of substrate utilization and product formation and their low G+C content. With the exception of the genus *Propionigenium*, they are clearly separated from all other genera by their 16S rRNA gene sequences.

Comparative 16S rRNA gene sequence analysis places the members of the genera *Propionigenium* and *Ilyobacter* (with the exception of *Ilyobacter delafieldii*) into the *Fusobacteria* phylum (Brune et al., 2002). Both genera form a distinct cluster, clearly separated from the *Sebaldella*–*Streptobacillus*–*Leptotrichia* lineage and the *Fusobacterium* branch. While the 16S rRNA gene sequences did not allow resolving the branching order within the *Ilyobacter*–*Propionigenium* cluster, the 23S rRNA gene sequences supported a monophyletic status at least for the genus *Ilyobacter* (Brune et al., 2002). Although the metabolic properties of *Propionigenium* and *Ilyobacter* species are sufficiently different to justify maintenance of two separate genera, the situation is unsatisfying and asks for a future taxonomic revision of this group.

List of species of the genus *Ilyobacter*

1. ***Ilyobacter polytropus*** Stieb and Schink 1985, 375^{VP} (Effective publication: Stieb and Schink 1984, 145.)

po.ly'tro.pus. N.L. masc. adj. *polytropus* (from Gr. masc. adj. *polytropos*) turning many ways, versatile, referring to metabolic versatility.

Rod-shaped cells, 0.7 × 1.5–3.0 μm in size with rounded ends, single or in pairs. Nonmotile, Gram-stain-negative, nonsporeforming.

Strictly anaerobic chemoorganotroph. 3-Hydroxybutyrate and crotonate fermented to acetate and butyrate. Glycerol fermented to 1,3-propanediol and 3-hydroxypropionate. Malate and fumarate fermented to acetate, formate, and propionate. Glucose and fructose fermented to acetate, formate, and ethanol. No other organic acids, sugars, or alcohols metabolized. Sulfate, sulfur, thiosulfate, and nitrate not reduced. Growth occurs in mineral media with a reductant. Indole not formed; gelatin and urea not hydrolyzed. No catalase activity. No cytochromes detectable.

Growth requires mineral media with a reductant and at least 1% sodium chloride.

Selective enrichment in NaCl-containing mineral media with 3-hydroxybutyrate as substrate.

pH Range: 6.5–8.5, optimum at 7.0–7.5. Temperature range: 10–35°C, optimum growth temperature 30°C. Habitats: anoxic marine or brackish water sediment.

DNA G+C content (mol %): 32.2 ± 0.5 (T_m).

Type strain: CuHbu1, ATCC 51220, DSM 2926.

Sequence accession no. (16S rRNA gene): AJ307981.

2. ***Ilyobacter insuetus*** Brune, Evers, Kalm, Ludwig and Schink 2002, 431^{VP}

in.su.e'tus. L. masc. part. adj. *insuetus* unusual, extraordinary, referring to the organism's metabolism.

Rod-shaped to coccoid cells, 0.8–1.0 μm in diameter and 1.0–1.5 μm long, with rounded ends. Nonmotile, Gram-stain-negative, nonsporeforming.

Strictly anaerobic chemoorganotroph. Quinic acid and shikimic acid utilized for growth and fermented to acetate, propionate, butyrate, H₂, and CO₂. No growth with sugars (cellobiose, fructose, glucose, erythrose, lactose, ribose, xylose), alcohols (*meso*-erythritol, ethanol, glycerol, mannitol), carboxylic acids (citrate, crotonate, fumarate, glycolate, 2-hydroxybutyrate, 3-hydroxybutyrate, 4-hydroxybutyrate, lactate, malate, 2-oxobutyrate, pyruvate, sorbate, tartrate), amino acids (alanine, aspartate, glycine, threonine), or aromatic compounds (gallate, phloroglucinol, protocatechuate, resorcinol, 3,4,5-trimethoxybenzoate, 3,4,5-trimethoxycinnamate). Sulfate, sulfur, thiosulfate, nitrate, and ferric iron not reduced. Strict anaerobe. No catalase activity; no superoxide dismutase activity; no cytochromes. Growth requires mineral media with a reductant and at least 0.7% sodium chloride.

Selective enrichment in NaCl-containing mineral media with quinic acid as the sole source of carbon and energy.

pH Range: 6.0–9.0, optimum at 7.0–8.0. Temperature range: 15–40°C, optimum growth temperature 30°C. Habitats: anoxic marine sediment.

DNA G+C content (mol %): 35.7 ± 1.0 (HPLC).

Type strain: VenChi2, ATCC BAA-291, DSM 6831.

Sequence accession no. (16S rRNA gene): AJ307980.

3. ***Ilyobacter tartaricus*** Schink 1985, 375^{VP} (Effective publication: Schink 1984, 413.)

tar.ta'ri.cus. N.L. n. *acidum tartaricum* tartaric acid; N.L. masc. adj. *tartaricus* referring to tartaric acid as isolation substrate.

Rod-shaped cells, 1.0–1.2 × 1.2–2.5 µm in size, often in chains. Surrounded by slime capsules, nonmotile, Gram-stain-negative, nonsporeforming.

Strictly anaerobic chemoorganotroph. Growth on L-tartrate, citrate, pyruvate, oxaloacetate, glucose, fructose, raffinose, glycerol. Fermentation products include acetate, formate, and ethanol. No growth on formate, acetate, lactate, methanol, ethanol, ethylene glycol, 2,3-butanediol, glycerate, malate, fumarate, glyoxylate, glycolate, mannose,

maltose, lactose, sucrose, cellobiose, sorbose, rhamnose, trehalose, xylose, arabinose, peptone, yeast extract. Sulfate, sulfur, thiosulfate or nitrate not reduced. Indole not formed; gelatin and urea not hydrolyzed. No catalase activity, no cytochromes.

Growth requires mineral media with a reductant and at least 1% sodium chloride.

Selective enrichment from marine sediments with L-tartrate as sole carbon and energy source.

pH Range: 5.5–8.0, optimum at 6.5–7.2. Temperature range: 10–40°C, optimum growth temperature 32°C.

Habitats: anoxic marine sediment.

DNA G+C content (mol%): 33.1 ± 1.0 (T_m).

Type strain: GraTa2, ATCC 35898, DSM 2382.

Sequence accession no. (16S rRNA gene): AJ307982.

Genus IV. ***Propionigenium*** Schink and Pfennig 1983, 896^{VP} (Effective publication: Schink and Pfennig 1982, 215.)

BERNHARD SCHINK AND PETER H. JANSSEN

Pro.pi.o.ni.ge'ni.um. N.L. n. *acidum propionicum* propionic acid; L. v. *genere* to make, produce; N.L. neut. n. *Propionigenium* propionic acid maker.

Strictly anaerobic chemoorganotrophic bacteria with fermentative metabolism, nonphotosynthetic, inorganic electron acceptors not used. Nonsporeforming.

Chemoorganotrophic, fermentative type of metabolism, preferentially using dicarboxylic acids as substrates. Media containing a reductant are necessary for growth. Catalase-negative. Isolated from anoxic marine or freshwater sediments.

DNA G+C content (mol%): 32.9–41.

Type species: ***Propionigenium modestum*** Schink and Pfennig 1983, 896^{VP} (Effective publication: Schink and Pfennig 1982, 215.).

Further descriptive information

The genus *Propionigenium* consists so far of two species, *Propionigenium modestum* and *Propionigenium maris*. *Propionigenium modestum* comprises four strains of physiologically and morphologically similar isolates from various sources (Schink and Pfennig, 1982). This genus was created to house strictly anaerobic bacteria that are able to grow by decarboxylation of succinate to propionate. Pure cultures could be obtained only with enrichment cultures from marine sources; freshwater enrichments grew much slower, and pure cultures were finally isolated when the sodium chloride concentration of the medium was increased to 100–150 mM. A further species, *Propionigenium maris*, was created later to comprise bacteria similar to *Propionigenium modestum* but which are metabolically much more versatile and are able to ferment, carbohydrates, amino acids, and other organic acids in addition to C4 dicarboxylic acids (Janssen and Liesack, 1995).

Propionigenium modestum was originally isolated from a black, anoxic, marine sediment sample taken from the Canal Grande in Venice, Italy (Schink and Pfennig, 1982). Similar strains were isolated later from many other marine habitats. Enrichments from freshwater sediments sometimes produced cells of similar morphology to *Propionigenium modestum*, and these could be cultivated only in media with increased (100–150 mM) sodium chloride concentrations. Also, *Propionigenium maris* was isolated from marine sediments (Janssen and Liesack, 1995).

It has to be assumed that anoxic marine sediments are the typical habitats of these bacteria. Their energy metabolism is based on sodium ions as coupling ions in energy conservation. With this ability, they are well adapted to a marine environment. Several marine bacteria have been found to use sodium ions as energy couplers in various functions, e.g., respiration.

Propionigenium maris-like bacteria were isolated also from burrows of bromophenol-producing marine infauna, where they apparently are involved in reductive debromination of bromophenols (Watson et al., 2000). They probably use organic excretions of the infauna as electron donors for this reductive reaction.

Enrichment and isolation procedures

A strictly anoxic, sulfide-reduced mineral medium with 20 mM succinate as the sole organic carbon and energy source, and incubation at 27–30°C has proven to be highly selective for the enrichment of *Propionigenium modestum* if marine sediment samples of about 5-ml volume are used as the inoculum. The carbonate-buffered standard medium used for enrichment and isolation has been described in detail (Schink and Pfennig, 1982; Widdel and Pfennig, 1981).

After two to three transfers in liquid medium, gas should no longer be formed by the enrichment cultures, and a dominant population of short, coccoid rods should be established. These bacteria can be isolated in anoxic agar deep dilution series (Pfennig, 1978) or in roll tubes (Balch et al., 1979). Streaking Petri dishes in an anoxic glove box has not yet been tried with these bacteria. Preparation of pure cultures requires two subsequent dilution series; purity should be checked after growth in selective mineral medium and in complex medium.

Propionigenium maris requires yeast extract (0.1% w/v) for growth in pure culture. Although it is not recommended to add yeast extract in the liquid enrichment cultures, it is needed in the purification step.

Maintenance procedures

Cultures are maintained either by repeated transfer at intervals of 2–3 months or by freezing in liquid nitrogen using techniques

common for strictly anaerobic bacteria. No information exists about survival upon lyophilization.

Differentiation of the genus *Propionigenium* from other genera

In phase-contrast microscopy, cells of *Propionigenium modestum* appear as short, coccoid rods with a diameter of 0.5–0.6 µm and a length of 0.5–2.0 µm, often in short chains. They are Gram-stain-negative and nonsporeforming. *Propionigenium maris* also forms coccoid to ovoid cells or short rod-like cells similar in size to *Propionigenium modestum*.

Both *Propionigenium* species are strictly anaerobic and do not tolerate increased oxygen tensions. They are specialists for the utilization of C4-dicarboxylic acids. Whereas *Propionigenium modestum* is restricted to use of only few such compounds,

Propionigenium maris uses also other substrates such as sugars and amino acids, and depends on yeast extract as a medium additive. No cytochromes have been detected, which is consistent with the absence of electron transport phosphorylation.

Early 16S rRNA gene sequence analyses revealed that *Propionigenium maris* and *Propionigenium modestum* are closely related and form a distinct lineage within a phylogenetically coherent group characterized by *Fusobacterium nucleatum* and other *Fusobacterium* species, together with *Clostridium rectum*, *Leptotrichia buccalis*, and *Sebaldella termitidis* (Both et al., 1991; Janssen and Liesack, 1995). This group has been elevated to the rank of phylum, *Fusobacteria*. In addition to *Propionigenium*, this phylum embraces the genera *Fusobacterium*, *Ilyobacter*, *Leptotrichia*, *Sebaldella*, *Streptobacillus*, and *Sneathia* (Garrity et al., 2002).

List of species of the genus *Propionigenium*

1. *Propionigenium modestum* Schink and Pfennig 1983, 896^{VP} (Effective publication: Schink and Pfennig 1982, 215.)

mo.de'stum. L. neut. adj. *modestum* modest, referring to an extremely modest type of metabolism.

Rod-shaped to coccoid cells, 0.5–0.6 in diameter × 0.5–2.0 µm long, with rounded ends, single, in pairs, or in chains. Nonmotile, Gram-stain-negative, nonsporeforming.

Strictly anaerobic chemoorganotroph. Succinate, fumarate, malate, aspartate, oxaloacetate, and pyruvate utilized for growth and fermented to propionate (acetate), and CO₂. No other organic acids and no sugars or alcohols metabolized. Sulfate, sulfur, thiosulfate, and nitrate not reduced. Indole not formed; gelatin and urea not hydrolyzed. No catalase activity.

Growth requires mineral media with a reductant and at least 1% sodium chloride. Selective enrichment in NaCl-containing mineral media with succinate as substrate.

pH range 6.5–8.4, optimum at 7.1–7.7. Temperature range 15–40°C, optimum 33°C. No cytochromes detectable. Habitats: anoxic marine or brackish water sediment.

DNA G+C content (mol%): 33.9 ± 1.0 (*T_m*).

Type strain: GraSucc2, ATCC 35614, DSM 2376.

Sequence accession no. (16S rRNA gene): X54275.

2. *Propionigenium maris* Janssen and Liesack 1996, 362^{VP} emend. Watson, Matsui, Leaphart, Wiegel, Rainey and Lovell 2000, 1040 (Effective publication: Janssen and Liesack 1995, 33.)

ma'ris. L. neut. n. *mare* the sea; L. gen. n. *maris* of the sea, referring to the tidal mat flats from which this organism was isolated.

Coccoid to oval short rods with rounded ends, 1.0 µm in diameter × 1.2–2.5 µm long; under some culture conditions up to 50 µm long. Gram-stain-negative, nonsporeforming.

Strictly anaerobic chemoorganotroph. Fermentative metabolism, external electron acceptors not used, however, bromophenols can be reductively dehalogenated. No cytochromes formed. In the presence of yeast extract, several carbohydrates and amino and organic acids are fermented. These substrates include succinate, fumarate, pyruvate, citrate, 3-hydroxybutyrate, glucose, fructose, maltose, aspartate, lysine, threonine, glutamate, and cysteine. Typical products of fermentation are propionate, acetate, and formate, depending on the substrate. Carbohydrates are fermented to formate, acetate, ethanol, and lactate. 3-Hydroxybutyrate is fermented to acetate and butyrate. Hydrogen is produced from carbohydrates and yeast extract, ammonia from amino acids, and sulfide from cysteine. Sulfate, sulfur, thiosulfate, and nitrate not reduced. Indole formed from L-tryptophan. Esculin and urea not hydrolyzed. No catalase activity.

Growth in salt-water media with at least 5 and up to 55 g NaCl per liter. Anoxic conditions required for growth.

pH range 5.3–8.8, optimum at 6.9–7.7. Temperature range 15–40°C, optimum 34–37°C. Habitat: anoxic marine or brackish water sediment.

DNA G+C content (mol%): 40.0 ± 1.0 (*T_m*)

Type strain: 10succ1, DSM 9537.

Sequence accession no. (16S rRNA gene): X84049.

Family II. **Leptotrichiaceae** fam. nov.

JAMES T. STALEY AND WILLIAM B. WHITMAN

Lep.to.tri.chi.a.ce'a.e. N.L. fem. n. *Leptotrichia* type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Leptotrichiaceae* the *Leptotrichia* family.

The family *Leptotrichiaceae* is described in part on the basis of phylogenetic analyses of the 16S rRNA gene sequences of its members. Facultative to obligately anaerobic organisms that stain as Gram-negative rods. All described species are nonmotile and fermentative. Ferment carbohydrates to produce various organic acids including lactic, acetic, formic or succinic depending on the substrate and species. Some species are

fastidious and require serum or blood for growth. Some species have been isolated from human clinical specimens and are pathogenic to humans. Some species occur in the human oral cavity and others in the hindgut of termites. Comprises the genera *Leptotrichia*, *Sneathia*, *Streptobacillus*, and *Sebaldella*.

Type genus: Leptotrichia Trevisan 1879, 138^{AL}.

Genus I. **Leptotrichia** Trevisan 1879, 138^{AL}

KIRSTIN J. EDWARDS AND SAHEER E. GHARIBIA

Lep.to.tri.chi'a. Gr. adj. *leptos* fine, small; Gr. fem. n. *thrix*, *thricos* hair; N.L. fem. n. *Leptotrichia* fine hair.

Straight or slightly curved rods, 0.5–3.0 × 5–15 μm, with **one or both ends pointed or rounded**. Frequently arranged in pairs, separate filaments, or chains, often with flattened ends. No club formation or branching. Nonmotile. Gram-stain-negative. **Anaerobic on first isolation; many strains subsequently grow aerobically in the presence of CO₂**. Optimum temperature 35–37°C. Good growth occurs at pH 7.0–7.4. Chemooorganotrophic. **Metabolize carbohydrates with formation of acid without gas. The major product of glucose fermentation is lactic acid.** Acetic and succinic acids may be produced in trace amounts. Hydrogen sulfide and indole are not produced. Nitrate is not reduced. The primary habitat is the oral cavity of humans, though also found in the female periurethral region and present in the oral cavity of some animals.

DNA G+C content (mol%): 25–29.7.

Type species: Leptotrichia buccalis (Robin 1853) Trevisan 1879, 147^{AL} (*Leptothrix buccalis* Robin 1853, 345).

Further descriptive information

Colonies of *Leptotrichia* grown anaerobically on blood agar or tryptone-yeast extract medium are distinctive. After 2–3 d of incubation they are smooth, colorless, 2–3 mm in diameter, convex and with a convoluted surface. The colonies are sometimes raised with a filamentous edge, particularly after incubation for 24 h or less (Hamilton and Zahler, 1957; Kasai, 1961). The colonies are nonhemolytic and nonadherent to the medium. Pleomorphism in colony morphology may be seen (Kasai, 1961). An anaerobic atmosphere with 5–10% CO₂ is essential for good growth of *Leptotrichia* on solid medium. Many strains become aerotolerant upon transfer. *Leptotrichia* is highly saccharolastic. Several mono- and disaccharides are fermented with the production of D- and L-lactic acid alone, or accompanied by trace amounts of acetic and succinic acids. CO₂ is not produced. A few strains hydrolyze starch within 2–4 d. Pyruvate is fermented with production of CO₂ and acetic and formic acids (Jackins and Barker, 1951). Within the *Leptotrichia* there is significant heterogeneity in enzymic/biochemical reactions (Eribe et al., 2002) and in cellular fatty acid content (Eribe et al., 2002; Hofstad and Jantzen, 1982). Significant variation between *Leptotrichia* is also observed in

SDS-PAGE profiles of whole-cell proteins and RAPD patterns of DNA (Eribe and Olsen, 2002).

The primary habitat is the human oral cavity, where they are typically found in plaque (Eribe et al., 2004; Hofstad, 1984), but they have also been isolated from the normal flora of the periurethral region of healthy girls and the genitalia of women (Evaldson et al., 1980; Moore et al., 1976; Söderberg et al., 1979) and occasionally been recovered from blood, mainly in immunocompromised patients with neutropenia and from endocarditis (Eribe et al., 2004; Hammann et al., 1993; Messiaen et al., 1996; Patel et al., 1999; Reig et al., 1985; Tee et al., 2001; Vernelen et al., 1996; Weinberger et al., 1991). *Leptotrichia buccalis* is normally considered to play a role in tooth decay and periodontal disease (Hofstad, 1984; Krywolap and Page, 1977) especially in immunocompromised patients. Though it is not solely dependent on tooth eruption since the organism has been isolated from the mouth of pre-dentate infants (McCarthy et al., 1965). It has also been isolated from animals which have been fed commercial pellets (Schwartz et al., 1995).

Differentiation of the genus *Leptotrichia* from other genera

The first full description of *Leptotrichia buccalis* described the organism as a Gram-negative bacterium related to *Fusobacterium nucleatum* (Böe and Thjotta, 1944; Thjötta et al., 1939). Hamilton and Zahler (1957), Gilmour et al. (1961), and Kasai (1965) concluded that *Leptotrichia buccalis* was a Gram-positive organism related to *Lactobacillus*. But an electron microscopy study and the isolation of a potent endotoxin from the organism definitely established that the organism is a Gram-negative bacterium (Hofstad and Selvig, 1969). Its ability to produce lactic acid as the only major acid from glucose fermentation distinguishes it from other closely related genera such as *Fusobacterium*, and analysis of 16S rRNA sequences clearly distinguishes *Leptotrichia* from other related genera (Figure 122). Until 1995, there was only one species defined, *Leptotrichia buccalis*. The closely related species "*Leptotrichia sanguinegens*" (Hanff et al., 1995b), also known as "*Leptotrichia microbii*" (Hanff et al., 1995a) was recently transferred to the genus *Sneathia* as *Sneathia sanguinegens* (Collins et al., 2001). The recently defined species, *Leptotrichia trevisanii* (Tee et al., 2001), *Leptotrichia goodfellowii*, *Leptotrichia hofstadii*,

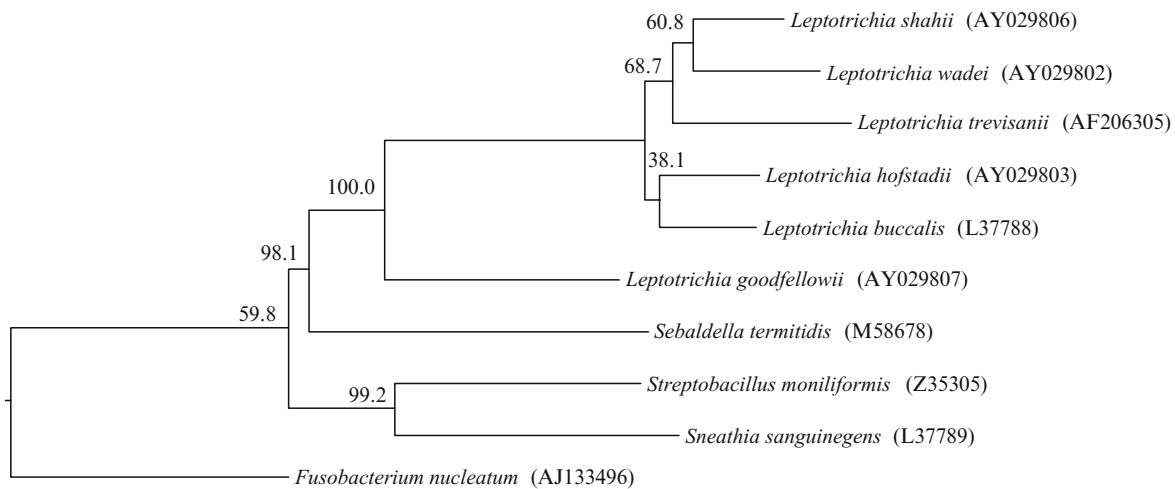

FIGURE 122. Phylogenetic tree of full-length 16S rRNA gene sequences of the genus *Leptotrichia* and related species. GenBank accession numbers are given after species names. The tree was constructed using the neighbor-joining method, and the numbers at branching points are bootstrap percentages.

Leptotrichia shahii, and *Leptotrichia wadei* (Eribe et al., 2004) have been added. The main characteristics of all species are described in Table 150. A further species has been described and named “*Leptotrichia amnionii*” (Shukla et al., 2002), how-

ever, 16S rRNA sequencing suggests that “*Leptotrichia amnionii*” would be better assigned to the genus *Sneathia* (Eribe et al., 2004), and a full description of the strain has not been validated.

List of species of the genus *Leptotrichia*

1. ***Leptotrichia buccalis*** (Robin 1853) Trevisan 1879, 147^{AL} (*Leptothrix buccalis* Robin 1853, 345)

buc.ca'lis. L. n. *bucca* the mouth; L. fem. suff. *-alis* suffix denoting pertaining to; N.L. fem. adj. *buccalis* buccal, pertaining to the mouth.

Straight or slightly curved rods, 0.8–1.5 × 5–15 μm, with one or both ends pointed or rounded. Frequently arranged in pairs, chains, or separate filaments. No club formation or branching. Nonmotile. Gram-stain-negative, often with Gram-stain-positive granules distributed evenly along the long axis. May be Gram-stain-positive in very young cultures. Anaerobic on first isolation; many strains subsequently grow aerobically in the presence of CO₂. Optimum growth temperature, 35–37°C; little or no growth occurs at 25°C. Good growth occurs at pH 7.0–7.4. Chemoorganotrophic. Metabolize carbohydrates with formation of acid without gas. The major product of glucose fermentation is lactic acid. Acetic and succinic acids may be produced in trace amounts. Catalase, hydrogen sulfide, and indole are not produced. Nitrate is not reduced. The main habitat is the oral cavity of humans, though also found in the female periurethral region, and can be present in the oral cavity of animals fed with commercial pellets.

DNA G+C content (mol%): 25 (*T_m*).

Type strain: ATCC 14201, CCUG 34316, CIP 105792, DSM 1135, JCM 12969, NCTC 10249.

Sequence accession no. (16S rRNA gene): L37788.

2. ***Leptotrichia goodfellowii*** Eribe, Paster, Caugant, Dewhirst, Stomberg, Lacy and Olsen 2004, 589^{VP}

good.fel'low.i.i. N.L. masc. gen. n. *goodfellowii* of Goodfellow, named in honor of Michael Goodfellow, for his contributions to microbial systematics.

The description is from Eribe et al. (2004). After 2–6 d of anaerobic incubation at 37°C, colonies on Columbia or BHI agar plates supplemented with 5% human blood, hemin, and menadione are 0.8–2.0 mm in diameter, speckled, convex, irregular, pink in the periphery, and grayish light brown in the rest of the colony. They have a glistening surface, are opaque, dry, and β-hemolytic. Catalase positive and esculin weakly positive. Oxidase and indole are not produced. Colonies grow best anaerobically and sparsely aerobically. Growth occurs at 37°C but not at 25 or 42°C; optimal temperature for growth is 37°C. Gram-stain-negative, nonsporeforming, nonmotile rods. Cells are arranged in pairs, some slightly curved, others in chains joined by flattened ends. Arginine dihydrolase, β-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, alkaline phosphatase, arginine arylamidase, leucine arylamidase, and histidine arylamidase are produced. Mannose is fermented. Isolated from human blood.

DNA G+C content (mol%): 25 (HPLC).

Type strain: LB 57, CCUG 32286, CIP 107915.

Sequence accession no. (16S rRNA gene): AY029807.

3. ***Leptotrichia hofstadii*** Eribe, Paster, Caugant, Dewhirst, Stomberg, Lacy and Olsen 2004, 589^{VP}

hof.stad'i.i. N.L. masc. gen. n. *hofstadii* of Hofstad, named in honor of Tor Hofstad, for his contributions to *Leptotrichia* taxonomy.

The description is from Eribe et al. (2004). After 2–6 d of anaerobic incubation at 37°C, colonies on Columbia or BHI agar plates supplemented with 5% human blood, hemin, and menadione are 0.5–1.8 mm in diameter. They have a glistening and granular surface, are opaque, dry, and β-hemolytic. Older colonies can be up to 4.0–6.5 mm, circular, convex, entire (some are irregular and lobate), and grayish in color with a dark central spot. Catalase positive and esculin weakly positive. Oxidase and indole are not produced. Colonies grow best anaerobically and sparsely aerobically. Growth occurs at 37°C but not at 25 or 42°C; optimal temperature is 37°C. Gram-stain-negative, nonsporeforming, nonmotile rods. Cells are arranged in pairs, some slightly curved, others in chains joined by flattened ends. β-Galactosidase-6-phosphate, α-glucosidase, β-glucosidase, and alkaline phosphatase are produced. Mannose is fermented.

Source: saliva of a healthy person.

DNA G+C content (mol%): 25 (HPLC).

Type strain: LB 23, CCUG 47504, CIP 107917.

Sequence accession no. (16S rRNA gene): AY029803.

4. *Leptotrichia shahii* Eribe, Paster, Caugant, Dewhirst, Stomberg, Lacy and Olsen 2004, 589^{VP}

sha'hi.i. N.L. masc. gen. n. *shahii* of Shah, named in honor of Haroun N. Shah, a Trinidad-born microbiologist, for his contributions to microbiology.

The description is from Eribe et al. (2004). After 2–6 days of anaerobic incubation at 37°C, colonies on Columbia or BHI agar plates supplemented with 5% human blood, hemin, and menadione are 1.0–1.5 mm in diameter, very filamentous to rhizoid or convoluted, pale-speckled, and grayish in color, with a dark central spot in old colonies. These are opaque, semi-dry in consistency, and nonhemolytic. Catalase-positive and esculin weakly positive. Oxidase and indole are not produced. Colonies grow best anaerobically and sparsely aerobically. Growth occurs at 25 and 37°C but not at 42°C; optimal temperature is 37°C. Gram-stain-negative, nonsporeforming, nonmotile rods. Cells are arranged in pairs, some slightly curved, others in chains joined by flattened ends. α-Glucosidase and α-arabinosidase are produced.

Source: a patient with gingivitis.

DNA G+C content (mol%): 25 (HPLC).

Type strain: LB 37, CCUG 47503, CIP 107916, VPI N06A-34.

Sequence accession no. (16S rRNA gene): AY029806.

5. **Leptotrichia trevisanii** Tee, Midolo, Janssen, Kerr and Dyall-Smith 2002, 686^{VP} (Effective publication: Tee, Midolo, Janssen, Kerr and Dyall-Smith 2001, 768.)

tre.vi.sa'ni.i. N.L. masc. gen. n. *trevisanii* of V. Trevisan, who proposed the genus *Leptotrichia* in 1879.

The description is from Tee et al. (2001). The organism is characterized by long, fusiform, nonmotile, Gram-stain-negative bacilli that are 0.8–0.9 × 6–13 µm with tapered ends. Many cells are slightly curved. Cells are arranged in pairs and chains and, where they join, the ends are flattened. Isolates are nonsporeforming, catalase positive, indole negative, and oxidase negative. They are negative for urease, negative for hydrolysis of the *p*-NP-sugars α-D-arabinoside, α-D-galactoside, and α-L-fucoside, and are unable to hydrolyze *O*-NP-β-D-galactoside. They are positive for hydrolysis of *p*-NP derivatives of α-D-glucoside, β-D-glucoside, *N*-acetyl-β-D-glucosamine, and *p*-NP-phosphate. The organism is unable to hydrolyze the naphthylamide derivatives of leucyl-glycine, glycine, proline, serine, and pyrrolidone, but is able to hydrolyze arginine and phenylalanine derivatives. *Leptotrichia trevisanii* grows both anaerobically and under 5% CO₂ (in air) on subsequent culture on solid media. It ferments glucose to produce lactic acid as the major organic end product. On horse blood agar plates, colonies appeared smooth, grayish in color, low convex, and erose edged; they showed a dark central spot with

transillumination and grew to about 2 mm diameter after 5 d of incubation. Older colonies showed a slightly convoluted surface.

DNA G+C content (mol%): 29.7 (HPLC).

Type strain: "Wee Tee" 1999, ATCC 700907, DSM 22070.

Sequence accession no. (16S rRNA gene): AF206305.

6. **Leptotrichia wadei** Eribe, Paster, Caugant, Dewhirst, Stomberg, Lacy and Olsen 2004, 591^{VP}

wade'i. N.L. masc. gen. n. *wadei* of Wade, named in honor of William G. Wade, for his contributions to microbiology.

The description is from Eribe et al. (2004). After 2–6 d of anaerobic incubation at 37°C, colonies on Columbia or BHI agar plates supplemented with 5% human blood, hemin, and menadione are 0.5–3.0 mm in diameter, convex, sparsely filamentous to irregular, and grayish brown in color, with a dark central spot in old colonies. The surface appearance is glistening and smooth with a rough edge. Colonies are opaque, dry in consistency, and β-hemolytic. Esculin and catalase are positive. Oxidase and indole are not produced. Growth occurs best anaerobically and sparsely aerobically at 37°C but not at 25 or 42°C. Gram-stain-negative, nonsporeforming, nonmotile rods. Cells are arranged in pairs, some slightly curved, others in chains joined by flattened ends. α-Glucosidase and β-glucosidase are produced.

Source: saliva of a healthy person.

DNA G+C content (mol%): 25 (HPLC).

Type strain: LB 16, CCUG 47505, CIP 107918.

Sequence accession no. (16S rRNA gene): AY029802.

Genus II. **Sebaldella** Collins and Shah 1986, 349^{VP}

SAHEER E. GHARIBIA AND KIRSTIN J. EDWARDS

Se.bal.del'la. N.L. dim. ending *-ella*; N.L. fem. dim. n. *Sebaldella* named after the French microbiologist Madeleine Sebald, who first described the organism.

Rods. Nonsporeforming. Nonmotile. Gram-stain-negative. Anaerobic. Acid produced from glucose and some other sugars. The **major end products of glucose fermentation are acetic and lactic acids**; formic acid may also be produced. Hexose monophosphate shunt enzymes, glucose-6-phosphate dehydrogenase, and 6-phosphogluconate dehydrogenase are absent. Glutamate dehydrogenase and malate dehydrogenase are absent. Nonhydroxylated and 3-hydroxylated long-chain fatty acids are present. The fatty acids are primarily of the straight-chain saturated and monounsaturated types. Menaquinones are absent.

DNA G+C content (mol%): 32–36.

Type species: **Sebaldella termitidis** (Sebald 1962) Collins and Shah 1986, 349^{VP} (*Sphaerphorus siccus* var. *termitidis* Sebald 1962, 124; *Bacteroides termitidis* Holdeman and Moore 1970, 33).

Enrichment and isolation procedures

Surface colonies are 1–2 mm in diameter, circular, and transparent to opaque. Colonies in deep agar are lenticular and nonpigmented.

Differentiation of the genus *Sebaldella* from other genera

Sebaldella differs from *Bacteroides fragilis* and related species by exhibiting a lower G+C content (32–36 mol%), by producing acetic and lactic acids as major end products of glucose fermentation, and by the absence of glutamate and malate dehydrogenases (Collins and Shah, 1986). *Sebaldella* also differs from the *Bacteroides fragilis* group in lipid composition. The long chain fatty acids of *Bacteroides* are predominantly of the straight-chain saturated, anteiso- and iso-methyl branched chain types, with monosaturated acids either absent or present in only trace amounts. In contrast, *Sebaldella* primarily synthesizes acids of the straight chain saturated and monosaturated types and methyl branched acids are absent (Miyagawa et al., 1979; Shah and Collins, 1983). *Sebaldella* and *Bacteroides* also differ in isoprenoid quinone composition, with *Bacteroides* possessing menaquinones and *Sebaldella* lacking respiratory quinones (Collins and Jones, 1981; Shah and Collins, 1980). Based on 16S rRNA studies, *Sebaldella* is phylogenetically distinct from *Bacteroides* and all other described eubacterial phyla (Paster et al., 1985).

List of species of the genus *Sebaldella*

1. ***Sebaldella termitidis*** (Sebald 1962) Collins and Shah 1986, 349^{VP} (*Sphaerphorus siccus* var. *termitidis* Sebald 1962, 124; *Bacteroides termitidis* Holdeman and Moore 1970, 33.)

ter.mi'ti.dis. L. n. *termes*, *-itis* wood-eating worm; N.L. fem. adj. *termitidis* pertaining to the termite.

The description is from Collins and Shah (1986). The Gram-stain-negative, obligately anaerobic, nonmotile, rod-shaped cells are 0.3–0.5 × 2–12 µm with central swellings and occur singly, in pairs, and in filaments. Surface colonies are 1–2 mm in diameter, circular, and transparent to opaque. Colonies in deep agar are lenticular and nonpigmented. Acetic and lactic acids are the major end products of glucose metabolism; formic acid may also be produced. Acid is produced from glucose, fructose, maltose, mannitol, mannose, rhamnose, sucrose, trehalose, and xylose. Acid is not produced from arabinose, melzitose, or starch; low levels of

acid may be produced from lactose (delayed reaction). Most strains produce H₂S. Gelatin is not liquefied; coagulated proteins are not attacked. Urease, chitinase, and indole are not produced. Nitrate is not reduced. Uric acid is degraded to CO₂, acetate, and ammonia. Malate dehydrogenase and glutamate dehydrogenase are not produced.

Nonhydroxylated and 3-hydroxylated long-chain fatty acids are present. The fatty acids are of the straight-chain saturated and monounsaturated types, with hexadecanoic and octadecenoic acids predominating. Menaquinones are not produced. Isolated from posterior intestinal contents of termites, where these organisms are part of the predominant bacterial flora.

DNA G+C content (mol%): 32–36 (Bd).

Type strain: ATCC 33386, NCTC 11300.

Sequence accession no. (16S rRNA gene): M58678.

Genus III. ***Sneathia*** Collins, Hoyles, Törnqvist, von Essen and Falsen 2002, 687^{VP} (Effective publication: Collins, Hoyles, Törnqvist, von Essen and Falsen 2001, 360.)

JULIE M.J. LOGAN, KIRSTIN J. EDWARDS AND SAHEER E. GHARIBIA

Sneathia n. l. fem. n. *Sneathia* named after the British microbiologist Peter H.A. Sneath, in recognition of his outstanding contributions to microbial systematics.

Gram-stain-negative, asporogenous, **rod-shaped bacteria**; nonmotile. Cells may display pleomorphism and filaments may be observed. **Anaerobic**, although some strains may show poor growth in CO₂. **Fermentative metabolism. Acid but no gas is produced from glucose.** Acid is not produced from ribose or maltose. Lactic acid, formic acid, and minor amounts of acetic acid are the end products of glucose metabolism; succinic acid may be produced. **Fastidious**; require serum or blood for growth. Optimum temperature for growth 35–37°C. Catalase and oxidase negative. Esculin and hippurate are hydrolyzed but starch is not. β-Glucuronidase is produced. Indole is not produced. Voges-Proskauer negative. Nitrate is not reduced to nitrite.

DNA G+C content (mol%): 22–25.

Type species: ***Sneathia sanguinegens*** Collins, Hoyles, Törnqvist, von Essen and Falsen 2002, 687 (Effective publication: Collins, Hoyles, Törnqvist, von Essen and Falsen 2001, 360.).

Further descriptive information

Originally, Hanff et al. (1995b) reported the isolation from blood cultures of an unusual Gram-stain-negative anaerobic rod-shaped organism from four obstetric patients with postpartum fever, two neonates, and a 100-year-old woman. This fastidious, serum-requiring bacterium was considered by Hanff et al. (1995b) to be a member of the genus *Leptotrichia* and was

designated "*Leptotrichia sanguinegens*". The species was, however, not validly published, and no type strain was designated. In 2001, Collins et al. isolated three strains from amniotic fluid and blood from non-obstetric patients that resembled the bacterium described by Hanff et al. (1995b). However, based on both phenotypic and phylogenetic evidence, Collins et al. concluded that these isolates corresponded to "*Leptotrichia sanguinegens*" and proposed the new genus and species *Sneathia sanguinegens*.

Differentiation of the genus *Sneathia* from other genera

Sneathia sanguinegens can be readily identified in the clinical laboratory on the basis of its cellular morphology and fastidious growth requirements combined with its API Rapid ID32A and ZYM biochemical profiles. In particular, using these systems it can be readily distinguished from *Streptobacillus moniliformis* by its positive β-glucuronidase reaction and by failing to produce chymotrypsin and proline arylamidase. Similarly, *Sneathia sanguinegens* can be easily distinguished from *Leptotrichia buccalis* in requiring serum or blood for growth, by producing β-glucuronidase, and by its negative α-glucosidase and β-glucosidase reactions. On the basis of 16S rDNA sequencing, *Sneathia* isolates demonstrated high sequence similarity of >99.8% and are distinct from their closest named relatives such as *Streptobacillus moniliformis*, *Sebaldella termitidis*, and *Leptotrichia buccalis* (Collins et al., 2001).

List of species of the genus *Sneathia*

1. ***Sneathia sanguinegens*** Collins, Hoyles, Törnqvist, von Essen and Falsen 2002, 687^{VP} (Effective publication: Collins, Hoyles, Törnqvist, von Essen and Falsen 2001, 360.)

san.gui.ne'gens. L. n. *sanguis*, *-inis* blood; L. part adj. *egens* needing; N.L. part. adj. *sanguinegens* needing blood; because the organism requires blood or serum.

Description is from Collins et al. (2001). Gram-stain-negative anaerobic or facultatively anaerobic, nonspore-forming, nonmotile, rod-shaped cells. Colonies on chocolate or blood agar are pin-point and convex after 72 h. Fastidious, requiring blood or serum for growth. Catalase and oxidase negative. Lactic acid, formic acid, and

minor amounts of acetic acid are the end products of glucose metabolism; succinic acid may be produced. Acid but no gas is produced from glucose. Acid may or may not be produced from mannose and raffinose. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, lactose, mannitol, maltose, melebiose, melezitose, methyl- β -D-glucopyranoside, pullulan, D-ribose, sorbitol, sucrose, tagatose, or trehalose. Alkaline phosphatase, acid phosphatase, arginine arylamidase, phosphoamidase, and β -glucuronidase are detected. Arginine dihydrolase, alanine arylamidase, alanine phenylalanine proline arylamidase, α -arabinosidase, chymotrypsin, cystine arylamidase, α -fructosidase, α -galactosidase, β -galactosidase, β -galactosidase-6-phosphate, α -glucosidase, β -glucosidase, glutamic acid decarboxylase, glycyl tryptophan arylamidase,

pyroglutamic acid arylamidase, leucine glycyl arylamidase, lipase C14, α -mannosidase, β -mannosidase, N-acetyl- β -glucosaminidase, proline arylamidase, trypsin, valine arylamidase, and urease are not detected. Activity may or may not be detected for ester lipase C8, esterase C4, glutamyl glutamic acid arylamidase, glycine arylamidase, histidine arylamidase, phenyl alanine arylamidase, leucine arylamidase, serine arylamidase, and tyrosine arylamidase. Indole-negative and Voges-Proskauer-negative. Esculin and hippurate are hydrolyzed but starch is not. Nitrate is not reduced to nitrite. Habitat is not known.

Source: human clinical specimens (blood, amniotic fluid).

DNA G+C content (mol %): 22–25 (HPLC).

Type strain: CCUG 41628, CIP 106906.

Sequence accession no. (16S rRNA gene): AJ344093.

Genus IV. *Streptobacillus* Levaditi, Nicolau and Poincloux 1925, 1188^{AL}

SAHEER E. GHARBIA AND KIRSTIN J. EDWARDS

Strep.to.ba.cil'lus. Gr.adj. *streptos* twisted, curved; L. masc. n. *bacillus* a small rod; N.L. masc. n. *Streptobacillus* a twisted or curved small rod.

Rods with rounded or pointed ends. Occur singly or form long, wavy chains. Nonsporeforming. Nonmotile. Gram-stain-negative. Conversion to L-phase or transitional-phase variant may occur spontaneously during cultivation. **Capable of growth anaerobically or aerobically. Ferments glucose to produce acid but not gas.** Optimum temperature 35–37°C. Catalase and oxidase negative. Indole not produced. Nitrate not reduced to nitrite. Require serum, ascitic fluid, or blood for growth. **Isolated from the throat and nasopharynx of wild and laboratory rats. Causes rat-bite fever in man.**

DNA G+C content (mol %): 24–26.

Type species: *Streptobacillus moniliformis* Levaditi, Nicolau and Poincloux 1925, 1188^{AL}.

Further descriptive information

The sole species forms small (1–2 mm), smooth, convex, grayish, nonhemolytic colonies on 5% horse blood Columbia agar after 72 h of incubation in an atmosphere of carbon dioxide at an optimum temperature of 35–37°C. Direct examinations reveal pleomorphic, Gram-stain-negative filamentous rods with lateral bulbous swellings. In serum-supplemented liquid media, bacterial growth shows a typical cottonball like appearance. The organisms exist in two variant types, the “normal” bacillary form and the inducible or spontaneously occurring L-form that exhibits the typical “fried-egg” colony morphology (Wittler and Cary, 1974). The latter is regarded as an apathogenic *Streptobacillus moniliformis* variant (Freundt, 1956). *Streptobacillus moniliformis* can be distinguished from other biochemically related bacteria by its negative reactions for catalase, oxidase, indole production and reduction of nitrate to nitrite (Savage, 1984).

Streptobacillus moniliformis is a pathogen for humans that was first isolated as a cause of rat-bite fever by Hugo Schottmüller in 1914. He named the organism *Streptothrix muris rattii*. Clinical pictures of the disease are similar despite two different modes of transmission. Oral uptake of *Streptobacillus moniliformis* via contaminated food leads to a disease known as Haverhill fever, named after the place (Haverhill, MA, USA) where the first

well-documented epidemic was observed (Place and Sutton, 1934). Affected individuals had consumed unpasteurized milk or milk products to which rats had access. In another well-documented epidemic (Chelmsford, UK), boarding school pupils became infected after using water from a spring in the vicinity of which rats were observed (McEvoy et al., 1987). As in Haverhill, *Streptobacillus moniliformis* was not isolated from captured rats. However, in both cases, epidemiological data suggested it was most probable that foodstuffs or water contaminated by rats were responsible for the epidemics.

Rats are also the source of the second type of human streptobacillosis, the so-called rat-bite fever. (Another form of rat-bite fever called sodoku is caused by *Spirillum minus* which is not the subject of this review.) *Streptobacillus moniliformis* can be transmitted by rat bite, but recent reports suggest that not only the rat bite, but also simple contact with (pet) rats (Clausen, 1987; Rygg and Bruun, 1992), may result in rat-bite fever. The disease is characterized by an acute onset with chills, vomiting, malaise, headache, irregularly relapsing fever, erythematous rash (especially of the extremities), and arthralgia. Untreated, it often leads to a severe septic polyarthritis and lymphadenopathy. If untreated, mortality is estimated to be about 13% (Roughgarden, 1965; Simon and Wilson, 1986). Complications of streptobacillary rat-bite fever are endocarditis (Rey et al., 1987; Rupp, 1992), pericarditis (Carbeck et al., 1967) brain abscess (Oeding and Pedersen, 1950), amnionitis (Faro et al., 1980), septicemia (Brown and Nunemaker, 1942; Dellamonica et al., 1979; Renaut et al., 1982; Rygg and Bruun, 1992), interstitial pneumonia, prostatitis, and pancreatitis (Delannoy et al., 1991).

So far as is known, the rat is the natural reservoir of *Streptobacillus moniliformis* and therefore plays the dominant role in harboring and transmitting the infectious agent. Most probably the microorganism is a member of the commensal flora of the upper respiratory tract. Hence, the main isolation sites in healthy rats are the nasopharynx (Strangeways, 1933), larynx, upper trachea (Peagle et al., 1976), and the middle ear (Koopman et al., 1991). Although of only low pathogenicity for

the rat, *Streptobacillus moniliformis* may act as a secondary invader (Weisbroth, 1979) in conjunction with presumptive pathogens such as *Pasteurella pneumotropica*, *Mycoplasma pulmonis* causing otitis media (Olson and McCune, 1968; Wullenweber et al., 1992), conjunctivitis (Young and Hill, 1974), bronchopneumonia (Bell and Elmes, 1969), and chronic pneumonia (Gay et al., 1972).

Taxonomic comments

This organism has been given various names over the years. They are found in original research papers as well as in textbooks on pathogenic bacteria. The list of references is: *Streptothrix muris ratti* (Schottmüller, 1914), *Nocardia muris* (de Mello and Pais, 1918), *Actinomyces muris ratti* (Lieske, 1921; Schottmüller, 1914), *Haverhillia multiformis* (Parker and Hudson, 1926), *Actinomyces muris* (de Mello and Pais, 1918; Topley and Wilson, 1936), *Asterococcus muris* (de Mello and Pais, 1918; Heilman, 1941), *Proactinomyces muris* (de Mello and Pais, 1918; Krasil'nikov, 1941), *Haverhillia moniliformis* (Levaditi et al., 1925; Prévot, 1948), *Actinobacillus muris* (de Mello and Pais, 1918; Wilson and Miles, 1955).

Differentiation of the genus *Streptobacillus* from other genera

Streptobacillus can be differentiated from genera which are found in the same habitat, including *Cardiobacterium*, *Actinobacillus*, and *Haemophilus*, on the basis of its serum requirement, flocculent growth in broth, small butyrous colony on agar, characteristic microscopic appearance, absence of catalase and oxidase activity, and failure to reduce nitrate to nitrite or produce indole. Related genera will be positive for one or more of the catalase, oxidase, nitrate reduction or indole production characteristics while *Streptobacillus* is negative for all (Lapage, 1974; Midgley et al., 1970).

Gas-liquid chromatography analysis of the fatty acid pattern shows palmitic, stearic, oleic, and linoleic acid as major components (Edwards and Finch, 1986). On the basis of numerical analysis of SDS-PAGE protein profiles, seven subgroups were identified among 31 *Streptobacillus moniliformis* cultures representing 22 different strains of human, murine, and avian origin isolated in Europe, USA, and Australia. As these groups show a close similarity, it was concluded that *Streptobacillus moniliformis* is a very homologous species (Costas and Owen, 1987).

Phylum XX. Dictyoglomi phyl. nov.

BHARAT K. C. PATEL

Dic'ty.o.glo'mi. N.L. n. *Dictyoglomus* type genus of the type order of the phylum; *-i* ending to denote phylum; N.L. neut. pl. n. *Dictyoglomi* the phylum of the order *Dictyoglomales*.

The phylum is currently represented by a single class, order, family, and genus. The phylum forms a deep line of descent with its related phyla *Thermomicrobia* and *Deinococcus-Thermus* (Figure 123). Gram-stain-negative, strictly anaerobic, thermophilic, and chemoorganotrophic rod-shaped to filamentous

cells that form spherical balls known as rotund bodies. Members produce a range of thermostable enzymes of significance to the biotechnology industries.

Type order: Dictyoglomales ord. nov.

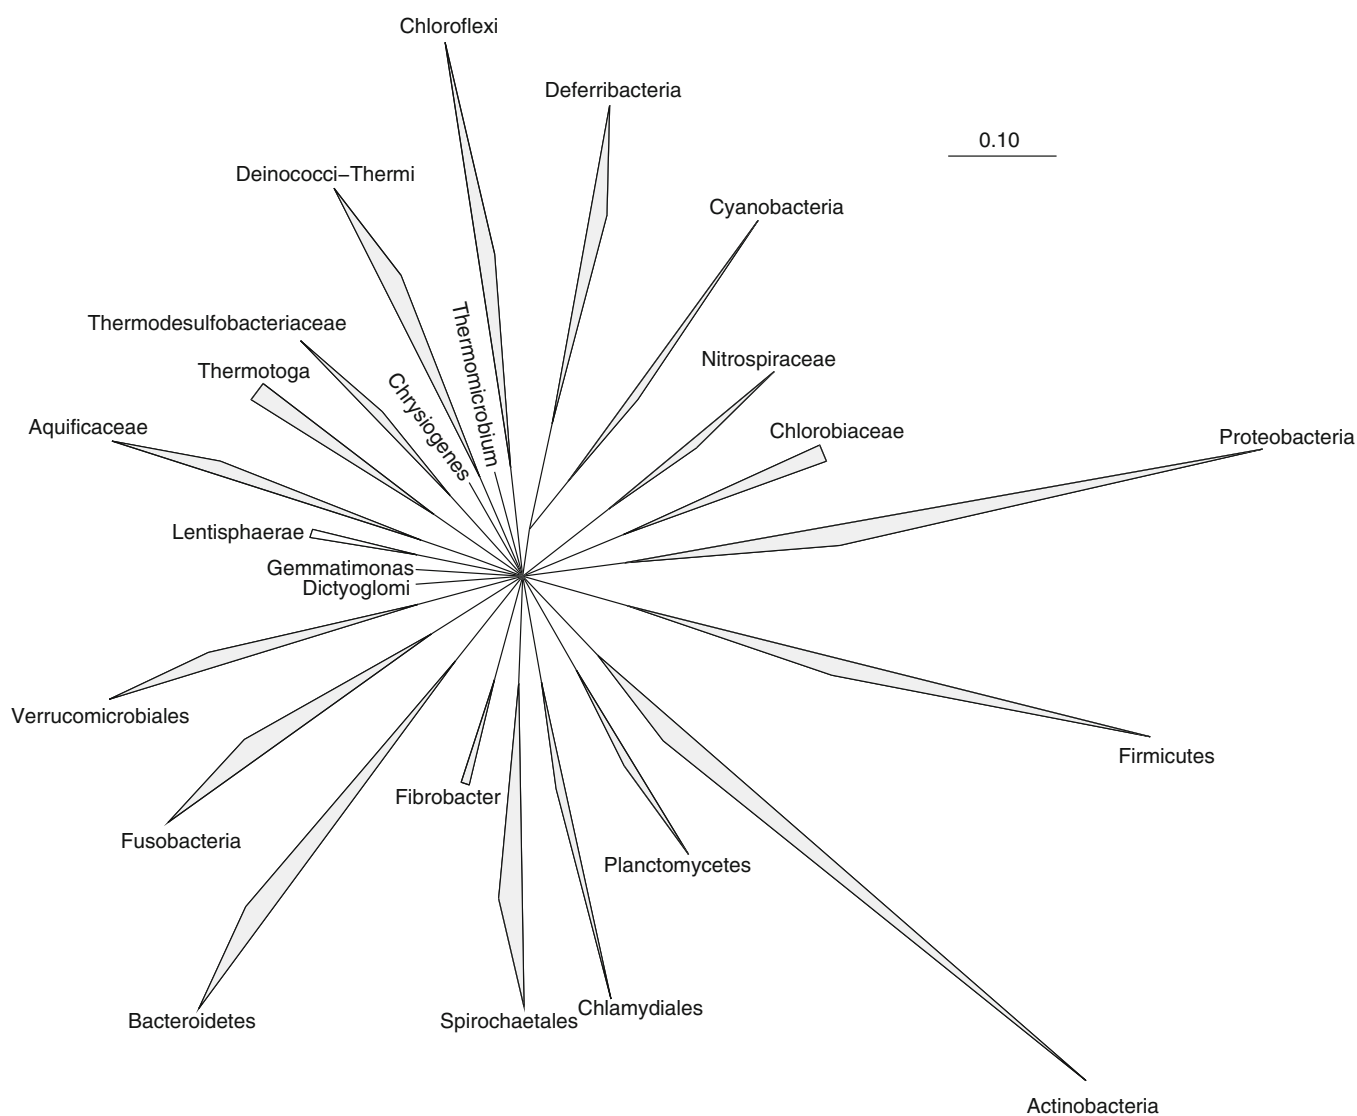

FIGURE 123. Phylogenetic position of phylum *Dictyoglomi*. The scale bar represents 10 changes per 100 nucleotides.

Class I. **Dictyoglomia** class. nov.

BHARAT K. C. PATEL

Dic.ty.o.glo'mi.a. N.L. n. *Dictyoglomus* type genus of the type order of the class; suff. *-ia* ending proposed by Gibbons and Murray and by Stackebrandt et al. to denote a class; N.L. neut. pl. n. *Dictyoglomia* the class of the order *Dictyoglomales*.

Slender (thin) rod to filamentous cells, 5–30 × 0.35–0.45 µm, occurring singly or in pairs. Spherical balls of cells, known as rotund bodies, are commonly observed. Stain Gram-negative, and cell walls possess an outer and an inner cell wall layer. Spores are not formed; cells are nonmotile and no flagella have been observed.

Thermophilic. Neutrophilic. Chemoorganotrophic, **strict anaerobe, ferments glucose. The principal fermentation end products are acetate, lactate, ethanol, CO₂, and H₂.** Occur in natural thermal hot springs and man-made thermal environments.

Type order: **Dictyoglomales** ord. nov.

Order I. **Dictyoglomales** ord. nov.

BHARAT K. C. PATEL

Dic'ty.o.glo.ma'les. N.L. neut. n. *Dictyoglomus* type genus of the order; *-ales* ending to denote an order; N.L. fem. pl. n. *Dictyoglomales* the order of *Dictyoglomus*.

Only one order, *Dictyoglomales*, currently exists, therefore the description of the order is the same as the class *Dictyoglomi*.

Type genus: **Dictyoglomus** Saiki, Kobayashi, Kawagoe and Beppu 1985, 253^{VP}.

Reference

Saiki, T., Y. Kobayashi, K. Kawagoe and T. Beppu. 1985. *Dictyoglomus thermophilum* gen. nov., sp. nov., a chemoorganotrophic, anaerobic, thermophilic bacterium. *Int. J. Syst. Bacteriol.* 35: 253–259.

Family I. **Dictyoglomaceae** fam. nov.

BHARAT K. C. PATEL

Dic'ty.o.glo.ma'ce.ae. N.L. neut. n. *Dictyoglomus* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Dictyoglomaceae* the family of *Dictyoglomus*.

Only one family, *Dictyoglomaceae*, is accepted in the order *Dictyoglomales*. The description of the family is the same as for the class. Only one genus is accepted in the family *Dictyoglomaceae*.

Type genus: **Dictyoglomus** Saiki, Kobayashi, Kawagoe and Beppu 1985, 256^{VP}.

Genus I. **Dictyoglomus** Saiki, Kobayashi, Kawagoe and Beppu 1985, 256^{VP}

BHARAT K. C. PATEL

Dic'ty.o.glo'mus. Gr. n. *dictyon* net; L. neut. n. *glomus* ball; N.L. neut. n. *Dictyoglomus* net ball.

Slender rod to filamentous cells (5–30 × 0.35–0.45 µm), which occur singly or in pairs. Nonsporeforming and nonmotile; **no flagella** have been observed. Stain Gram-negative, and cell walls possess outer and an inner cell wall layers. **Spherical balls of cells**, termed rotund bodies, formed due to either cell aggregation or by cell division, are commonly observed. The walls of the cells in the rotund bodies are portioned with the rotund bodies acquiring the outer wall layer with the cells attached to the inner wall layer. **Thermophilic, neutrophilic, chemoorganotrophs** which are strict anaerobes. **Ferment carbohydrates to acetate, lactate, ethanol, CO₂, and H₂.** **Occur in natural thermal hot springs** and man-made thermal environments (Table 151).

DNA G+C content (mol%): 29–34.

Type species: **Dictyoglomus thermophilum** Saiki, Kobayashi, Kawagoe and Beppu 1985, 256^{VP}.

Further descriptive information

Dictyoglomus species can easily be identified as they all form thin filaments and rotund bodies (Figure 124) similar to that observed for *Thermus* species. Only three out of 95 positive enrichment cultures initiated from 370 volcanic hot spring samples yielded *Dictyoglomus* isolates (Patel et al., 1987). None was isolated from the 300 positive enrichment cultures initiated from non-volcanic geothermal waters of the Great Artesian Basin of Australia (Patel, unpublished results), suggesting that, unlike other thermoanaerobes, *Dictyoglomus* species are restricted in nature.

Members of *Dictyoglomus* have so far been isolated only from natural and man-made thermal habitats. To date, two species (*Dictyoglomus thermophilum* H-6-12^T (Saiki et al., 1985) and *Dictyoglomus turgidum* Z-1310^T) (Svetlichnii and Svetlichnaya, 1988), both of which have been isolated from volcanic hot springs,

have been validly published. Several other strains have also been described. These include *Dictyoglomus* strains Z-1311 to Z-1317 and *Dictyoglomus* strain Rt46-B1 (formerly named *Fervidothrix*), Rt8N2, and Tos-80-la-d. All of these were isolated from volcanic hot springs (pH ranging from 2.8 to 9.0 and temperatures ranging from 55 to 90°C) from Japan, Italy, and Russia (Patel et al., 1986, 1987; Plant et al., 1987; Svetlichnii and Svetlichnaya, 1988). *Dictyoglomus* strain B1 was isolated from a man-made pulp mill cooling tower which had a temperature range

of 70–80°C and a pH range of 5.5–6.5 (Mathrani and Ahring, 1991, 1992).

With the exception of *Dictyoglomus* strain B isolated from a cooling tower of a pulp mill, all other *Dictyoglomus* isolates are reported to be nutritionally versatile and use a wide range of carbohydrates. However, all strains studied to date are slow growers with a generation time reported to vary between 260 and 600 min depending on the substrate used. A variety of extracellular enzymes have been identified for their potential in

FIGURE 124. Large spherical rotund bodies of *Dictyoglomus thermophilum* (strain H-6-12¹). (top) Phase-contrast microphotograph; bar = 10 μm . (bottom) Thin section of cells showing that they are connected by the outer cell wall layer to form the rotund bodies; bar = 0.5 μm .

biotechnology. A number of reports have shown that xylanases from *Dictyoglomus* strains have the potential to pretreat wood pulp in paper manufacturing processing and achieve comparable levels of whiteness with much less bleach (Kenealy and Jeffries, 2003; Morris et al., 1998; Ratto et al., 1994). This has led to marked improvements in methods for the production of xylanases, both by conventional culture methods (Adamsen et al., 1995) and by gene recombinant techniques (Gibbs et al., 1995; Te'o et al., 2000).

The structure of a xylanase has also been elucidated (Sunna and Bergquist, 2003) and metagenomic approaches have been used to clone and study *Dictyoglomus*-like xylanase genes directly from natural volcanic thermal samples. Amylases from *Dictyoglomus* are reported to have a high degree of homology to amylases from a number of hyperthermophilic members of domain *Archaea*. This has stimulated an interest in the origin, evolution, and functioning of amylolytic enzymes in thermophilic and

hyperthermophilic microbes (Fukusumi et al., 1988; Horinouchi et al., 1988; Janecek, 1998; Jeon et al., 1997; Kobayashi et al., 1988). Studies on other enzymes such as mannases (Gibbs et al., 1999) and phosphofructokinase (Ding et al., 1999, 2000) have also been reported. Nielsen et al. (2007) provided evidence that the bioaugmentation of xylanase-producing *Dictyoglomus* species and cellulase/xylanase-producing *Caldicellulosiruptor* species in cattle manure, led to a 93% increase in methane production. Their physiological processes in pure and/or mixed cultures are not well understood but if this significant gap in our knowledge were to be bridged, then we may be able to significantly improve the microbial energy-yielding processes. At the time of writing, the genomes of *Dictyoglomus thermophilum* and *Caldicellulosiruptor saccharolyticus* are being sequenced, and it will be interesting to await the analysis of the data in a bid to unravel the mysteries of their metabolic pathways.

Enrichment and isolation procedures

Members of the genus *Dictyoglomus* can be enriched and isolated on complex anaerobic media containing yeast extract and/or peptones and a variety of fermentable polysaccharides. All media are prepared and dispensed anaerobically using Hungate techniques in an atmosphere of 100% nitrogen. *Dictyoglomus thermophilum* are grown in a medium containing per liter (pH 7.2): 1.5 g KH_2PO_4 , 4.2 g $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 0.5 g NH_4Cl , 0.38 g $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 0.05 g CaCl_2 , 0.039 g $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, 1.0 g Na_2CO_3 , 2.0 mg resazurin, 1.0 g L-cysteine, HCl, 10.0 ml Trace Metal Solution (from a $\times 100$ stock containing per liter 290.0 mg $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 240.0 mg $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 17.0 mg Na_2SeO_3 , 200.0 mg $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$, 280.0 mg $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$), 2.0 g yeast extract, and 2.0 g peptone) and 10.0 ml filter-sterilized Wolfe's vitamin solution (from a $\times 100$ stock solution containing 2.0 mg biotin, 2.0 mg folic acid, 10.0 mg pyridoxine hydrochloride, 5.0 mg thiamine HCl, 5.0 mg riboflavin, 5.0 mg nicotinic acid, 5.0 mg calcium D-(+)-pantothenate, 0.1 mg vitamin B12, 5.0 mg *p*-aminobenzoic acid, and 5.0 mg thioctic acid), added aseptically to the sterile medium with soluble starch (5 g/l) as the fermentable substrate.

Dictyoglomus turgidum and *Dictyoglomus* strain B are cultured on a complex medium containing xylan as the fermentable substrate, whereas *Dictyoglomus* strain Rt46-B1 and a number of other volcanic hot spring isolates are enriched on the complex medium Trypticase Yeast Extract Medium (TYE). TYE contains glucose as the fermentable substrate (Patel et al., 1985a, b). Enrichments are usually initiated by adding sediment and/or water samples into anaerobic medium followed by incubation for up to 7 d at temperatures 70–80°C. In general, the use of glucose should be avoided if the enrichments are to be incubated for more than a few days at temperatures higher than 70°C as furfurals, a toxic by-product are produced under these conditions. Polysaccharides such as xylan and starch are preferable, as they do not form furfurals.

Maintenance procedures

Dictyoglomus strains grown in Trypticase Yeast Extract Starch (TYES) or Trypticase Yeast Extract Glucose (TYEG) Medium remain viable for at least up to 3 months on the bench at room temperature and can be successfully subcultured. For long-term storage, mid-exponential-phase grown cultures are preserved in a 50:50 glycerol:TYEG medium to which 0.1 ml of iron sulfide (Brock and Od'ea, 1977) is added, and cultures are stored at –20 or –80°C.

Differentiation of the genus *Dictyoglomus* from other genera

Though members of *Dictyoglomus* are thermophilic (optimum growth temperature $>70^{\circ}\text{C}$), strictly anaerobic, carbohydrate-fermenting bacteria, they can be differentiated from all other thermoanaerobes due to their unique slender filamentous-shaped cells and their phylogenetic position in the tree of life. *Dictyoglomus* strains possess a number of phenotypic traits, such as the production of rotund bodies, that are in common with certain members of the order *Thermotogales* and *Thermales*. Members of *Dictyoglomus* and of the order *Thermotogales* can be readily differentiated from *Thermales* as the former contains large amounts of C_{16} and C_{18} fatty acids whereas the latter contain C_{15} iso and C_{17} iso in their cell envelope phospholipid fatty acids (Patel et al., 1991). There are numerous phenotypic features which differentiate members of the *Thermotogales* order and *Dictyoglomus* species, e.g., the presence of terminal spheroids or blebs (ballooning of the ends of the cell) in members of the order *Thermotogales* but not in *Dictyoglomus* species. Morphologically, members of *Dictyoglomus* species are slender filamentous cells. Additionally, members of *Thermotogales* appear to be restricted to volcanic springs and oilfields with low salinity, but this is not the case with *Dictyoglomus* species. Furthermore, *Dictyoglomus* strains are slow growers (e.g., 4.3–10 h generation

times in batch cultures in a complex glucose medium), but members of the order *Thermotogales* are fast growers (1.5 h generation time in the same medium).

Taxonomic comments

Early 16S rRNA gene based phylogeny placed *Dictyoglomus thermophilum* H-6-12^T and *Dictyoglomus* strain Rt46-B1 as a deep line of descent in the vicinity of the phylum *Thermotogales* (Love et al., 1993). The high concentrations of saturated phospholipid fatty acids in the cell membranes is another trait that is shared between members of *Dictyoglomus* and the phylum *Thermotogales* (Patel et al., 1991). However, the phylogenetic relationship was not confidently predicted by bootstrap analysis, and the inclusion of different sequences changed the tree topology suggesting that the placement of members of *Dictyoglomus* as a deep line of descent was tenuous. The re-evaluation of the phylogeny, based on the selection of new sequences that have been added to the 16S rRNA database, suggests that the members of *Dictyoglomus* do form a separate line of descent, but that it is closer to the members of the phylum *Firmicutes* (Figure 1).

List of species of the genus *Dictyoglomus*

1. ***Dictyoglomus thermophilum*** Saiki, Kobayashi, Kawagoe and Beppu 1985, 256^{VP}

ther.mo'phil.um Gr. n. *thermê* heat; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) loving; N.L. neut. adj. *thermophilum* heat-loving.

Rods to filaments measuring 5–20 × 0.4–0.6 μm **that occur singly, in pairs, and in bundles**. Several to several dozen cells form large spherical bodies (50–100 μm in diameter) known as rotund bodies (Figure 124). Stain Gram-negative. Nonsporeforming, the cells are nonmotile, and flagella are not observed. Pigment is not formed. **Strict fermentative anaerobe** which grows optimally at 73°C (temperature growth range of >45 and $<80^{\circ}\text{C}$) and a pH of 7 (pH range of >5.4 and <8.9). Amygdalin, arabinose, cellobiose, fructose, fucose, galactose, glucose, lactose, maltose, raffinose, xylose, mannose, melezitose, melibiose, pectin, starch, ribose, sucrose, trehalose, and insoluble potato starch can be utilized but not rhamnose, glycerol, inositol, mannitol, sorbitol, pyruvate, cellulose, xylitol, insoluble corn, and wheat starch. **Acetate, lactate, H₂, and CO₂ are produced from insoluble potato starch fermentation**. Tests for methyl red, indole production, and nitrate reduction are negative. Voges-Proskauer test is positive. Catalase is produced. Growth is inhibited by antibacterial agents such as streptomycin, tetracycline, neomycin, and tunicamycin at 10 μg/ml, and chloramphenicol, vancomycin, and actinomycin D at 100 μg/ml. Lysozyme (78 μg/ml) and sodium dodecyl sulfate (1%) independently do not lyse the cells, but lysozyme sensitizes cells to subsequent lysis by sodium dodecyl sulfate (0.1%).

DNA G+C content (mol%): 29 (T_m).

Type strain: H-6-12, ATCC 35947, DSM 3960.

Sequence accession no. (16S rRNA gene): X69194.

2. ***Dictyoglomus turgidum*** corrig. Svetlichnii and Svetlichnaya 1995, 879^{VP} (Effective publication: Svetlichnii and Svetlichnaya 1988, 369.)

tur'gi.dum L. neut. adj. *turgidum* swollen, inflated, because the cells form spherical aggregates.

Rods to filaments measuring 10–30 × 0.3–0.4 μm which occur singly, in pairs, and in bundles. Several to several dozen cells form large spherical bodies (50–100 μm in diameter) known as rotund bodies. Stain Gram-negative. Nonsporeforming; the cells are nonmotile and flagella are not observed. Pigment is not formed. **Strict fermentative anaerobe** which grows optimally at 72°C (temperature growth range of 48–86°C) and a pH of 7 (pH range of 5.2–9.0). Cellobiose, fructose, glucose, lactose, maltose, raffinose, sucrose, rhamnose, inositol, mannitol, sorbitol, pyruvate, starch, pectin, glycogen, microcrystalline cellulose, carboxymethylcellulose, lignin, humic acids, yeast extract, peptone, casein hydrolysate, and Casmino acids are fermented, but not rabinose, galactose, xylose, mannose, and glycerol. Ethanol, acetate, H₂, and CO₂ are produced as end products of fermentation. Growth is inhibited by antibacterial agents such as 100 μg/ml streptomycin, 50 μg/ml chloramphenicol and penicillin, but it is resistant to 100 μg/ml vancomycin and rifampin.

Source: hot springs of Uzon volcano crater, Kamchatka, Russia.

DNA G+C content (mol%): 32.5 (T_m).

Type strain: Z-1310, DSM 6724.

Sequence accession no. (16S rRNA gene): not determined.

Gem.ma'ti.mo'nas. L. adj. *gemmatus* provided with buds; L. fem. n. *monas* a unit; N.L. fem. n. *Gemmatimonas* a budding unit.

Gram-stain-negative. Cells are **motile, rod-shaped. Spores are not formed**. Cells divide by binary fission but often show budding forms. Mesophilic. Heterotrophic. Cells grow under aerobic conditions. **The major respiratory quinone is MK-9**. The main fatty acids are C_{15:0} iso, C_{16:1} and C_{14:0}. The cell wall contains no diaminopimelic acid (DAP) isomers.

DNA G+C content (mol%): 66.0 (HPLC).

Type species: **Gemmatimonas aurantiaca** Zhang, Sekiguchi, Hanada, Hugenholtz, Kamagata and Nakamura 2003, 1161^{VP}.

Further descriptive information

The genus *Gemmatimonas* contains only one species, *Gemmatimonas aurantiaca*. The type strain, T-27^T, is a Gram-stain-negative, rod-shaped aerobe. Cells often appear to divide by budding division. Strain T-27^T grows at 25–35°C with an optimum growth temperature of 30°C, while no growth is observed below 20°C or above 37°C within 20 d of incubation. The pH range for growth is 6.5–9.5, with an optimum at pH 7.0. Cells are rod-shaped, Gram-stain-negative, motile, 0.7 µm in width and 2.5–3.2 µm in length (mean size 2.8 µm) (Figure 125). Spore formation is not observed. Diffusible pigment production is not observed. Electron microscopy reveals that cells of strain T-27^T possess a Gram-stain-negative cell envelope, with the cytoplasmic and outer membranes readily visible (Figure 126). Electron-dense and transparent inclusion bodies are present in transmission electron micrograph (TEM) images (Figure 126). Cells reproduce by binary fission and often show budding morphology, suggesting asymmetrical cell division (Figures 125 and 126).

Strain T-27^T is able to utilize a limited range of substrates, such as yeast extract, peptone, succinate, acetate, gelatin and benzoate. Neisser staining is positive and 4,6-diamidino-2-phenylindole (DAPI)-stained cells display a yellow fluorescence, indicative of polyphosphate inclusions. Menaquinone-9 is the major respiratory quinone. The cellular fatty acids of the strain are mainly composed of C_{15:0} iso, C_{16:1} and C_{14:0}. The G+C content of the genomic DNA is 66 mol%.

Comparative analyses of 16S rRNA gene sequences indicate that strain T-27^T belongs to the candidate division BD (also called KS-B), a phylum-level lineage in the bacterial domain, to date comprised exclusively of environmental 16S rDNA clone sequences. Hence, a new genus and species were proposed,

Gemmatimonas aurantiaca, as the first cultivated representative of the *Gemmatimonadetes*. Environmental sequence data indicate that this phylum is widespread in nature and has a phylogenetic breadth (19% 16S rDNA sequence divergence) that is greater than well-known phyla such as the *Actinobacteria* (18% divergence).

Based on the standard set of phenotypic tests, strain T-27^T is not physiologically conspicuous. Many phylogenetically diverse bacteria are Gram-stain-negative aerobic heterotrophs and a number of bacteria can accumulate polyphosphate, including "*Candidatus* Accumulibacter phosphatis" (a member of the *Proteobacteria*; Hesselmann et al., 1999), *Microtholmus phosphovorius* and *Tetrasphaera* species (members of the *Actinobacteria*) (Hanada et al., 2002; Maszenan et al., 2000; Nakamura et al., 1995). Strain T-27^T also has a pedestrian, if somewhat limited, carbon substrate utilization profile. Therefore, if isolates are screened using only phenotypic tests, phylogenetically novel microorganisms may be overlooked. The chemotaxonomic and ultrastructural data obtained for strain T-27^T, however, hint at a

FIGURE 125. Phase-contrast photomicrograph of cells of *Gemmatimonas aurantiaca* strain T-27^T grown aerobically in NM-1 liquid medium at 30°C, often showing asymmetrical cell division. Bar, 10 µm.

FIGURE 126. Electron micrographs of cells of *Gemmatimonas aurantiaca* strain T-27^T. (a) Transmission electron micrograph showing a Gram-negative cell envelope structure. Bar, 0.5 μm . (b) Transmission and scanning (inset) electron micrographs of cells of strain T-27^T, suggesting asymmetric cell division. Budding structures are shown by arrows. Bar, 0.25 μm (inset, 0.5 μm).

more exotic ancestry. The strain has an unusual combination of dominant fatty acids: 45% C_{15:0} iso (usually characteristic of Gram-stain-positive bacteria) and 27% C_{16:1} (more often found in Gram-stain-negative heterotrophs). Similarly, it is unusual for Gram-stain-negative bacteria to lack DAP in their cell-wall peptidoglycan and to grow aerobically using MK-9 as the major respiratory quinone. Also, the cell envelope is unusual in that the space between the membranes (periplasmic space) is atypically wide for Gram-stain-negative organisms. Genome sequencing now under way will give further insight into this novel lineage within the domain bacteria.

Enrichment and isolation procedures

Strain T-27^T was isolated from a laboratory-scale sequential batch wastewater treatment process operated under enhanced biological phosphorous removal (EBPR) conditions. A strategy was taken to isolate slowly growing, polyphosphate-accumulating

bacteria that may be important but uncharacterized members of EBPR communities. Low-speed centrifugations were applied initially to sonicated sludge samples to enrich for heavy and/or large cells that may contain various accumulated materials, such as polyphosphate, poly- β -hydroxyalkanoate and glycogen. Following enrichment, cells were plated onto a heterotrophic agar medium, NM-1, and incubated for up to 12 weeks. Pinpoint and slowly appearing colonies were preferentially selected from the isolation plates and purified through repeated isolation of single colonies on NM-1 media. Twenty isolates were obtained in this manner and checked for polyphosphate inclusions by Neisser staining. Among the Neisser-positive isolates (13/20), one strain, designated T-27^T, warranted further investigation based upon its novel 16S rRNA gene sequence. After 2 weeks incubation, colonies of strain T-27^T were circular, smooth, faintly orange to pink and only 1–2 mm in diameter. This slow growth, resulting in pinpoint colonies, may explain why no closely related isolates have been obtained in pure culture previously.

Taxonomic comments

Comparative sequence analysis indicates that strain T-27^T is not closely related to any known cultured microorganisms in recognized bacterial phyla (85% sequence identity). Instead, it is a member of candidate division BD, a previously known phylum-level lineage in the domain *Bacteria* containing only environmental clones obtained from a number of diverse habitats (Hugenholtz et al., 2001). The environmental clones most closely related to strain T-27^T (Ebpr21 and SBRH63, 99 and 97% sequence identity, respectively) were obtained from two geographically remote activated sludges operated under EBPR conditions (Hugenholtz et al., 2001; Liu et al., 2001). This suggests that strain T-27^T and related organisms may be ubiquitous polyphosphate-accumulating bacteria in EBPR processes. Based on the phylogenetic analysis, the phylum *Gemmatimonadetes* is comprised of four subclasses (subclasses 1–4), and the strain T-27^T belongs to subclass 1 (Zhang et al., 2003). Refer to Zhang et al. (2003) for the evolutionary-distance dendrogram of the type strain, associated representatives of this phylum, and other bacterial phyla.

Over 2000 environmental clone sequences belonging to the *Gemmatimonadetes* are identified in the public databases (as of July 2010) by similarity searches and comparative analysis. They are retrieved not only from terrestrial (soils, activated sludge, saline cave waters and clinical samples) but marine habitats (deep-sea sediments, gas hydrates, arctic bacterioplankton, coastal mobile mud, and marine sponge symbionts). Recently, it was found that members of the phylum *Gemmatimonadetes* make up an average of 2% of soil bacterial communities (Jansen, 2006). Recently, four other isolates within this phylum have been isolated from soil (Davis et al., 2005; Joseph et al., 2003), but they remain unnamed. Although they belong to the same subclass as *Gemmatimonas aurantiaca*, their 16S rRNA genes are 7–8% divergent from those of *Gemmatimonas aurantiaca* and 5–7% divergent from each other. These four isolates therefore could extend the phylogenetic coverage of this phylum.

Differentiation of the species of the genus *Gemmatimonas*

The type and only species is *Gemmatimonas aurantiaca*.

List of species of the genus *Gemmatimonas*

1. *Gemmatimonas aurantiaca* Zhang, Sekiguchi, Hanada, Hugenholtz, Kamagata and Nakamura 2003, 1161^{VP}
 au.ran'ti.a'ca. N.L. fem. adj. *aurantiaca* orange-colored.

Cells are **rod-shaped** (0.7 µm in width and 2.5–3.2 µm in length; mean size 2.8 µm). Cells possess a **Gram-stain-negative** cell envelope. Cells reproduce by **binary fission** and often show **budding** morphology. Growth occurs between 25 and 35°C with the optimum at 30°C. The pH range is 6.5–9.5. Optimum growth occurs at pH 7.0. The optimum doubling time of growth is 12 h. Catalase and oxidase are produced. **Aerobic**. No fermentative growth is observed. Nitrate reduction is negative.

Neisser staining is positive. Cells are stained yellow with DAPI. Menaquinone-9 is the major respiratory quinone. The cellular fatty acids of the strain are mainly composed of C_{15:0} iso, C_{16:1} and C_{14:0}. The following can be utilized as sole carbon sources: yeast extract, peptone, succinate, acetate,

gelatin and benzoate. The following can be utilized weakly as sole carbon sources: glucose, sucrose, galactose, melibiose, maltose, formate and hydroxybutyrate. The following carbon sources are not utilized: fructose, mannose, lactose, trehalose, raffinose, arabinose, xylose, rhamnose, glycerol, ethanol, propanol, erythritol, mannitol, sorbitol, lactate, citrate, pyruvate, propionate, malate, butyrate, glutamate, aspartate, alanine, starch, glycogen, gentiobiose, turanose, methyl pyruvate, 2-oxoglutarate, α-ketovalerate, serine, histidine, glycine, leucine and Casamino acids.

Source: the type strain was isolated from a laboratory-scale anaerobic-aerobic sequential batch reactor operated under EBPR conditions.

Phylum XXII. Lentisphaerae Cho, Vergin, Morris and Giovannoni 2004a, 1005^{VP} (Effective publication: Cho, Vergin, Morris and Giovannoni 2004b, 617.)

BRIAN P. HEDLUND, JANG-CHEON CHO, MURIEL DERRIEN AND KYLE C. COSTA

Len.ti.spha.e'rae. N.L. fem. n. *Lentisphaera* type genus of the type order of the phylum; N.L. fem. pl. n. *Lentisphaerae* phylum of the genus *Lentisphaera*. *Lentisphaerae* the phylum of bacteria having 16S rRNA gene sequences related to those of members of the *Lentisphaerales*.

The phylum *Lentisphaerae* is defined by phylogenetic analysis based on 16S rRNA gene sequences of cultured strains from seawater and human feces and environmental clone sequences retrieved mainly from **marine habitats, freshwater habitats, anaerobic digesters, and vertebrate feces**. The phylum includes two bacterial genera, *Lentisphaera* and *Victivallis*, both of which are **chemo-organotrophic cocci** with a **Gram-negative** cell structure. **Saccharolytic**, only able to use mono- and di-saccharides, sugar alcohols, or sugar acids. Both produce **extracellular slime material**.

Type order: **Lentisphaerales** Cho, Vergin, Morris and Giovannoni 2004a, 1005^{VP} (Effective publication: Cho, Vergin, Morris and Giovannoni 2004b, 617.).

Further descriptive information

The phylum *Lentisphaerae* has been shown to be related to the phyla *Planctomycetes*, *Chlamydiae*, and *Verrucomicrobia* along with candidate phyla “*Poribacteria*” and OP3 within the so-called PVC superphylum (Cho et al., 2004b; Wagner and Horn, 2006). Within the PVC superphylum, *Lentisphaerae* are most closely related to the *Verrucomicrobia*, with which they share an obligately chemo-organotrophic metabolism focused on carbohydrate metabolism and the general characteristic of being difficult to isolate in pure culture. Possibly, these two phyla are difficult to isolate because they are both K-strategists (Noll et al., 2005). As such, they may be outgrown in enrichment cultures owing to relatively slow growth rates, or inhibited by high concentrations of organic substrates in common isolation media. In addition, these phyla, particularly *Lentisphaerae*, are generally outnumbered by other bacteria in nature (Cho et al., 2004b; Lee et al., 1996; Zoetendal et al., 2003) and several isolates cannot grow on 1.5% (w/v) agar plates, which are used in most microbiology studies (Janssen et al., 2002, 2004; Sangwan et al., 2005; Zoetendal et al., 2003). Attempts to grow these organisms should probably involve serial dilutions of natural samples into media containing low concentrations of monosaccharides, disaccharides, sugar alcohols, or sugar acids as growth substrates. Since this isolation strategy is minimally selective, high throughput isolation and screening approaches are recommended. It may be productive to avoid standard agar plates (1.5% w/v) in favor of broth culture, gellan gum, or semisolid agar.

Prior to the isolation of *Lentisphaera* (Cho et al., 2004b) and *Victivallis* (Zoetendal et al., 2003), sequences in this lineage were grouped within candidate phylum VadinBE97, known only from cultivation-independent microbial censuses (Rappe and Giovannoni, 2003). Currently, 16S rRNA genes representing uncultured bacteria make up >90% of the sequences in the phylum. These environmental clones comprise several unique order- to family-level lineages (Figure 127, Table 152). The two cultivated orders plus three uncultivated lineages were termed subgroups L1–L5 by Cho et al. (2004b); however, to account for the paraphyly of subgroup L4, accommodate new sequences, and avoid confusion, we use the term subphylum to denote well-supported deep monophyletic groups of three or more environmental clone sequences. This term has no taxonomic value, therefore the taxonomy of these subphyla should be re-evaluated and formally addressed as new organisms are isolated and characterized.

The two cultivated genera belong to two well-supported clades, formally designated the orders *Lentisphaerales* and *Victivallales*. The order *Lentisphaerales* occupies a deep phylogenetic position within the *Lentisphaerae* and is comprised of *Lentisphaera* along with two other 16S rRNA gene sequences from marine environments. This clade is well supported and phylogenetically distant from other members of the phylum.

The order *Victivallales* is comprised of *Victivallis*, indigenous to the human colon, along with 16S rRNA gene sequences from a turkey cecum (Scupham, 2007), dugong feces, termite gut contents, and anaerobic digesters fed with waste from a wine distillery or municipal sludge (Chouari et al., 2005; Delbes et al., 2000; Gordon et al., 1997). The order *Victivallales* groups with subphylum 3 (formerly subgroup L2 (Cho et al., 2004b), which is represented by 16S rRNA gene sequences from the cattle rumen, an anaerobic wine distillery waste digester (Gordon et al., 1997), and freshwater lake and river sediments (Crump and Hobbie, 2005; Nercessian et al., 2005). Subphylum 4 (formerly subgroup L3 (Cho et al., 2004b) and subphylum 5 are each comprised of sequences from mucosal secretions of marine invertebrates or deep-sea marine sediments (Alain et al., 2002; Li et al., 1999; Zhu et al., 2008).

Subphyla 6 and 7 form a well-supported clade. Subphylum 6 16S rRNA gene sequences have been recovered from a variety

FIGURE 127. Maximum likelihood tree with heuristic correction produced by using ARB (Ludwig et al., 2004). Solid squares represent nodes supported by maximum likelihood, parsimony, and distance (neighbor-joining, Kimura 2-parameter correction). Open nodes were supported by two of the three methods. Parsimony and neighbor joining trees were made with 1000 bootstraps and heuristic corrections. Alignments were unmasked. The dataset was purged of sequences suggested to be anomalous by Mallard (Ashelford et al., 2006).

TABLE 152. Habitat distribution of the orders of *Lentisphaera* including major uncultivated groups

	Freshwater		Marine					
	Sediment	Water	Sediment	Water	Invertebrate mucus	Vertebrate digestive tract	Anaerobic digesters	Hypersaline
Order <i>Lentisphaerales</i>				•				
Order <i>Victivallales</i>						•	•	
Subphylum 3, uncultivated	○				•	•	○	
Subphylum 4, uncultivated			○		•			
Subphylum 5, uncultivated	•	○						
Subphylum 6, uncultivated	○							•

Symbols: •, strains isolated and/or 16S rRNA gene clones from several different cultivation-independent studies of habitat type; ○, more than one 16S rRNA gene clone from a cultivation-independent study of habitat type. No symbol, little or no evidence of colonization of the habitat.

of anaerobic habitats, including municipal sewage (Chouari et al., 2005), anoxic freshwater sediments (Briee et al., 2007; Elshahed et al., 2007), and feces of a wild gorilla (Frey et al., 2006). Subphylum 7 is composed of clone sequences from aquatic habitats varying in salinity, including a basal sequence from a freshwater lake (Eiler and Bertilsson, 2004), a marine

clone from the marine tube worm *Alvinella pompejana*, and several derived sequences isolated from hypersaline environments (Humayoun et al., 2003; Isenbarger et al., 2008). The branching pattern within subphylum 7 suggests a freshwater ancestor with later niche invasion into saline and hypersaline environments.

Len.ti.spha.e'ra. L. adj. *lentus* sticky; L. fem. n. *sphaera* sphere; N.L. fem. n. *Lentisphaera* a sticky sphere.

Cells are spherical (coccus). Gram-stain negative. Gram-negative cell structure. Cells have thin layer of extracellular slime and buds or appendages around the cells. Nonmotile. Strictly aerobic, chemoheterotrophic, and facultatively oligotrophic bacteria. Do not produce pigments. Require NaCl for growth. **Do not utilize amino acids as sole carbon sources. Produce transparent exopolymers.** The major cellular fatty acids are C_{16:1} ω9c (50.8%) and C_{14:0} (25.9%). **The genome size is 6.02 Mb, based on full-genome sequencing.** Phylogenetically, the genus belongs to the order *Lentisphaerales* in the phylum *Lentisphaerae*.

DNA G+C content (mol%): 48–49.

Type species: Lentisphaera araneosa Cho, Vergin, Morris and Giovannoni 2004a, 1005^{VP} (Effective publication: Cho, Vergin, Morris and Giovannoni 2004b, 618.).

Further descriptive information

The genus *Lentisphaera* currently contains only one species with the type strain, *Lentisphaera araneosa* HTCC2155^T. Phylogenetic analyses based on almost complete 16S rRNA gene sequences of strains HTCC2155^T and HTCC2160 show that the genus forms a distinct clade together with *Victivallis vadensis* and several environmental sequences of the candidate phylum VadinBE97. The phylogenetic clade containing the genera *Lentisphaera* and *Victivallis* is clearly separated from the nearest phylum, *Verrucomicrobia* (Figure 128). Based on this phylogenetic analysis, the genus *Lentisphaera* is classified as the type genus in the order *Lentisphaerales* of the phylum *Lentisphaerae*. The comparative analyses of 16S rRNA gene sequence show that *Lentisphaera araneosa* has

only 65.1–82.1% similarity with the sequences of representatives of all other phyla in the domain *Bacteria*.

Cells are nonmotile, spherical forms with 0.8 μm in diameter, dividing by binary fission. Cells have a Gram-stain-negative cell structure. Flagella, endospore, and intracellular granules are not found. Colonies are 0.6–1.1 mm in diameter, milkish, uniformly circular, convex, and opaque, with smooth surfaces and entire margins, after incubation on marine agar 2216 at 20°C for 3 weeks. The genus *Lentisphaera* is an obligately aerobic, NaCl-requiring, and psychrotolerant marine chemoheterotroph. The temperature range, pH range, and salinity range for growth are 4–25°C (optimum at 16–20°C), pH 7.0–9.0 (optimum at pH 8.0), and 0.75–15% (w/v) of NaCl (optimum at 3.0%), respectively. β -Galactosidase activity is positive. Catalase, oxidase, denitrification, indole production, glucose acidification, arginine dihydrolase, urease, and hydrolysis of esculin and gelatin are negative. Cells utilize the following carbon sources (0.02%) as sole carbon sources; D-glucose, D-galactose, D-fructose, β -lactose, D-trehalose D-cellobiose, D-maltose, D-mannose, D-glucosamine, D-mannitol, D-sorbitol, pyruvic acid, succinic acid, and D-malic acid. However, the cells do not utilize amino acids as sole carbon sources.

The most important physiological property of the genus *Lentisphaera* is transparent exopolymer (TEP) production in oligotrophic conditions. The genus produces TEP in artificial seawater medium (ASW; 30 g of NaCl, 1.0 g of $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, 4.0 g of Na_2SO_4 , 0.7 g of KCl, 0.15 g of $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.5 g of NH_4Cl , 0.2 g of NaHCO_3 , 0.1 g of KBr, 0.27 g of KH_2PO_4 , 0.04 g

of $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$, 0.025 g of H_3BO_3 , 0.001 g of NaF, 10 ml of Tris-Cl [pH 8.0]), and 1 ml of SN trace metal solution (Waterbury et al., 1986) per 1 l deionized water) and LNHM medium (0.2 μm -filtered and autoclaved seawater supplemented with 1.0 μM NH_4Cl and 0.1 μM KH_2PO_4) amended with 1 \times mixed carbons (MC; LNHM plus 1 \times MC); 1 \times MC was composed of 0.001% (w/v) of each of the following carbon compounds: D-glucose, D-ribose, succinic acid, pyruvic acid, glycerol, N-acetyl D-glucosamine, and 0.002% (v/v) of ethanol. The culture medium increases in viscosity at the end of exponential growth phase and reaches a maximum in stationary phase. The TEP stains bright to deep blue with the dye Alcian Blue. The composition of the TEP is rhamnose (62.2%), galactose (14.2%), mannose (12.2%), and glucose (11.4%).

Lentisphaera araneosa was isolated from the surface seawater of the Pacific Ocean; thus its major habit is considered to be marine environments. The members of the phylum *Lentisphaerae* including cultured and uncultured members seem to inhabit mainly marine environments and animal (or human)-related anaerobic terrestrial environments. Marine habitats include seawaters of the Arctic Ocean, the Pacific Ocean, deep-sea sediments, and mucous of the hydrothermal vent polychaete *Paralvinella palmiformis*. Bulk nucleic acid hybridization values determined by using *Lentisphaera araneosa*-specific probe (5'-TTAGCAAGTAAGGATATGGGT-3') from the Pacific Ocean and the oligotrophic Atlantic seawater samples indicate that *Lentisphaera araneosa* is a common marine bacterium which accounts for less than 1% of total bacterial 16S rRNA.

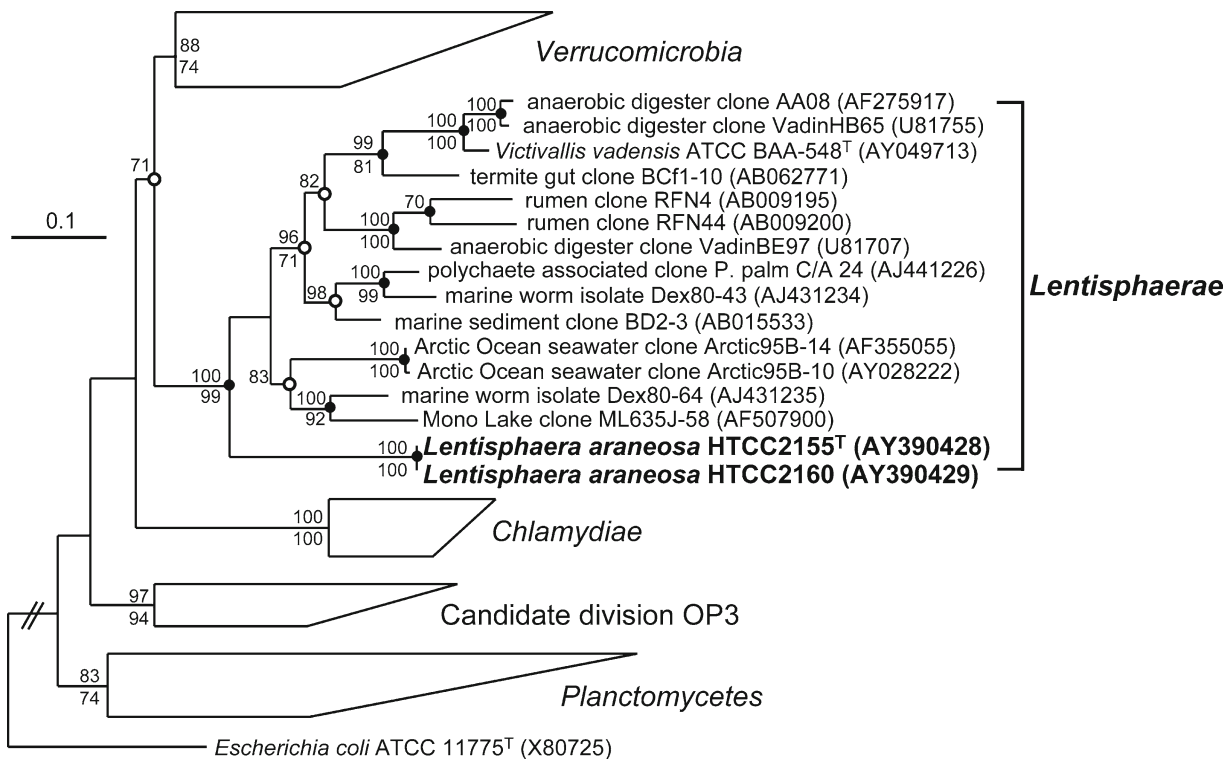

FIGURE 128. Maximum-likelihood 16S rRNA phylogenetic tree showing the phylogenetic positions of the genus *Lentisphaera* and the phylum *Lentisphaerae*. Bootstrap proportions over 70% from both neighbor-joining (above nodes) and maximum parsimony (below nodes) are shown. The closed circles and open circles at each node in the *Lentisphaerae* indicate recovered nodes in all three treeing methods and recovered nodes in two treeing methods respectively. Scale bar, 0.1 substitutions per nucleotide position.

Enrichment and isolation procedures

The original liquid cultures of *Lentisphaera araneosa* were cultivated from the Oregon coast of the Pacific Ocean surface by a dilution-to-extinction method, using LNHM amended with 1× MC after incubation at 16°C for 21 d. The liquid cultures were spread on LNHM plus 1× MC agar medium and colonies were isolated after incubation for 20 d at 16°C. The colonies were transferred on marine agar 2216 and stored as glycerol suspension in liquid nitrogen. Currently there is no special method to enrich *Lentisphaera* from the mixed marine microbial community. Because the growth rate of *Lentisphaera araneosa* is much slower than that of standard colony forming marine bacteria, use of an oligotrophic medium such as LNHM plus 1× MC medium or 1/10 marine R2A is recommended rather than Zobell's medium or marine agar 2216 for the isolation of *Lentisphaera araneosa* from the complex marine microbial community. Recommended incubation temperature to isolate the genus is 16°C.

Maintenance procedures

Frozen stocks as a glycerol suspension (10–30%) stored in liquid nitrogen or at –70°C are routinely used to start a new culture. Either colonies scraped from the surface of agar medium or broth cultures can be used for preparing glycerol stocks. Neither marine broth 2216 nor 1/10 marine R2A broth is suitable for maintaining or preserving the cultures. Incubating the cultures in LNHM plus 1× MC medium or ASW plus 10× MC is recommended for the maintenance and storage of the cultures. Working cultures can be maintained on marine agar 2216 at 16°C for 2 months. Working cultures (slants) can be maintained at 4°C for 3 months.

Procedures for testing special characters

Colonies of *Lentisphaera araneosa* can be visualized as small rounded colonies after 10 d of incubation. To check for culture

purity, DAPI stained cells are viewed by epifluorescent microscopy. When *Lentisphaera araneosa* is cultured in ASW plus 10× MC medium, the viscosity of the medium can be easily checked by swirling the culture flasks and measuring viscosity. *Lentisphaera araneosa* can be specifically identified by using *Lentisphaera araneosa*-specific PCR primers HTCC2155-195F (5'-AAGGTTACGCTTAGGGATGA-3') and HTCC2155-1345R (5'-GTAGCTGATGCCATTTACT-3'), and a standard PCR protocol using an annealing temperature of 55°C.

Differentiation of the genus *Lentisphaera* from other related genera

Phylogenetically, the most closely related genus is *Victivallis* within the order *Victivallales* in the phylum *Lentisphaera*. The genus *Lentisphaera* is differentiated from the genus *Victivallis* by 16S rDNA sequence similarity (84.4%), habitat (seawater vs human), oxygen requirement (obligately aerobic vs obligately anaerobic), mode of glucose utilization (oxidation vs fermentation), DNA G+C composition (48.3 mol% vs 59.2 mol%), and optimum growth temperature (20°C vs. 37°C).

Taxonomic comments

The genus *Lentisphaera* is the type genus of the order *Lentisphaerales*, which encompasses bacteria retrieved from marine habitats, within the phylum *Lentisphaerae*. The phylum *Lentisphaerae* was named after the genus *Lentisphaera*, although *Victivallis* is the first validly published genus in the phylum. Because the category phylum is not covered by the Rules of the Bacteriological Code, *Lentisphaerae* as nomenclature of the phylum is legitimate. As the phylum contains some cultured-but-undescribed species and many uncultured organisms, culturing endeavors and more formal description of novel taxa in the phylum would be very helpful to elucidate the taxonomy of the phylum *Lentisphaerae*.

List of species of the genus *Lentisphaera*

1. ***Lentisphaera araneosa*** Cho, Vergin, Morris and Giovannoni 2004a, 1005^{VP} (Effective publication: Cho, Vergin, Morris and Giovannoni 2004b, 618.)

a.ra.ne.o'sa. L. fem. adj. *araneosa* similar to cobwebs, pertaining to the morphology of transparent exopolymer particles produced by the species.

The characteristics of the species are as described for the genus.

DNA G+C content (mol%): 48–49 (HPLC).

Type strain: HTCC2155, ATCC BAA-859, KCTC 12141.

Sequence accession no. (16S rRNA gene): AY390428.

Vic.ti.val.la.ce'ae. N.L. fem. n. *Victivallis* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Victivallaceae* the family of the genus *Victivallis*

The family comprises the genus *Victivallis* and uncultured 16S rRNA genes from mainly anaerobic environments that branch within the phylum *Lentisphaerae*. Clones have been retrieved from the intestinal contents of humans, dugongs, turkeys, and termites, as well as anaerobic digesters and wastewater. The

delineation of the family is primarily based on phylogenetic information from 16S rRNA sequences.

Type genus: Victivallis Zoetendal, Plugge, Akkermans and de Vos 2003, 214^{VP}.

Genus I. **Victivallis** Zoetendal, Plugge, Akkermans and de Vos 2003, 214^{VP}

MURIEL DERRIEN, CAROLINE M. PLUGGE, WILLEM M. DE VOS AND ERWIN G. ZOETENDAL

Vic.ti.val'lis. L. masc. n. *victus* food; L. fem. n. *vallis* valley; N.L. fem. n. *victivallis* food valley which refers to the Wageningen "Food Valley". This is an area in The Netherlands in which food science is a major research topic.

Coccioid cells, occurring singly and in pairs. The diameters of the cells vary between 0.5 and 1.3 µm. **Gram-negative cell structure. Nonmotile. Strictly anaerobic.** *Victivallis* does not grow on standard agar plates, but beige, shiny, lens-shaped colonies are formed on agar plates with 0.75% (w/v) agar after 10 d of incubation. Cells grow optimally at 37°C and pH 6.5. Growth of *Victivallis* is **chemoorganotrophic** and restricted to a variety of **sugars. Acetate, ethanol, H₂ and bicarbonate** are the main fermentation products from glucose.

16S rRNA gene sequence analysis indicated that *Victivallis* belongs to the recently described order *Victivallales* of the phylum *Lentisphaerae*. The closest cultured relative is *Lentisphaera araneosa* (84.4% 16S rRNA gene similarity).

DNA G+C content (mol%): 59.2 (HPLC).

Type species: Victivallis vadensis Zoetendal, Plugge, Akkermans and de Vos 2003, 214^{VP}.

Further descriptive information

Light microscopic and transmission electronic microscopic (TEM) analyses revealed that *Victivallis vadensis* is a coccioid cell

with Gram-negative cell structure (Figure 129). The cells are variable in diameter (0.5–1.3 µm) and surrounded by haloes, which consist of an extracellular slime layer. In addition, many intracellular electron-dense structures are observed (Figure 129).

Victivallis vadensis was initially isolated in a bicarbonate-buffered anaerobic mineral salts medium (for details see Plugge (2005) supplemented with 10 mM cellobiose and 0.7% (v/v) clarified sterile rumen fluid. However, rumen fluid is not required for growth. In this basal medium *Victivallis* can be cultivated using cellobiose, fructose, galactose, glucose, lactose, lactulose, maltose, maltotriose, mannitol, melibiose, myo-inositol, raffinose, rhamnose, ribose, sucrose and xylose as sole carbon and energy source. All sugars are utilized fermentatively. Besides growth on the above-mentioned defined media, *Victivallis* grows well on Wilkens–Chalgren broth (Oxoid; 16 g/l) and the medium described by Kamlage et al. (1999) (designated KA medium) with minor modifications [no hemin, bacteriological peptone (Oxoid) instead of tryptic peptone from meat], both supplemented with 0.7% clarified sterile rumen fluid. Optimal growth conditions include strict anoxic conditions, pH 6.5,

FIGURE 129. Transmission electronic micrograph of the type strain, *Victivallis vadensis*. Scale bar, approximately 0.5 μm .

temperature of 37°C and addition of 0.2% yeast extract. Under these conditions, the doubling time may reach 0.5 h. *Victivallis* can grow syntrophically with *Methanospirillum hungatei* JF-1^T (DSM 864) in co-culture; glucose is converted exclusively to acetate and methane.

Little is known about the habitat of *Victivallis* since it has only been isolated from a single fecal sample. Denaturing gradient gel electrophoretic analysis (DGGE) of 16S rRNA genes indicated that it is not a dominant member from this fecal sample. Two related uncultured *Victivallales* clones which share only 94% 16S rRNA sequence similarity with *Victivallis vadensis* were detected in an anaerobic digester that was fed with wastewater containing plant material (Godon et al., 1997). This indicates that *Victivallis* may also be present in these types of habitats.

Enrichment and isolation procedures

Victivallis can be enriched and eventually isolated from human feces in liquid anaerobic basal medium, with cellobiose as sole carbon and energy source, by repeated transfers in serial dilution. For a detailed protocol concerning the preparation of basal medium see Plugge (2005). Incubations are performed at 37°C under anaerobic conditions under a gas phase of 182 kPa (1.8 atm) N₂/CO₂ (80:20, v/v). The antibiotics streptomycin and polymyxin B may be used to inhibit growth of potential

contaminants. Triplicate incubations in soft agar (0.75%) with subsequent transfer of single colonies into liquid medium will result in the isolation of *Victivallis*. Growth in liquid cultures will take 1 d; formation of colonies on soft agar will take approximately 10 d.

Maintenance procedures

Victivallis can be stored in basal medium containing cellobiose or any other sugar for several months at 4°C under anaerobic conditions. For longer periods up to several years, cultures can be maintained in basal medium containing 25% glycerol and 0.1% of a titanium-citrate solution (100 mM) at -80°C. *Victivallis* can also be freeze-dried.

Procedures for testing special characters

Victivallis cells are characterized as coccoid cells with Gram-negative cell structure varying in size between 0.5 and 1.3 μm , and surrounded by a slime layer. This slime layer increases the viscosity of TE or 1× PBS when cells are washed with these solutions for DNA isolation. A special characteristic of *Victivallis* is its inability to grow on standard agar plates.

Differentiation of the genus *Victivallis* from other genera

Phylogenetic analysis of 16S rRNA genes revealed that *Victivallis* belongs to the order *Victivallales* of the phylum *Lentisphaerae* (Figure 130). The closest cultured relative of the type strain *Victivallis vadensis* is *Lentisphaera araneosa*, another isolate from the phylum *Lentisphaerae*, although it only shares 84.4% similarity at the 16S rRNA gene level (Cho et al., 2004). While *Victivallis* and *Lentisphaera* both have limited metabolic capacities, the two genera differ by: habitat (human intestine vs sea water); oxygen requirement (strict anaerobe vs strict aerobe), glucose utilization (fermentation vs oxidation), DNA G+C composition (59.2 vs 48.3 mol%), and optimum growth temperature (37°C vs 20°C).

Taxonomic comments

To date, *Victivallis vadensis* is the only isolate representing the genus *Victivallis* and order *Victivallales*. This limits our ability to comprehensively describe this group at the order, genus and species level. Fortunately, culture-independent data shows the detection of bacteria that are more closely related (94% 16S rRNA gene sequence similarity). This suggests that additional species of *Victivallis* or of a closely related genus are waiting to be isolated.

Differentiation of the species of the genus *Victivallis*

Only one species is described, the type species *Victivallis vadensis*.

List of the species of the genus *Victivallis*

1. *Victivallis vadensis* Zoetendal, Plugge, Akkermans and de Vos 2003, 214^{VP}

va.den'sis. N.L. fem. adj. *vadensis* of or belonging to Vada, referring to Wageningen. *Victivallis vadensis* refers to the Wageningen "Food Valley".

Cells are coccoid-shaped, 0.5–1.3 μm , nonmotile, with Gram-stain-negative cell structure and surrounded by an extracellular slime layer. Cells occur singly or in pairs. In pure culture, the cells can grow on a variety of sugars, only

under strictly anaerobic conditions. Glucose is converted to acetate, ethanol, H₂ and bicarbonate. Growth on solid agar media is possible below 0.75% (w/v) agar. Cells grow optimally on bicarbonate-buffered mineral salts medium with cellobiose at 37°C and pH 6.5.

Source: human feces.

DNA G+C content (mol%): 59.2 (HPLC).

Type strain: Cello, DSM 14823, ATCC BAA-548.

Sequence accession no. (16S rRNA gene): AY049713.

Phylum XXIII. Verrucomicrobia phyl. nov.

BRIAN P. HEDLUND

Ver.ru'co.mi.cro'bi.a. N.L. fem. pl. n. *Verrucomicrobiales* type order of the phylum; N.L. neut. pl. n. *Verrucomicrobia* the *Verrucomicrobiales* phylum.

The phylum *Verrucomicrobia* is defined by phylogenetic analysis of 16S rRNA gene sequences of cultured strains and environmental clone sequences retrieved from a wide variety of environments. All cultivated members of the phylum stain Gram-negative; many have intracellular compartments bounded by internal membranes. Menaquinones are the dominant respiratory quinones; ubiquinones have not been detected. Most members are chemoheterotrophs, preferring carbohydrates including complex natural polysaccharides. Recently isolated members are thermoacidophilic methylotrophs.

Type order: Verrucomicrobiales Ward-Rainey, Rainey, Schlesner and Stackebrandt 1996, 625^{VP} (Effective publication: Ward-Rainey, Rainey, Schlesner and Stackebrandt 1995, 3249.) emend. Yoon, Matsuo, Adachi, Nozawa, Matsuda, Kasai and Yokota 2008, 1002.

Further descriptive information

To date, there are seven class-level groups in the phylum including three classes that have been formally defined, *Verrucomicrobiae*, *Spartobacteria*, and *Opitutae*. Two additional subphyla groups include recently cultivated organisms that have not yet been formally defined. Lastly, two subphyla groups are represented solely by 16S rRNA gene sequences from cultivation-independent studies (Figure 131). Each class-level group exhibits distinct habitat preferences that are not yet fully elucidated (Table 153). Classes *Verrucomicrobiae*, *Spartobacteria*, and *Opitutae* are each described in their own class chapters. Here, traits of the four remaining class-level groups are described.

Subphylum 3 is known mostly from 16S rRNA gene sequences from cultivation-independent studies of soils and marine environments. Recently, six strains were isolated from soils by prolonged incubation on gellan gum-solidified medium with xylan as the sole carbon and energy source, including Ellin 514, Ellin 516, and Ellin 518 (Sangwan et al., 2005; Figure 132). The genus name "*Pedosphaera*" will be proposed to encompass these Gram-stain-negative, saccharolytic cocci (Sangwan and Janssen, pers. Comm.). Ellin 514 has been shown to have a compartmentalized cell including a membrane-enclosed compartment containing a condensed nucleoid and ribosomes (termed the pirellulosome) and a ribosome-free compartment between the pirellulosome and the cytoplasmic membrane (termed the paryphoplasm) (Lee et al., 2009). This cellular architecture has also been described in *Verrucomicrobium*, *Prostheco bacter*, and *Chthoniobacter* species (Lee et al., 2009). The phylogenetic structure of subphylum 3 includes two primary lineages (Figure 132). The lineage including "*Pedosphaera*" is comprised almost entirely of 16S rRNA genes recovered from soil habitats (Cruz-Martinez

et al., 2009; Janssen, 2006; Sangwan et al., 2005) where it is typically the second most abundant class-level group of *Verrucomicrobia* in clone libraries at 0–4.7% of total 16S rRNA gene clones (Janssen, 2006). The second lineage is comprised of 16S rRNA genes recovered from marine habitats, particularly in the deep sea (Lau and Armbrust, 2006; Penn et al., 2006).

Subphylum 6 has been predominantly recovered from methane-emitting mud volcanoes showing evidence of methane consumption (Alain et al., 2006; Niemann et al., 2006). Subsequently, three separate groups reported isolation of methanotrophic *Verrucomicrobia* from thermoacidic mud volcanoes, provisionally named "*Methylacidiphilum infernorum*" (Dunfield et al., 2007), "*Methylacidiphilum kamchatkensis*" (Islam et al., 2008), and "*Acidimethylosilex fumarolicum*" (Pol et al., 2007). "*Methylacidiphilum infernorum*" and "*Methylacidiphilum kamchatkensis*" were isolated from Hell's Gate, New Zealand, and Uzon Caldera, Kamchatka, Russia, respectively. These two isolates have similar pH growth optima at pH 3.5 and ranges from pH 0.8 to 5.8. The temperature ranges for growth were 40–65°C with optima at 55°C. However, only "*Methylacidiphilum kamchatkensis*" appears to be able to fix atmospheric N₂. "*Acidimethylosilex fumarolicum*" was isolated from the Pozzouli Solfatara, Italy with a pH range of 1.0–6.0 (optimum 2.5) at 60°C. All three isolates have three divergent operons encoding the components of the particulate (membrane-bound) methane monooxygenase (pMMO) and possess intracellular membrane structures described as tubular or polyhedral which are likely to increase membrane surface area for pMMO in the absence of stacked membrane structures typical of methylotrophic *Proteobacteria*. Analysis of pyrosequencing data from "*Acidimethylosilex fumarolicum*" (Pol et al., 2007) and a complete genome from "*Methylacidiphilum infernorum*" (Hou et al., 2008) show simple, modified methanotrophic pathways with many homologs from methylotrophic *Proteobacteria*. The genome size of "*Methylacidiphilum infernorum*" is much smaller than *Proteobacteria* methylotrophs at 2.3 Mb; it was suggested that genes for C1 metabolism were obtained by horizontal gene transfer from *Proteobacteria*.

Subphylum 5 is known only by cultivation-independent studies (Figure 133). Two major clades exist. One is found primarily in anaerobic sediments such as those showing anaerobic ammonia oxidation activity (Freitag and Prosser, 2003), contaminated aquifers (Dojka et al., 1998), geothermal mats (both marine and freshwater) (Hirayama et al., 2007), RNA from freshwater sediments (Nercessian et al., 2005), and hypersaline terminal-basin lakes (Humayoun et al., 2003). The second clade is also found in anaerobic habitats such as those listed above, however, this clade has also been detected in digestive tracts of vertebrates

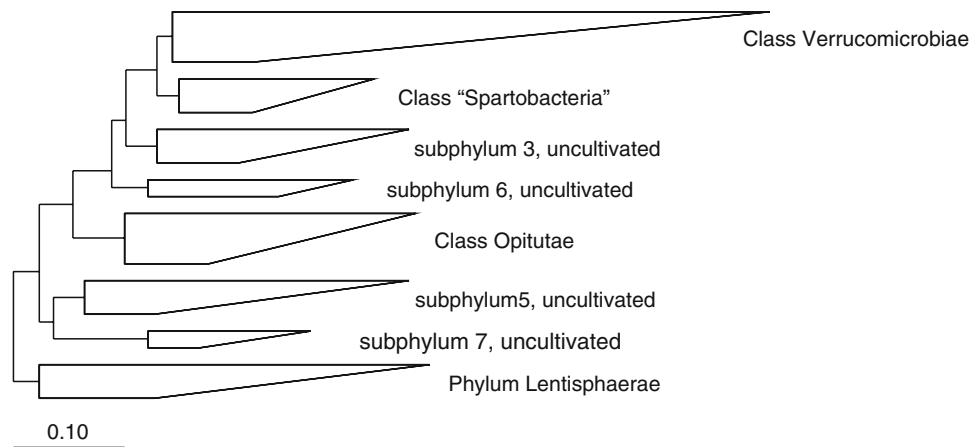

FIGURE 131. Phylogeny of *Verrucomicrobia* calculated with maximum likelihood methods with heuristic correction showing nearly complete 16S rRNA gene sequences present in version 91 of the SILVA database (Pruesse et al., 2007). All class-level groups were included and wedged to show the relationship between existing classes and class-level groups or “subphyla” not yet formally described. Subphylum 3 includes strains recently isolated by Janssen’s group but not yet formally described. The genus name “*Pedosphaera*” will be proposed (Sangwan et al., 2005). Recent thermoacidophilic methylotrophs provisionally named “*Methylacidiphilum inferorum*” (Dunfield et al., 2007), “*Methylacidiphilum kamchatkensis*” (Islam et al., 2008), “*Acidimethylosilex fumarolicum*” (Pol et al., 2007), and related 16S rRNA gene sequences belong to subphylum 6. The phylogeny was produced by using ARB (Ludwig et al., 2004) using *Escherichia coli* 16S rRNA gene nucleotides 110–1274. Alignments were unmasked.

TABLE 153. Habitat distribution of the classes of *Verrucomicrobia* including uncultivated class-level groups from studies published prior to June 2008^{a,b}

Habitat	Class <i>Verrucomicrobiae</i>	Class <i>Opitutae</i>	Class <i>Spartobacteria</i>	Class 3, uncultivated ^c	Class 5, uncultivated	Class 6, uncultivated ^c	Class 7, uncultivated

<i>Symbionts or commensals:</i>							
Vertebrate	●				●		
Invertebrate	●	●	●	○	○	○	○
Geothermal		○		○	○	●	○

^aSymbols: ●, multiple strains isolated from different samples and/or >25% of 16S rRNA gene clones in the class from cultivation-independent studies come from habitat type; ○, single strain isolated or multiple strains from the same sample and/or <25% of 16S rRNA gene clones from cultivation-independent studies come from habitat type. No symbol, little or no evidence of colonization of the habitat.

^bHere, class-level groups of *Verrucomicrobia* are used synonymously with original subphylum designations (Hugenholtz et al., 1998).

^cAlthough listed as “uncultivated” here, classes 3 and 6 are now represented in culture (Dunfield et al., 2007; Islam et al., 2008; Pol et al., 2007; Sangwan et al., 2005).

(Frey et al., 2006). Subphylum 7 is also represented only by 16S rRNA gene sequences from a variety of environments, although it is currently only represented by a small number of sequences. Subphylum 7 appears to be monophyletic with subphylum 5, although it is separated by a relatively large phylogenetic distance and is treated separately here.

The relationship between the *Verrucomicrobia* and other phyla has been the subject of some research. It was originally suggested by phylogenetic analyses of a relatively small number of 16S rRNA gene sequences that the *Verrucomicrobia* were most closely related to the *Planctomycetes* and the *Chlamydia* (Hedlund et al., 1996, 1997; Ward-Rainey et al., 1995). Recently, this has been supported by more robust analyses based on alignments of

large numbers of 16S rRNA gene sequences (Wagner and Horn, 2006), concatenated ribosomal proteins (Hou et al., 2008), and BLAST analysis of putative proteins from whole-genome sequences (Hou et al., 2008). It has been proposed that the *Verrucomicrobia* belong to the so-called PVC superphylum, which is comprised of the well-characterized phyla *Planctomycetes*, *Verrucomicrobia*, and *Chlamydia* along with the *Lentisphaera*, *Poribacteria*, and candidate phylum OP3. The relationships among these phyla and others will likely be further clarified through comparisons of whole genomes of a number of *Verrucomicrobia* (Galperin, 2008). The relationship between the *Verrucomicrobia* and *Planctomycetes* is also bolstered by the report of very similar cell compartmentalization (Lee et al., 2009).

FIGURE 132. Phylogeny of *Verrucomicrobia* subphyla 3 and 6. Calculated as in Figure 131. Subphylum 3 includes strains Ellin 514, Ellin 516, and Ellin 518 recently isolated by Janssen’s group but not yet formally described. The genus name “*Pedosphaera*” will be proposed (Sangwan et al., 2005). Recent thermoacidophilic methylotrophs provisionally named “*Methylacidiphilum inferorum*” (Dunfield et al., 2007), “*Methylacidiphilum kamchatkensis*” (Islam et al., 2008), “*Acidimethylsilex fumarolicum*” (Pol et al., 2007), and related 16S rRNA gene sequences belong to subphylum 6. The phylogeny was produced by using ARB (Ludwig et al., 2004) using *Escherichia coli* 16S rRNA gene nucleotides 110–1274. Alignments were unmasked.

Four members of the *Verrucomicrobia*, representing three class-level lineages, were used for detailed ultrastructural characterization using cryosubstituted cross sections revealing complex cell structure. All four *Verrucomicrobia* were characterized by the presences of an intracytoplasmic membrane that bounds a condensed nucleoid and ribosomes and a ribosome-free paryphoplasm between the intracytoplasmic membrane and the cytoplasmic membrane. As in the *Planctomycetes*, the function of the complex cell structure is not currently understood.

Class I. *Verrucomicrobiae* Hedlund, Gosink and Staley 1998, 328^{VP} (Effective publication: Hedlund, Gosink and Staley 1997, 35.) emend. Yoon, Matsuo, Adachi, Nozawa, Matsuda, Kasai and Yokota 2008, 1002

BRIAN P. HEDLUND

Verru.co.mi.cro.bi'a.e. N.L. fem. pl. n. *Verrucomicrobiales* type order of the class; *-ae* ending to denote a class; N.L. fem. pl. n. *Verrucomicrobiae* the *Verrucomicrobiales* class.

On the basis of 16S rRNA gene sequence analyses, this group comprises one of the primary lineages in the phylum *Verrucomicrobia* and is equivalent to subdivision 1 (Hugenholtz et al., 1998) of the phylum. The majority of its members inhabit marine and freshwater habitats or vertebrate digestive tracts, including humans, however, some have been recovered from soils. The *Verrucomicrobia* currently comprise one order, at present represented by three families, *Verrucomicrobiaceae*, *Akkermansiaceae*,

and *Rubritaleaceae*. Each family includes one or more cultivated and taxonomically described genus and is found primarily in a single habitat type, namely, freshwater habitats, vertebrate digestive tracts, and marine habitats, respectively. All members of this group stain Gram-negative.

Type order: Verrucomicrobiales Ward-Rainey, Rainey, Schlesner and Stackebrandt 1996, 625^{VP} (Effective publication: Ward-Rainey, Rainey, Schlesner and Stackebrandt 1995, 3249.)

emend. Yoon, Matsuo, Adachi, Nozawa, Matsuda, Kasai and Yokota 2008, 1002.

Further descriptive information

There are at least three well-supported family-level groups within the class *Verrucomicrobia*, each of which have been formally described, *Verrucomicrobiaceae*, *Akkermansiaceae*, and *Rubritaleaceae* (Figure 134).

The family *Verrucomicrobiaceae* is represented by the genera *Verrucomicrobium* and *Prostheco bacter* as well as 16S rRNA genes from cultivation-independent studies primarily from freshwater habitats. Both genera possess prosthecae. Although prosthecae are phylogenetically widespread, particularly among members of the *Alphaproteobacteria*, the *Verrucomicrobiaceae* are distinguished by the possession of fimbriae, menaquinones, and specialization in carbohydrate degradation (Hedlund et al., 1997). *Prostheco bacter* has become the focus of investigation since the discovery of homologs of tubulin genes, *btubA* and *btubB*, in *Prostheco bacter vanneerveni*, *Prostheco bacter dejongei*, *Prostheco bacter debontii*, and *Prostheco bacter fusiformis* (Jenkins et al., 2002). A number of studies have elucidated the distribution of these tubulin genes and those encoding other structural components among *Verrucomicrobia* as well as the biochemical properties of their gene products. Although initial analysis of the partial-genome sequence of *Prostheco bacter dejongei* failed to reveal genes of the *fts* operon (Jenkins et al., 2002) which is normally involved in contractile ring formation and function during bacterial cell division, the genome sequence of *Verrucomicrobium spinosum* did contain *ftsZ* and *ftsA* (Yee et al., 2007). Subsequently, degenerate-primed PCR eventually yielded both genes from four *Prostheco bacter* species (Pillhofer et al., 2007b) and genomic studies revealed ancestral division and cell wall (*dcw*) gene clusters (*ddl*, *ftsQ*, *ftsA*, and *ftsZ*) in all three formally described classes of *Verrucomicrobia* as well as a taxonomically uncharacterized strain in subphylum 3, strain Ellin514 (Pillhofer et al., 2008). Bacterial tubulins appear to have a narrow phylogenetic distribution in the *Verrucomicrobia* since genome projects of members of five class-level groups (subphyla) have failed to reveal tubulin homologs. Furthermore, a new species of *Prostheco bacter*, *Prostheco bacter fluviatilis*, was recently described, which, based on negative PCR results, may lack bacterial tubulin genes (Takeda et al., 2008). However, it should be noted that ectosymbionts of the marine ciliate *Euplotidium* that belong to the *Opitutales*, class *Opitutae*, also appear to have tubulins based on biochemical and structural studies, although no gene sequences exist therefore it is currently not possible to determine whether the genes from *Prostheco bacter* are evolutionarily related (Petroni et al., 2000). The patchy distribution of tubulin genes in the *Verrucomicrobiaceae* justifies relegation of these genes to the pan-genome, rather than the core genome, which strongly suggests a non-essential role in these organisms. Consistent with this patchy phylogenetic distribution is the variable genomic context of tubulin genes and a kinesin-like gene among *Prostheco bacter* genomes (Pillhofer et al., 2007a). Thus, all available data suggest that cell division in *Verrucomicrobia* is likely to be dependent on prototypical *dcw* components and that bacterial tubulins and the universally conserved kinesin-like gene serve an alternate, non-essential function. The presence of the bacterial actin homolog that is responsible for maintaining shapes other than a sphere (*mreB*) in *Verrucomicrobiales*, and the apparent absence of tubulins in

Prostheco bacter fluviatilis, seem to rule out a role for tubulins in prosthecae formation or maintenance. Biochemical studies of *Prostheco bacter* tubulin gene products show that *BtubA* and *BtubB* form dimers that polymerize to form protofilaments *in vitro* with concomitant GTP hydrolysis in the absence of a chaperone, and the protofilaments aggregate to form pairs and, subsequently, bundles that are dozens of protofilaments thick (Schlieper et al., 2005; Sontag et al., 2005, 2009). Ultimately, the biological role of *Prostheco bacter* tubulins may best be addressed genetically; no genetic system to study *Verrucomicrobia* has yet been described.

The families *Akkermansiaceae* and *Rubritaleaceae* are each represented by one cultivated genus, *Akkermansia* and *Rubritalea*, respectively. *Akkermansia* and closely related 16S rRNA gene sequences have been recovered exclusively from intestinal contents of vertebrates, including humans, mice, rabbits, and dugong, suggesting a wide distribution in phylogenetically, ecologically, and physiologically distinct mammals (Hayashi et al., 2002; Hold et al., 2002; Salzman et al., 2002; Nelson et al., 2003; Mangin et al., 2004; Eckburg et al., 2005; R.A. Hutson and M.D. Collins, not published). Some related 16S rRNA gene sequences have been reported from soils or freshwater habitats, but it is currently unclear whether these represent free-living organisms or fecal contaminants. Several species of *Rubritalea* have been isolated from diverse marine invertebrates and sediments, and many related 16S rRNA gene sequences have been recovered from cultivation-independent censuses of marine habitats, particularly pelagic samples (Scheuermayer et al., 2006). However, a few 16S rRNA gene sequences have been recovered from freshwater samples and from activated sludge. The lack of habitat- or host-specific phylogenetic structure among *Rubritaleaceae* environmental clones may suggest a marine clade with salinity broad tolerance.

Since the chapters for this edition of *Bergey's Manual* were prepared, three additional genera in the *Verrucomicrobiaceae*, collectively represented by ten strains and six new species, were isolated from marine sediment, water, and red alga: *Persicirhabdus*, *Roseobacillus*, and *Luteolibacter* (Yoon et al., 2008). The descriptions of these organisms are generally consistent with the class description provided here. It was suggested that these isolates be placed in the family *Verrucomicrobiaceae*, the only existing family of the *Verrucomicrobiales* at the time; however, with the updated taxonomy proposed here, all three new genera should be placed in the *Rubritaleaceae*.

Ver.ru.co.mi.cro.bi.a'les. N.L. neut. n. *Verrucomicrobium* type genus of the order; *-ales* ending to denote an order; N.L. fem. pl. n. *Verrucomicrobiales* the order of the genus *Verrucomicrobium*

Encompasses bacteria isolated from freshwater or marine aquatic ecosystems and from animal feces, within the class *Verrucomicrobiae*. The order contains the families *Verrucomicrobiaceae*, *Akkermansiaceae*, and *Rubritaleaceae*. Delineation of the order is determined primarily by phylogenetic information from 16S rRNA gene sequences. All stain Gram-negative and have a Gram-negative cell structure. All are chemoorganotrophic. Includes obligate aerobes, facultative anaerobes, and strict anaerobes.

Type genus: Verrucomicrobium Schlesner 1988, 221^{VP} (Effective publication: Schlesner 1987, 56.).

Ver.ru.co.mi.cro.bi.a.ce'ae. N.L. neut. n. *Verrucomicrobium* type genus of the family; L. suff. -aceae ending to denote a family; N.L. fem. pl. n. *Verrucomicrobiaceae* the *Verrucomicrobium* family

Prothecate cells with fimbriae. Rod- or vibrioid-shaped; cells may be fusiform. Nonsporeforming. Nonmotile. **Cells stain Gram-negative and have a Gram-negative cell structure. Aerobic or facultatively anaerobic via fermentation.** Mesophilic. **Chemoorganotrophic. Saccharolytic.** Use predominantly mono- and disaccharides and their derivatives. Menaquinones are the only respiratory quinones that have been detected.

DNA G+C content (mol%): 54–60.

Type genus: **Verrucomicrobium** Schlesner 1988, 221^{VP} (Effective publication: Schlesner 1987, 56.).

Further descriptive information

Encompasses bacteria isolated from freshwater lakes and associated 16S rRNA gene sequences recovered from freshwater environments and soils within the order Verrucomicrobiales. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences.

Key to the genera of the family
Verrucomicrobiaceae

1. The DNA G+C content is 58–59 mol%. Cells are rod-shaped with many short (<2 µm) prosthecae. Fimbriae extend from tips of prosthecae. Growth on monosaccharides or disaccharides as carbon and energy sources aerobically or via fermentation without gas production. Isolated from fresh water or brackish environments.
→ Genus I. *Verrucomicrobium*
2. The DNA G+C content is 54–60 mol%. Fusiform cells are rod- or vibrioid-shaped with a single prostheca extending from the old pole of the cell. Growth on monosaccharides or disaccharides under aerobic conditions. Unable to grow anaerobically. Isolated from freshwater environments.
→ Genus II. *Prosthecobacter*

Genus I. **Verrucomicrobium** Schlesner 1988, 221^{VP} (Effective publication: Schlesner 1987, 55.)

HEINZ SCHLESNER

Ver.ru.co.mi.cro'bi.um. L. fem. n. *verruca* wart; N.L. neut. n. *microbium* (from Gr. adj. *mikros* small and Gr. n. *bios* life), a microbe; N.L. neut. n. *Verrucomicrobium* warty microbe.

Unicellular bacterium, rod shaped with numerous prosthecae extending from all locations on the cell surface. **Fimbriae varying in length and number extrude from the tips of the prosthecae.** Gram-stain-negative; nonmotile. Nonsporeforming. PHB is not stored. No gas vesicles. Mesophilic. Chemoorganotrophic; facultatively anaerobic. Glucose is fermented; nitrate is not reduced under anaerobic conditions. Oxidase and catalase positive. The cell wall contains *m*-diaminopimelic acid. The main respiratory quinone is MK10. MK9, MK10(H₂), and MK11 are minor quinones. Major fatty acids are C_{14:0}, C_{14:0} iso, C_{15:0} anteiso, C_{15:0}, C_{16:1} ω5, C_{16:0}, C_{17:1} ω12. The major phospholipids are phosphatidylglycerol and phosphatidylmethylethanolamine.

DNA G+C content (mol%): 58–59.

Type species: **Verrucomicrobium spinosum** Schlesner 1988, 221^{VP} (Effective publication: Schlesner 1987, 55.).

Further descriptive information

Verrucomicrobium spinosum is the only described species of *Verrucomicrobium*. Bacteria with multiple prosthecae are grouped in different phyla: the phototrophic *Ancalochloris* (Gorlenko and

Lebedeva, 1971) and *Prosthecochloris* (Gorlenko, 1970) are members of the phylum *Chlorobi* (Garrity and Holt, 2001), while the heterotrophic bacteria *Ancalomicrobium*, *Prosthecomicrobium* (Staley, 1968), and *Stella* (Vasilyeva, 1985) are *Proteobacteria* (Garrity and Holt, 2001). None of the above, however, has fimbriate prosthecae as does *Verrucomicrobium spinosum* (Figure 135; Schlesner, 1992).

Prothecate bacteria with fimbriae extending from the tips of prosthecae have rarely been observed. Such bacteria occurred in an enrichment culture of Lake Plußsee water to which vitamin solution no. 6 (see below) was added (P. Hirsch, Kiel, personal communication). Lake Plußsee is a small eutrophic lake near Plön, Holstein, Germany. The type strain of *Verrucomicrobium spinosum* was isolated from Lake Vollstedter See (Holstein, Germany), a shallow (max. depth 2 m) eutrophic lake. Another strain came from the Schrevenparkeich, a pond in a public park in Kiel, Germany. This pond was very eutrophic because flocks of water fowl lived there and were fed by visitors to the park.

Isolates of *Verrucomicrobium* utilize the following for carbon and energy: esculin, amygdalin, cellobiose, fructose, galactose,

FIGURE 135. Morphology of *Verrucomicrobium spinosum*. Numerous fimbriae are excreted from the tips of short conical and tube-like prosthecae. Negatively stained with phosphotungstic acid.

glucose, glucuronate, glycerol, lactose, maltose, mannose, melibiose, melizitose, *N*-acetylglucosamine, raffinose, rhamnose, salicin, sucrose, and trehalose. Amino acids and sugar alcohols are not utilized. The following are fermented with acid but no gas production: cellobiose, fructose, galactose, glucose, lactose, maltose, mannose, melibiose, *N*-acetylglucosamine, rhamnose, sucrose, and trehalose. No growth occurs on acetate, adipate, *D*-arabinose, *L*-arabinose, aspartic acid, butyrate, caproate, ethanol, formate, fucose, glutamic acid, glutamine, histidine, β -hydroxybutyrate, inositol, inulin, lactate, lyxose, malate, mannitol, methanol, 2-oxoglutarate, proline, propionate, pyruvate, ribose, serine, sorbitol, sorbose, succinate, threonine, and valerate. Ammonia, *N*-acetylglucosamine, nitrate, and urea are used as sole nitrogen sources. Gelatin and starch are hydrolyzed, but casein and Tween 80 are not. Phosphatase and urease are produced. However, thiosulfate is not reduced to H_2S , and ammonia is not produced from peptone.

Oligonucleotide cataloging and reverse transcriptase sequencing of 16S rRNA (Albrecht et al., 1987) as well as sequencing of the 5S rRNA (Bomar and Stackebrandt, 1987) indicates that *Verrucomicrobium spinosum* is a representative of a novel phylum. This finding is supported by the sequence analyses of 16S rRNA (Ward-Rainey et al., 1995) and 23S rRNA (Ward et al., 2000) genes. The presence of *dnaK* (HSP70) multigene family was reported (Ward-Rainey et al., 1997).

Enrichment and isolation procedures

Verrucomicrobium species can be enriched in Erlenmeyer flasks with 50 ml of enrichment medium over a sediment of $CaCO_3$.

Enrichment medium: *N*-acetylglucosamine, 1.0 g; Hutner's basal salts (Cohen-Bazire et al., 1957), 20 ml; vitamin solution no. 6 (Staley, 1968), 10 ml. Combine ingredients, dilute to 1 l with distilled water, and adjust pH to 9.7. Autoclave, cool to room temperature, then add $NaH_2PO_4 \cdot H_2O$ aseptically to give a concentration of 0.65 mmol/liter.

Upcoming colonies have to be examined microscopically for prosthecae cells. This is conveniently done by applying the time-saving toothpick-procedure (Hirsch et al., 1977) which even allows the examination of very small colonies: A sterile wooden toothpick is dipped onto a colony and then on the agar surface of a Petri dish containing the appropriate medium, thus inoculating the agar. To allow inoculation of a single Petri dish with bacteria from a large number of colonies, a grid can be drawn with a marker on the backside of the Petri dish with areas of about 5×5 mm. After inoculation of the agar medium, the toothpick generally contains enough bacteria to prepare a smear for microscopic examination. Three specimens can be placed on one slide. Prosthecae bacteria from positive colonies will be isolated by subsequent streaks on agar-solidified medium M13 (for recipe see chapter "Genus *Blastopirellula*").

Maintenance procedures

The strains can be kept on agar slants with M13 at 4–6°C for several months. For long-term preservation, lyophilization or storage in liquid nitrogen is recommended. Deep freezing at –70°C with 50% glycerol is also possible.

Differentiation of the genus *Verrucomicrobium* from other closely related taxa

Verrucomicrobium is easily distinguished from the anaerobic phototrophic genera *Ancalochloris* and *Prosthecochloris* and also from the heterotrophic genus *Stella* that normally has six appendages lying in one plane. The most morphologically similar genera are *Ancalomicrobium* and *Prosthecomicrobium*. The major phenotypic features for differentiation of *Verrucomicrobium* are the fimbriae extruding from the tips of the prosthecae, which are not found in the genera *Ancalomicrobium* and *Prosthecomicrobium*. The respiratory quinones of *Verrucomicrobium spinosum* are menaquinones while in the genera *Ancalomicrobium*, *Prosthecomicrobium*, and *Stella* only ubiquinone Q10 was found (Sittig and Schlesner, 1993). Another important feature is the DNA base ratio which is considerably lower in *Verrucomicrobium* (Table 154).

List of species of the genus *Verrucomicrobium*

1. ***Verrucomicrobium spinosum*** Schlesner 1988, 221^{VP} (Effective publication: Schlesner 1987, 55.)

spi'no.sum. L. neut. adj. *spinosum* thorny, spiny.

Cells measure 0.8–1.0 × 1.0–3.8 μm. Conical prosthecae with a length of about 0.5 μm extend in all directions from the cell surface. Occasionally, one or two longer prosthecae (up to 2 μm) may occur, and often one of them is polarly inserted. These prosthecae are more or less tube-like. Colonies on medium M 13 are light yellow. Growth is optimal between 26 and 33°C, and the maximum growth temperature is 34°C. The organism is stenohaline (i.e., able to tolerate artificial sea water up to a salinity of 17‰ or 1%

(w/v) NaCl). Only a limited number of substrates can be utilized as the sole carbon and energy source, mainly hexoses, di- or trisaccharides, or derivatives of glucose. C₁- or C₂-compounds are not utilized, nor are fatty acids or amino acids. Various sugars are fermented without gas formation. Nitrate is not reduced under anaerobic conditions.

Other characters are listed in Table 154. The chemical composition is identical to that in the genus description.

DNA G+C content (mol%): 59 (T_m).

Type strain: ATCC 43997, DSM 4136, IFAM 1439.

Sequence accession no. (16S rRNA gene): X90515.

Genus II. ***Prostheco bacter*** Staley, de Bont and de Jonge 1980, 595^{VP} (Effective publication: Staley, de Bont and de Jonge 1976, 341.)

BRIAN P. HEDLUND

Pros.the.co.bac'ter. Gr. fem. n. *prosthece* appendage; N.L. masc. n. *bacter* masc. form of Gr. neut. n. *baktron* rod; N.L. masc. n. *Prostheco bacter* appendage (-producing) rod.

Unicellular, Gram-stain-negative, fusiform rod shaped to vibrioid bacteria with a single polar prostheca. Nonmotile. Prosthecae do not branch and do not bear buds. Cells attach to various substrata by a holdfast structure located at the distal tip of the prostheca. **Reproduction by binary fission results in the formation of a partially to fully differentiated prosthecate daughter cell which is a mirror image of the mother cell.** Rosettes are rare in pure culture, and, when formed, are comprised of few cells. **Chemoorganotrophic.** Growth occurs in defined media using ammonium salts as nitrogen source and glucose as carbon source. Obligately **aerobic. Catalase-positive.** Cell wall contains *m*-diaminopimelic acid. Menaquinones are dominant respiratory quinones.

DNA G+C content (mol%): 54–60.

Type species: ***Prostheco bacter fusiformis*** Staley, de Bont and de Jonge 1980, 595^{VP} (Effective publication: Staley, de Bont and de Jonge 1976, 341.).

Further descriptive information

Prostheco bacter was originally described in the literature by Henrici and Johnson (1935) and isolated into pure culture

many years later (de Bont et al., 1970). To date, only four strains have been isolated, and each represents a unique species within the genus. *Prostheco bacter* is obligately aerobic and saccharolytic, exhibiting strong growth on a variety of mono- and disaccharides (de Bont et al., 1970; Hedlund et al., 1997) (Table 155). During growth on the defined medium MMB (Staley et al., 1976) with glucose, menaquinone MK-6(H₂) was the major quinone detected (Hedlund et al., 1996).

Electron microscopy shows that cells of *Prostheco bacter* has a cell structure that is typical of Gram-stain-negative prokaryotes and that *Prostheco bacter* appendages contain cytoplasmic material (Figure 136). The cells are heavily fibrillated except for the distal tips of the prosthecae.

Study of the 95% complete genome of *Prostheco bacter de jonei* revealed genes highly homologous to alpha and beta tubulins in eukaryotes, denoted *btuba* (for bacterial tubulin a) and *btubb* (for bacterial tubulin B) (Jenkins et al., 2002), and homologs of these are found in other *Prostheco bacter* species, including two homologs of each tubulin in *Prostheco bacter debontii* (Pillhofer et al., 2007). These genes are genuine tubulin homologs since they share higher primary sequence homology to eukaryotic tubulins than

FIGURE 136. Phase-contrast micrographs of the four species of *Prosthecobacter*. (a) *Prosthecobacter fusiformis* (FC4); (b) *Prosthecobacter vanneervanii* (FC2); (c) *Prosthecobacter debontii* (FC3); (d) *Prosthecobacter dejongeii* (FC1). Bar = 10 μ m. (Reproduced with permission from Staley et al., 1976. *Antonie van Leeuwenhoek* 42: 333–342.)

they do to the bacterial tubulin homolog *ftsZ*. In addition, the putative amino acid sequences for BtubA and BtubB possess 9 of 9 motifs specific for tubulin and only 2–3 of the 6 FtsZ signature motifs. The presence of tubulin genes in the *Prosthecobacter* genome indicates a shared ancestry between verrucomicrobia and eukaryotes either through lateral gene transfer or larger genome fusion as may occur through an ancient endosymbiosis. The finding that *Prosthecobacter* contains few eukaryotic signature proteins suggests the former (Staley et al., 2005). The observation that microtubule-like structures in the verrucomicrobial ectosymbiont of the ciliate *Euplotidium* cross-react with anti-tubulin antibodies, and the demonstration that polymerization of these microtubule-like structures is sensitive to nocodazole and low temperature (4°C) provides a clue that tubulins may be found elsewhere within the verrucomicrobia (Petroni et al., 2000). However, the putative tubulin homologs in *Euplotidium* symbionts have not been sequenced, and tubulin homologs are absent from the genome of *Verrucomicrobium* (Pilhofer et al., 2007).

Some work has been done to try to elucidate the function of *Prosthecobacter* tubulins. Jenkins et al. (2002) showed that the tubulins are cotranscribed along with a third gene that is highly homologous to a kinesin light chain; kinesin is the motor protein for microtubule motor protein in eukaryotes. However, *Prosthecobacter* tubulins overexpressed in *Escherichia coli* do not cross-react with anti-bovine tubulin antibodies, and no microtubule-like structures are visible in electron micrographs (Jenkins et al., 2002). Comparative modeling suggested *Prosthecobacter* tubulins are more stable as monomers than dimers, suggesting polymerization does not occur (Jenkins et al., 2002); however, they were subsequently shown to form protofilaments in *Escherichia coli* with equimolar amounts of BtubA/B (Schlieper et al., 2005; Sontag et al., 2005). Like eukaryotic microtubules,

BtubA/B protofilaments are GTP and magnesium-dependent; however, unlike eukaryotic tubulins BtubA/B, protofilaments form *in vitro* without chaperones (Schlieper et al., 2005). Crystal structures of both BtubA and a BtubA/B have been solved confirming they are highly similar to eukaryotic tubulins, including surface loops (Schlieper et al., 2005). Unfortunately, the role of BtubA/B in *Prosthecobacter* remains unknown.

Phylogeny and classification. Only four strains of *Prosthecobacter* have been isolated, each representing a distinct species according to DNA–DNA hybridization, 16S rDNA homologies of 94.6–97.9%, and morphological and phenotypic differences (Hedlund et al., 1997). The genus is clearly distinct from the most closely related cultivated organism, *Verrucomicrobium spinosum*, since *Prosthecobacter* forms a monophyletic clade and is morphologically and physiologically distinct.

Enrichment and isolation procedures

Isolation of *Prosthecobacter* into pure culture requires persistence and patience. Only four isolates have been described in the literature. Three of the four *Prosthecobacter* strains were isolated by enriching heterotrophs in freshwater samples using the enrichment procedure of Houwink (1951) by adding peptone to 0.01% to the water sample and incubating 1–3 weeks. When *Prosthecobacter* cells were visible in the enrichment, the sample was streaked onto the same medium solidified with 1.5% agar. Colonies were screened by phase-contrast microscopy.

Maintenance procedures

Lyophilized cultures stored at –20°C have been revived after at least 20 years of storage. In addition, cultures containing MMB supplemented with 15% glycerol (v/v) and stored at –80°C have been successfully revived after several years.

Procedures for testing special characteristics

For determination of carbon substrates, Hedlund et al. (1997) added filter-sterilized substrates to 0.2% (w/v) to the defined medium MMB (Staley et al., 1976) in microtiter wells and measured growth at 3-, 5-, and 10-d incubations at room temperature.

Differentiation of the genus *Prostheco bacter* from other closely related taxa

Prostheco bacter can be distinguished from other heterotrophic prosthecate bacteria based on morphology and motility. *Prosthecomicrobium*, *Ancalomicrobium*, and *Verrucomicrobium* possess many prosthecae per cell, allowing differentiation from singly prosthecate *Prostheco bacter*. *Caulobacter* and *Asticcacaulus* are similar in possessing a single polar or subpolar prostheca yet they divide asymmetrically, yielding a motile non-stalked daughter cell and a sessile stalked mother cell. *Prostheco bacter*, like its relative *Verrucomicrobium*, is heavily fimbriate and *Prostheco bacter* prosthecae are distinct from *Caulobacter* and *Asticcacaulus* because they lack crossbands and possess a bulbous tip (Figure 137). *Prostheco bacter* and its close relative *Verrucomicrobium* can also be distinguished from the prosthecate *Alphaproteobacteria* based on the predominance of menaquinones for respiration, rather than ubiquinones. Due to the morphological diversity within the genus, presumptive *Prostheco bacter* isolates should be identified by 16S rDNA sequencing or other molecular method.

Taxonomic comments

Prostheco bacter was observed in freshwater samples by Henrici and Johnson (1935), who described them as the “fusiform type” of *Caulobacter*, and, prior to phylogenetic studies, the organisms were referred to in the literature as “fusiform caulobacters”. Given their phylogenetic position in the *Verrucomicrobia*, it

FIGURE 137. Shaded electron micrograph of *Prostheco bacter vanneervanii* showing numerous radiating fimbriae and distinctive bulbs at prostheca tips (arrow). Bar = 2 μm . (Reproduced with permission from Hedlund et al., 1996. *Int. J. Syst. Bacteriol.* 46: 960–966.)

is clear *Prostheco bacter* is phylogenetically unrelated to the *Alphaproteobacteria* *Caulobacter* and *Asticcacaulus*.

Family II. **Akkermansiaceae** fam. nov.

BRIAN P. HEDLUND AND MURIEL DERRIEN

Ak.ker.man.si.a.ce'a.e. N.L. fem. n. *Akkermansia* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Akkermansiaceae* the *Akkermansia* family.

Ovoid cells. Nonsporeforming. Nonmotile. **Cells stain Gram-negative and have a Gram-negative cell structure. Strictly anaerobic.** Mesophilic. **Chemoorganotrophic and obligately fermentative.** Able to ferment mucin.

DNA G+C content (mol%): 47.6.

Type genus: *Akkermansia* Derrien, Vaughan, Plugge and de Vos 2004, 1474^{VP}.

Encompasses bacteria isolated from the human intestine and associated 16S rRNA gene sequences recovered from intestines or feces of humans and other mammals within the order *Verrucomicrobiales*. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences. Currently, the family includes only the genus *Akkermansia*.

Genus I. **Akkermansia** Derrien, Vaughan, Plugge and de Vos 2004, 1474^{VP}

MURIEL DERRIEN, CAROLINE M. PLUGGE, WILLEM M. DE VOS AND ERWIN G. ZOETANDAL

Ak.ker.man'si.a. N.L. fem. n. *Akkermansia* named after Antoon Akkermans, Dutch microbiologist recognized for his contribution to microbial ecology.

Oval-shaped cells, occurring singly, in pairs, and rarely in chains, about 0.6 μm \times 0.7 μm . **Gram-stain-negative. Nonmotile. Strictly anaerobic.** Colonies are distinct, whitish in color, and reach maximum size on 0.75% agar plates after 6 d of incubation. Cells grow optimally at 37°C and pH 6.5. Growth is **chemoorganotrophic** and restricted to a small number of sugars. **Acetate, propionate, and ethanol** are the major fermentation products from mucin. Mucolytic in pure culture.

The 16S rRNA gene sequence indicates that the genus *Akkermansia* belongs to the phylum *Verrucomicrobia* and, together with the genera *Verrucomicrobium* and *Prostheobacter*, belongs to the order *Verrucomicrobiales*.

DNA G+C content (mol%): 47.6.

Type species: *Akkermansia muciniphila* Derrien, Vaughan, Plugge and de Vos 2004, 1474^{VP}.

Further descriptive information

For the growth of *Akkermansia*, a mucin based medium is recommended. In active cultures, *Akkermansia* appears oval-shaped (Figure 138), with diameter of 0.7 μm in light microscopy. It is usually detected in pairs or aggregates and rarely in chains. The doubling time of the strain is approximately 1.5 h in mucin medium. *Akkermansia* forms round and white colonies that are about 0.7 mm in diameter after 6 d of anaerobic incubation in 0.75% agar. No motility is observed under the microscope. Filaments have been observed by electronic microscopy and can be attributed to extracellular polymers. During mucin fermentation, acetate, propionate, and ethanol are produced as major end products. No growth is observed on glucose, cellobiose, lactose, galactose, xylose, fucose, rhamnose, maltose, succinate, acetate, fumarate, butyrate, lactate, casitone, Casamino acids, tryptone, peptone, yeast extract, proline, glycine, aspartate, serine, threonine, glutamate, alanine, *N*-acetylglucosamine, or *N*-acetylgalactosamine. The only mucin-free medium known to support growth contains peptone, yeast extract, tryptone, casitone, *N*-acetylglucosamine, *N*-acetylgalactosamine, and glucose.

The type species, *Akkermansia muciniphila*, was originally isolated from a fecal sample from a healthy volunteer.

Consistent with other studies in which *Akkermansia* was found in different 16S rRNA clone libraries, the bacterium accounted

FIGURE 138. Scanning electronic micrograph of the type strain, *Akkermansia muciniphila*, grown in mucin medium. Bar = 1 μm .

for around 1% of the total fecal cells (Derrien et al., submitted). *Akkermansia* was detected in many fecal and intestinal samples (Hayashi et al., 2002; Hold et al., 2002; Salzman et al., 2002; Nelson et al., 2003; Mangin et al., 2004; Eckburg et al., 2005; R.A. Hutson and M.D. Collins, not published). *Akkermansia* has never been detected in environmental samples such as water, soil, or anaerobic digesters from which most of the *Verrucomicrobia* members are isolated.

Enrichment and isolation procedures

Akkermansia can be enriched using a bicarbonate buffered mineral salts medium prepared according to Plugge (2005). This basal medium is supplemented with 0.25% (v/v) commercial hog gastric mucin purified with ethanol precipitation (Hoskins and Boulding, 1981). Growth is optimal at 37°C under strict anaerobic conditions provided by a gas phase of 182 kPa

(1.8 atm.) N₂/CO₂ (80:20, v/v). Growth in liquid cultures is apparent after 1 d. Isolated colonies can be obtained by inoculating a liquid culture into the same medium containing 0.75% agar and incubating the bottles for about 6 d.

Maintenance procedures

Akkermansia can be stored in basal medium containing mucin for several months at 4°C under anaerobic conditions. For long-term storage, cultures can be maintained at -80°C in mucin medium containing 25% glycerol as a cryoprotectant, or they can be freeze-dried.

Procedures for testing special characteristics

Based on the *Akkermansia* 16S rRNA gene sequence, a specific 20-base-long oligonucleotide probe for fluorescent *in situ* hybridization (FISH) has been developed and validated against a panel of intestinal pure cultures (Table 156). The validation was done by increasing the stringency using formamide. The specific conditions of hybridization are 20% formamide at 50°C (Derrien et al., submitted). In addition, two specific primers for PCR were also designed based on the 16S rRNA gene sequence and validated: AM1 and AM2 (Table 156). They allow the amplification of a 300-bp fragment and were validated against intestinal clones and pure cultures. The optimum annealing temperature is 56°C (Derrien et al., submitted).

Differentiation of the genus *Akkermansia* from other genera

Based on the differences in the 16S rRNA sequences, *Akkermansia* can be clearly distinguished from other genera of the order *Verrucomicrobiales* (Figure 139), which includes *Prostheco-*

TABLE 156. Nucleic acid composition of the primers and probe specific to the type species *Akkermansia muciniphila* 16S rRNA gene sequence

Designation	Sequence (5' → 3')	Direction
AM1 (PCR primer)	CAG CAC GTG AAG GTG GGG AC	Forward
AM2 (PCR primer)	CCT TGC GGT TGG CTT CAG AT	Reverse
MUC 1437 (FISH probe)	CCTTGCGGTTGG CTTCAGAT	

(Hedlund et al., 1997; Staley et al., 1976) and *Verrucomicrobium* (Schlesner, 1987). Although *Akkermansia* shares some common features with *Prostheco-* and *Verrucomicrobium* (Gram-stain-negative, growth without vitamins), *Akkermansia* is clearly differentiated from the genera *Prostheco-* and *Verrucomicrobium* with respect to its habitat (human versus environmental habitats), oxygen requirement (strict anaerobic versus strict aerobic), shape (oval-shaped versus rod-shaped), and DNA G+C composition (47.6 mol% vs. 54.6–60.1 mol% for *Prostheco-* and 57.9–59.3 mol% for *Verrucomicrobium*).

Taxonomic comments

The nearly complete 16S rRNA gene sequence (1433 nt) of the type species of *Akkermansia* showed 99% identity to human colonic clones HuCA18 and HuCC13 (Hold et al., 2002) and mouse colonic clone L10-6 (Salzman et al., 2002). The most closely related cultivated species was *Verrucomicrobium spinosum*, which is only distantly related (92% based on 16S rRNA sequence similarity).

List of species of the genus *Akkermansia*

1. *Akkermansia muciniphila* Derrien, Vaughan, Plugge and de Vos 2004, 1474^{VP}

mu.ci.ni'phi.la. N.L. neut. n. *mucinum* mucin; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *muciniphila* mucin-loving.

Cells are oval-shaped, nonmotile, and Gram-stain-negative. The long axis of single cells is 0.6–0.7 µm, depending on the growth substrate used. Cells occur singly, in pairs, in short chains, and in aggregates. Growth occurs at 20–40°C and pH 5.5–8.0, with optimum growth at 37°C and pH 6.5. Strictly anaerobic. Able to grow on gastric mucin, brain heart infusion (Difco), and Columbia broth (Difco), and on *N*-acetylglucosamine, *N*-acetylgalactosamine, and glucose when these three sugars are in the presence of peptone, yeast

extract, casitone, and tryptone. Cellobiose, lactose, galactose, xylose, fucose, rhamnose, maltose, succinate, acetate, fumarate, butyrate, lactate, casitone, Casamino acids, tryptone, peptone, yeast extract, proline, glycine, aspartate, serine, threonine, and glutamate do not support growth. Capable of using mucin as carbon, energy, and nitrogen source. Able to release sulfate in a free form from mucin fermentation. In mucin medium, cells are covered with filaments. Growth occurs without vitamins. Colonies appear white with a diameter of 0.7 mm in soft agar mucin medium.

DNA G+C content (mol%): 47.6 (HPLC).

Type strain: Muc, ATCC BAA-835, CIP 107961.

Sequence accession no. (16S rRNA gene): AY271254.

Family III. **Rubritaleaceae** fam. nov.

BRIAN P. HEDLUND

Ru.bri.ta.le.a.ce'a.e. N.L. fem. n. *Rubritalea* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Rubritaleaceae* the *Rubritalea* family.

Cocoid or rod-shaped bacteria from **marine habitats**. Cells stain **Gram-negative** and have a **Gram-negative cell structure**. **Non-motile**. Obligately aerobic or facultatively anaerobic, reducing nitrate to nitrite. Oxidize a wide variety of organic molecules for growth. **Menaquinones** are the only respiratory quinones detected.

DNA G+C content (mol%): 47.7–52.4.

Type genus: **Rubritalea** Scheuermayer, Gulder, Bringmann and Hentschel 2006, 2123^{VP}.

Further descriptive information

Encompasses bacteria isolated from marine habitats and associated 16S rRNA gene sequences recovered from marine environments within the order *Verrucomicrobiales*. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences. Currently, the family is represented only by the genus *Rubritalea*.

Genus I. **Rubritalea** Scheuermayer, Gulder, Bringmann and Hentschel 2006, 2123^{VP}

BRIAN P. HEDLUND, JAEWOO YOON AND HIROAKI KASAI

Ru.bri.ta'le.a. L. adj. *ruber -bra -brum* red; L. fem. n. *talea* a rod, staff; N.L. fem. n. *Rubritalea* a red-colored rod.

Cocoid or rod-shaped bacteria from **marine habitats**. **Gram-stain-negative**; have a **Gram-negative cell structure**. **Nonmotile**. Obligately aerobic or facultatively anaerobic, reducing nitrate to nitrite. Colonies are **red or pink** in color due to carotenoids. Some produce squalene. Cell walls contain *meso-diaminopimelic acid*. **Chemoorganotrophic**. Oxidize a wide variety of organic molecules for growth. Most abundant cellular fatty acids are **C_{14:0} iso, C_{16:0} iso, and C_{16:1} ω7c** (Table 157). **Menaquinones** are the only respiratory quinones detected, primarily MK-8 and MK-9. Phylogenetically, the genus belongs to the order *Verrucomicrobiales* in the phylum “*Verrucomicrobia*”.

DNA G+C content (mol%): 47.7–52.4.

Type species: **Rubritalea marina** Scheuermayer, Gulder, Bringmann and Hentschel 2006, 2123^{VP}.

Further descriptive information

The genus *Rubritalea* currently includes five species, including the type species *Rubritalea marinus* (Figure 140, Table 158). Each of the species of *Rubritalea* were isolated from marine environments, and all 16S rRNA gene sequences closely related to *Rubritalea* that have been recovered from cultivation independent studies originate from marine samples. Therefore, all data suggest that this genus is an exclusive and widely distributed inhabitant of the marine environment, however, it is noteworthy that not all species of *Rubritalea* require sodium ions. The natural habitat of *Rubritalea* species within the marine habitat is less clear. Four of the five species were isolated from marine invertebrates, including *Rubritalea marina* from homogenized tissue of the Mediterranean sponge *Axinella polyoides* (Scheuermayer et al., 2006), *Rubritalea spongiae* from an unidentified sponge off the coast of Japan (Yoon et al., 2007), and *Rubritalea squalenifaciens* from *Halichondria okadai* off the coast of Japan (Kasai et al., 2007). In addition, *Rubritalea tangerina* was isolated from homogenized visceral tissue from a sea hare (Yoon et al., 2007). In contrast, *Rubritalea sabuli* was isolated from marine sediment off the island of Pohnpei, part of the Federated States of Micronesia (Yoon et al., 2008). Scheuermayer et al. (2006) pointed out that sponges may not

be the natural habitat of *Rubritalea marina*. Although sponges host specific and robust intracellular commensal populations, sponges are filter-feeders and therefore also concentrate planktonic microorganisms for phagocytosis. The authors recovered related 16S rRNA gene sequences from both bulk sea water and sponges from the location from which *Rubritalea marina* was isolated. There was no particular phylogenetic structure suggesting a specific association, suggesting *Rubritalea marina* may derive from the planktonic environment. An alternative hypothesis is that *Rubritalea* is a symbiont of sponges with a planktonic dispersal form, however, the isolation of species from visceral tissue of a sea hare and from marine sediments, and the lack of environment-specific phylogenetic clustering within the genus, suggest this genus may be more widely distributed in marine environments.

Each of the species of *Rubritalea* produces red or pink non-diffusible pigments that are extractable in methanol, ethanol, and/or acetone. The acetone-extracted pigments of *Rubritalea squalenifaciens* have been the best characterized (Kasai et al., 2007; Shindo et al., 2008). Carotenoid pigments were separated from squalene in acetone extracts by an HPLC/PAD (photodiode array detection)/APCI (atmospheric pressure chemical ionization)-MS (mass spectrometry) system (TermoFinnigan). The carotenoid absorption maxima were at 312, 470, 490, and 518 nm (Kasai et al., 2007). Further mass spectrometry work identified three novel acyl glyco-carotenoid acids, diapolycopenedioic acid xylosyl esters, one of which was shown to have potent antioxidant activity in a singlet oxygen suppression model (Shindo et al., 2008). *Rubritalea spongiae* and *Rubritalea tangerina* contain the same pigments as shown by the HPLC/PAD/APCI-MS system (Yoon et al., 2007). *Rubritalea sabuli* contained carotenoid with the same UV-visible absorption spectrum, however, the HPLC retention time was different, and the molecule could not be identified by MS due to the presence of several different molecules in the extract (Yoon et al., 2008). Less work was done on the pigment of *Rubritalea marina*, however, the absorption maximum at 495 nm suggests a similar carotenoid (Scheuermayer et al., 2006).

(Reproduced with permission from Kasai et al., 2007. *Int. J. Syst. Evol. Microbiol.* 57: 1630–1634.)

Electron microscopy has identified possible buds in *Rubritalea marina*. However, no such structures were identified in other species of *Rubritalea*, and it was suggested that the other species divide by binary fission. Electron microscopy has shown that *Rubritalea* has a Gram-negative cell structure (Figure 140).

Enrichment and isolation procedures

Each of the species of *Rubritalea* was isolated by directly plating mechanically homogenized samples (tissues of marine invertebrates or sand) onto an unselective, complex, marine medium solidified with 1.5% agar. At present, no specific enrichment and isolation strategies are known for the genus.

Maintenance procedures

For long-term storage, *Rubritalea* can be maintained at –80°C in 75% artificial sea water medium containing 30% glycerol as a cryoprotectant or they can be freeze-dried.

Differentiation of the genus *Rubritalea* from other genera

Phylogenetically, the most closely related genera are *Prosthecobacter*, *Verrucomicrobium*, and *Akkermansia* within the order

Verrucomicrobiales in the phylum “*Verrucomicrobia*” (Figure 141). The genus *Rubritalea* is differentiated from *Prosthecobacter* and *Verrucomicrobium* by 16S rRNA gene sequence similarity, habitat (marine vs freshwater), and by morphology. Both *Prosthecobacter* and *Verrucomicrobium* are prosthocate and have fimbriae. *Rubritalea* is differentiated from *Akkermansia* by 16S rRNA gene sequence similarity, habitat (marine vs freshwater), and relation to oxygen; *Akkermansia* is a fermentative obligate anaerobe.

List of species of the genus *Rubritalea*

- Rubritalea marina*** Scheuermayer, Gulder, Bringmann and Hentschel 2006, 2123^{VP}
ma.ri'na. L. fem. adj. *marina* of or belonging to the sea, marine.

Description as for the genus. Coccioid or rod-shaped, and red in color. Able to reduce nitrate to nitrite. Able to grow

in medium containing 60–160% ASW, at pH values 6.8–8.2 and at temperatures 8–30°C. Menaquinones MK-8 and MK-9 are present. Catalase-negative. Oxidase-positive. Able to grow with glucose, xylose, melibiose, cellobiose, lactose, pyruvate, or pectin as the sole energy source under aerobic conditions. Positive for alkaline phosphatase, esterase (C4),

FIGURE 141. Neighbor-joining tree showing the phylogenetic relationship of genus *Rubritalea* and related species of the family *Verrucomicrobiaceae* within the phylum "*Verrucomicrobia*" based on 16S rRNA gene sequences. Numbers at nodes are percentage bootstrap values derived from 1000 replications. Sequence determined in this study is shown in bold. The sequence of *Escherichia coli* ATCC 11775^T was used as an outgroup. Bar = 2% estimated difference in nucleotide sequence position. (Modified with permission from Yoon et al., 2008. Int. J. Syst. Evol. Microbiol. 58: 992–997.)

esterase lipase (C8), leucine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β -glucosidase, and β -galactosidase. Positive for oxidation of dextrin, D-cellobiose, D-fructose, D-galactose, α -D-glucose, D-mannose, D-melibiose, acetic acid, and formic acid.

Source: the Mediterranean sponge *Axinella polypoides*.

DNA G+C content (mol%): 50.9 (HPLC).

Type strain: Pol012, CIP 108984, DSM 177716.

Sequence accession no. (16S rRNA gene): DQ302104.

2. ***Rubritalea sabuli*** Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2008, 994^{VP}

sa'bu.li. L. gen. n. *sabuli* of sand.

Description as for the genus. Obligately aerobic, not able to reduce nitrate to nitrite. Coccoid (0.6–0.8 μ m in diameter) or rod-shaped (0.5–1.0 \times 1.2–1.5 μ m). Colonies grown on MA are circular, convex, and pink in color. The temperature range for growth is 10–37°C, with optimal growth at 30–37°C and no growth at 4 or 45°C. The pH range for growth is 6.5–8.5. NaCl is not required for growth, but is tolerated

up to 8% (w/v). The major respiratory menaquinones are MK-8 and MK-9. Catalase-positive. Oxidase-negative. Positive for alkaline phosphatase, leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and *N*-acetyl- β -glucosaminidase tests. Negative for esterase (C4), esterase lipase (C8), lipase (C4), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, α -galactosidase, β -galactosidase, β -glucuronidase, α -glucosidase, β -glucosidase, α -mannosidase and α -fucosidase tests. Dextrin, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, L-arabinose, cellobiose, D-fructose, D-galactose, gentiobiose, D-glucose, D-lactose, lactulose, maltose, D-mannose, melibiose, methyl β -D-glucoside, trehalose, furanose, methyl pyruvate, acetic acid, D-glucuronic acid, succinic acid, alaninamide, L-alanine, L-alanyl glycine, L-glutamic acid, L-serine, and L-threonine are oxidized.

Source: marine sediment on the island of Pohnpei, Micronesia.

DNA G+C content (mol%): 47.7 (HPLC).

Type strain: YM29-052, KCTC 22127, MBIC08323.

Sequence accession no. (16S rRNA gene): AB353310.

3. **Rubritalea spongiae** Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2007, 2339^{VP}

spon.gi'ae. L. gen. n. *spongiae* of a sponge, referring to the isolation source of the microorganism.

Description as for the genus. Cells are coccoid (0.6–1.0 µm in diameter) or rod-shaped (0.5–1.0 × 0.8–1.2 µm). Aerobic; not able to reduce nitrate to nitrite. Colonies on 1/2 strength R2A agar with 75% artificial sea water are circular, convex, and reddish pink in color. The temperature range for growth is 4–37°C, with optimum growth at 30–37°C. No growth occurs at 45°C. The pH range for growth is 6.5–8.0. NaCl is required for growth; tolerates up to 7% (w/v) NaCl. Catalase- and oxidase-positive. Major respiratory menaquinones are MK-8 and MK-9. Positive for alkaline phosphatase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-fucosidase. Negative for esterase (C4), esterase lipase (C8), lipase (C4), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase and α-mannosidase. D-Fructose, L-fucose, D-glucose, D-mannitol, D-melibiose, D-sorbitol, acetic acid, *cis*-aconitic acid, α-ketobutyric acid, α-ketoglutaric acid, inosine, and α-D-glucose 1-phosphate are oxidized, but cyclodextrin, dextrin, glycogen, Tween 40, Tween 80, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, adonitol, L-arabinose, D-arabitol, cellobiose, iso-erythritol, D-galactose, gentiobiose, myo-inositol, α-D-lactose, lactulose, maltose, D-mannose, methyl β-D-glucoside, D-psicose, D-raffinose, L-rhamnose, sucrose, trehalose, furanose, xylitol, pyruvic acid methyl ester, succinic acid monomethyl ester, citric acid, formic acid, D-galactonic acid lactone, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, D-glucuronic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, itaconic acid, α-ketovaleric acid, DL-lactic acid, malonic acid, propionic acid, quinic acid, D-saccharic acid, sebacic acid, succinic acid, bromosuccinic acid, succinamic acid, glucuronamide, alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, L-aspartic acid, L-glutamic acid, glycyl L-aspartic acid, glycyl L-glutamic acid, L-histidine, hydroxy-L-proline, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglytamic acid, D-serine, L-serine, L-threonine, DL-carnitine, γ-aminobutyric acid, urocanic acid, uridine, thymidine, phenylethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, glycerol, DL-α-glycerol phosphate, and D-glucose 6-phosphate are not oxidized.

Source: an unidentified marine sponge.

DNA G+C content (mol%): 48.0 (HPLC).

Type strain: YM21–132, KCTC 12906, MBIC08281.

Sequence accession no. (16S rRNA gene): AB297805.

4. **Rubritalea squalenifaciens** Kasai, Katsuta, Sekiguchi, Matsuda, Adachi, Shindo, Yoon, Yokota and Shizuri 2007, 1633^{VP}

squa.le.ni.fa'ci.ens. N.L. n. *squalenum* squalene; L. part. adj. *faciens* producing, from L. v. *facio* to produce; N.L. part. adj. *squalenifaciens* squalene-producing.

Description as for the genus. Cells are rod-shaped and red-pink in color. Able to reduce nitrate to nitrite. Grows in sea water medium containing 1–4% NaCl, at pH 7.5–8.5, and temperatures of 15–37°C. Menaquinones MK-8, MK-9 and MK-10 are present. The peptidoglycan in the cell wall contains

meso-diaminopimelic acid, glutamic acid, and alanine. Able to grow with N-acetyl-D-glucosamine, D-galactose, D-glucose, lactose, melibiose, sucrose, or xylose as the sole carbon source under aerobic conditions. Positive for catalase, oxidase, alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and N-acetyl-β-glucosaminidase. Produces acid from N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, D-glucose, D-glucuronic acid, D-galactose, D-melibiose, and D-trehalose.

Source: the marine sponge *Halichondria okadai*.

DNA G+C content (mol%): 52.4 (HPLC).

Type strain: HOact23, DSM18772, MBIC08254, NBRC 103619.

Sequence accession no. (16S rRNA gene): AB277853.

5. **Rubritalea tangerina** Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2007, 2340^{VP}

tan.ge'ri.na. N.L. fem. adj. *tangerina* tangerine, referring to the reddish-orange color of colonies.

Description as for the genus. Coccoid (0.5–0.8 µm in diameter) or rod-shaped (0.5–0.8 × 1.0–1.5 µm). Facultatively anaerobic; able to grow on half strength R2A agar with 75% artificial sea water in an AnaeroPack (Mitsubishi Gas Chemical Co., Inc.). Able to reduce nitrate to nitrite. Colonies grown on half-strength R2A agar with 75% artificial sea water are circular, convex, and reddish orange in color. Temperature range for growth is 15–37°C, with optimum growth at 30–37°C. No growth occurs at 4 or 45°C. pH Range for growth is 6.5–8.5. NaCl is not required for growth, but can tolerate up to 9% (w/v) NaCl. Catalase-negative but oxidase-positive. Major respiratory menaquinones are MK-8 and MK-9.

Positive for alkaline phosphatase, leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and N-acetyl-β-glucosaminidase. Negative for α-galactosidase, β-galactosidase, α-glucosidase, valine arylamidase, trypsin, esterase (C4), esterase lipase (C8), lipase (C4), cystine arylamidase, chymotrypsin, β-glucuronidase, β-glucosidase, α-mannosidase, and α-fucosidase. L-Fucose, D-mannose, *cis*-aconitic acid, citric acid, succinic acid, α-D-glucose 1-phosphate and D-glucose 6-phosphate are oxidized, but cyclodextrin, dextrin, glycogen, Tween 40, Tween 80, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, adonitol, L-arabinose, D-arabitol, cellobiose, iso-erythritol, D-fructose, D-galactose, gentiobiose, D-glucose, myo-inositol, α-D-lactose, lactulose, maltose, D-mannitol, D-melibiose, methyl-β-D-glucoside, D-psicose, D-raffinose, L-rhamnose, D-sorbitol, sucrose, trehalose, furanose, xylitol, pyruvic acid methyl ester, succinic acid monomethyl ester, acetic acid, formic acid, D-galactonic acid lactone, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, D-glucuronic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, itaconic acid, α-ketobutyric acid, α-ketoglutaric acid, α-ketovaleric acid, DL-lactic acid, malonic acid, propionic acid, quinic acid, D-saccharic acid, sebacic acid, bromosuccinic acid, succinamic acid, glucuronamide, alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, L-aspartic acid, L-glutamic acid, glycyl L-aspartic acid, glycyl L-glutamic acid, L-histidine, hydroxy-L-proline, L-leucine, L-ornithine,

L-phenylalanine, L-proline, L-pyroglutamic acid, D-serine, L-serine, L-threonine, DL-carnitine, caminobutyric acid, urocanic acid, inosine, uridine, thymidine, phenylethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, glycerol, and DL- α -glycerol phosphate are not oxidized.

Source: the visceral specimen of an unidentified sea hare.
DNA G+C content (mol%): 50.3 (HPLC).
Type strain: YM27-005, KCTC 12907, MBIC08282.
Sequence accession no. (16S rRNA gene): AB297806.

Class II. Opitutae Choo, Lee, Song and Cho 2007, 535^{VP}

JANG-CHEON CHO, PETER H. JANSSEN, KYLE C. COSTA AND BRIAN P. HEDLUND

O.pi.tu'ta.e. N.L. fem. pl. n. *Opitutaes* type order of the class; -ae ending to denote a class; N.L. fem. pl. n. *Opitutae* class of the order *Opitutaes*.

On the basis of 16S rRNA gene sequence analyses, this group comprises one of the primary lineages in the phylum *Verrucomicrobia* and is equivalent to subdivision 4 (Hugenholtz et al., 1998) of the phylum. The majority of its members inhabit soils, marine environments, or invertebrate digestive tracts; however, some have been recovered from freshwater lakes, hypersaline microbial mats, or coastal hot springs. Others are obligate ectosymbionts of marine cilia. The *Opitutae* currently comprise two orders, the type order *Opitutaes*, at present represented by the genera *Opitutus* and *Alterococcus*, and the order *Puniceicoccales*, represented by the genera *Puniceicoccus*, *Cerasicoccus*, *Coraliomargarita*, and *Pelagicoccus*. All members of this group stain Gram-negative. All tested members are resistant to β -lactam antibiotics and apparently lack a peptidoglycan cell wall.

Type order: **Opitutaes** Choo, Lee, Song and Cho 2007, 536^{VP}.

Further descriptive information

To date, there appear to be two well-supported family level groups within the class *Opitutae*, both of which have been formally described, *Puniceicoccaceae* and *Opitutaceae* (Figure 142).

The family *Puniceicoccaceae* is represented by the genera *Puniceicoccus*, *Cerasicoccus*, *Coraliomargarita*, and *Pelagicoccus* all of which were isolated from marine or estuarine habitats. *Puniceicoccus*, *Cerasicoccus*, and *Coraliomargarita* form a phylogenetic cluster along with 16S rRNA gene sequences recovered primarily from marine environments (e.g., Schafer et al., 2000; Sekar et al., 2006). In addition to those formally characterized genera and sequences from uncultivated organisms, closely related but taxonomically uncharacterized isolates also exist. "*Fucophilus fucoidanalyticus*" was isolated from gut contents of the sea cucumber *Stichopus japonicus* based on its ability to degrade fucoidan obtained from macroalgae on which the sea cucumber grazes (Sakai et al., 2003a). Subsequently, enzymes responsible for fucoidan hydrolysis were used to digest fucose and the resulting

oligosaccharide products were identified (Sakai et al., 2003b). Additionally, 16S rRNA gene sequences representing "*Lentimomas marisflavi*" and isolate YN31-114 exist in GenBank. A separate phylogenetic cluster of *Puniceicoccaceae* is comprised entirely of sequences obtained through cultivation-independent studies. This group includes two subclades, one represented by sequences retrieved from marine environments (e.g., Suzuki et al., 2001; DeLong et al., 2006) and the other retrieved from termite gut contents, freshwater lakes, and other continental habitats (Hongoh et al., 2005; Nakajima et al., 2005; Tajima et al., 2000). The genus *Pelagicoccus* is somewhat phylogenetically distinct from other members of the family and may warrant a separate family designation in the future. *Verrucomicrobia* ectosymbionts of the marine ciliate *Euplotidium* also group with the *Puniceicoccaceae* (Petroni et al., 2000). The *Euplotidium* ectosymbionts, termed epixenosomes, divide by binary fission, forming rows of structures on the surface of the ciliate host. As they mature, they form intracellular bundles of tubules that form a basket and an apical zone of condensed DNA similar to chromatin. When the ciliate is disturbed by predators, the epixenosomes are ejected as harpoon-like structures which offer protection from grazing. Several lines of evidence suggest that epixenosome tubules are homologous to eukaryotic microtubules, including tubule diameter, 22 ± 3 nm, and sensitivity to several microtubule inhibitors. The discovery of tubulins in the genus *Prostheco bacter* (Jenkins et al., 2002) raises the possibility that tubulins are widespread in the *Verrucomicrobia* and are evolutionarily ancient in the lineage (Jenkins et al., 2002; Löwe et al., 2004). However, it has been argued that tubulin genes in some *Verrucomicrobia* reflect recent horizontal transfer based on the patchy distribution of tubulin genes in the phylum, the clear relationship between *Verrucomicrobia* tubulins and those in contemporary eukaryotes, and the presence of canonical division and cell-wall gene content in *Verrucomicrobia* (Jenkins et al.,

FIGURE 142. Maximum likelihood phylogeny of *Verrucomicrobia* with heuristic correction showing nearly complete 16S rRNA gene sequences present in version 91 of the SILVA database (Pruesse et al., 2007). All class-level groups were included, but all those except the *Opitutae* were wedged. The phylogeny was produced by using ARB (Ludwig et al., 2004) using *Escherichia coli* 16S rRNA gene nucleotides 110–1274. Alignments were unmasked.

2002; Pilhofer et al., 2007, 2008; Schlieper et al., 2005; Sontag et al., 2005). These epixenosomes have been called "*Candidatus Epixenosoma ejectans*", though no formal proposal for this nomenclature exists.

The family *Opitutaceae* is represented by two phylogenetically, physiologically, and ecologically distinct genera, *Opitutus* and *Alterococcus*. However, *Alterococcus* is quite phylogenetically

distinct from *Opitutus* and 16S rRNA genes obtained in cultivation-independent studies, so it is possible that a separate family may be proposed in the future to accommodate *Alterococcus* as the phylogenetic depth and breadth of the *Opitutae* is elucidated. The phylogenetic breadth of the *Opitutae* is well represented taxonomically when taxonomically uncharacterized isolates from larval termite guts are considered (Stevenson

et al., 2004). These isolates include four strains which, based on their phylogenetic distance from *Opitutus* and *Alterococcus* (<93% 16S rRNA gene identity), likely represent two different genera in the *Opitutaceae*, one represented by strain TAV1 and the other represented by TAV2, 3, and 4. The isolates were obtained by plating homogenized material from freshly collected larval termite guts onto agar plates with dilute yeast extract and peptone as the growth substrate and incubating under hypoxic conditions [2% (v/v) O₂] with 5% (v/v) CO₂.

Catalase was added to the medium to protect cells from oxidative damage. Although they were not characterized in detail, Stevenson suggested that all four strains were facultative or aerotolerant anaerobes and all were small cocci, similar to *Opitutus*. Environmental 16S rRNA gene sequences related to *Opitutus* have been described from a variety of soils, freshwater habitats, activated sludge, and termite gut contents (e.g., Glöckner et al., 2000; Holmes et al., 2000; Shinzato et al., 2005; Morales et al., 2006).

Order I. **Opitutales** Choo, Lee, Song and Cho 2007, 536^{VP}

JANG-CHEON CHO, PETER H. JANSSEN, WUNG YANG SHIEH AND BRIAN P. HEDLUND

O.pi.tu.ta'les. N.L. masc. n. *Opitutus* type genus of the order; *-ales* ending to denote an order; N.L. fem. pl. n. *Opitutales* the order of the genus *Opitutus*.

Encompasses bacteria isolated from soil environments and a coastal marine hot spring within the class *Opitutae*. The order contains the family *Opitutaceae*. Delineation of the order is determined primarily by phylogenetic information from 16S rRNA gene sequences. All known members of the order are cocci that are Gram-stain-negative. All are chemoorganotrophic facultative or obligate anaerobes capable of fermenting carbohydrates.

Type genus: Opitutus Chin, Liesack and Janssen 2001, 1967^{VP}.

References

Family I. **Opitutaceae** Choo, Lee, Song and Cho 2007, 536^{VP}

JANG-CHEON CHO, PETER H. JANSSEN, WUNG YANG SHIEH AND BRIAN P. HEDLUND

O.pi.tu.ta.ce'a.e. N.L. masc. n. *Opitutus* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Opitutaceae* the family of the genus *Opitutus*.

Cocci or coccobacilli that are 0.4–0.9 µm in diameter. Non-sporeforming. **Motile** via a single flagellum. **Gram-stain-negative**. Colonies are nonpigmented. **Facultatively or obligately anaerobic**. Mesophilic or moderately thermophilic. **Chemoorganotrophic**. **Ferment mono- and disaccharides to organic acids** with or without production of H₂ and CO₂. Peptides and amino acids are not fermented.

DNA G+C content (mol%): 65–67.

Type genus: Opitutus Chin, Liesack and Janssen 2001, 1967^{VP}.

Further descriptive information

Encompasses all bacteria within the order *Opitutales*. Currently, the family comprises the genera *Opitutus* and *Alterococcus* together with strains isolated from termite guts that have not been taxonomically characterized. Related 16S rRNA genes representing uncultured bacteria have been retrieved mainly from soil environments, arthropod guts (termites and beetles),

and freshwater. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences.

Key to the genera of the family *Opitutaceae*

1. The DNA G+C content is 65 mol%. Cocci less than 0.7 µm in diameter. Growth occurs at 10–37°C. Strictly anaerobic. Ferments mono-, di-, and polysaccharides. Reduces nitrate to nitrite. Catalase-negative. Isolated from flooded soils.
→ Genus I. *Opitutus*
2. The DNA G+C content is 65.5–67.0 mol%. Cocci more than 0.7 µm in diameter. Growth occurs at 38–58°C. Facultatively anaerobic. Ferments mono- and disaccharides. Grows aerobically on peptides. Catalase-positive. Isolated from coastal hot springs.
→ Genus II. *Alterococcus*

Genus I. **Opitutus** Chin, Liesack and Janssen 2001, 1967^{VP}

PETER H. JANSSEN

O.pi.tu'tus. L. fem. n. *Ops*, *Opis* a Roman Earth and harvest goddess; L. part. adj. *tutus* protected; N.L. masc. n. *Opitutus* the one protected by *Ops*.

Cocci or coccobacilli. Stain **Gram-negative**. **Motile** with flagellum. No endospores. **Anaerobe**; media containing a suitable reductant shorten the lag phase. Chemo-organotrophic metabolism. **Monosaccharides, disaccharides, and polysaccharides are fermented**, but alcohols, amino acids, and organic acids are not. Acetate, propionate, CO₂, and H₂ are the fermentation end products; the ratios of these are dependent on the partial pressure of H₂. **Nitrate is reduced to nitrite**. Sulfate, sulfur, thiosulfate, and fumarate are not used as terminal electron acceptors.

DNA G+C content (mol%): 65.

Type species: Opitutus terrae Chin, Liesack and Janssen 2001, 1968^{VP}.

Further descriptive information

Cell pellets are pink in color, and cells contain cytochrome *b*. Glucose is fermented by a modified Embden-Meyerhof-Parnas pathway, with a pyrophosphate-dependent 6-phosphofruktokinase (Janssen, 1998). The ratio of the major organic end products, acetate and propionate, is dependent on the partial pressure of hydrogen, with a shift to increased propionate production occurring at hydrogen partial pressures of greater than 20 Pa (Chin and Janssen, 2002).

The type strain of *Opitutus terrae* appears to be an obligate anaerobe, but related strains appear to be at least aerotolerant

anaerobes (Janssen et al., 1997; Stevenson et al., 2004). Similarly, while the type strain reduces nitrate, other isolates do not appear able to do so (Chin et al., 1999; Janssen et al., 1997).

Enrichment and isolation procedures

Janssen et al. (1997) enriched three strains closely related to *Opitutus terrae* from small inocula prepared by diluting slurries of anaerobic soils in anaerobic media containing mono- and disaccharides. Later, Chin et al. (1999) used similar methods to isolate the type strain of *Opitutus terrae* and two closely related strains, also from anaerobic soil. The growth substrates in those experiments were polysaccharides. Stevenson et al. (2004) isolated four strains closely related to members of the genus *Opitutus* from the digestive tract of worker larvae of the termite *Reticulitermes flavipes* by inoculating gut homogenates onto agar plates with yeast extract as the growth substrate. These plates were incubated under hypoxic conditions [2% (v/v) O₂] with 5% (v/v) CO₂. These isolates are therefore at least aerotolerant, and Stevenson et al. (2004) suggest that some strains may be facultative anaerobes. At this time, there is no known selective medium for *Opitutus* strains. The strategies used by Stevenson et al. (2004) and Sangwan et al. (2005), monitoring cultures using a PCR-based assay or with group-specific oligonucleotide probes targeting 16S rRNA to detect the presence of members of the phylum *Verrucomicrobia*, are the only approaches published to obtain isolates other than by chance isolation.

Maintenance procedures

Cultures of *Opitutus terrae* and its close relatives can be stored for at least 1 year at 4°C in anaerobic media in sealed bottles or tubes either completely filled or under a nitrogen plus carbon dioxide headspace. Maintenance is by subculture at 3- to 6-month intervals.

Taxonomic comments

The genus is represented by only one isolate assigned to a named species, *Opitutus terrae*. This means that the assignment of characteristics to the generic and specific descriptions is somewhat arbitrary. Other related isolates (Chin et al., 1999; Janssen et al., 1997) have not been assigned to named species, but appear to be related to *Opitutus terrae*, and are members of that species or of other species of the genus *Opitutus*. These unassigned isolates appear to be phenotypically similar, and their 16S rRNA genes share significant 16S rRNA gene sequence identity (95.3–100%) with *Opitutus terrae*. In the absence of more detailed characterization of other isolates, and the delineation of further species, the separation of genus- and species-specific characteristics is somewhat arbitrary. The four isolates obtained from termite gut (Stevenson et al., 2004) are less closely related to *Opitutus terrae* (<93% 16S rRNA gene sequence identity), and their taxonomic status is less certain. All of these isolates are taxonomically distinct from *Alterococcus agarlyticus* and "*Fucophilus fucoidanolyticus*", with which they share <90% 16S rRNA gene sequence identity.

List of species of the genus *Opitutus*

1. ***Opitutus terrae*** Chin, Liesack and Janssen 2001, 1968^{VP} ter'ra.e. L. gen. n. *terrae* of the earth.

Cocci, 0.4–0.6 µm in diameter. Gram-stain-negative. Motile by means of a flagellum. No spores are formed. The colonies in agar deeps are unpigmented and granular in appearance.

Grows with glucose, fructose, galactose, mannose, galacturonic acid, mannitol, arabinose, cellobiose, maltose, sucrose, lactose, melibiose, xylan, pectin, and starch. Xylose, ribose, sorbose, methyl- α -glucopyranoside, cellulose, chitin, arabinogalactan, pyruvate, lactate, fumarate, malate, tartrate, citrate, crotonate, glycerol (\pm acetate), aspartate, alanine, serine, leucine, isoleucine, glutamate, proline, lysine, and H₂ (\pm acetate) do not support growth of the type strain. Propionate and acetate are the major end products of fermentation. Succinate, lactate, formate, ethanol, and H₂ are

also produced. Methanol is also formed from pectin. Nitrate is reduced to nitrite. Sulfur, sulfate, sulfite, thiosulfate, and fumarate are not used as electron acceptors. Esculin is hydrolyzed, but gelatin and urea are not.

Anaerobe. The type strain grows at pH 5.5–9.0, with maximum growth rates at pH 7.5–8.0. Growth of the type strain is possible at temperatures of 10–37°C, but not at 4°C or at 40°C.

The type strain was isolated from artificial rice paddy systems constructed using soil from rice paddies in Vercelli, Italy.

DNA G+C content (mol%): 65 (draft genome sequence).

Type strain: Pb90-1, DSM 11246.

Sequence accession no. (16S rRNA gene): AJ229235.

Genus II. **Alterococcus** Shieh and Jean 1998, 644^{VP}

BRIAN P. HEDLUND AND WUNG YANG SHIEH

Al.te.ro.coc'cus. L. adj. *alter*, *-tera*, *-terum* another, different; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*) a grain or berry; N.L. masc. n. *Alterococcus* another coccus.

Spherical cells with **Gram-negative cell structure**. Gram-stain-negative. **Motile** by means of a single flagellum. **Facultative anaerobes** capable of aerobic growth on peptone and yeast extract. **Ferment monosaccharides or disaccharides for carbon and energy**. Ferment glucose primarily to butyrate, together with propionate or formate. Lactate and acetate also produced. No gas produced. Do not ferment peptides. **Agarolytic**. Oxidase- and catalase-positive. **Moderately thermophilic**, growing at 40–56°C but not 30 or 60°C. **Slightly halophilic**, growing in media containing 1–3%

NaCl but not in those containing 0 or 5% NaCl. **Require sodium**. C_{15:0} anteiso is the most abundant cellular fatty acid. Phylogenetically, the genus belongs to the order *Opitutales* in the phylum *Verrucomicrobia*. Isolated from two hot springs in the intertidal zone of Lutao, Taiwan, based on their ability to hydrolyze agar in an agar-solidified marine medium.

DNA G+C content (mol%): 65.5–67.0.

Type species: ***Alterococcus agarolyticus*** Shieh and Jean 1998, 644^{VP}.

Further descriptive information

The genus *Alterococcus* currently contains only one species and five strains, with the type strain, *Alterococcus agarolyticus* BCRC 17102^T (original designation, CCRC 19135^T), and no closely related isolates or 16S rRNA gene sequences from cultivation-independent studies. The only other named genus in the Opitutales is *Opitutus*. *Opitutus terrae* was one of several strains of ultramicrobacteria belonging to the *Verrucomicrobia* that were isolated from rice paddy soils (Janssen et al., 1997). In addition, capnophilic, facultatively anaerobic isolates from termite guts (Stevenson et al., 2004) are as yet undescribed taxonomically. Related 16S rRNA genes representing a number of uncultivated organisms from soils, freshwater, activated sludge, and arthropod guts share less than 90% 16S rRNA gene sequence percentage identity.

Alterococcus was isolated from two different coastal hot springs on the island of Lutaο, off Taiwan, which were fed seawater heated to 39–51°C. The temperature (48°C) and salinity (2.0–2.5% Na⁺ w/v) optima of *Alterococcus* suggest it is indigenous to that habitat. As such, *Alterococcus* is the only known thermophilic member of the *Verrucomicrobia*, though 16S rRNA gene sequences belonging to the *Verrucomicrobia* have been recovered from ~70°C sediment taken from Obsidian Pool, Yellowstone National Park (Hugenholtz et al., 1998).

Cells stain Gram-negative and have a Gram-negative cell structure (Figures 143 and 144). Cells are spherical, 0.8–0.9 μm

FIGURE 143. (a) Phase-contrast micrograph showing coccoid cells of *Alterococcus agarolyticus* strain ADT3^T. (b) One coccoid cell with a single flagellum (partially covered by the grid) as viewed by transmission electron microscopy. (Reprinted with permission from Shieh and Jean, 1998. *Can. J. Microbiol.* 44: 637–648.)

FIGURE 144. Ultrathin section electron micrograph of *Alterococcus agarolyticus* strain ADT3^T, showing a spherical cell with Gram-negative cell structure. (Reprinted with permission from Shieh and Jean, 1998. *Can. J. Microbiol.* 44: 637–648.)

in diameter and divide by binary fission. Cells are motile via a single flagellum. The preferred medium for aerobic growth is PY broth, which can be solidified with 1.5% (w/v) Bacto agar (Difco) or partially solidified with 0.5% (w/v) Bacto agar. PY broth contains (per l) 4.0 g of Bacto Peptone (Difco), 2.0 g of Bacto yeast extract (Difco), 20 g of NaCl, 0.5 g of MgSO₄·7H₂O, 0.01 g of CaCl₂, and 4.5 g of 3-(*N*-morpholino)-2-hydroxypropanesulfonic acid (MOPSO; Sigma), pH 7.0. The medium can be supplemented with carbohydrates (0.5% w/v) for fermentative growth. The genus *Alterococcus* is capable of fermenting the following substrates at 0.5%: cellobiose, galactose, glucose, lactose, sucrose, trehalose, and xylose. Cells grown in PYG (PY containing 0.5% glucose) or semisolid PY agar produce butyrate together with propionate or formate as the primary fermentation products, with lesser amounts of lactate, and acetate. No gas is formed. When grown for 2 days at 50°C on PY plates containing 1.5% agar (w/v), colonies are white, circular, opaque, and surrounded by shallow depressions in the agar, indicative of agarolytic activity. The temperature range, pH range, and salinity range for growth are 38–58°C (optimum, 48°C), pH 7.0–8.5 (optimum, pH 8.0), and 1.0–3.0% (w/v) of NaCl (optimum, 2.0–2.5%), respectively. Agarase, catalase, and oxidase are positive. Arginine dihydrolase, lysine and ornithine decarboxylases, DNase, lipase (Tween 80), gelatinase, and casein hydrolysis are negative. Amylase is weak.

When grown to early stationary phase in PY broth, the most abundant cellular fatty acid was C_{15:0} anteiso with lesser amounts of C_{16:0}, C_{16:0} iso, C_{17:0}, C_{14:0}, C_{16:0} 2-OH, and C_{18:0}.

Enrichment and isolation procedures

Samples from coastal 39–51°C hot springs are serially diluted and spread directly onto PY agar. Agarolytic colonies appearing after 3–7 d incubation in the dark at 50°C are streaked on the same medium for purity.

Maintenance procedures

Cultures can be maintained for at least 3 months at 45°C. Long-term storage can be achieved by suspending the cells in NaCl/

glycerol solution (2 g of NaCl and 15 g of glycerol in 100 ml of deionized water) and freezing the cell suspension in liquid nitrogen or at -80°C after pre-cooling to -4°C for 1 h.

Differentiation of the genus *Alterococcus* from other related genera

Phylogenetically, the most closely related genus *Opiritatus* is within the order *Opiritales*. *Alterococcus* is differentiated from the genus *Opiritatus* by 16S rDNA sequence dissimilarity (<90% identity), habitat (coastal hot springs vs soils), sodium requirement, maximum growth temperature (58°C vs 37°C), cell size (0.8–0.9 μm vs 0.4–0.6 μm diameter), relationship to oxygen (facultative anaerobe vs anaerobe), carbohydrate

fermentation products (mixed acid vs organic acids with H_2 and CO_2) and DNA G+C composition (65.5–67.0 mol% vs 74 mol%). Since few *Verrucomicrobia* isolates exist, suspected relatives of *Alterococcus* should not be identified without 16S rRNA gene sequencing.

Taxonomic comments

This genus was originally placed in the *Enterobacteriaceae* as a sister taxon to *Escherichia* and *Shigella* (Shieh and Jean, 1998); however, subsequent phylogenetic analyses of the almost complete 16S rRNA gene from the type strain indicated that the genus is a deeply branching member of the order *Opiritales* in the *Verrucomicrobia*.

List of species of the genus *Alterococcus*

1. *Alterococcus agarolyticus* Shieh and Jean 1998, 644^{VP}

a.ga.ro.ly'ti.cus. N.L. n. *agarum* (from Malayan n. *agar*) agar, a complex gelling polysaccharide from marine red algae; N.L. masc. adj. *lyticus* (from Gr. masc. adj. *lutikos*), able to loosen, able to dissolve; N.L. masc. adj. *agarolyticus* agar-dissolving.

Young colonies are white, circular, and opaque and form shallow depressions on PY agar media after 1–2 d of incubation and deep depressions after 1 week. The characteristics are as described for the genus. Cells spherical, normally 0.8–0.9 μm in diameter and occurring mostly singly or in pairs. Despite the presence of a buffer, cultures in PYG broth reduce the pH by 1.5 and 2.1 units under aerobic

and anaerobic conditions, respectively. Cells lyse rapidly after growth. Liquefy agar and ferment glucose, cellobiose, galactose, lactose, sucrose, trehalose, and xylose. Cannot ferment amino acids. Grow only aerobically on peptone and yeast extract. Growth occurs between 38 and 58°C , optimum 48°C ; 1.0–3.5% NaCl, optimum 2.0–2.5%; pH 7.0–8.5. Cells are susceptible to ampicillin, chloramphenicol, erythromycin, penicillin G, and tetracycline.

DNA G+C content (mol%): 65.5–67.0 (HPLC).

Type strain: ADT3, BCRC 17102 (original designation, CCRC 19135), CIP 106113.

Sequence accession no. (16S rRNA gene): AF075271.

Further descriptive information

Encompasses Gram-stain-negative bacteria retrieved mainly from marine and aquatic environments, within the order *Puniceococcales*. Currently, the family comprises the genera *Puniceicoccus*, *Pelagicoccus*, *Coraliomargarita*, *Cerasicoccus*, and "*Fucophilus*", together with several uncultured marine and lacustrine bacteria. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences.

Key to the genera of the family *Puniceicoccaceae*

1. The DNA G+C content is 52.1 mol%. Cells are nonmotile and colonies are pale red. Capable of anaerobic growth.

Catalase- and oxidase-negative. Produces acid from cellobiose, glucose, and lactose. Requires Na⁺ ions. Isolated from marine environments.

→Genus I. *Puniceicoccus*

2. The DNA G+C content is 54 mol%. Cells are nonmotile and colonies are pale pink. Obligately aerobic. Catalase- and oxidase-positive. Produces acid from glucose, lactose, and mannose. Hydrolyzes starch. Does not require Na⁺ ions. Isolated from marine environments.

→Genus II. *Cerasicoccus*

3. The DNA G+C content is 53.9 mol%. Cells are nonmotile and colonies are white. Obligately aerobic. Catalase-negative and oxidase-positive. Produces acid from mannitol and mannose. Requires Na⁺ ions. Isolated from marine environments.

→Genus III. *Coraliomargarita*

4. The DNA G+C content is 51.6–57.2 mol%. Cells of some species are motile and colonies are white. Obligately aerobic or facultatively anaerobic. Oxidase-positive. Some species produce acid from cellobiose, lactose, and melibiose. Requires Na⁺ ions. Isolated from marine environments.

→Genus IV. *Pelagicoccus*

Genus I. **Puniceicoccus** Choo, Lee, Song and Cho 2007, 536^{VP}

JANG-CHEON CHO

Pu.ni.ce.i.coc'cus. L. adj. *puniceus* pinkish red; N.L. masc. n. *coccus* from Gr. masc. n. *kokkos* a berry; N.L. masc. n. *Puniceicoccus* a pinkish-red-colored coccus.

Facultatively anaerobic **nonmotile cocci** (0.6–1.0 μ m in diameter). **Gram-stain-negative.** Chemoheterotrophic. **Produces carotenoid pigments.** Requires NaCl for growth. Oxidase- and catalase-negative. Utilizes a variety of carbon compounds as sole carbon sources. The predominant fatty acids are C_{15:0} anteiso and C_{18:0}. The major quinone is **MK-7**.

DNA G+C content (mol%): 52.1.

Type species: **Puniceicoccus vermicola** Choo, Lee, Song and Cho 2007, 536^{VP}.

Further descriptive information

Colonies on marine agar 2216 grown at 30°C for 5 d are 0.3–0.5 mm in diameter, uniformly circular, smooth, convex, opaque, and pale-reddish colored. Colony size increases up to 3 mm in diameter after 3 weeks of incubation. While the organism is facultatively anaerobic, anaerobic cultures grow much slower than aerobic cultures.

The temperature, pH, and NaCl concentration ranges for growth are 8–37°C (optimum, 25–30°C), pH 5.0–12.0 (optimum, pH 9.0), and 1.0–7.5% (w/v) NaCl (optimum, 3.0–3.5%). The cellular fatty acid constituents are C_{15:0} anteiso (30.9%), C_{18:0} (24.7%), C_{16:0} (7.9%), C_{17:0} (7.0%), C_{14:0} iso (5.3%), C_{14:0}

(4.9%), C_{17:0} anteiso (3.6%), C_{18:0} 3-OH (2.5%), and C_{12:0} 3-OH (2.1%). Tests for nitrate reduction, indole production, glucose fermentation, arginine dihydrolase, urease, esculin hydrolysis, gelatinase, and PNPG (β -galactosidase) are negative.

Enzyme activities (API ZYM test) and carbon source oxidation results (Biolog test) are shown in Choo et al. (2007). The type strain of the genus is resistant to ampicillin, chloramphenicol, gentamicin, kanamycin, penicillin G, rifampin, streptomycin, and vancomycin but susceptible to erythromycin and tetracycline.

Enrichment and isolation procedures

The organism was isolated from the digestive tract of a marine clamworm, *Periserrula leucophryna*, inhabiting a tidal flat of the Yellow Sea. The organism can be isolated by spreading animal-tissue homogenates on marine agar 2216 after incubation for at least 1 week. Currently, there is no special method to enrich *Puniceicoccus* from the mixed marine microbial community.

Maintenance procedures

Frozen stocks as a glycerol suspension (10–30%) stored in liquid nitrogen or at –70°C are routinely used to start a new

culture. Lyophilization of liquid cultures is also recommended for long-term storage. Working stock cultures can be maintained on slants at 4°C for 3 months.

Differentiation of the genus *Puniceicoccus* from other genera

A recent report by Yoon et al. (2007b) provides a table of characteristics that differentiate *Puniceicoccus* from the other related genera *Cerasicoccus*, *Coraliomargarita*, and *Pelagicoccus*.

Taxonomic comments

The genus *Puniceicoccus* is the type genus of the family *Puniceicoccaceae* and the order *Puniceococcales*. Classification of *Puniceicoccus* as a separate genus of the class *Opitutae* is based on 16S rDNA sequence-based phylogeny as well as phenotypic characteristics. According to 16S rDNA sequence analyzes, the most closely related genera to the genus *Puniceicoccus* are *Cerasicoccus*, *Coraliomargarita*, and *Pelagicoccus*. The only species currently included in the genus is *Puniceicoccus vermicola*.

List of species of the genus *Puniceicoccus*

1. *Puniceicoccus vermicola* Choo, Lee, Song and Cho 2007, 536^{VP}

ver.mi'co.la. L. n. *vermis* worm; L. suff. *-cola* from L. n. *incola* inhabitant; N.L. n. *vermicola* inhabitant of worms.

The characteristics of the species are as described for the genus.

DNA G+C content (mol%): 52.1 (HPLC).

Type strain: IMCC 1545, JCM 14086, KCCM 42343, NBRC 101964.

Sequence accession no. (16S rRNA gene): DQ539046.

Genus II. *Cerasicoccus* Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2007a, 2070^{VP}

JAEWOO YOON AND BRIAN P. HEDLUND

Ce.ra.si.coc'cus. L. neut. n. *cerasum* a cherry; Gr. masc. n. *kokkos* berry; N.L. masc. n. *Cerasicoccus* pale-pink-colored coccus, referring to the pale-pink colour of the bacterium.

Cocci, about 0.8 µm × 1.0 µm in diameter. **Gram-stain-negative**. **Nonmotile**. **Obligately aerobic**; nitrate not reduced. Growth is **chemoorganotrophic** and restricted to a small number of sugars and organic acids. Colonies are pale pink due to carotenoids. **Neither muramic acid nor diaminopimelic acid identified in cell-wall extracts**. **Resistant to β-lactam antibiotics**. Predominant cellular fatty acids are C_{14:0} and C_{18:1 ω9c}. The major respiratory quinone is **MK-7**.

DNA G+C content (mol%): 54.0.

Type species: *Cerasicoccus arenae* Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2007a, 2070^{VP}.

Further descriptive information

Only a single strain of *Cerasicoccus* has ever been isolated. Like other members of the order *Puniceococcales*, *Cerasicoccus* was isolated from the marine environment. Sequences closely related to *Cerasicoccus* have not been described in cultivation-independent censuses, so their ecological function and distribution in nature remain unclear.

Cells of *Cerasicoccus* are uniform cocci about 0.8 µm × 1.0 µm in diameter (Figure 145). Amino acid analysis of the cell-wall hydrolysate indicates the absence of muramic acid and diaminopimelic acid in the cell wall, which suggests that the strain does not contain peptidoglycan. Consistent with this, *Cerasicoccus* is highly resistant to β-lactam antibiotics. However, like other members of the order *Puniceococcales*, no detailed studies of the cell structure of *Cerasicoccus* have been conducted, so it is currently unknown whether these cells possess a structure similar to peptidoglycan or whether they have two membranes or one.

Enrichment and isolation procedures

Currently no procedures to enrich *Cerasicoccus* are known. Strain YM26-026^T was isolated from marine sand collected from the shore of the Gulf of Touni, Touni-cho, Kamaishi, Iwate,

Japan. The sample was washed gently with 0.1 N HCl for 5 min, neutralized by addition of 5 ml of sterile seawater, and then homogenized with a glass rod. The homogenate (50 µl) was

FIGURE 145. Transmission electron micrograph of negatively stained cell of *Cerasicoccus arenae* strain YM26-026^T. Bar = 500 nm. (Reproduced with permission from Yoon et al., 2007a. Int. J. Syst. Evol. Microbiol. 57: 2067–2072.)

plated onto medium "P" (Yoon et al., 2007b) and incubated at 25°C for 30 d. A pale-pink pigmented colony was subsequently purified on marine broth 2216 (Difco) containing 1.5% agar.

Maintenance procedures

For long-term storage, *Cerasicoccus* can be maintained at -80°C in 75% artificial seawater medium containing 30% glycerol as a cryoprotectant or they can be freeze-dried.

Procedures for testing special characteristics

API 20E, API 50CH, and API ZYM strips (bioMérieux) were used to determine physiological and biochemical characteristics. API 20E, API 50CH, and API ZYM were read after 72 h incubation at 30°C and 4 h incubation at 37°C, respectively. β -Lactam antibiotic susceptibility was determined on 1/5 marine agar 2216, using 8 mm paper discs (Advantec) at the following antibiotic concentrations: ampicillin (1, 10, 100, 500, or 1000 μ g/ml) and penicillin G (1, 10, 100, 500, or 1000 μ g/ml). Cell walls were prepared by the methods described by Schleifer and Kandler (1972) and amino acids in an acid hydrolysate of the

cell walls were identified by TLC (Harper and Davis, 1979) and by HPLC, as their phenylthiocarbonyl derivatives, with a model LC-10AD HPLC apparatus (Shimadzu) equipped with a Wakopak WS-PTC column (Wako Pure Chemical Industries, 1989) (Yokota et al., 1993).

Differentiation of the genus *Cerasicoccus* from other genera

Cerasicoccus shares many phenotypic characteristics with other members of the order *Puniceicoccales*, which includes *Puniceicoccus* (Choo et al., 2007), *Pelagicoccus* (Yoon et al., 2007b, d), and *Coralimargarita* (Yoon et al., 2007c). All are marine cocci that are Gram-stain-negative. All are extremely resistant to β -lactam antibiotics and lack muramic acid and *meso*-diaminopimelic acid. All have similar DNA G+C content (53.9–57.4 mol%) and possess menaquinones MK-7 as the predominant respiratory quinone. Due to the relatively small number of isolates representing each of these genera, differential phenotypic characteristics are difficult to identify at present, therefore, 16S rRNA gene sequencing and phylogenetic analysis is recommended for differentiation (Figure 146).

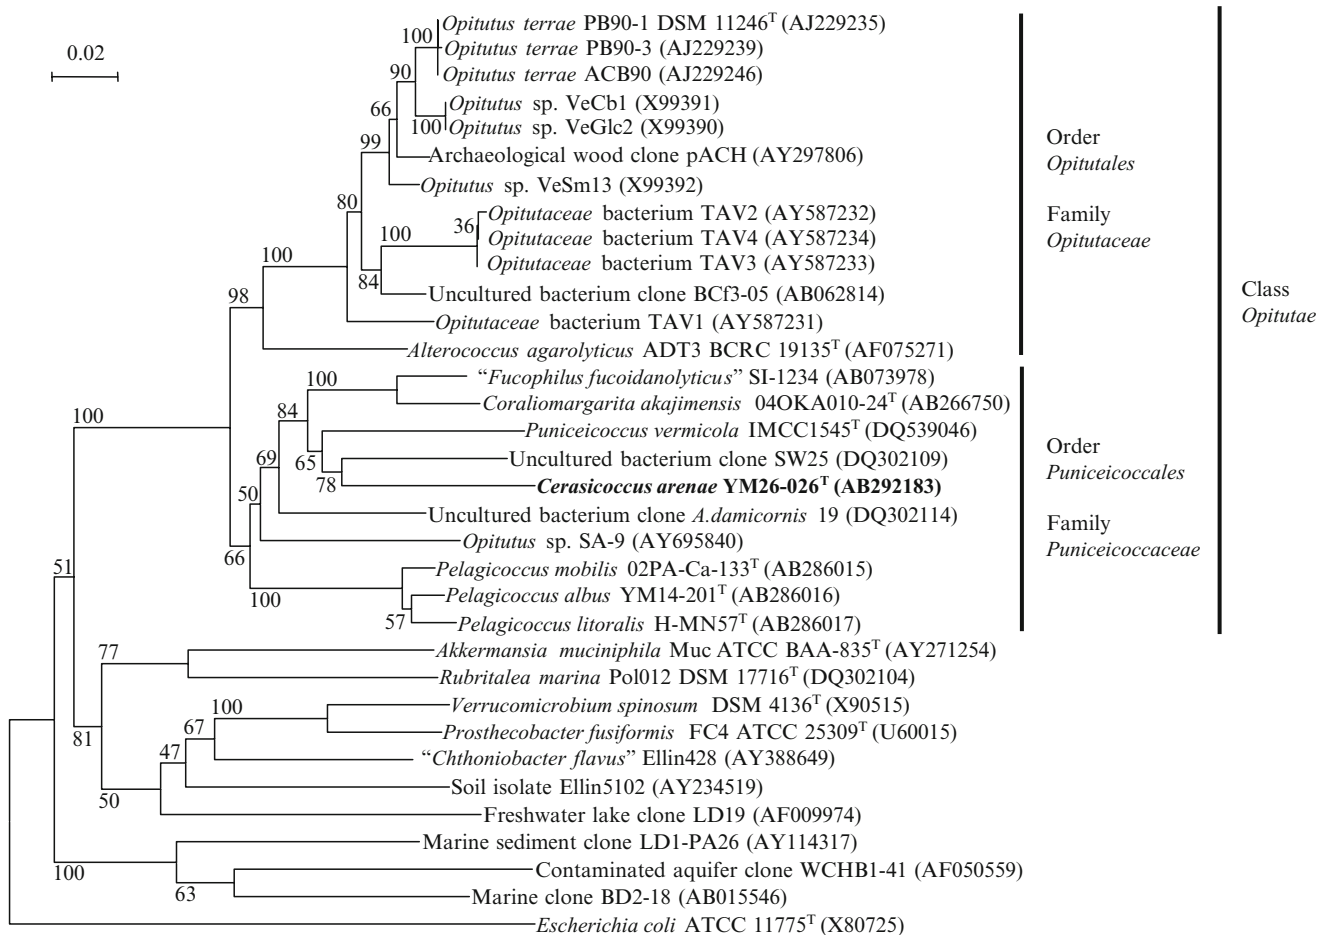

FIGURE 146. Neighbor-joining phylogenetic tree based on 16S rRNA gene sequences analysis showing the position of *Cerasicoccus* in the class *Opitutae*. Numbers at the nodes indicate bootstrap value derived from 1000 replications. Bar = 2% sequence divergence. (Modified with permission from Yoon et al., 2007a. *Int. J. Syst. Evol. Microbiol.* 57: 2067–2072.)

List of species of the genus *Cerasicoccus*

1. ***Cerasicoccus arenae*** Yoon, Matsuo, Matsuda, Adachi, Kasai and Yokota 2007a, 2070^{VP}
a.re'na.e. L. gen. n. *arenae* of sand.

Main characteristics are the same as those given for the genus. Neither cellular gliding movement nor swarming growth is observed. Colonies grown on 1/5 marine agar medium are circular, convex, and pale-pink pigmented. The temperature range for growth is 10–30°C, optimally at 25–30°C. No growth occurs at 4 or 45°C. The pH range for growth is 6–9. Seawater is not required for growth. Growth occurs from 0 to 8% (w/v) NaCl. Growth occurs in the presence of ampicillin (1–1000 µg/ml) and penicillin G (1–1000 µg/ml). Esculin and starch are hydrolyzed but agar, DNA, gelatin, and urea are not hydrolyzed. The reactions for *o*-nitrophenyl-β-D-galactosidase (ONPG) and tryptophan deaminase are positive, but acetoin, citrate utilization, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide, and indole production are negative. Acid is produced from L-arabinose, D-xylose, galactose, glucose, fructose, mannose, methyl-α-D-glucopyranoside, esculine ferric citrate, lactose, gentiobiose, D-turanose, and 5-keto-gluconate, but not from trehalose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol and

erythritol, mannitol, sorbitol, glycerol, D-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl-β-D-xylopyranoside, sorbose, rhamnose, dulcitol, inositol, methyl-α-D-mannopyranoside, N-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, melibiose, sucrose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gluconate, and 2-keto-gluconate. Alkaline phosphatase, naphthol-AS-BI-phosphohydrolase, and β-galactosidase are positive, but acid phosphatase, α-galactosidase, α-glucosidase, leucine arylamidase, valine arylamidase, trypsin, esterase (C4), esterase lipase (C8), lipase (C4), cysteine arylamidase, chymotrypsin, β-glucuronidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are negative. The usual components of bacterial cell walls such as muramic acid and diaminopimelic acid could not be detected. Major fatty acid components (>1.0%) include C_{14:0} iso (3.5%), C_{14:0} (38.7%), C_{14:0} 2-OH (4.4%), C_{16:0} (2.3%), C_{16:0} 3-OH (1.3%), C_{18:1} ω9c (43.3%), C_{18:0} (1.5%), and C_{20:0} (1.5%).

DNA G+C content (mol%): 54.0 (HPLC).

Type strain: YM26-026, KCTC 12870, MBIC 08280, NBRC 103621.

Sequence accession no. (16S rRNA gene): AB292183.

Genus III. ***Coralimargarita*** Yoon, Yasumoto-Hirose, Katsuta, Sekiguchi, Matsuda, Kasai and Yokota 2007c, 962^{VP}

JAEWOO YOON AND BRIAN P. HEDLUND

Co.ra.li.o.mar.ga.ri'ta. Gr. n. *koralion* coral; L. fem. n. *margarita* a pearl; N.L. fem. n. *Coralimargarita* coral pearl, referring to a white-colony-forming coccoid microorganism isolated from seawater in a sample bottle of hard coral.

Cocci, about 0.5 µm × 1.2 µm in diameter. **Gram-stain-negative. Nonmotile. Obligately aerobic**; nitrate not reduced. Growth is **chemoorganotrophic** and restricted to a small number of mono- and disaccharides, sugar alcohols, and organic acids. Colonies are white. **Neither muramic acid nor diaminopimelic acid identified in cell-wall extracts. Resistant to β-lactam antibiotics.** Predominant cellular fatty acids are C_{14:0}, C_{18:1} ω9c, and C_{18:0}. The major respiratory quinone is **MK-7**.

DNA G+C content (mol%): 53.9.

Type species: ***Coralimargarita akajimensis*** Yoon, Yasumoto-Hirose, Katsuta, Sekiguchi, Matsuda, Kasai and Yokota 2007c, 962^{VP}.

Further descriptive information

Only a single strain of *Coralimargarita* has ever been isolated. Like other members of the order *Puniceococcales*, *Coralimargarita* was isolated from the marine environment. Few sequences closely related to *Coralimargarita* have been described in cultivation independent censuses, so their ecological function and distribution in nature remain unclear.

Cells of *Coralimargarita* are uniform nonmotile cocci about 0.5 µm × 1.2 µm in diameter (Figure 147). Amino acid analysis of the cell-wall hydrolysate indicates the absence of muramic acid and diaminopimelic acid in the cell wall, suggesting that the strain does not contain peptidoglycan. Consistent with this, *Coralimargarita* is highly resistant to β-lactam antibiotics. However, like other members of the order *Puniceococcales*, no

detailed studies of the cell structure of *Coralimargarita* have been conducted, so it is currently unknown whether these cells possess a structure similar to peptidoglycan.

Enrichment and isolation procedures

Currently no procedures to enrich *Coralimargarita* are known, however, in the future it may be possible to devise strategies to enrich for or isolate *Coralimargarita* based on its resistance to β-lactam antibiotics. *Coralimargarita* was isolated from a sample containing the hard coral *Galaxea fascicularis* Linnaeus 1767 and surrounding seawater, which was diluted 1/10 in autoclaved, filtered seawater (v/v) and plated onto MA [3.74 g of marine broth 2216 (Difco), 750 ml of filtered seawater, 250 ml of distilled water, and 15 g of agar].

Maintenance procedures

For long-term storage, *Coralimargarita* can be maintained at –80°C in 75% artificial seawater medium containing 30% glycerol as a cryoprotectant, or they can be freeze-dried.

Procedures for testing special characteristics

API 20E and API 50CH strips (bioMérieux) were used to determine physiological and biochemical characteristics. API 20E, API 50CH, and API ZYM were read after 48 h incubation at 30°C and 48 h incubation at 30°C, respectively. β-Lactam antibiotic susceptibility test against novel isolate checked on 1/5 marine agar 2216, using 8 mm paper disc (Advantec)

FIGURE 147. Transmission electron micrograph of negatively stained cell of *Coraliomargarita akajimensis* strain 04OKA010-24^T. Bar = 500 nm. (Reproduced with permission from Yoon et al., 2007c. *Int. J. Syst. Evol. Microbiol.* 57: 959–963.)

at the following antibiotic concentrations: ampicillin (1, 10, 100, 500, or 1000 µg/ml) and penicillin G (1, 10, 100, 500, or 1000 µg/ml) (Yoon et al., 2007b). Cell walls were prepared by the methods described by Schleifer and Kandler (1972) and amino acids in an acid hydrolysate of the cell walls were identified by TLC (Harper and Davis, 1979) and by HPLC, as their phenylthiocarbamoyl derivatives, with a model LC-10AD HPLC apparatus (Shimadzu) equipped with a Wakopak WS-PTC column (Wako Pure Chemical Industries) (Yokota et al., 1993).

Differentiation of the genus *Coraliomargarita* from other genera

Coraliomargarita shares many phenotypic characteristics with other members of the order *Puniceococcales*, which includes *Puniceococcus* (Choo et al., 2007), *Pelagicoccus* (Yoon et al., 2007b, d), and *Cerasicoccus* (Yoon et al., 2007a). All are marine cocci that are Gram-stain-negative. All are extremely resistant to β-lactam antibiotics and lack muramic acid and *meso*-diaminopimelic acid. All have similar DNA G+C content (51.6–57.4 mol%) and possess menaquinones MK-7 as the predominant respiratory quinone. Due to the relatively small number of isolates representing each of these genera, differential phenotypic characteristics are difficult to identify at present, therefore, 16S rRNA gene sequencing and phylogenetic analysis is recommended for differentiation (Figure 148).

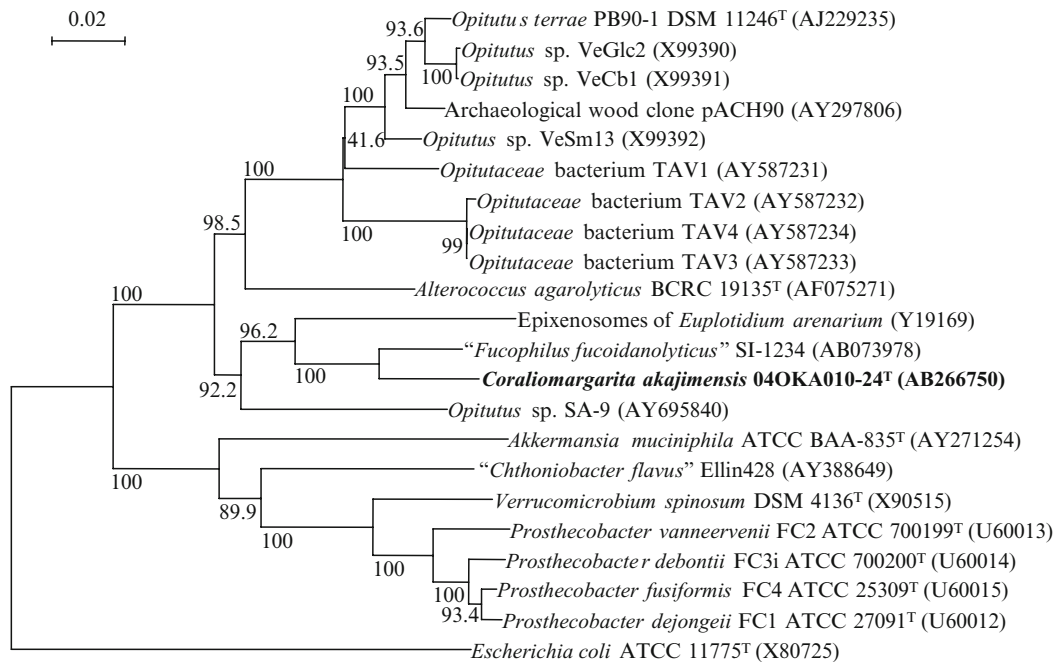

FIGURE 148. Neighbor-joining phylogenetic tree based on 16S rRNA gene sequences analysis showing the position of *Coraliomargarita* in the class *Opitutae*. Numbers at the nodes indicate bootstrap value derived from 1000 replications. Bar = 2% sequence divergence. (Modified with permission from Yoon et al., 2007c. *Int. J. Syst. Evol. Microbiol.* 57: 959–963.)

List of species of the genus *Coraliomargarita*1. *Coraliomargarita akajimensis* Yoon, Yasumoto-Hirose, Katsuta, Sekiguchi, Matsuda, Kasai and Yokota 2007c, 962^{VP}

a.kaji.men'sis. N.L. fem. adj. *akajimensis* pertaining to Akajima, an island in Okinawa, from which the type strain was isolated.

Main characteristics are the same as those given for the genus. In addition, cells are cocci, 0.5–1.2 μm in diameter. Neither cellular gliding movement nor swarming growth is observed. Colonies grown on 1/2 R2A agar medium with 75% Artificial seawater are circular, convex, and white. The optimum temperature range for growth is 20–30°C, and no growth occurs at 4 or 45°C. The pH range for growth is 7.0–9.0. NaCl is required for growth and can be tolerated in an up to 5% solution (w/v). Urea and DNA are hydrolyzed but agar, casein, esculin, and gelatin are not hydrolyzed. Acetoin, *o*-nitrophenyl- β -D-galactosidase (ONPG), and tryptophan deaminase are positive, but the reactions for citrate utilization, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide, and indole production are negative. Acid is produced from glycerol, galactose, fructose, mannose, mannitol, sorbitol, trehalose,

D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, and 5-keto-gluconate but not from erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl- β -D-xylopyranoside, glucose, sorbose, rhamnose, dulcitol, inositol, methyl- α -D-mannopyranoside, methyl- α -D-glucopyranoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, gluconate, and 2-keto-gluconate. The usual components of bacterial cell walls such as muramic acid and diaminopimelic acid could not be detected. Major fatty acid components (>2.0%) include C_{14:0} iso (8.2%), C_{14:0} (24.2%), C_{15:0} anteiso (2.9%), C_{16:0} (3.3%), C_{18:1} ω 9c (23.5%), C_{18:0} (15.5%), C_{19:0} (2.8%), and C_{21:0} (6.9%).

Source: seawater in the sampling bottle of the hard coral, *Galaxea fascicularis* Linnaeus 1767, collected at Majanohama, Akajima in Japan.

DNA G+C content (mol%): 53.9 (HPLC).

Type strain: 04OKA010-24, IAM 15411, JCM 23193, KCTC 12865, MBIC 06463, NBRC 103620.

Sequence accession no. (16S rRNA gene): AB266750.

Genus IV. *Pelagicoccus* Yoon, Yasumoto-Hirose, Matsuo, Nozawa, Matsuda, Kasai and Yokota 2007d, 1381^{VP}

JAEWOO YOON AND BRIAN P. HEDLUND

Pe.la.gi.coc'cus. L. n. *pelagus* the open sea, the ocean; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*), berry; N.L. masc. n. *Pelagicoccus* referring to a coccoid-shaped bacterium from the sea.

Cocci, 0.5 μm \times 1.2 μm in diameter. **Gram-stain-negative**. Some species motile via one or more flagella. Obligately aerobic or facultatively anaerobic; nitrate not reduced. Growth is **chemoorganotrophic** and restricted to a small number of mono- and disaccharides, polysaccharides, and organic acids. Colonies are white or pale yellow. **Neither muramic acid nor diaminopimelic acid identified in cell-wall extracts. Resistant to β -lactam antibiotics**. Predominant cellular fatty acids are C_{16:0}, C_{16:1} ω 7c, and C_{15:0} anteiso. The major respiratory quinone is **MK-7**.

DNA G+C content (mol%): 51.6–57.4.

Type species: *Pelagicoccus mobilis* Yoon, Yasumoto-Hirose, Matsuo, Nozawa, Matsuda, Kasai and Yokota 2007d, 1381^{VP}.

Further descriptive information

All strains of the genus *Pelagicoccus* have been isolated from shallow coastal marine or estuarine waters. All of the isolates were associated with natural or unnatural solid substrates, suggesting that these organisms are normally epibionts rather than free-living in their environment. Since *Pelagicoccus croceus* was isolated from a marine plant and *Pelagicoccus albus* and *Pelagicoccus litoralis* were enriched by using an in situ cultivation approach using plant exudates as enrichment substrates, the outer surface of marine plants is likely a common habitat of members of this genus. However, these organisms have never been enumerated in their environment, and they have not been detected or studied by cultivation-independent approaches so their ecological function and full distribution in nature remain unclear.

Cells of *Pelagicoccus* are uniform cocci, with different size, depending on the species (Figure 149). *Pelagicoccus mobilis* is motile via one or more flagellum; neither flagella nor mobility

has been observed in the other species of *Pelagicoccus*. Some cells of *Pelagicoccus mobilis* have cell appendages. Amino acid analysis of the cell-wall hydrolysate indicates the absence of muramic acid and diaminopimelic acid in the cell wall, which suggests that the isolates do not contain peptidoglycan. Consistent with this, *Pelagicoccus* is highly resistant to β -lactam antibiotics. However, like other members of the order *Puniceococcales*, no detailed studies of the cell structure of *Pelagicoccus* have been conducted, so it is currently unknown whether these cells possess a structure similar to peptidoglycan.

Enrichment and isolation procedures

Currently no procedures to specifically enrich *Pelagicoccus* are known. However, with the knowledge that neither muramic acid nor diaminopimelic acid were identified in cell-wall extracts, and that *Pelagicoccus* isolates are resistant to high concentrations of β -lactam antibiotics, a future strategy that relies on resistance to these antibiotics may be devised.

Pelagicoccus mobilis was isolated by plating a seawater sample from a coral reef near Palau directly onto marine broth 2216 (Difco) supplemented with 1% (w/v) CaCO₃ and 1.5% (w/v) agar (Yoon et al., 2007d). *Pelagicoccus croceus* was isolated from a homogenate of a leaf of the marine plant *Enhalus acoroides* (L.f.) Royale from the Kuirra River mangrove estuary, Iriomotejima, Okinawa, Japan. The leaf was homogenized in sterile distilled water, diluted, and plated directly onto diluted, solidified marine broth 2216 (Difco) supplemented with 10 mg jack bean lectin concanavalin A (Wako)/ml. To prepare this medium, 3.74 g marine broth 2216, 15 g agar, 250 ml artificial seawater (Lyman and Fleming, 1940) and 750 ml distilled water were

FIGURE 149. Transmission electron micrographs of negatively stained cells of *Pelagicoccus mobilis* (a–c), *Pelagicoccus albus* (d), and *Pelagicoccus litoralis* (e). Bar = 500 nm. (Reproduced with permission from Yoon et al., 2007d. *Int. J. Syst. Evol. Microbiol.* 57: 1377–1385.)

mixed and autoclaved, after which a solution of 2.5 ml concanavalin A prepared at a concentration of 4 mg/ml in sterile distilled water was added (Yoon et al., 2007b).

Pelagicoccus albus and *Pelagicoccus litoralis* were enriched *in situ* by using polyurethane foam (PUF) blocks impregnated with agar containing dilute organic compounds (Yasumoto-Hirose et al., 2006). Strains of *Pelagicoccus albus* were enriched by a 3-d incubation of a PUF block off the coast of Palau. The PUF block was impregnated with sterile seawater containing 0.1% (w/v) 7-hydroxyflavone and 1.5% (w/v) agar. Strains of *Pelagicoccus litoralis* were enriched by a 2-week incubation of PUF blocks supplemented with HV agar (Hayakawa and Nonomura, 1987) in 90% seawater containing 0.1% (w/v) collidine or 0.1% (w/v) vanillin. PUF blocks were homogenized with a glass rod in 5 ml of sterile seawater. A 50–100 ml sample of the homogenate was plated onto “P” medium (*Pelagicoccus albus*; Yoon et al., 2007d) or onto HV medium containing 90% seawater with 40 mg/ml of nalidixic acid and 100 mg/ml of cycloheximide (*Pelagicoccus litoralis*; Yoon et al., 2007d).

Maintenance procedures

For long-term storage, *Pelagicoccus* can be maintained at -80°C in 75% artificial seawater medium containing 30% glycerol as a cryoprotectant or they can be freeze-dried.

Procedures for testing special characteristics

API 20E, API 50CH, and API ZYM strips (bioMérieux) were used to determine physiological and biochemical characteristics. API 20E and API 50CH tests were read after 72 h incubation at 30°C and API ZYM tests were read after 4 h incubation at 37°C , respectively. β -Lactam antibiotic susceptibility test against novel isolate checked on marine agar 2216 and half-strength R2A agar, using 8 mm paper disc (Advantec) at the following antibiotic concentrations: ampicillin (1, 10, 100, 500, or 1000 $\mu\text{g}/\text{ml}$) and penicillin G (1, 10, 100, 500, or 1000 $\mu\text{g}/\text{ml}$) (Yoon et al., 2007b). Cell walls were prepared by the methods described by Schleifer and Kandler (1972) and amino acids in an acid hydrolysate of the cell walls were identified by TLC (Harper and Davis, 1979) and by HPLC, as their phenylthiocarbamoyl derivatives, with a model LC-10AD HPLC apparatus (Shimadzu) equipped with a Wakopak WS-PTC column (Wako Pure Chemical Industries, 1989) (Yokota et al., 1993).

Differentiation of the genus *Pelagicoccus* from other genera

Pelagicoccus shares many phenotypic characteristics with other members of the order *Puniceococcales*, which includes *Puniceococcus* (Choo et al., 2007), *Coraliomargarita* (Yoon et al., 2007c), and *Cerasicoccus* (Yoon et al., 2007a). All are

marine cocci that are Gram-stain-negative. All are extremely resistant to β -lactam antibiotics and lack muramic acid and *meso*-diaminopimelic acid. All have similar DNA G+C content (51.6–57.4 mol%) and possess menaquinone MK-7 as the predominant respiratory quinone. Due to the relatively small number of isolates representing each of these genera, differential phenotypic characteristics are difficult to identify at present, therefore, 16S rRNA gene sequencing and

phylogenetic analysis are recommended for differentiation (Figure 150).

Differentiation of the species of the genus *Pelagicoccus*

The species of *Pelagicoccus* can be differentiated by 16S rRNA gene sequencing and phylogenetic analysis (Figure 150). Characteristics that may be useful in the differentiation of the species of the genus *Pelagicoccus* are listed in Table 159.

List of species of the genus *Pelagicoccus*

1. *Pelagicoccus mobilis* Yoon, Yasumoto-Hiorse, Matsuo, Nozawa, Matsuda, Kasai and Yokota 2007d, 1381^{VP}

mo.bi'lis. L. masc. adj. *mobilis* movable, mobile, referring to the ability to move by flagella.

Main characteristics are the same as those given for the genus. In addition, cells are obligately aerobic cocci, 0.5–0.7 μ m in diameter. Motile by means of single or multiple flagella. Appendages are found on some cells. Neither cellular gliding movement nor swarming growth is observed.

Colonies grown on 1/2 R2A agar medium with 75% artificial seawater are circular, convex, and white. The temperature range for growth is 20–37°C, optimally at 28–30°C, but no growth occurs at 4 or 45°C. The pH range for growth is 7.0–9.0. NaCl is required for growth; can tolerate up to 4% (w/v) NaCl. Growth occurs in the presence of ampicillin (1–1000 μ g/ml) and penicillin G (1–1000 μ g/ml). Catalase reaction is negative, whereas oxidase is positive. Esculin and urea are hydrolyzed, but agar, DNA, starch, and gelatin are

FIGURE 150. Maximum-likelihood phylogenetic tree showing the positions of *Pelagicoccus* strains. The numbers at the branch nodes are bootstrap values based on 1000 replications. The sequence of *Escherichia coli* ATCC 11775^T was used as the outgroup. Bar = 0.05 substitutions per site. (Modified with permission from Yoon et al., 2007d. Int. J. Syst. Evol. Microbiol. 57: 1377–1385.)

not hydrolyzed. The reactions for acetoin, *o*-nitrophenyl-β-D-galactosidase (ONPG), tryptophan deaminase, citrate utilization, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide, and indole production are negative. Acid is produced from esculin ferric citrate, salicin, cellobiose, lactose, sucrose, trehalose, starch, glycogen, and gentiobiose, but not from glycerol, galactose, fructose, mannose, mannitol, sorbitol, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, 5-keto-gluconate, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl-β-D-xylopyranoside, glucose, sorbose, rhamnose, dulcitol, inositol, methyl-α-D-mannopyranoside, methyl-α-D-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, maltose, melibiose, inulin, melezitose, raffinose, xylitol, gluconate, and 2-keto-gluconate. Alkaline phosphatase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and N-acetyl-β-glucosaminidase are positive, but esterase (C4), esterase lipase (C8), lipase (C4), leucine arylamidase, valine arylamidase, cysteine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, α-mannosidase, and α-fucosidase are negative. The usual components of bacterial cell walls such as muramic acid and diaminopimelic acid could not be detected. Major fatty acid components (>1.0%) include C_{14:0} (5.8%), C_{15:0} (5.9%), C_{16:0} (23.3%), C_{17:0} (2.1%), C_{16:1 ω7c} (15.1%), C_{14:0 iso} (2.1%), C_{16:0 iso} (2.3%), and C_{15:0 anteiso} (29.8%).

Sequence accession no. (16S rRNA gene): AB286015.

2. ***Pelagicoccus albus*** Yoon, Yasumoto-Hiorse, Matsuo, Nozawa, Matsuda, Kasai and Yokota 2007d, 1381^{VP}
al'bus. L. masc. adj. *albus* white, referring to the dull-white color of colonies.

Main characteristics are the same as those given for the genus. In addition, cells are facultatively anaerobic cocci, 0.8–1.2 µm in diameter. Neither cellular gliding movement nor swarming growth is observed. Colonies grown on 1/2 R2A agar medium with 75% artificial seawater are circular, convex, and white. The temperature range for growth is 15–37°C, optimally at 25–27°C, but no growth occurs at 4 or 45°C. The pH range for growth is 6.5–9.0. NaCl is required for growth; can tolerate up to 7% (w/v) NaCl. Growth occurs in the presence of ampicillin (1–1000 µg/ml) and penicillin G (1–1000 µg/ml). Catalase- and oxidase-positive. DNA and esculin are hydrolyzed but agar, starch, gelatin, and urea are not. The reactions for acetoin, *o*-nitrophenyl-β-D-galactosidase (ONPG), and tryptophan deaminase are positive, but citrate utilization, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide, and indole production are negative. Acid is produced from esculin ferric citrate and 5-keto-gluconate, but not from glycerol, galactose, fructose, mannose, mannitol, sorbitol, trehalose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, L-arabitol, L-arabitol, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl-β-D-xylopyranoside, glucose, sorbose, rhamnose, dulcitol, inositol, methyl-α-D-mannopyranoside, methyl-α-D-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, gluconate, and 2-keto-gluconate. Alkaline

phosphatase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α -galactosidase, β -galactosidase, and α -glucosidase are positive, but leucine arylamidase, valine arylamidase, trypsin, esterase (C4), esterase lipase (C8), lipase (C4), cysteine arylamidase, chymotrypsin, β -glucuronidase, β -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase are negative. The usual components of bacterial cell walls such as muramic acid and diaminopimelic acid could not be detected. Major fatty acid components (>1.0%) include C_{14:0} (4%), C_{15:0} (1.7%), C_{16:0} (23.8%), C_{18:0} (1.2%), C_{16:1} ω 7c (14.5%), C_{16:0} iso (2.3%), C_{15:0} anteiso (37.5%), C_{13:0} 2-OH (5.5%), and C_{16:0} 3-OH (1.4%).

Source: seawater from Palau using an *in situ* cultivation technique.

DNA G+C content (mol%): 57.2 (HPLC).

Type strain: YM14-201, IAM 15421, JCM 23202, KCTC 13124, MBIC 08272.

Sequence accession no. (16S rRNA gene): AB286016.

3. **Pelagicoccus croceus** Yoon, Oku, Matsuo, Matsuda, Kasai and Yokota 2007b, 2877^{VP}

cro.ce'us. L. masc. adj. *croceus* saffron-colored, yellow, golden, referring to the pale yellow color of colonies.

Main characteristics are the same as those given for the genus. In addition, cells are obligately aerobic, nonmotile cocci, 0.5–1.0 μ m in diameter. Neither cellular gliding movement nor swarming growth is observed. Colonies grown on 1/5-strength marine agar 2216 are circular, convex, and pale yellow. The temperature range for growth is 20–30°C, optimally at 25–30°C, but no growth occurs at 4 or 45°C. The pH range for growth is 6.5–9.0. NaCl is required for growth; tolerates up to 5% (w/v). Growth occurs in the presence of ampicillin (1–1000 mg/ml) and penicillin G (1–1000 mg/ml). Catalase- and oxidase-positive. Nitrate is not reduced. Esculin is hydrolyzed but agar, DNA, starch, gelatin, and urea are not. The reaction for ONPG is positive, but acetoin, tryptophan deaminase, citrate utilization, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, hydrogen sulfide, and indole production are negative. Acid is produced from methyl β -D-xylopyranoside, methyl α -D-mannopyranoside, esculin ferric citrate, lactose, melibiose, D-turanose, D-lyxose, D-tagatose, and 5-ketogluconate, but not from sucrose, glycerol, galactose, fructose, mannose, mannitol, sorbitol, trehalose, D-fucose, L-fucose, D-arabitol, L-arabitol, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, glucose, sorbose, rhamnose, dulcitol, inositol, methyl α -D-glucopyranoside, *N*-acetyl-D-glucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, gluconate, or 2-ketogluconate. Alkaline phosphatase, leucine arylamidase, and acid phosphatase are positive, but β -galactosidase, naphthol-AS-BI-phosphohydrolase, α -galactosidase, α -glucosidase, valine arylamidase, trypsin, esterase (C4), esterase lipase (C8), lipase (C4), cysteine arylamidase, chymotrypsin, β -glucuronidase, β -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase are negative. The usual components of bacterial cell walls such as muramic acid and diaminopimelic acid could not be detected. Major

fatty acid components (>1.0 %) include C_{14:0} (1.3%), C_{15:0} (21.2%), C_{16:0} (20.7%), C_{17:0} (6.8%), C_{15:1} ω 6c (2.6%), C_{16:1} ω 7c (12.7%), C_{18:1} ω 9c (1.5%), C_{16:0} iso (1.8%), C_{15:0} anteiso (25.4%), and C_{17:0} anteiso (1.5%).

Class III. *Spartobacteria* class. nov.

PETER H. JANSSEN, KYLE C. COSTA AND BRIAN P. HEDLUND

Spar.to.bac.te'ri.a. Gr. adj *spartos* sown, in relation to the Spartoi, the sown men of the Cadmus myth, who sprung from the soil; L. neut. n. *bacterium* (from Gr. dim. neut. n. *bakterion* a small rod) rod; N.L. neut. pl. n. *Spartobacteria* sown small rods.

On the basis of 16S rRNA gene sequence analyses, this group comprises one of the primary lineages in the phylum *Verrucomicrobia* and is equivalent to subdivision 2 (Hugenholtz et al., 1998) of the phylum. The majority of its members appear to be soil-inhabiting bacteria, while some are endosymbionts of nematodes. A few 16S rRNA gene sequences have been recovered from freshwater habitats. The *Spartobacteria* currently comprise one order, the *Chthoniobacteriales*, and a single family, *Chthoniobacteriaceae*. All members of this group are Gram-stain-negative.

Type order: **Chthoniobacteriales** ord. nov.

Further descriptive information

To date, there appear to be three groups within the class *Spartobacteria*; however, since they are only separated by shallow branch length and only one is represented by pure cultures, they are currently all grouped within the family *Chthoniobacteriaceae* (Figure 151). Each of these groups is found predominantly in soils, where they are the dominant verrucomicrobia in PCR-based censuses of soil bacteria (Axelrood et al., 2002; Borneman and Triplett, 1997; Chow et al., 2002; Dunbar et al., 2002; Furlong et al., 2002; Holmes et al., 2000; Janssen, 2006; Liles et al., 2003; Macrae et al., 2000; Ochsenreiter et al., 2003; Ward-Rainey et al., 1995). *Spartobacteria* comprise up to 21.1% of 16S rRNA gene clones in clone libraries derived from soil DNA and are generally highly represented. Janssen (2006) reported a mean of 6.3% spartobacteria clones in a compilation of 16S rRNA gene clone library data derived from 21 studies of diverse soils using bacterial and universal PCR primers and Sanger DNA sequencing. More recent studies based on 454 pyrosequencing of hundreds of thousands of 16S rRNA gene fragments from geographically disparate soil samples showed somewhat lower

percentages of sequences representing the phylum *Verrucomicrobia* (0.11–5%) (Elshahed et al., 2008; Fulthorpe et al., 2008; Lauber et al., 2009; Roesch et al., 2007). One phylotype, EA25, was shown by quantitative PCR to comprise up to 2×10^8 cells per gram of soil (Lee et al., 1996). *Spartobacteria* appear to be highly active in some soils, comprising from ~1 to ~10% of bacterial 16S rRNA in soils (Buckley and Schmidt, 2001, 2003; Felske and Akkermans, 1998; Felske et al., 1998, 2000).

The family *Chthoniobacteriaceae* is represented by ten isolates of which the species *Chthoniobacter flavus* is the only that has been taxonomically characterized (Sangwan et al., 2005). *Chthoniobacter flavus* is an aerobic saccharolytic heterotroph isolated from Australian soil (Sangwan et al., 2004). Relatives of this group have been detected in phylogenetic censuses of diverse soils including an alpine meadow (Costello and Schmidt, 2006), a broad-leaf evergreen forest (Chan et al., 2006), farm soil (Tringe et al., 2005), and grasslands. A somewhat separate clade is represented by three candidate species that appear to be obligate intracellular symbionts of different species of nematode (Vandekerckhove et al., 2002, 2000). Related 16S rRNA gene sequences have been recovered from geographically and geochemically distinct soils (Chan et al., 2006; Graff and Conrad, 2005; Kim et al., 2007), a contaminated aquifer (Dojka et al., 1998), and a sulfidic cave stream (Macalady et al., 2006). These uncultivated phylotypes are distant from "*Candidatus* Xiphinematobacter", so it is unclear whether they have a symbiotic or free-living lifestyle. A more distantly related phylotype from a humic lake may or may not be related to this group (Newton et al., 2006). The third group in the class is represented only by 16S rRNA gene sequences retrieved from soils and has no cultivated relatives.

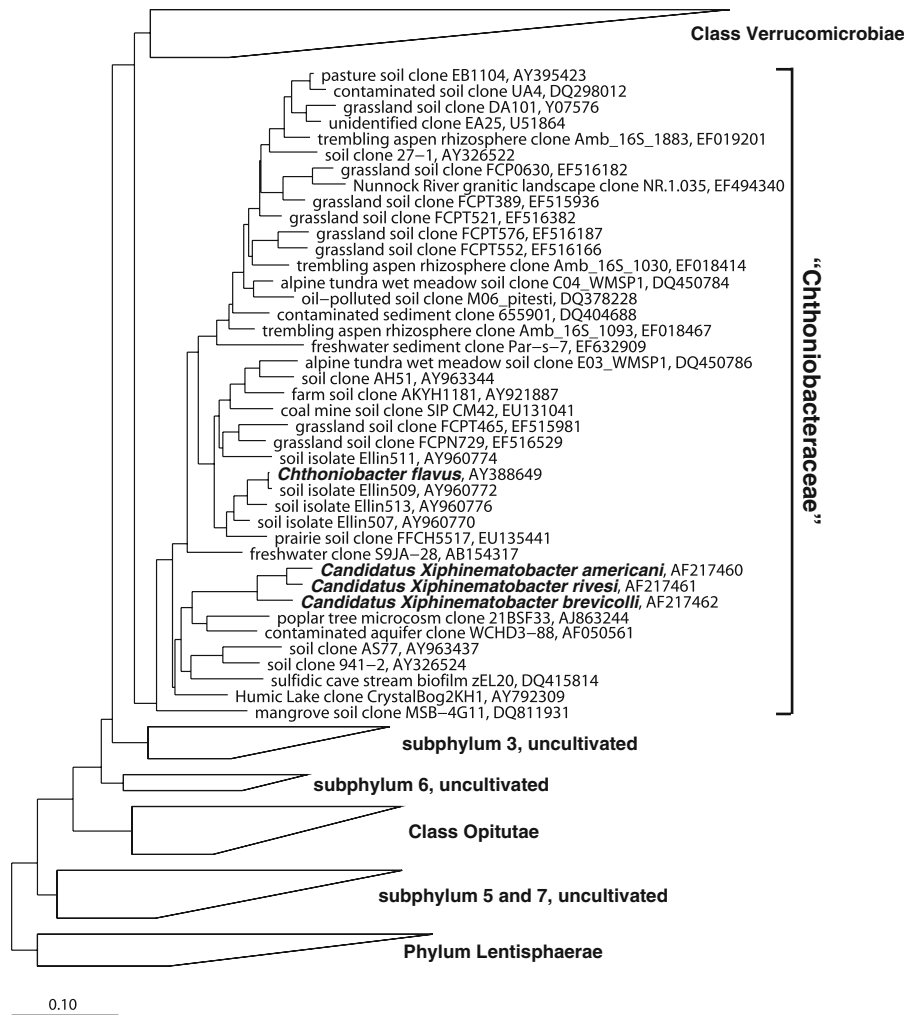

FIGURE 151. Maximum likelihood phylogeny of *Verrucomicrobia* with heuristic correction showing nearly complete 16S rRNA gene sequences present in version 91 of the SILVA database (Pruesse et al., 2007). All class-level groups were included, but all those except the *Spartobacteria* were wedged. The phylogeny was produced by using ARB (Ludwig et al., 2004) using *Escherichia coli* 16S rRNA gene nucleotides 110–1274. Alignments were unmasked.

Order I. Chthoniobacterales ord. nov.

PETER H. JANSSEN AND BRIAN P. HEDLUND

Chtho.ni.o.bac.ter.a'les. N.L. masc. n. *Chthoniobacter* type genus of the order; *-ales* ending to denote an order; N.L. fem. pl. n. *Chthoniobacterales* the *Chthoniobacter* order.

Encompasses bacteria isolated from soil environments and maternally transmitted endosymbionts of nematodes within the class *Spartobacteria* (Sangwan et al., 2004). The order contains the family *Chthoniobacteraceae*. Delineation of the order is determined primarily by phylogenetic information from 16S rRNA gene sequences. All known members of the order are rod-shaped or pleomorphic cells that are Gram-stain-negative and have a Gram-stain-negative cell structure.

Type genus: **Chthoniobacter** gen. nov.

Reference

- Sangwan, P., X. Chen, P. Hugenholtz and P.H. Janssen. 2004. *Chthoniobacter flavus* gen. nov., sp. nov., the first pure-culture representative of subdivision two, *Spartobacteria* classis nov., of the phylum *Verrucomicrobia*. *Appl. Environ. Microbiol.* 70: 5875–5881.

Family I. **Chthoniobacteraceae** fam. nov.

PETER H. JANSSEN AND BRIAN P. HEDLUND

Chtho.ni.o.bac.te.ra.ce'ae. N.L. masc. n. *Chthoniobacter* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Chthoniobacteraceae* the *Chthoniobacter* family.

Rod-shaped or pleomorphic cells that stain **Gram-negative**. Non-motile. Nonsporeforming. Includes free-living micro-organisms in soil and symbionts of nematodes. Free-living organisms are aerobic and saccharolytic and use predominantly mono-, di-, and polysaccharides and their derivatives. Menaquinones are the only respiratory quinones detected, primarily MK-10 and MK-11.

DNA G+C content (mol%): 61.

Type genus: **Chthoniobacter** Sangwan, Chen, Hugenholtz and Janssen 2010^{VP} (Effective publication: Sangwan, Chen, Hugenholtz and Janssen 2004, 5880.)

Further descriptive information

Encompasses bacteria isolated from soil and associated 16S rRNA gene sequences recovered from soils and obligate cytoplasmic symbionts of nematodes within the order *Chthonobacteriales*. Delineation of the family is determined primarily by phylogenetic information from 16S rRNA gene sequences. Currently the family is represented by the genera *Chthoniobacter* and "*Candidatus* Xiphinematobacter".

Genus I. **Chthoniobacter** Sangwan, Chen, Hugenholtz and Janssen 2010^{VP} (Effective publication: Sangwan, Chen, Hugenholtz and Janssen 2004, 5880.)

PETER H. JANSSEN

Chtho.ni.o.bac'ter. Gr. adj. *chthonios* born from the soil, also the name of one of the Spartoi of the Gr. Cadmus myth; N.L. masc. n. *bacter* the equivalent of Gr. neut. n. *baktron* rod or staff; N.L. masc. n. *Chthoniobacter* rod from the soil.

Rods. Gram-stain-negative, with Gram-negative cell-wall structure. Nonmotile. No endospores. **Aerobe**. Chemo-organotrophic metabolism. **Monosaccharides, disaccharides, and polysaccharides support growth. Cells contain menaquinones and yellow pigment.**

DNA G+C content (mol%): 61.

Type species: **Chthoniobacter flavus** Sangwan, Chen, Hugenholtz and Janssen 2010^{VP} (Effective publication: Sangwan, Chen, Hugenholtz and Janssen 2004, 5880.)

Enrichment and isolation procedures

Janssen et al. (2002) isolated the type strain of *Chthoniobacter flavus* from soil using plates of diluted nutrient agar at pH 6.0. Later, Sangwan et al. (2005) screened colonies appearing on a range of media with a group-specific oligonucleotide probe to detect the presence of members of the phylum *Verrucomicrobia*, and obtained another nine isolates closely related to *Chthoniobacter flavus*. These were all isolated from soil. Some of these isolates may belong to *Chthoniobacter flavus*, but others are likely to be members of new species of the genus. At this time, there is no known selective medium for strains of *Chthoniobacter* spp. The strategy used by Sangwan et al. (2005) of screening with group-specific oligonucleotide probes to detect the presence of

members of the phylum *Verrucomicrobia* is the only published approach to obtain isolates other than by chance isolation.

Maintenance procedures

Cultures of *Chthoniobacter flavus* can be stored at -70°C in Difco nutrient broth containing 15% (v/v) glycerol. Cultures on plates can be maintained by 6-monthly subculture, and the plates stored at 4°C in sealed polyethylene bags.

Taxonomic comments

Only one strain, the type strain of *Chthoniobacter flavus*, has been formally assigned to this genus. Of nine strains of verrucomicrobia isolated by Sangwan et al. (2005), six were closely related to *Chthoniobacter flavus*, and shared >96% 16S rRNA gene sequence identity with the type strain. These are probably members of the genus *Chthoniobacter*. The other three other isolates appear to be more distantly related (<93% 16S rRNA gene sequence identity with *Chthoniobacter flavus*), but all nine strains were phenotypically very similar to each other and to *Chthoniobacter flavus*. In the absence of more detailed characterization of other isolates, and the delineation of further species, the separation of genus- and species-specific characteristics is somewhat arbitrary.

List of species of the genus *Chthoniobacter*

1. **Chthoniobacter flavus** Sangwan, Chen, Hugenholtz and Janssen 2004, 5880

fla'vus L. masc. adj. *flavus* yellow.

Cells are oval in shape, singly or in pairs, each 1.4 μm long and 0.9 μm in diameter. Cells are not motile and have no flagella. Cells contain poly- β -hydroxybutyrate and polyphosphate inclusions. Gram-stain negative, and Gram-negative

cell-envelope structure, with peptidoglycan with direct cross-linkages of the A1 γ meso-Dpm type. The major cellular fatty acids are tetradecanoic acid, 12-methyl-tetradecanoic acid, *cis*-9-hexadecenoic acid and/or 2-hydroxy-13-methyl-tetradecanoic acid, and hexadecanoic acid. Yellow pigmentation. Cells contain menaquinones MK-10 and MK-11. Form convex and entire colonies on agar surfaces.

Aerobic growth with sugars, sugar polymers, and pyruvate, but not with other organic acids, amino acids, or alcohols. No growth under anaerobic conditions, or with nitrate as electron acceptor. Catalase- and oxidase-negative. No *nifH* gene.

Grows at pH values of 4–7, and at temperatures between 25 and 34°C, but not at 37°C.

The type strain was isolated from pasture soil in Victoria, Australia.

DNA G+C content (mol%): 53 (draft genome sequence).

Type strain: Ellin428, ATCC BAA-1822.

Sequence accession no. (16S rRNA gene): AY388649.

Genus II. "*Candidatus Xiphinematobacter*" Vandekerckhove, Willems, Gillis and Coomans 2000, 2203

TOM T. M. VANDEKERCKHOVE, JASON B. NAVARRO, AUGUST COOMANS AND BRIAN P. HEDLUND

Xi.phi.ne.ma.to.bac'ter. Gr. neut. n. *Xiphinema*, -atos the genus name of the host organism; N.L. masc. n. *bacter* the equivalent of Gr. neut. n. *baktron* a rod; N.L. masc. n. *Xiphinematobacter* the rod-shaped microbe associated with *Xiphinema*.

Full-grown cells are **rod-shaped with rounded ends, 0.7–1.0 × 2.1–3.2 μm**; however, cells in the J₁ (first juvenile) stage of nematode development have a wrinkled, pleomorphic shape. The longer entities usually consist of a mother cell from which a daughter cell is budding, giving rise to serial pairs typical of this bacterial genus. In thin sections **cells have two or three membranes** consisting of, from inside to outside, a cytoplasmic membrane, an electron-dense outer membrane, and, in many individuals, a vacuolar membrane which is probably derived from the host cell membrane and which often shows discontinuities. **No peptidoglycan layer is evident**; however, a periplasmic hexagonally arrayed monolayer of 10 nm protein units is sometimes present. **Gram-stain-negative, nonmotile, and nonsporulating. DNA is often condensed at cell poles.** Bacteria live as **obligate cytoplasmic symbionts with maternal transmission in nematodes of the *Xiphinema americanum* group (Nematoda, Longidoridae), in which they are presumed to induce thelytokous (mother-to-daughter) parthenogenesis.**

DNA G+C content (mol%): not determined.

Type species: "*Candidatus Xiphinematobacter brevicolli*" Vandekerckhove, Willems, Gillis and Coomans 2000, 2203.

Further descriptive information

Intracellular bacterial symbionts in the female reproductive tissue of the dagger nematode *Xiphinema* (Figure 152) were identified by Vandekerckhove et al. (2000), who recovered 16S rRNA gene sequences representing the phylum *Verrucomicrobia* in three closely related species of nematode. Phylogenetic analysis showed that the symbionts make up a distinct monophyletic lineage within the class *Spartobacteria*. Subsequently the endosymbionts were confirmed as members of the phylum by fluorescent *in situ* hybridization (FISH) using a *Verrucomicrobia*-specific probe (Vandekerckhove et al., 2002) and the symbionts were grouped within the genus "*Candidatus Xiphinematobacter*".

DAPI (4',6-diamidino-2-phenylindole) staining confirms transmission electron microscopic observations that "*Candidatus Xiphinematobacter*" DNA is normally condensed at cell poles (Figure 153), similar to cells of ectosymbionts of the ciliate *Euplotidium* (Petroni et al., 2000). Unravelling of the vertical (maternal) transmission pathway by conventional epifluorescence microscopy upon DAPI staining (Coomans et al., 2000) is corroborated by confocal laser scanning fluorescence

microscopy using the FISH approach (Vandekerckhove et al., 2002).

"*Candidatus Xiphinematobacter*" appears to be the only bacterium living in association with dagger nematodes. Even the guts of *Xiphinema* specimens are devoid of other bacteria since these nematodes feed on root hair cells through a 400–450 nm diameter stylet, which shears incoming cells or blocks their entry. In juveniles, the endosymbionts occur in the gut epithelial cells. However, to be transmitted vertically "*Candidatus Xiphinematobacter*" must access the developing oocytes as host nematodes molt from the final juvenile stage (J₄) to adult. It appears that the primary route for the endosymbionts to travel from the gut epithelium to the oocytes occurs indirectly through yolk transfer (Coomans et al., 2000). Yolk is synthesized by the gut epithelia and secreted into the adjacent ovarian wall (or nurse) cells, in which endosymbionts proliferate. From there endosymbionts appear to be transferred to developing oocytes again with the yolk. "*Candidatus Xiphinematobacter*" undergoes a second proliferation in the egg; bacteria move to surround the nucleus of the intestinal stem cell of the early embryo (Figure 152), poisoning them to grow within the gut epithelia of the developing juvenile.

"*Candidatus Xiphinematobacter*" has been demonstrated in the male gut epithelium of rare males of *Xiphinema*; however they are less numerous and more often coccus-like than in an average female. Endosymbionts are not found in the ripe testes (Figure 152) and vertical transmission through sperm is highly unlikely since sperm contain an extremely reduced cytoplasm. There is no evidence of an extracellular or free-living phase of "*Candidatus Xiphinematobacter*" and horizontal transmission seems extremely unlikely.

"*Candidatus Xiphinematobacter*" has been observed in each of the hundreds of female specimens of the *Xiphinema americanum* group that have been examined, though occasionally individuals with few symbionts are discovered. It has been suggested that "*Candidatus Xiphinematobacter*" symbionts induce thelytokous (mother-to-daughter) parthenogenesis in their nematode hosts since males of these species are rare (Coomans and Willems, 1998). This activity was previously only ascribed to the alphaproteobacterium *Wolbachia*, which is an obligate intracellular symbiont of arthropods and filarial nematodes. Indeed, the only known parthenogenic species of *Xiphinema*, members of the *Xiphinema americanum* group, are

FIGURE 152. Light microscopy of *Xiphinema brevicollum*. Arrowheads point to DNA lumps (often two, sometimes more when budding) at bacterial cell poles. (a) Transmitted light. Adult female with relevant parts of reproductive system. The morphology is described in more detail in Coomans and Claeys (1998). (b) DAPI epifluorescence (Coomans et al., 2000). Intrauterine egg with dividing nucleus and endosymbiont accumulation at the egg pole where the gut stem cell will arise. A few very bright somatic nematode nuclei are also visible at the periphery. (c, d) Confocal fluorescence using FISH with the verrucomicrobial 16S rRNA probe EUB338-III (Vandekerckhove et al., 2002). Adult female (c) with densely packed symbionts in an ovary and underlying gut, and adult male (d) with testis lacking symbionts.

also the only members of the genus known to harbor bacterial endosymbionts. It is unknown whether other sex ratio altering strategies employed by *Wolbachia* are used by "Candidatus Xiphinematobacter", such as induction of feminization, killing of male embryos, or cytoplasmic incompatibility (reviewed by Stouthamer et al., 1999).

Phylogeny and classification

The three candidate species of "Candidatus Xiphinematobacter" are symbionts of different species of host nematode. The symbionts are phylogenetically well defined; they form a monophyletic group and share a mean 93% 16S rRNA gene homology. Related nucleic acid sequences from soil may or may not represent endosymbionts. The congruent branching order of "Candidatus Xiphinematobacter" and host nematodes phylogenies is consistent with the vertical, rather than horizontal, transmission of the symbionts.

Differentiation of the genus "Candidatus Xiphinematobacter" from closely related taxa

"Candidatus Xiphinematobacter" can be presumptively identified by its location within intestinal cells or ovarian cells in juveniles or adults, respectively, of "dagger" nematodes of the *Xiphinema americanum* group (Nematoda, Longidoridae). The genus *Wolbachia* is not found in this group of nematodes.

Furthermore, "Candidatus Xiphinematobacter" displays a possibly unique combination of morphological peculiarities such as the occurrence of numerous serial pairs of cells (e.g., Figures 152 and 153), polar lumps of DNA (e.g., Figures 152 and 153), and an aberrant Gram-stain-negative cell wall where the peptidoglycan layer is replaced by a paracrystalline protein monolayer (Figure 153).

Confirmation of the phylogenetic identification can be obtained by 16S rRNA gene sequencing and phylogenetic staining (e.g., FISH), as done by Vandekerckhove et al. (2000).

List of species of the genus "Candidatus Xiphinematobacter"

1. "**Candidatus Xiphinematobacter brevicolli**" Vandekerckhove, Willems, Gillis and Coomans 2000, 2203
bre.vi.col'li. N.L. gen. n. *brevicolli* of the *brevicollum* species, i.e., lives in the species *Xiphinema brevicollum*.

Characteristics as for the genus, of which it is the type species. Specific host is the nematode *Xiphinema brevicollum*, with which it has established the oldest of the three symbioses. It shares a mean corrected 16S rRNA gene identity with

FIGURE 153. Transmission electron microscopy of “*Candidatus Xiphinematobacter*” endosymbionts of dagger nematodes (Vandekerckhove et al., 2000). (a) Typical appearance of an actively budding cell. (b) Pleomorphic cell variant observed in the J_1 stage of nematode development. (c) Serial pair of bacterial mother and daughter cells just before budding off. Note the polar DNA lumps in both cells and the trilaminar envelope around them (as detailed in part d). (d) High magnification of the trilaminar structure surrounding “*Candidatus Xiphinematobacter*”. Note the absence of a peptidoglycan layer in the periplasm (left, cross section), which is replaced by a paracrystalline monolayer of hexagonally arrayed globular proteins (right, tangential section).

“*Candidatus Xiphinematobacter americani*” sp. nov. and “*Candidatus Xiphinematobacter rivesi*” sp. nov. of about 90%.

DNA G+C content (mol%): not determined.

Type strain: no type strain.

Sequence accession no. (16S rRNA gene): AF217462.

2. “*Candidatus Xiphinematobacter americani*” Vandekerckhove, Willems, Gillis and Coomans 2000, 2203

a.me.ri.ca’ni. N.L. gen. n. *americani* of the *americanum* species, i.e., lives in the species *Xiphinema americanum*.

Characteristics as for the genus. Specific host is the nematode *Xiphinema americanum*. Closest relative is “*Candidatus Xiphinematobacter rivesi*” sp. nov., having a 16S rRNA gene sequence 3.15% distant.

DNA G+C content (mol%): not determined.

Type strain: no type strain.

Sequence accession no. (16S rRNA gene): AF217460.

3. “*Candidatus Xiphinematobacter rivesi*” Vandekerckhove, Willems, Gillis and Coomans 2000, 2203

ri.ve’si. N.L. gen. n. *rivesi* of Rives, i.e., lives in the species *Xiphinema rivesi*.

Characteristics as for the genus. Specific host is the nematode *Xiphinema rivesi*. Closest relative is “*Candidatus Xiphinematobacter americani*” sp. nov., having a 16S rRNA gene sequence 3.15% distant.

DNA G+C content (mol%): not determined.

Type strain: no type strain.

Sequence accession no. (16S rRNA gene): AF217461.

Order I. *Chlamydiales* Storz and Page 1971, 334^{AL}

CHO-CHOU KUO, MATTHIAS HORN AND RICHARD S. STEPHENS

Chla.my.di.a'les. N.L. fem. n. *Chlamydia* type genus of the order; -ales ending to denote an order; N.L. fem. pl. n. *Chlamydiales* the *Chlamydia* order.

Gram-stain-negative, obligately intracellular microorganisms that live in eukaryotes and may cause various diseases. The mode of multiplication within the cytoplasmic vacuoles is characterized by reorganization of small, rigid-walled, metabolically inactive infectious forms (elementary bodies) into large, flexible-walled, metabolically active forms (reticulate bodies) that are generally noninfectious and divide by binary fission. The developmental cycle is complete when the reticulate bodies reorganize into

elementary bodies that survive extracellularly to infect new host cells upon their release from the host cell. The order *Chlamydiales* traditionally contained a single family, the *Chlamydiaceae*, which included the type genus *Chlamydia*. The recent discovery of novel chlamydia-related bacteria expanded the order *Chlamydiales* to include four additional families, having 80–90% 16S rRNA sequence similarity with the *Chlamydiaceae* (Everett et al., 1999; Rurangirwa et al., 1999; Thomas et al., 2006). Three

further families are added based on the descriptions of “*Candidatus* Piscichlamydia salmonis”, “*Candidatus* Clavichlamydia salmonicola”, and “*Candidatus* Rhabdochlamydia porcellionis” (Draghi et al., 2004; Karlsen et al., 2008; Kostanjsek et al., 2004), respectively, all of which show 80–90% 16S rRNA sequence similarity with all other *Chlamydiales* families (Figure 154).

For classification of members of the *Chlamydiales* at the family and genus level, the 16S rRNA sequence similarity thresholds proposed by Everett et al. (1999) are currently accepted. Members of a *Chlamydiales* family generally share $\geq 90\%$ 16S rRNA similarity with each other; members of a *Chlamydiales* genus generally share $\geq 95\%$ 16S rRNA sequence similarity, with the *Chlamydiaceae* being a notable exception. As the proposed separation of the *Chlamydiaceae* into the two genera *Chlamydia* and *Chlamydothila* (Everett et al., 1999) is not being used consistently in the scientific literature, it was recently proposed to

abandon the genus name *Chlamydothila* and to transfer all *Chlamydothila* species to the genus *Chlamydia* (Bavoil and Wyrick, 2006; Kalayoglu and Byrne, 2006).

The order *Chlamydiales* consists currently of eight families, *Chlamydiaceae*, *Clavichlamydiaceae*, *Criblamydiaceae*, *Parachlamydiaceae*, *Piscichlamydiaceae*, *Rhabdochlamydiaceae*, *Simkaniaceae*, and *Waddliaceae*.

Further evidence for an even greater diversity of yet uncultured chlamydiae exists (Corsaro et al., 2003; Horn and Wagner, 2001; Ossewaarde and Meijer, 1999). Several oligonucleotide probes for the identification of chlamydiae by fluorescence *in situ* hybridization at different taxonomic levels are available (Loy et al., 2007; Poppert et al., 2002).

DNA G+C content (mol%): 35.8–41.3.

Family I. Chlamydiaceae Rake 1957, 957^{AL}

CHO-CHOU KUO AND RICHARD S. STEPHENS

Chla.my.di.a.ce’ae. N.L. n. *Chlamydia* type genus of the family; -aceae ending to denote family; N.L. fem. pl. n. *Chlamydiaceae* the *Chlamydia* family.

In the previous edition of *Bergey’s Manual of Systematic Bacteriology* (Volume 1, 1984), the family contained a single genus, *Chlamydia*. The family was emended to include an additional genus, *Chlamydothila*, by Everett et al. in 1999. The new genus and five species, *Chlamydothila abortus*, *Chlamydothila caviae*, *Chlamydothila felis*, *Chlamydothila pecorum*, *Chlamydothila pneumoniae*, and *Chlamydothila psittaci* were validly published, but

the scientific community has not uniformly adopted the use of the new genus name. For this reason, in this edition of the *Manual* the original genus *Chlamydia* is retained as the sole genus in the family and the five additional species are classified in the genus.

DNA G+C content (mol%): 39–45.

Type genus: **Chlamydia** Jones, Rake and Stearns 1945, 55^{AL}.

Chla.my'di.a. Gr. fem. n. *chlamys*, *chlamydis* a cloak; N.L. fem. n. *Chlamydia* a cloak.

Coccioid, nonmotile, obligate intracellular organisms, 0.2–1.5 µm in diameter that parasitize and multiply in the cytoplasm of eukaryotic cells within membrane bound vacuoles, termed inclusions, by a unique developmental cycle. The cycle is characterized by physical changes in the outer membrane and nucleoid structure of metabolically inert elementary bodies that change into larger metabolically active reticulate bodies that divide by binary fission. The cycle is complete when reticulate bodies reorganize into intermediate bodies then to elementary bodies that exit the host cells and start a new generation of the developmental cycle. In a young inclusion, only reticulate bodies are present. However in a mature inclusion, all three forms (reticulate, intermediate, and elementary bodies) are present because the developmental cycle is not synchronized. The intracellular survival of the organism is facilitated by its ability to prevent fusion of lysosomes to chlamydia-containing inclusions by an unknown mechanism.

Elementary bodies are 0.2–0.4 µm in diameter, have electron-dense DNA condensed with protein and a few ribosomes, and are surrounded by rigid trilaminar cell walls resistant to sonic lysis. Elementary bodies are infectious. **Reticulate bodies** are 0.6–1.5 µm in diameter, have less dense, fibrillar nuclear material, more ribosomes, and plastic trilaminar walls that are sensitive to sonic lysis. Reticulate bodies are not infectious. **Intermediate bodies** are organisms in transition from reticulate bodies to elementary bodies that are variable in size and have a small plaque of dense nuclear material in the center of the cytoplasm with a characteristic target-like appearance. Infectivity of intermediate bodies has not been demonstrated.

Cell walls of elementary and reticulate bodies exhibit regular hexagonal arrays of subunits on the inner surface and single patches of hexagonal ordered hemispheric projections on their outer surface that resemble in structure the type III secretion apparatus of Gram-stain-negative bacteria. Cell walls contain lipopolysaccharide and are analogous in structure and composition to walls of Gram-stain-negative bacteria, however, muramic acid is either absent or is present only in trace amounts in elementary bodies.

Chlamydiae cause a variety of diseases in humans, other mammals, and birds. Cultivation of *Chlamydia* in cell-free medium has not been achieved. They may be propagated in laboratory animals, the yolk sac of chicken embryos, or in cell culture. Chlamydiae require their hosts for low-molecular-weight synthetic intermediates that they use to synthesize DNA, RNA, proteins, and lipids. The genome size is among the smallest of prokaryotes, 1–1.3 × 10⁶ bp.

DNA G+C content (mol%): 39–45.

Type species: *Chlamydia trachomatis* (Busacca 1935) Rake 1957, 958^{AL} [*Rickettsia trachomae* (sic) Busacca 1935, 567].

Further descriptive information

The voluminous *Chlamydia* literature has been exhaustively reviewed elsewhere. Some classical reviews, but mainly recent publications in books and articles of broad coverage on the subject treated in this chapter have been cited individually under

TABLE 160. Characteristics of chlamydial elementary and reticulate bodies^{a,b}

Characteristic	Elementary	Reticulate
<i>General:</i>		
Diameter (µm)	0.2–0.4	0.5–1.5
Density (g/cm ³)	1.21	1.18
Time of appearance in developmental cycle	Late	Early
Infectivity for new host cells	+	–
Intravenous lethality for mice	+	–
Immediate cytotoxicity in cell culture	+	–

^bAdapted and modified from Table 9.13 in the chapter on the Genus *Chlamydia* in *Bergey's Manual of Systematic Bacteriology*, 1984, Vol. 1, p. 730.

^cThese experiments were conducted with mixtures of the two chlamydial cell types, so it is not certain whether only one or both types were responsible for the observed metabolic activity.

Further Reading. Articles on the specific subjects discussed in this chapter are cited in the Bibliography Section in this book.

Cell morphology and developmental cycle. The structural forms of chlamydiae as well as their composition and biology are highly dependent on the developmental cycle. Therefore, the description of these characteristics can only be described in the context of the developmental cycle. The properties of the two principal cell forms are summarized in Table 160 and Figure 155. The developmental cycle may be divided into three phases: (1) attachment and entry of elementary bodies into host cells and their reorganization into reticulate bodies,

FIGURE 155. Elementary body form of chlamydiae is round, except for *Chlamydia pneumoniae* which is pear-shaped. (a) *Chlamydia trachomatis* serovar B, strain TW-5, (b). *Chlamydia pneumoniae* strain TW-183. The reticulate body is round for all species. Bars = 0.1 μm . (Reproduced with permission from Grayston et al., 1989. Int. J. Syst. Bacteriol. 39: 88–90.)

(2) multiplication of reticulate bodies, and (3) conversion of a large fraction of the reticulate body population into a new generation of elementary bodies that are released from the host cells. The cycle is not synchronized, and each of the first two phases overlaps into the next succeeding one (Figure 156).

The initial stage of interaction between chlamydiae and host cells involves the electrostatic interaction of elementary bodies with host cells, which requires divalent cations (Kuo and Grayston, 1976). This interaction is enhanced by polycations and inhibited by polyanions (Kuo et al., 1973). The binding is further secured by other ligands, such as the hsp70 molecular chaperone (Raulston et al., 1993), the OmcB protein (Stephens et al., 2001; Ting et al., 1995), and the major outer-membrane protein (Su et al., 1990). Ligands, such as the high mannose oligosaccharide, may be involved (Kuo et al., 1996). These interactions lead to the entry of elementary bodies into host cells by microfilament independent and perhaps receptor-mediated endocytosis (Wyrick et al., 1989), although the mechanism remains uncharacterized. Candidate receptors, mannose receptor (Kuo et al., 2002), mannose 6-phosphate/insulin-like growth factor-2 receptor (Puolakkainen et al., 2005), and estrogen receptor (Davis et al., 2002), have been suggested, however, use of these receptors may vary in different cell types and species. Uptake of chlamydia appears to be an actin-mediated process that may be directed by *Chlamydia*-specific proteins (Clifton et al., 2005).

Ingestion of chlamydial elementary bodies requires expenditure of energy by the host but not by the parasite. Elementary bodies contain intrinsic ATPase activity. Disulfide bonds of the major outer-membrane protein of chlamydiae are reduced perhaps by the reducing agents of the host cell, such as glutathione,

FIGURE 156. Transmission electron micrograph of thin sections of mouse fibroblasts (L cells) infected with *Chlamydia psittaci* strain menin-gopneumonitis. Bars = 1.0 μm . (a) At 2.5 h after infection. The arrow points to an elementary body that has just begun to differentiate into a reticulate body. (b) at 12 h after infection. The arrow points to a dividing reticulate body. (c) at 20 h after infection. The chlamydial population is almost entirely composed of dividing reticulate bodies. (d) at 30 h after infection. Some reticulate bodies are still dividing, but others have begun to reorganize into elementary bodies. EB, elementary body; RB, reticulate body; IB, intermediate body – a chlamydial cell intermediate in appearance between an elementary body and a reticulate body. (Reproduced with permission from Tribby et al., 1973. J. Infect. Dis. 127: 155–163.)

to render the outer membrane permeable to host ATP which is then hydrolyzed by ATPase to generate energy for chlamydial metabolism immediately after entry into the host cells (Peeling et al., 1989). Ingested elementary bodies enter host cells inside phagosomes, which are cytoplasmic vacuoles surrounded by membranes derived from the plasma membranes of the host cell. Following ingestion of the phagocytized microorganisms and throughout the developmental cycle, some unidentified chlamydial activity(ies) prevents the fusion of lysosomes with phagosomes and destruction of the phagocytized organism. This fundamental property is seen only with live, but not with dead, elementary bodies. The *Chlamydia*-bearing phagosomes are transported rapidly (within minutes) to a perinuclear region within the host cell (Majeed and Kihlstrom, 1991). In a monkey model of subcutaneous autotransplantation of salpingeal

fimbrial tissues, this process happens within 10 min (Patton et al., 1998). Within the inclusion vacuole, the elementary body transforms quickly into the initial reticulate body which then grows and divides. The reticulate body is devoid of infectivity; its initially dense nucleoid is dispersed into more evenly distributed fibrillar DNA, ribosomes increase in number, and the cell wall becomes thinner, more flexible, and more fragile. Completion of the reorganization is signaled by division of the reticulate body, which is first seen 8–10 h after infection (Chi et al., 1987).

Multiplication of chlamydiae is by binary fission of reticulate bodies without apparent septation. Budding of daughter cells that are much smaller in size, contain no nucleoids, and are not infectious has been observed. Nuclear segregation is accomplished by separation of two low electron-dense zones filled with fine fibrillar material and indentation of walls at the plane of separation. From approximately 10–16 h after infection, a large fraction of the reticulate bodies is at some stage of division. The proportion of dividing forms decreases thereafter, but division occurs throughout the developmental cycle. Generally, within 24 h after infection, the inclusion contains only reticulate bodies (Figure 156), and the doubling time during exponential-phase growth is 2–3 h. Multiplication of reticulate bodies takes place within an expanding membrane-bound vacuole, or inclusion, that is an extension in time and space of the phagocytic vacuole in which the parent elementary body was brought into the host cell. Chlamydiae acquire endogenously synthesized macromolecules produced by the Golgi apparatus, including sphingolipids (Scidmore et al., 1996). Thus, the biogenesis of the inclusion membrane, including the acquisition of lipids, occurs by the intersection of the lipid distribution pathway. In addition, proteins produced by the reticulate body remodel the inclusion membrane (Rockey and Rosquist, 1994). By 12–15 h after infection, chlamydial inclusions are large enough to be seen by ordinary light microscopy of stained cells or by phase-contrast microscopy of live cells. Near the end of the developmental cycle, an inclusion may contain hundreds of chlamydial cells and fill nearly the entire cytoplasm of the host cell.

At 20–25 h after infection, host cell-associated infectivity begins to appear, and elementary bodies are seen again in electron micrographs (Figure 156). The beginning of the maturation process is signaled by the up-regulation of nuclear-binding protein genes that produce eukaryotic-like histone proteins that condense nuclear material into an electron-dense mass located at the center of the cytoplasm. These condense within reticulate bodies to form intermediate bodies (Hackstadt et al., 1991; Wagar and Stephens, 1988). Mature elementary bodies do not divide. Reticulate bodies continue to divide and reorganize into elementary bodies until the host cell can no longer support the multiplication of chlamydiae. Therefore, there is no clear-cut termination to the developmental cycle, although the end is usually considered to come 48–72 h after infection, at which time the maximum yields of infectious elementary bodies are obtained depending on the chlamydial strain. At this stage, all three developmental forms (reticulate, intermediate, and elementary bodies) coexist in an inclusion (Figure 156). The mechanism by which chlamydiae are released from host cells is poorly understood. Under cinematographic observation, the reticulate bodies are stationary and localized at the periphery of the inclusion, while the elementary bodies are in Brownian

movement (Neeper et al., 1990). At the point of contact with the inclusion membrane the outer envelope of the reticulate body is rearranged into a rigid, well-developed trilaminar structure (Figure 157) (Peterson and de la Maza, 1988; Yang et al., 1994). Prior to the release of the inclusion contents, inclusions appear to rotate within the cell, extend and retract large blunt protrusions at the plasma membrane of the host cell which last 1–2 h, and eventually rupture to release the contents of the inclusion (Neeper et al., 1990). Two independent modes of cellular exit that occur with approximately equal frequency *in vitro* have been characterized. One is extrusion of the inclusion from the infected cell (Hybiske and Stephens, 2007; Neeper et al., 1990), and the second mechanism is lysis of the intracellular inclusion followed by lysis of the cell (Hybiske and Stephens, 2007). Terminal release of lysosomal enzymes may speed dissolution of moribund cells. The yield of infectious chlamydiae per host cell varies from 10 to nearly 1000 depending on many factors such as the chlamydial strain, the host cell, the culture conditions, and the method by which infectivity is measured.

Cell walls and fine structure. The chlamydial cell exhibits a double-layer outer membrane (cell wall), a cytoplasmic membrane that is separated from the outer membrane by a narrow periplasmic space (Figure 155), hexagonally arrayed subunits lining the inner surface, and spatially related patches of hexagonal projections on its outer surface (Figure 158) (Matsumoto, 1981, 1982). The hexagonally arranged projections are likely type III secretion system-like structures (Bavoil and Hsia, 1998; Hsia et al., 1997). It appears that these structures are also found in the reticulate body (Matsumoto, 1981). The morphology of chlamydial organisms is typically round except for the human biovar of *Chlamydia pneumoniae* which is pleiomorphic but typically pear-shaped and exhibits a large periplasmic space (Figure 155). *Chlamydia pneumoniae* with round morphology have been isolated, though these isolates also have a wider periplasmic space than the typical round elementary bodies

FIGURE 157. (Miyashita et al., 1997). One half of the protein content of the outer membrane is in the form of one protein with a molecular weight of approximately 40,000 (Caldwell et al., 1981) and having species and type-specific immunoreactivity (Kuo and Chi, 1987).

Nutrition and growth. Chlamydiae competitively acquire biosynthetic intermediates from the metabolic pools of their hosts, a process augmented by treatment of the host cell with cycloheximide or emetine (Alexander, 1968; Plaunt and Hatch, 1988; Reed et al., 1981). Chlamydiae have free access to some constituents of these pools but not to exogenous substrates for ATP synthesis. Therefore, it is essential that chlamydiae transport and use exogenous ATP for their own biosynthetic needs. Nutritional requirements of chlamydiae cannot be strictly defined because cell-free growth has not been achieved. Therefore, determinations of the nutritional requirements of chlamydiae have been performed in embryonated eggs or in cultured cells. The observed requirements for amino acids determined in cell culture (Allan and Pearce, 1983a, b; Kuo and Grayston, 1990a) indicate that the number of required amino acids varies among the species, the biovars within the species, and the cell types (HeLa or McCoy) used for determination (Table 161).

Metabolism. Investigations of the metabolism of host-free chlamydiae must be interpreted with two cautions in mind: (1) that the metabolic activities detected using host-free preparations are not due to contamination with host enzymes; and (2) that the correct cell type, i.e., the reticulate body or elementary body, is examined. Metabolic activity is traditionally analyzed at 20 h post-infection when the metabolic activity of chlamydiae is at its peak and the organisms are all in the reticulate body form, or at 48 h post-infection when there are mixed populations of developmental forms and the majority are elementary bodies. It has long been apparent that the reticulate body is the metabolically active cell type, while the elementary body is metabolically inactive. In recent years, the cloning of mutant cells deficient in specific enzymes of energy and nucleotide

metabolic pathways has provided additional means for analyzing chlamydial metabolism (Ilfiee-Lee and McClarty, 1999; Tjaden et al., 1999).

When separated from host cells, chlamydiae have few metabolic activities. They do not catabolize glucose, but they produce carbon dioxide from glucose 6-phosphate, glutamate, pyruvate, and aspartate in the presence of ATP, NADP, and other cofactors (Ilfiee-Lee and McClarty, 1999). However, chlamydiae do not metabolize glutamate beyond succinate, and glutamate does not serve as an energy source.

Cytochromes, flavins, and reactions that result in a net gain of ATP have not been demonstrated. Because chlamydiae have appeared in the past to be unable to synthesize their own high energy compounds, they have been described as “energy parasites” (Hatch et al., 1982). Genomic analysis has, however, revealed that *Chlamydia* species encode enzymes of energy producing pathways and substrate-level phosphorylation, indicating that the energy burden of the chlamydiae is at least partially fulfilled by the *Chlamydia* themselves (Ilfiee-Lee and McClarty, 1999).

Chlamydiae synthesize protein, lipid, and glycogen. Glycogen is produced and deposited within cytoplasmic inclusions of *Chlamydia trachomatis*, *Chlamydia muridarum*, and *Chlamydia suis*, but not in amounts detectable by iodine staining in inclusions of other chlamydial species (Gordon and Quan, 1965). Folic acid and its derivatives are synthesized by most strains of *Chlamydia trachomatis*, *Chlamydia muridarum*, and *Chlamydia suis* but not by other chlamydial species (Lin and Moulder, 1966). Chlamydiae also synthesize lipids such as phosphatidyl glycerol and branched-chain fatty acids that are characteristic of prokaryotes and are not found in their host cells (Reed et al., 1981).

Chlamydiae are auxotrophic for ATP, GTP, and UTP. CTP is obtained from the host cell or synthesized from UTP (Tipples and McClarty, 1993). Chlamydiae contain two structural genes encoding nucleotide transport proteins (Npt), Npt1_{ct} and Npt2_{ct}, respectively, for the uptake of ribonucleoside triphosphate and transport of energy. Npt1_{ct} mediates uptake of ATP by chlamydiae and Npt2_{ct} mediates the exchange of ADP for ATP after ATP is catabolized to ADP by chlamydiae (Tjaden et al., 1999). Paradoxically, chlamydiae have the functional capacity to produce their own ATP and reducing power because they contain the required functional enzymes. These enzymes are pyruvate kinase, phosphoglycerate kinase, and glyceraldehyde-3-phosphate dehydrogenase of glycolysis and glucose-6-phosphate dehydrogenase of the pentose phosphate pathway. The existence of these enzymes has been demonstrated by complementation in *Escherichia coli* mutants deficient in these specific genes (Ilfiee-Lee and McClarty, 1999).

Genetics. The DNA G+C content ranges from 39 to 45 mol% (T_m) (Table 162). The percentage DNA homology between the species and between the biovars within the species is presented in Table 162 (Cox et al., 1988; Fukushi and Hirai, 1992; Gerloff et al., 1970; Kingsbury and Weiss, 1968). Genome sequences for ten strains representing five chlamydial species have been reported with many more in progress. *Chlamydia* species have small genomes relative to most free-living organisms. The genome size varies from 1.03×10^6 bp for *Chlamydia trachomatis* to 1.23×10^6 bp for *Chlamydia pneumoniae* (Table 163). One of the remarkable outcomes from comparing genomes is how similar they are despite being separated

by a 100 million years of evolution. Gene content identity of any chlamydial genome to that for the prototypical *Chlamydia trachomatis* (D/UW-3/Cx) is greater than 90%. Given the similarity of the intracellular environment (niche) and the small genome size for all *Chlamydia* species, it could be expected that they would share a largely identical complement of genes. However, even more remarkable is the high level of conservation of the order of their genes, called genome synteny. Gene order is one of the least-conserved characteristics of bacteria as synteny is the first genomic property to be lost during evolution. This has not been the case for the *Chlamydiaceae*. For example, alignment of the genomes of *Chlamydia trachomatis* and *Chlamydia muridarum* results in precise conservation of gene order throughout the entire genome despite the fact that they are separated from a common ancestor over 50 million years ago as evidenced by sharing only 56% nucleotide identity between the genomes. Measurement of synteny between all available genomes reveals analogous outcomes (Table 163). The conclusion is that species

of *Chlamydia* have been separated for a long geological time as reflected, for example, in 16S rRNA phylogenetic analyses; nevertheless, they have changed very incrementally in the framework of biological evolution.

Mutants. Targeted mutant strains have not been generated due to the lack of a genetic tool for *Chlamydiaceae*. A nitrosoguanidine-generated, temperature-sensitive attenuated mutant of *Chlamydia abortus* has been isolated and is used as a live vaccine against abortion of ewes in Europe (Rodolakis, 1983).

Plasmids. Most *Chlamydia* species have a conserved 7500 bp plasmid (Joseph et al., 1986; Palmer and Falkow, 1986) that is not required for growth *in vitro* (Peterson et al., 1990). The plasmid has been detected in nearly all isolates of *Chlamydia trachomatis*, *Chlamydia psittaci* and in one strain of *Chlamydia pneumoniae* (Thomas et al., 1997). There are four plasmid copies per elementary body chromosome for *Chlamydia trachomatis* (Pickett et al., 2005). Clinical isolates representing the

lymphogranuloma venereum (LGV) biovar and the genital biovar that lack the common plasmid have been characterized (Peterson et al., 1990; Stothard et al., 1998). This suggests that the plasmid is not essential for growth and persistence *in vivo* (i.e., pathogenesis). Plasmids from each species encode eight analogous proteins whose functions in the biology of *Chlamydia* are unknown, further mystifying the role of plasmid in chlamydial biology.

Phages. Several phages that infect *Chlamydia* species termed chlamydiaphages have been isolated and characterized. The first chlamydiaphage, named Chp1, was isolated from a *Chlamydia psittaci* outbreak in a duck farm in England in 1982 (Richmond et al., 1982; Storey et al., 1989a; Storey et al., 1989b). Chp1 forms large characteristic paracrystalline virion arrays that allow its identification by transmission electron microscopy. Several other chlamydiaphages were subsequently isolated from *Chlamydia caviae* (PhiCPG1) (Hsia et al., 2000), *Chlamydia pneumoniae* (PhiAR39) (Read et al., 2000), *Chlamydia abortus* (Chp2) (Liu et al., 2000), and *Chlamydia pecorum* (Chp3) (Garner et al., 2004). However, phages have not been isolated from *Chlamydia trachomatis* or *Chlamydia muridarum*. All chlamydiaphages isolated to date are members of the microviridae and are genetically and structurally related to phages of *Spiroplasma melliferum* and *Bdellovibrio bacteriovorus* and more distantly to the coliphage phiX174. The phage host range is specified by a peptidic loop of the major capsid protein, VP1 (Read et al., 2000), and sequence variation within the loop is consistent with the observed overlapping host ranges of the phages. For instance, PhiCPG1 and PhiAR39, which have identical VP1 sequences, are both able to infect *Chlamydia caviae* and *Chlamydia pneumoniae*. However, Chp2, whose VP1 sequence differs, may also infect *Chlamydia caviae* and other *Chlamydia* species (Everson et al., 2002), suggesting that distinct receptors to multiple phages exist at the surface of chlamydiae. Receptors for these phages have not been identified. The phage infectious cycle was characterized by transmission electron microscopy for phage PhiCPG1 infection of *Chlamydia caviae* (Hsia et al., 2000). Briefly, PhiCP1 virions gain access to intracellular chlamydiae by first attaching to and cointernalizing with extracellular elementary bodies. Once inside, the nascent inclusion virions infect the newly formed reticulate body. Abundant phage progeny are generated by rolling circle replication of the single-stranded DNA genome and packaging into phage procapsids. Phage-infected reticulate bodies appear as aberrantly enlarged cells similar to *in vitro* persistent forms of chlamydiae. Infectious phage progeny are released by phage-specified lysis of the inclusion membrane approximately 24 h post phage infection.

Antigenic structure. All chlamydiae share a similar antigenic framework consisting of common and specific antigenic determinants (Table 164). Monoclonal antibodies to the most important chlamydial antigens are commercially available. The *Chlamydiaceae* are characterized by a common lipopolysaccharide (LPS) antigen. This antigen is heat-stable and is the antigen for complement fixation tests. The common antigenic determinant is a LPS core terminating in a 2-keto-3-deoxyoctanoic acid (Brade et al., 1986). Antibodies to LPS react strongly to antigen present within inclusions and in the reticulate body membranes, however, reactivity to elementary bodies by immunofluorescence is weak. All chlamydiae encode a major 60,000 molecular weight heat-shock protein (HSP-60) family member

TABLE 164. Structure and function of the major immunoreactive antigens identified in *Chlamydia*^a

Molecular weight	Name	Function
≥ 98,000	Pmp	Unknown. Six Pmp subtypes: A, B, C/D, E/F, G/I, and H
75,000	HSP	Chaperone HSP-70 family
60,000	OmcB	Structural, cysteine-rich OMP
60,000	HSP	Chaperone HSP-60 family
40,000	OmpA (MOMP)	Outer-membrane porin. Contains serological determinants of species-, subspecies-, and serovar-specificity
40,000	PorB	Outer-membrane porin
12,500	OmcA	Structural lipoprotein, cysteine-rich OMP
~12,000	LPS	Endotoxin, genus antigen

^aAbbreviations: Pmp, polymorphic membrane protein; HSP, heat shock protein; Crp, cysteine-rich protein (cross linking of disulfide bonding of cysteine-rich proteins give rigidity to the outer membrane of the EB); Omc, outer membrane complex protein; MOMP, major outer membrane protein; LPS, lipopolysaccharide.

(Bavoil et al., 1990) that is associated with seroreactivity in individuals at risk for pathogenic sequelae of infection (Wagar et al., 1990). This should not be confused with another 60,000 molecular weight protein (OmcB) that is cysteine-rich and present in elementary-body outer membranes but not reticulate-body outer membranes (Batteiger et al., 1985; Hatch et al., 1986). This protein is a potent immunogen and useful marker for serological studies of chlamydial infection.

A major antigen is the major outer-membrane protein (OmpA or MOMP) that is the quantitatively predominant protein in *Chlamydia trachomatis* (Caldwell et al., 1981) and other *Chlamydia* species (Campbell et al., 1990). This protein is an outer membrane porin (Bavoil et al., 1984) and is antigenically complex (Stephens et al., 1982). For *Chlamydia trachomatis* and *Chlamydia suis*, four variable sequence (VS) loops are exposed on the surface and accessible to binding by antibodies (Stephens et al., 1988). *Chlamydia trachomatis* serovar-specific antigens have been mapped and are associated with vs1 and vs2; more broadly reactive determinants, including a species-specific antigen, are localized with vs4. For *Chlamydia trachomatis* (Fan and Stephens, 1997) and *Chlamydia pneumoniae* (Wolf et al., 2001), some of the OmpA antigenic determinants are conformation dependent. Sequence based antigenic variations of this protein singularly account for the antigenic specificities originally characterized by the micro-immunofluorescence test in which 15 prototype serovars were defined (Figure 159) (Wang and Grayston, 1970). Serovars A through K, including Ba, are associated with ocular and urogenital tract infection and serovars L₁, L₂, and L₃ are serovars of the LGV biovar. Antigenic variation is thought to derive from selection by the host immune response to infection (Stephens, 1989). While the other *Chlamydia* species genomes each have *ompA*, only *Chlamydia trachomatis*, *Chlamydia pecorum*, and *Chlamydia suis* have alleles of *ompA* that significantly differ among isolates. A new porin, PorB, was discovered following genome sequencing (Kubo and Stephens, 2000). Like OmpA, PorB is surface-exposed but, unlike OmpA, PorB is not quantitatively predominant and does not display significant sequence variation among isolates within a species.

An entire multigene family of antigens [polymorphic membrane proteins (Pmps)] was also discovered from genome

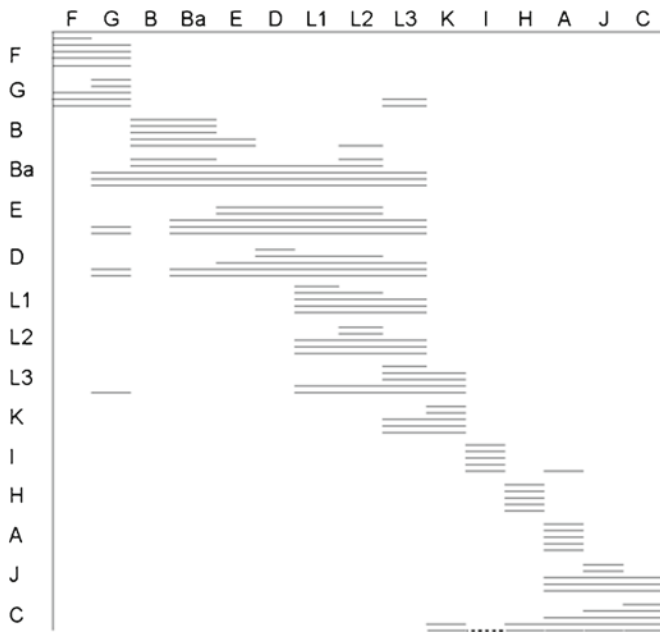

FIGURE 159. Microimmunofluorescence pattern of *Chlamydia trachomatis* antisera prepared in mice. A difference of one line expresses a twofold difference from the homologous titer which is shown with five lines. (Reproduced with permission from Wang et al., 1973. *Infect. Immun.* 7: 356–360; adapted from the 1984 edition of the *Bergey's Manual of Systematic Bacteriology*, vol. 1; Chapter Genus I *Chlamydia*, Figure 9.14.)

sequencing to include nine representatives in *Chlamydia trachomatis* (Stephens et al., 1998) and 21 representatives in *Chlamydia pneumoniae* (Kalman et al., 1999) and intermediate numbers of paralogs for other species. The protein sequences are very different, but they are unambiguously related (Grimwood et al., 2001). The functions of these proteins are unknown, but some have been shown to be surface-exposed outer-membrane proteins, and their expression is dependent upon phase variation.

Antibiotic sensitivity. The susceptibility of chlamydiae to antibiotics has been tested in yolk sac of chicken embryos (Gordon et al., 1957; Molder et al., 1955) or cell culture (Kuo and Grayston, 1988; Kuo et al., 1977b). The growth of chlamydiae in culture is inhibited by the tetracyclines, macrolides, azalides, chloramphenicol, rifampin, and fluoroquinolones. Chlamydial multiplication is not blocked by aminoglycosides, bacitracin, or vancomycin. *Chlamydia trachomatis*, *Chlamydia muridarum*, and *Chlamydia suis* are sensitive to sulfonamides, whereas other species, except the 6BC strain of *Chlamydia psittaci*, are resistant. Beta-lactam antibiotics (penicillin), which inhibit the synthesis of peptidoglycan, interrupt the developmental cycle by preventing the maturation of reticulate bodies into elementary bodies. However, if these antibiotics are removed, development proceeds normally. The inhibitory effect of penicillin on chlamydiae which contain no or only trace amounts of muramic acid has been attributed to the presence of penicillin-binding proteins in their outer membrane (Barbour et al., 1982). D-Cycloserine acts similarly to penicillin, but *Chlamydia trachomatis* is much more susceptible to growth inhibition by this antimicrobial than is *Chlamydia psittaci*. Antagonism is not observed among sulfa drugs, tetracycline, erythromycin, chloramphenicol, penicillin,

and ciprofloxacin. An additive inhibition is observed between tetracycline and penicillin, tetracycline and erythromycin, tetracycline and chloramphenicol, erythromycin and penicillin, erythromycin and chloramphenicol (How et al., 1985) and azalides and rifampin derivatives (Kuo, C.C., unpublished data). Synergistic activity is observed between trimethoprim and sulfamethoxazole (How et al., 1985). The drugs of choice for treatment of chlamydial infections are tetracyclines, macrolide, and azalides. Long-acting antibiotics (doxycycline) and those antibiotics that achieve high intracellular concentrations (azithromycin) are preferred.

Chlamydial strains resistant to sulfonamides, penicillin, chlorotetracycline, and rifampin have been produced by *in vitro* passage in the presence of these drugs. However, stable drug-resistant mutants of *Chlamydia trachomatis* or *Chlamydia pneumoniae* have not been isolated. *Chlamydia suis* in American pigs is resistant to tetracycline by virtue of the integration in its genome of a Tet(R) transposon-like genetic element from another bacterium (Dugan et al., 2004).

Pathogenesis. Chlamydiae are among the most widely distributed pathogens of humans and animals and they produce variable clinical syndromes. Humans are the natural hosts of *Chlamydia trachomatis* (Grayston and Wang, 1975) and the human biovar of *Chlamydia pneumoniae* (Kuo et al., 1986). *Chlamydia trachomatis* causes ocular infection, which may lead to blindness (trachoma), a disease still found in tropical and subtropical endemic areas (Grayston et al., 1985), and it causes genitourinary tract infections, which may cause tubal factor infertility (fallopian tube obstruction), which is a serious complication of chronic salpingitis (Grayston and Wang, 1975) (Table 165). The human biovar of *Chlamydia pneumoniae* is a common respiratory pathogen with manifestations of pharyngitis, bronchitis, and pneumonia (Grayston et al., 1989) and is associated with atherosclerosis and coronary heart disease (Kuo et al., 1993) (Table 165). The organism has been isolated from the atherosclerotic lesions of the artery. A unique characteristic of human infection with these chlamydial agents is their ability to establish persistent or chronic infection, as exemplified by the difficulty in reisolating the organism from lesion sites, such as from the occluded fallopian tube in *Chlamydia trachomatis*

TABLE 165. Diseases caused by human chlamydial agents

Species	Biovar	Disease or syndrome

^aTrachoma biovar in old nomenclature

salpingitis (Campbell et al., 1993) and from the lungs and atherosclerotic arteries in *Chlamydia pneumoniae* infections (Kuo et al., 1993). However, the presence of organisms (chlamydial DNA, RNA, and antigens) can still be detected by PCR, RT-PCR, or immunohistochemistry. This observation has been attributed to the arrest of the developmental cycle at the reticulate body stage by depletion of intracellular tryptophan or other required amino acids (Allan and Pearce, 1983b, a). Tryptophan may become limiting as a result of gamma-interferon produced in the context of the host's innate immune response (Beatty et al., 1994). Gamma-interferon induces indoleamine 2,3 dioxygenase (IDO) that catabolizes oxidative decyclization of tryptophan (Kane et al., 1999).

Chlamydia psittaci causes systemic infection in birds and the infection is often asymptomatic (Table 166). *Chlamydia psittaci* is highly infectious to humans. Humans may contract *Chlamydia psittaci* infection by the airborne route, either by direct contact with infected birds or indirectly by inhalation of dust contaminated with excreta of infected birds. The major manifestation of *Chlamydia psittaci* infection in humans is atypical pneumonia, and the infection in humans is often systemic. Psittacosis is a term used to describe the infections acquired from a psittacine bird, and ornithosis is the infection contracted from birds other than psittacine. *Chlamydia psittaci* is widespread in wild and domestic birds including parrots, parakeets, pigeons, ducks, and turkeys. Outbreaks of *Chlamydia psittaci* infection may occur in poultry, and transmissions of infection to poultry farmers occur sporadically. Quarantine of trapped wild birds in combination with preventive antibiotic (tetracycline) treatment

has been effective in controlling spread of infection from wild to domesticated birds.

Mammalian chlamydial species cause various diseases unique to their hosts (Table 166). The major syndromes caused by mammalian chlamydial agents are: pneumonitis in mice caused by *Chlamydia muridarum*; conjunctivitis and respiratory infection in koalas caused by the biovar koala of *Chlamydia pneumoniae*; encephalitis, polyarthritis, pneumonia, enteritis, and genital infection caused by *Chlamydia pecorum* in ruminants, and urogenital infection and infertility in koala; conjunctivitis, pneumonia, and enteritis in swine caused by *Chlamydia suis*; abortion in sheep, goats, and cattle caused by *Chlamydia abortus*; follicular conjunctivitis and interstitial keratitis in guinea pigs caused by *Chlamydia caviae*; and conjunctivitis in cats caused by *Chlamydia felis*. Human infection due to other mammalian chlamydial infections is rare, because mammalian chlamydial agents are much less virulent to humans. Sporadic cases of severe flu-like infection and abortion occur after exposure of farmers in the third trimester of pregnancy to *Chlamydia abortus* by contact with aborting sheep or goats (Herring et al., 1987; Johnson et al., 1985). Pet owners or laboratory personnel may develop conjunctivitis acquired from cats with conjunctivitis due to *Chlamydia felis* (Schachter et al., 1969).

Phylogenetic relationships based on 16S rRNA. Several investigators have evaluated the relationships among many of the *Chlamydia* and *Chlamydia*-related organisms by tree-methologies using 16S rRNA (Corsaro et al., 2002; Everett et al., 1999; Petersson et al., 1997; Pudjiatmoko et al., 1997; Weisburg et al., 1986). Complete 16S rRNA sequences of most of

<i>Chlamydia psittaci</i>	Birds	Systemic, often latent respiratory and enteric infection
<i>Chlamydia suis</i>	Swine	Conjunctivitis, pneumonia, enteritis, polyarthritis

^aOnly one isolate from a horse with serous nasal discharge has been reported.

the prototypical strains are available, and the resulting trees from different reports using the same or different methods are markedly similar. All *Chlamydia*-related organisms are deeply separated from other bacteria and form their own bacterial division as they lack a significant relationship to other bacterial divisions (Pace, 1997). Distantly related organisms such as the *Piscichlamydia* (Draghi et al., 2004), *Protochlamydia* (Collingro et al., 2005a, b), and *Parachlamydia* (Amann et al., 1997) are distinct from chlamydial organisms that establish the strongly monophyletic *Chlamydiaceae* family (Figure 160). Three groups diverged from a common ancestor that contain species related to the *Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia pneumoniae* groups. New species names have also been proposed (Everett et al., 1999), which are often representative of the relationship with the natural host and are adopted herein. The *Chlamydia trachomatis* grouping contains the murine biovar mouse pneumonitis (MoPn) (Nigg and Eaton, 1944) *Chlamydia muridarum* and related organisms isolated from pigs named *Chlamydia suis* (Hoelzle et al., 2000). The *Chlamydia psittaci* grouping contains strains from birds (*Chlamydia psittaci*), cats (*Chlamydia felis*), guinea pigs (*Chlamydia caviae*), and ruminants and pigs (*Chlamydia abortus*). The third group contains *Chlamydia pneumoniae* (Grayston et al., 1989), originally isolated from humans, and *Chlamydia pecorum* isolated from cattle (Fukushi and Hirai, 1992).

Analyzes of a variety of other single components such as protein and 23S rRNA sequences support these relationships. The application of simple DNA amplification procedures for the detection of novel 16S or 23S sequences related to *Chlamydia* has resulted in the detection of *Chlamydia*-like organisms

from many animals, fish, reptiles, and environmental samples. These activities will likely continue, but many do not result in full-length gene sequences and are not supported by microbiological isolation.

Enrichment and isolation procedures

Laboratory handling of *Chlamydia*-containing specimens and growth of chlamydiae should be conducted by employing biosafety level 2 (BSL-2) or higher containment facilities and practice (Chosewood and Wilson 2007). Strains from all chlamydial species grow in the yolk sacs of chicken embryos. All chlamydial strains multiply in a variety of cell cultures with the assistance of infection-promoting procedures such as pretreatment of host cells with polycations (Kuo et al., 1972b), centrifugation of the inoculum onto host cell monolayers (Gordon et al., 1969), and inhibition of the synthesis of host macromolecules with cycloheximide (Ripa and Mardh, 1977). The efficiency of growth in cell culture varies among the species and the biovars within the species. For example, *Chlamydia psittaci* grows more efficiently than other mammalian chlamydial species in both chicken embryos and cell cultures, while the LGV biovar multiplies more readily than the trachoma and genital biovars of *Chlamydia trachomatis* in both systems. Chlamydiae also infect and are lethal to mice following intracerebral inoculation. This test of virulence varies among chlamydial strains and is similar to their behavior in chicken embryos and cell cultures. *Chlamydia psittaci* strains are particularly virulent to humans. The risk is so great that attempts to isolate *Chlamydia psittaci* from birds should be made only by experienced workers in specially equipped laboratories.

Collection and processing of specimens. Collection of an appropriate specimen for isolation of chlamydiae depends on the disease, the host, and the chlamydial agent. Clinical samples, especially swab samples from the bodily openings and intestinal tissues, are contaminated with other bacteria and yeasts, therefore antibacterial and antifungal agents that are not inhibitory to chlamydiae are added to the transport medium. Frequently used isolation mixtures contain gentamicin, or streptomycin and vancomycin, and amphotericin B. Clinical samples are usually suspended in phosphate buffer containing sucrose and glutamate or cell culture medium, supplemented with suitable antimicrobial agents. A suitable medium contains 0.2 M sucrose in phosphate buffer and 10 µg/ml gentamicin and 3.75 µg/ml amphotericin B. Intracellular chlamydiae are released by shaking with glass beads or by sonication. Specimens may be kept at 4°C if inoculated within 24 h. If they must be held for longer times, they should be frozen at -75°C or lower.

Isolation in cell culture. The cell lines most commonly used for isolation of chlamydiae are McCoy cells (a heterodiploid mouse line) (Gordon et al., 1969) and HeLa 229 cells (derived from a human cervical carcinoma) (Kuo et al., 1977a; Kuo et al., 1972b). Other cell lines are used for certain species. For example, HL (human line) (Kuo and Grayston, 1990b) and Hep-2 (human nasopharyngeal carcinoma) (Roblin et al., 1992) cells for *Chlamydia pneumoniae* and L-929 (mouse fibroblast) or BGMK (buffalo green monkey kidney) cells for *Chlamydia psittaci*, *Chlamydia pecorum*, *Chlamydia felis*, and *Chlamydia suis*. Enhancement of infection is achieved by pretreating cell monolayers with 20 µg/ml di-ethyl-amino-ethyl (DEAE)-dextran,

FIGURE 160. 16S rRNA gene phylogeny of *Chlamydiaceae* and *Chlamydiaceae*-related organisms using neighbor joining with Jukes–Cantor distance corrections. Bar = 0.05 substitutions/site.

centrifuging the inoculum onto the monolayer at 1000–3000× g for 1 h at 20–35°C, and incubating the inoculated cells with medium containing 0.5–1.0 µg/ml cycloheximide. After 2 or 3 d of incubation at 35 or 37°C, the presence of chlamydial inclusions is determined by fluorescent antibody stain of the cell monolayer.

Isolation in chicken embryos. Six-to-seven-day-old fertile hen eggs from a flock maintained on antibiotic-free feed are candled for viability, inoculated into their yolk sacs and incubated at 35–37°C for 14 d (T'ang et al., 1957). On the third day of incubation, eggs containing dead embryos are discarded. The eggs are candled every day thereafter. All dead embryos are examined for the presence of chlamydiae by staining impress smears of the yolk sac with Gimenez or modified Macchiavello. Negative primary passage may be passed again blind. Criteria for positive isolation are the presence of elementary bodies and serially transmissible embryo mortality in the absence of contaminating bacteria or viruses. For isolation of human strains of chlamydiae, the yolk sac is less sensitive than cell culture.

Isolation in mice. Most chlamydial strains tested were found to infect mice after intranasal instillation. BALB/c or A/J inbred mice are preferred for isolation. Under light metofane or isoflurane anesthesia, 20–40 µl of the inoculum is deposited on the nostrils of 3 week-old mice that readily inhale the inoculum due to anesthesia-induced hyperventilation. This method has been used for isolation of chlamydiae from avian hosts and of virulent strains from other hosts, but is less sensitive than cell culture for isolation of low-virulence strains. Within one week after inoculation, mice develop typical lung lesions consisting of grayish foci of consolidation, sometimes involving a major portion of the lung. For verification of the infection, mice are sacrificed after 1 week, and impression smears from lesions are stained with Gimenez or FITC-labeled monoclonal antibody against chlamydial LPS, or lung tissue is examined by PCR. Standard bacteriological culture is used to confirm the absence of contaminating bacteria, and cell culture is used for exclusion of viral infections. In negative isolation attempts, subculture in BGMK cells is preferred over blind passages.

Maintenance procedures

Chlamydiae are maintained and propagated in chicken embryos and cell cultures by the procedure just described. Chlamydiae are best preserved by freezing at –75°C or lower in buffers containing sucrose and glutamic acid, such as SPG (sucrose, 75 g; KH₂PO₄, 0.52 g; Na₂HPO₄, 1.22 g; glutamic acid, 0.72 g; H₂O to 1 l; pH 7.4–7.6).

Chlamydiae can be propagated to a high titer by serial passages in chicken embryo yolk sac cultures or cell monolayer cultures in a large flask. For example, it is possible to achieve 100% infection of HeLa 229 cells by serial passage without the assistance of centrifugation or inhibitors of host-cell macromolecular synthesis with *Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia muridarum* (Kuo et al., 1977a) and of HL (human line) (Kuo and Grayston, 1990b) and Hep-2 (Roblin et al., 1992) cells with *Chlamydia pneumoniae*. After amplification of chlamydial titer to grow to 100% infectivity in stationary cell cultures, the LGV biovar of *Chlamydia trachomatis* and *Chlamydia psittaci* can be propagated in a suspension culture of L-cells. Alternatively, BGMK monolayer cells can be used for effective propagation of chlamydiae, and elementary bodies released

into the culture medium can be concentrated into stocks of high purity and infectivity (Li et al., 2005).

Procedures for testing special characters

Several methods are used for quantification of infectivity titer and enumeration of bacterial particles. For example, *Chlamydia psittaci*, the LGV biovar *Chlamydia trachomatis*, and *Chlamydia muridarum* readily form plaques on monolayers of L-cells (a heterodiploid mouse line) after extended incubation. Ocular and genital biovar strains of *Chlamydia trachomatis* can also be coaxed to form plaques (Matsumoto et al., 1998). The infectivity titer is expressed as plaque forming units. A simple method is to determine the inclusion-forming units by infecting a monolayer by centrifugation and culturing infected cells with medium containing inhibitors of host macromolecular synthesis, incubating for 48–72 h, and staining with Giemsa, iodine, or fluorescent antibodies and counting the inclusions. The number of chlamydial inclusions in each of a number of microscopic fields is counted. The inclusion counts are standardized, and the titer is expressed in term of inclusion forming units per milliliter (Furness et al., 1960). The burst size is defined in term of the number of infectious elementary bodies produced from a single inclusion. For example, the burst size of *Chlamydia pneumoniae* in HL cells is 73 with the assistance of centrifugation and inhibition of host cell macromolecular synthesis by cycloheximide. The m.o.i. is the number of infectious organisms inoculated per cell in a monolayer culture. Chlamydial infectivity in cell culture, chicken embryos, and mice may be expressed in term of the 50% infectious dose or the 50% lethal dose. Infectivity for chicken embryos inoculated via the yolk sac may also be estimated from the nearly linear relation between the logarithm of the inoculum dilution and the survival time of the inoculated embryos.

Total bacterial counts may be obtained by electron microscopic examination of grids of known geometry onto which purified chlamydial particles have been deposited. The particle counts are greater than inclusion forming units. This may be as much as a factor of 30 with *Chlamydia trachomatis* cultured in HeLa cells and purified by sucrose gradient centrifugation (C.-C. Kuo, unpublished data).

The ocular and genital biovars of *Chlamydia trachomatis* may be differentiated by testing their ability to grow in tryptophan-free medium supplemented with indole. Because the genital biovar is able to utilize exogenous indole for the synthesis of tryptophan while the ocular biovar is not, growth is observed with the genital but not with the ocular biovar (Fehlner-Gardiner et al., 2002).

Applications of real-time quantitative amplification of chlamydial and host DNA and gene sequence techniques provide robust methods for the quantification of chlamydiae and determination of growth rates *in vitro*, and for measuring chlamydial infectious burdens *in vivo*.

Differentiation of the family *Chlamydiaceae* from closely related families

The common properties and 16S rRNA relatedness of five families of the order *Chlamydiales* have been described in the preceding section under the Order *Chlamydiales*. Therefore, only some other biological and pathogenic characteristics useful for differentiation of the family *Chlamydiaceae* from the families *Parachlamydiaceae*, *Piscichlamydiaceae*, *Waddliaceae*, and *Simkaniaceae* are presented below.

The natural hosts for *Parachlamydiae* are free-living amoebae, although they have been recovered from soil (Collingro et al., 2005a, b); for *Piscichlamydia*, Atlantic salmon (Draghi et al., 2004); for *Waddlia*, bovines (Dilbeck et al., 1990); and for *Simkania*, soil (Kahane et al., 1995). Isolations of *Simkaniaceae* from humans with respiratory infection have been reported. However, the pathogenesis of *Parachlamydia* in humans has not been described. These intracellular microorganisms form inclusions and exhibit similar developmental cycles. However, the developmental forms vary in morphology. Specifically, *Piscichlamydia* forms variable elongated reticulate bodies with distinctive head and tail cells and the intermediate form which does not evolve to the elementary form (Draghi et al., 2004). Antigenically, cross-reactivity to chlamydial LPS has been demonstrated with *Piscichlamydia*, but not with *Parachlamydia*.

Differentiation of species, biovars, and serovars of the genus *Chlamydia*

Nine species of *Chlamydia* are currently recognized including *Chlamydia trachomatis*, *Chlamydia muridarum*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Chlamydia suis*, *Chlamydia abortus*, *Chlamydia caviae*, and *Chlamydia felis*. *Chlamydia trachomatis* is further subdivided into three biovars (Table 167) and *Chlamydia pneumoniae* into three biovars (Table 168). In the following sections, if the chlamydial property being described is not common to all members of the genus, the species or biovars to which the description applies will be stated.

Characteristics useful for differentiation of the species of *Chlamydia* are listed in Tables 161, 162, and 163. Nucleic acid-based techniques have emerged as technically easier for use in species differentiation than direct determination of biological differences. Initially, whole-genome hybridization and restriction fragment length polymorphism (RFLP) methods required large quantities of pure DNA of all chlamydial species to be differentiated. These methods have been largely replaced by PCR amplification of genes containing species-specific nucleotide signature sequences. These species signatures are then determined by RFLP, oligonucleotide probing, or, increasingly, by DNA sequencing of the amplification product. Direct sequencing has the advantage that the nucleotide sequences can be immediately aligned to sequences deposited in GenBank, and comparison

^ana, No information is available.

^bNo second isolate to confirm.

^cIsolates with oval elementary bodies have been reported for the human biovar. However, unlike the elementary body of other chlamydial species which demonstrates a tight periplasmic space, these isolates still manifest a discernible periplasmic space, although less wide than that described originally for pear-shaped elementary bodies of *Chlamydia pneumoniae*.

with amplification products from standards of the chlamydial species is unnecessary. The availability in the near future of genome sequences of all chlamydial species, even for multiple strains of *Chlamydia trachomatis* and *Chlamydia pneumoniae*, allows the use of any gene with species signatures. Nevertheless, it will be preferable to rely for routine differentiation on the *ompA* and rRNA genes. The *ompA* gene contains highly polymorphic serovar determinants interspersed among conserved domains that allow genus-specific priming and species as well as serovar differentiation (Kaltenboeck et al., 1993, 1997). The 16S and 23S rRNA genes (but not the intergenic rRNA gene spacer sequence) are less polymorphic but allow design of primers with higher GC content than *ompA* primers, and thus more robust and sensitive PCR methods for direct amplification and species differentiation in disease specimens (DeGraves et al., 2003).

Differentiation of the three biovars of *Chlamydia trachomatis* is listed in Table 167. Differentiation of the three biovars of *Chlamydia pneumoniae* is provided in Table 168.

Only a single serovar or serotype has been identified by the micro-immunofluorescence test in all chlamydial species, except for *Chlamydia trachomatis* which has 15 serovars, and for *Chlamydia psittaci* which has 6 serovars. Cross-reaction patterns of the micro-immunofluorescence antibody reaction in *Chlamydia trachomatis* are depicted in Figure 159 (Wang et al., 1973). No cross-reactivities are observed when *Chlamydia psittaci* serovar-specific monoclonal antibodies are used in the micro-immunofluorescence test for differentiation of *Chlamydia psittaci* serovars (Andersen, 1991).

Taxonomic considerations

The *Chlamydiales* represent a large clade of the bacteria that were pathogens of single eukaryotic cells nearly one billion years ago (Greub and Raoult, 2003; Stephens, 2002). Since that time, they have become obligate intracellular pathogens that have had very limited opportunity to acquire genes from other organisms. The ability to sample the microbial gene pool has played a decisive role in the adaptation to changing environments, evolution, and speciation of bacteria. From the perspective of chlamydiae, the intracellular vacuole is a largely invariant environment whether it is within a single-celled organism, or within a cell of a bird, koala, or human. During this billion years of history, all bacteria acquired and collected mutations in their 16S rRNA genes while rapidly evolving and adapting to novel environmental niches (i.e., speciation). The

chlamydiae, too, collected 16S rRNA mutations, however, chlamydiae lacked the opportunity or the necessity to evolve in significantly new directions. While there has been considerable gene loss, even the amount of intragenomic recombination has been limited as evidenced by the high level of genome synteny among *Chlamydia* species.

From 1971, chlamydiae have been classified within one order (*Chlamydiales*) and one family (*Chlamydiaceae*) and with one genus (*Chlamydia*) (Molder et al., 1984). With the advent of PCR, *Chlamydia*-like DNA has been found in many types of animals and environmental samples; the extent of diversity of *Chlamydia* began to emerge, and this continues today, unfortunately without microbiological isolation. During this period, there was a growing need for more accommodating and accurate polyphasic taxonomic characterization, and this proceeded through a deliberate process highlighted by the detailed and comprehensive characterization of *Chlamydia pneumoniae* (Grayston et al., 1989) and *Chlamydia pecorum* (Fukushi and Hirai, 1992). In 1999, the taxonomy of *Chlamydia* was thrown in disarray and created confusion in the field (Schachter et al., 2001) when Everett et al. (1999) proposed a new second genus for the order *Chlamydiales* and family *Chlamydiaceae* in 1999. The genus proposal was based upon an arbitrary difference of greater than 4% in 16S rRNA gene sequences. This resulted in the separation of *Chlamydia pneumoniae*, *Chlamydia pecorum*, and *Chlamydia psittaci* into a new genus *Chlamydophila* leaving the *Chlamydia trachomatis* biovars in the original *Chlamydia* genus. This separation was inconsistent with the 4% genus threshold, since the 16S rRNA genes of several species within the proposed *Chlamydophila* genus differ by 4% or more.

One of the goals of taxonomy is to maintain stability in the nomenclature and to avoid unnecessary confusion according to Principle 1, Subprinciples 1 and 2 of the International Code of Nomenclature of Bacteria (Sneath, 1992). Indeed, for bacterial pathogens, renaming them even though it may be justified scientifically, may not be advisable. For example, the Judicial Commission of the International Committee on Nomenclature of Bacteria rejected the proposal for renaming the pathogen, *Yersinia pestis*, as a subspecies *Yersinia pseudotuberculosis* thereby giving rise to the name *Yersinia pseudotuberculosis* subspecies *pestis* even though this was justified based on DNA–DNA hybridization (Becovier et al., 1980; Judicial Commission, 1985). Because of the ruling of the Judicial Commission, the validated name *Yersinia pseudotuberculosis* subsp. *pestis* was rejected and the name *Yersinia pestis* was conserved on the approved list, due to the inherent confusion its renaming would cause to the field as well as the potential hazard it posed as a *nomen periculosum* for the general public welfare (Judicial Commission, 1985; Williams, 1984).

These principles can be applied to the pathogens of the family *Chlamydiaceae*. Therefore, for this edition of *Bergey's Manual of Systematic Bacteriology*, the sole genus name *Chlamydia* is being retained for all of the species of the family *Chlamydiaceae*, all of which are human or animal pathogens.

Until now there has been a single *Chlamydia trachomatis* biovar designation called the trachoma biovar that included

strains responsible for natural ocular infection and trachoma and strains that naturally caused urogenital infection and disease. Although the trachoma-causing strains were typically represented by serovars A–C and the urogenital strains by serovars D–K, no biological markers were available to differentiate strains that caused these different diseases. It now appears that trachoma-causing strains lack a functional tryptophan synthase, whereas urogenital strains contain a functional enzyme (Fehlner-Gardiner et al., 2002). The enzymic function can easily be tested *in vitro* or by gene sequence techniques for non-isolated samples. It is proposed that trachoma strains lacking tryptophan synthase function compose the “trachoma” biovar and those from the urogenital tract that have a functional enzyme compose a new “genital” biovar. Thus, *Chlamydia trachomatis* consists of three biovars including ocular, genital, and LGV.

List of species of the genus *Chlamydia*

1. ***Chlamydia trachomatis*** (Busacca 1935) Rake 1957, 958^{AL}
[*Rickettsia trachomae* (sic) Busacca 1935, 567]

tra.cho'ma.tis. Gr. n. *trachusma*-atos roughness; N.L. n. *trachoma*, -atis the disease trachoma; N.L. gen. n. *trachomatis* of trachoma.

The characteristics are as described for the genus and as listed in Tables 161, 162, 163, and 167. The inclusion morphology is depicted in Figure 161.

All *Chlamydia trachomatis* isolates have come from humans. *Chlamydia trachomatis* isolates are classified into three biovars, ocular, genital, and lymphogranuloma venereum (LGV) on the basis of tissue tropism, pathogenesis in humans and laboratory animals, and their biological characteristics in cell cultures (Kuo et al., 1972a). The molecular basis of the separation of ocular from genital biovar is the ability to utilize exogenous indole for tryptophan biosynthesis by the genital, but not by the ocular biovar. The LGV biovar also utilizes indole for tryptophan biosynthesis. Three biovars are genetically (Table 162) and serologically (Figure 159) closely related. Serologically distinguishable from other chlamydial species by the species-specific monoclonal antibody in the micro-immunofluorescence test. Isolates are serotyped by the same test, however, a broad-reactivity among BED serovars and LGV are noted. Strains of ocular biovars parasitize mucous membranes of the conjunctiva, while strains of the genital biovar parasitize the squamous and columnar epithelium of the urogenital mucosa. The LGV biovar has tropism for lymphoid organs and is more invasive than the other two biovars. This behavior parallels its behavior in animals and cultured cells.

DNA G+C content (mol%): 43–44.2 (T_m).

Type strain: A/Har-13 (Trachoma type A strain HAR-13), ATCC VR-571-B.

Sequence accession no. (16S rRNA gene): D89067, E17344, NR 025888.

Further information concerning the three biovars of *Chlamydia trachomatis* is given below:

(i) Biovar ocular. Chlamydiae of this biovar exclusively parasitize the conjunctival mucosal cells. Transmission is by discharge from the inflamed eyes commonly in family or school. The primary infection is in the form of follicular conjunctivitis, which may heal spontaneously. However, in endemic areas, repeated infections sustain the chronicity of infection and cause scarring

of the conjunctiva and cornea. The end stage of the disease is blindness. Table 165 lists the diseases caused by the ocular biovar of *Chlamydia trachomatis*. Serovars of the ocular biovar are A, B, Ba, and C.

DNA G+C content (mol%) of five strains: 44.0 (T_m).

Type strain: PK-2, serovar C, ATCC VR-576.

Sequence accession no. (16S rRNA gene) for strain C/TW-3/OT: D85720.

(ii) Biovar genital. Strains of this biovar are sexually transmitted. The primary site of infection is the mucosal membranes of the urogenital tract. Diseases caused by the genital biovar are listed in Table 165. The infection may be auto-transferred to the conjunctiva or to contacts to cause acute follicular conjunctivitis. Chronic infection due to the genital biovar of *Chlamydia trachomatis* is a common cause of infertility in women. Serovars of genital isolates are D through K. No difference in the virulence among the serovars has been observed.

DNA G+C content (mol%) of two strains is: 44.2 (T_m).

Type strain: UW-3/Cx, serovar D, ATCC VR-885.

Sequence accession no. (16S rRNA gene) for strain D/UW-3Cx: D85721.

(iii) Biovar lymphogranuloma venereum (LGV). Strains of this biovar are sexually transmitted and cause systemic infection with the major manifestation of lymphadenopathy or swelling of lymph nodes draining the extragenitalia. Three serovars are recognized which are L₁, L₂, and L₃.

DNA G+C content (mol%): 43.0 (T_m).

Type strain: 434, serovar L₂, ATCC VR-902B.

Sequence accession no. (16S and 23S rRNA genes): U68443.

2. *Chlamydia abortus* comb. nov. Everett, Bush and Andersen 1999 (*Chlamydothila abortus* Everett, Bush and Andersen 1999, 434)

a.bor'tus. L. n. *abortus*, -us an abortion, a miscarriage; L. gen. n. *abortus* of an abortion, a miscarriage.

The characteristics are as described for the genus and as listed in Tables 162, 163, and 166. This species was separated from *Chlamydia psittaci* with the establishment of five new

FIGURE 161. Two different morphologies of chlamydial inclusions. Infected host cell monolayers were fixed with methanol and stained with May-Greenwald Giemsa. Bars = 20 μ m. Arrows point to a typical inclusion. (a) Vacuolar, glycogen-positive (*Chlamydia trachomatis*, *Chlamydia muridarum* and *Chlamydia suis*). (b) Solid, glycogen-negative (*Chlamydia psittaci*, *Chlamydia pneumoniae*, *Chlamydia pecorum*, *Chlamydia abortus*, *Chlamydia caviae* and *Chlamydia felis*). (Courtesy of author, C.-C. Kuo.)

species in addition to *Chlamydia trachomatis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Chlamydia abortus is endemic in ruminants, and it is a frequent cause of late-term abortion in flocks of sheep or goats (enzootic abortion of ewes, EAE), but less frequently in cattle. It has also been associated with seminal vesiculitis in bulls and with bovine infertility. *Chlamydia abortus* has also infrequently been identified as the cause of abortion in other mammals such as horse and pig, and experimentally causes abortion in laboratory animals such as rabbits, guinea pigs, and mice. Infection of pregnant women with *Chlamydia abortus* is typically contracted during contact with small ruminants and can cause flu-like symptoms of systemic infection followed by abortion (Herring et al., 1987; Johnson et al., 1985). *Chlamydia abortus* isolates worldwide represent a single serovar and have virtually identical *ompA* and rRNA genes.

DNA G+C content (mol%): not determined.

Type strain: B577, Ovine Chlamydial Abortion strain B-577, ATCC VR-656.

Sequence accession no. (16S rRNA gene): AB001783, D85709.

3. ***Chlamydia caviae*** comb. nov. Everett, Bush and Andersen 1999 (*Chlamydophila caviae* Everett, Bush and Andersen 1999, 434.)

ca.vi'ae. N.L. gen. n. *caviae* of *Cavia*, of the guinea pig (*Cavia cobaya*) because the type strain was isolated from *Cavia cobaya*.

The characteristics are as described for the genus and as listed in Tables 162, 163, and 166. This species was separated from *Chlamydia psittaci* with the establishment of five new species in addition to *Chlamydia trachomatis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Chlamydia caviae is a chlamydial pathogen that has exclusively been isolated from guinea pigs. The *ompA* sequences of five *Chlamydia caviae* isolates are identical. The primary isolation site is the conjunctiva (guinea pig inclusion conjunctivitis, GPIC), but inoculation of the guinea pig genital tract results in disease and infertility that are remarkably similar to those caused by human genital infection with *Chlamydia trachomatis*.

DNA G+C content (mol%): not determined.

Type strain: GPIC, ATCC VR 813.

Sequence accession no. (16S rRNA gene): D85708.

4. ***Chlamydia felis*** comb. nov. Everett, Bush and Andersen 1999 (*Chlamydophila felis* Everett, Bush and Andersen 1999, 434.)

fe'lis. L. n. *felis*, -is a cat; L. gen. n. *felis* of a cat.

The characteristics are as described for the genus and as listed in Table 162, 163, and 166. This species was separated from *Chlamydia psittaci* with the establishment of five new species in addition to *Chlamydia trachomatis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Chlamydia felis is frequently isolated from conjunctivitis and rhinitis in cats. All strains represent a single serovar, have highly conserved *ompA* genes, and rRNA genes differ by less than 0.6%. Human conjunctivitis caused by infection with *Chlamydia felis* contracted from pet cats appears to be common (Schachter et al., 1969).

DNA G+C content (mol%): not determined.

Type strain: FP Baker, ATCC VR-120.

Sequence accession no. (16S rRNA gene): D85701.

5. ***Chlamydia muridarum*** Everett, Bush and Andersen 1999, 431^{VP}

mu.ri.da'rum. N.L. pl. gen. n. *muridarum* of the *Muridae* (i.e., the mouse/hamster family).

The characteristics are as described for the genus and as listed in Tables 162, 163, and 166. This species was separated from *Chlamydia trachomatis* with the establishment of five new species in addition to *Chlamydia trachomatis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Two virtually identical *Chlamydia muridarum* strains are currently known, isolated from the lungs of clinically healthy mice (strain MoPn Nigg II) and from the intestinal tract of a hamster with proliferative ileitis (strain SFPD). Strain MoPn has been found to be highly virulent for mice and can cause severe interstitial pneumonia. It is also frequently used in mouse models of chlamydial genital tract infection and infertility.

DNA G+C content (mol%): 42–44 (T_m).

Type strain: Nigg II, ATCC VR123.

Sequence accession no. (16S rRNA gene): D85718.

6. ***Chlamydia pecorum*** Fukushi and Hirai 1992, 307^{VP}

pe.co'rum. L. gen. pl. n. *pecorum* of flocks of sheep or herds of cattle.

The characteristics are as described for the genus and as listed in Tables 162, 163, and 166. This was the fourth species established for the genus, after *Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia pneumoniae*.

Chlamydia pecorum has been isolated from ruminants, swine, and koalas, and is frequently found in low numbers on the mucosal membranes of healthy host animals. *Chlamydia pecorum* causes severe diseases in these animals such as sporadic bovine encephalomyelitis (SBE) in feedlot cattle, and enteritis, pneumonia, polyarthritis, and urogenital infection in cattle and swine. In koalas, *Chlamydia pecorum* causes keratoconjunctivitis, vaginitis, cystitis, and infertility, and is strongly associated with the decline of the koala population in combination with stress resulting from destruction of the koala habitat. *Chlamydia pecorum* isolates show polymorphic *ompA* genes, suggesting the existence of numerous as yet uncharacterized serovars. Human infection with *Chlamydia pecorum* has not been observed.

DNA G+C content (mol%): 39.3 (T_m).

Type strain: Bo/E58, ATCC VR-628.

Sequence accession no. (16S rRNA gene): D88371.

7. ***Chlamydia pneumoniae*** Grayston, Kuo, Campbell and Wang 1989, 88^{VP}

pneu.mo'ni.ae. Gr. n. *pneumonia* pneumonia, inflammation of the lungs; N.L. gen. n. *pneumoniae* of pneumonia.

The characteristics are as described for the genus and as listed in Tables 162, 163, 165, 166, and 168. The inclusion morphology is depicted in Figure 155.

The proposal for establishing this species, which was the third species in the genus, was based on the ultrastructural morphology of the elementary bodies that is typically pear-shaped (Figure 155), presence of a species-specific antigen identifiable with a species-specific monoclonal antibody, and its clear separation from the two other species by the DNA–DNA homology (Table 162). The species includes three

biovars: human, koala, and horse (Table 168). Since 1983, no other isolate has been obtained to confirm the original isolate from horse (Spencer and Johnson, 1983; Willis et al., 1990). The inclusions contain no glycogen, hence stain negative with iodine. Diseases caused by *Chlamydia pneumoniae* in humans are listed in Table 165 and diseases in animals in Table 166.

DNA G+C content (mol%): 40 (T_m).

Type strain: TW-183, ATCC VR-2282.

Sequence accession no. (16S rRNA gene): L06108, NR 026527, Z49873.

8. **Chlamydia psittaci** (Lillie 1930) Page 1968, 60^{AL} (*Rickettsia psittaci* Lillie 1930, 778)

psit'ta.ci. L. n. *psittacus* a parrot; L. gen. n. *psittaci* of a parrot.

The characteristics are as described for the genus and as listed in Tables 162 and 163. This was the type species and strain of the first two species, *Chlamydia trachomatis* and *Chlamydia psittaci*, established for the genus.

Chlamydia psittaci is comprised of six serovars, A–F, of avian chlamydial isolates (Andersen, 1991, 1997) that cause latent and clinically overt infections of the intestinal and respiratory tracts in many species of birds. Upon exposure of birds to crowding and stress, these infections often become severe, with diarrhea, air sacculitis, pneumonia, and fatal systemic spread with pericarditis and splenomegaly. Human *Chlamydia psittaci*-induced disease, typically contracted by inhalation of dried bird feces, is called psittacosis or ornithosis if contracted from psittacine or from non-psittacine birds, respectively. Psittacosis is characterized by early flu-like symp-

oms followed by severe, sometimes fatal atypical interstitial pneumonia that requires intensive antibiotic and symptomatic therapy and resolves only slowly after several weeks. *Chlamydia psittaci* isolates should be handled only in a biosafety level 3 laboratory.

DNA G+C content (mol%): 41.3 (T_m).

Type strain: 6BC, Psittacosis strain 6 BC, ATCC VR-125.

Sequence accession no. (16S rRNA gene): AB001778, U68447.

9. **Chlamydia suis** Everett, Bush and Andersen 1999, 431^{VP}

su'is. L. n. *suis suis* a swine; L. gen. n. *suis* of a swine.

The characteristics are as described for the genus and as listed in Tables 163 and 166. This species was separated from *Chlamydia trachomatis* with the establishment of five new species in addition to *Chlamydia trachomatis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

The S45 type strain of *Chlamydia suis* was isolated by Koelbl in the 1960s in Austria from a pig with inapparent intestinal infection (Koelbl, 1969; Koelbl et al., 1970). Since 1995, high incidences and tetracycline-resistant strains of *Chlamydia suis* have been found in enteric and conjunctival porcine specimens, suggesting that *Chlamydia suis* infections are endemic in swine (Dugan et al., 2004). *Chlamydia suis* strains show marked *ompA* gene polymorphism, particularly of the variable domains, but less than 1.1% 16S rRNA gene diversity. This suggests the existence of numerous serovars, similar to *Chlamydia trachomatis*. Human infection with *Chlamydia suis* has not been observed.

DNA G+C content (mol%): not determined.

Type strain: S45, ATCC VR-1474.

Sequence accession no. (16S rRNA gene): U73110.

Other organisms

Chlamydia-like organisms have been described in reptiles (turtle, tortoise, and boar) (Homer et al., 1994; Vanrompay et al., 1994), amphibians (frog) (Bodetti et al., 2002), bivalves (mussel and clam) (Cajaraville and Angulo, 1991; Harshbarger and Chang, 1977; Page and Cutlip, 1982), and crab (Sparks et al., 1985). These *Chlamydia*-like organisms have ultra-structural morphology and developmental forms resembling those of chlamydiae in that the organisms grow within a cytoplasmic vacuole (inclusion) and undergo a developmental cycle from

the reticulate body-like form to an elementary body-like form. The relatedness of these organisms to other *Chlamydia* species has been demonstrated by electron microscopy, PCR analysis of OMP and rRNA genes, and immunoreactivity with *Chlamydia*-specific antibodies. Isolation of the organisms by inoculation of chicken eggs has been reported from Moorish tortoise and green sea turtle (Homer et al., 1994; Vanrompay et al., 1994). However, taxonomic relatedness of these microorganisms to other chlamydial organisms has yet to be determined.

Family II. "Candidatus Clavichlamydiaceae"

MATTHIAS HORN

Cla.vi.chla.my.di.a.ce'ae. N.L. fem. n. *Clavichlamydia* type genus of the family; -aceae ending to denote a family, N.L. fem. pl. n. *Clavichlamydiaceae* the *Clavichlamydia* family.

The family "Candidatus Clavichlamydiaceae" is currently solely based on 16S rRNA sequences moderately related to members of the *Chlamydiaceae* (around 90% sequence similarity) (Figure 154). The family "Candidatus Clavichlamydiaceae" is a sister

family of the *Chlamydiaceae* and contains a single genus, "Candidatus Clavichlamydia".

Type genus: "Candidatus Clavichlamydia" corrig. Karlsen, Nylund, Watanabe, Helvik, Nylund and Plarre 2008.

Genus I. "Candidatus Clavichlamydia" corrig. Karlsen, Nylund, Watanabe, Helvik, Nylund and Plarre 2008

MATTHIAS HORN

Cla.vi.chla.my'di.a. L. n. *clava* a knotty branch, rough stick, cudgel, club; N.L. fem. n. *Chlamydia* taxonomic name of a bacterial genus; N.L. fem. n. *Clavichlamydia* a club *Chlamydia* (the morphology of the bacteria includes the characteristic head-and-tail cells that have been described earlier from salmonid fish suffering from epitheliocystis).

Pleomorphic or elongated, nonmotile, obligate intracellular bacteria, up to 2 µm in length. Cells show a **developmental cycle** with morphologically distinct stages and thrive **inside a host vacuole**. Organisms were found within gill lesions of fish and are differentiated from all other chlamydiae by the morphology of the proposed **elementary bodies, which show a characteristic head-and-tail form** (Figure 162). Members have not yet been obtained in cell culture.

Type species: "Candidatus Clavichlamydia salmonicola" corrig. Karlsen, Nylund, Watanabe, Helvik, Nylund and Plarre 2008.

Further descriptive information

Three distinct morphological forms, representing different developmental stages, have been observed inside the host-derived vacuole that surrounded the bacteria. The proposed reticulate bodies are large pleomorphic cells (up to 2 µm) with

FIGURE 162. Morphological diversity of developmental stages of the *Chlamydiae*. (a) "*Candidatus Clavichlamydia salmonicola*", (b) *Criblamydia sequanensis* and (c) "*Candidatus Rhabdochlamydia porcellionis*". Images are reproduced from Kostanjsek et al. (2004), Thomas et al. (2006) and Karlsen et al. (2008). See text for details.

an inner structure resembling the reticulate bodies of *Chlamydiaceae* (Figure 162). The proposed intermediate bodies were slightly smaller with a condensed cytoplasm. The proposed elementary bodies were about 1 μm long and consisted of a head and a tail region (Figure 162). Transitional forms between these three developmental stages have been observed (Karlsen et al., 2008). Bacteria with a similar morphology have previously been observed in the gills of steelhead trout and lake trout, and in nonproliferative gill lesions of Atlantic salmon (Bradley et al., 1988; Draghi et al., 2004; Rourke et al., 1984), but these bacteria were never identified on a molecular level.

Pathogenesis. "*Candidatus Clavichlamydia salmonicola*" has been found infecting the gills of salmonid fish in freshwater (Atlantic salmon, *Salmo salar*, and wild brown trout, *Salmo trutta*), forming large cysts (up to 56 μm) consisting of single hypertrophied epithelial cells. Although a direct causal relationship has not yet been demonstrated, "*Candidatus Clavichlamydia salmonicola*" has been suggested to represent one possible etiological agent of epitheliocystis in fish from freshwater and marine environments (Karlsen et al., 2008).

List of tentative species of the genus "*Candidatus Clavichlamydia*"

1. "*Candidatus Clavichlamydia salmonicola*" corrig. Karlsen, Nylund, Watanabe, Helvik, Nylund and Plarre 2008.
sal.mo.ni.co'la L. n. *salmo-onis* salmon; L. suff. *-cola* (from L. n. *incola*), inhabitant, dweller; N.L. n. *salmonicola* a salmon-dweller (infecting fish of the genus *Salmo*).

References

- Bradley, T.M., C.E. Newcomer and K.O. Maxwell. 1988. Epitheliocystis associated with massive mortalities of cultured lake trout *Salvelinus namaycush*. *Dis. Aquat. Org.* 4: 9–17.
- Draghi, A., 2nd, V.L. Popov, M.M. Kahl, J.B. Stanton, C.C. Brown, G.J. Tsongalis, A.B. West and S. Frasca, Jr. 2004. Characterization of "*Candidatus piscichlamydia salmonis*" (order *Chlamydiales*), a chlamydia-like bacterium associated with epitheliocystis in farmed Atlantic salmon (*Salmo salar*). *J. Clin. Microbiol.* 42: 5286–5297.

Taxonomic note

The two available 16S rRNA sequences from the genus *Clavichlamydia* share slightly greater than 90% similarity with the 16S rRNA sequences of *Chlamydia abortus*, *Chlamydia felis*, *Chlamydia pecorum*, *Chlamydia pneumoniae*, and *Chlamydia psittaci*, but slightly less than 90% with *Chlamydia muridarum*, *Chlamydia suis*, and *Chlamydia trachomatis*. While the unique morphology of the developmental stages of members of the genus "*Candidatus Clavichlamydia*" might favor the placement of this genus into a new family separate from the *Chlamydiaceae*, this might be subject to change when more sequence information and additional descriptions become available.

The names *Clavochlamydiaceae*, *Clavochlamydia*, and "*Candidatus Clavochlamydia salmonicola*" have been changed by the editors to "*Candidatus Clavichlamydiaceae*", "*Candidatus Clavichlamydia*", and "*Candidatus Clavichlamydia salmonicola*" during preparation of this chapter. The connecting vowel must be "i" because the first part of the name is derived from Latin.

The genus "*Candidatus Clavichlamydia*" corrig. is based on the description of "*Candidatus Clavochlamydia salmonicola*" (Karlsen et al., 2008) (Figure 154).

Family III. **Criblamydiaceae** Thomas, Casson and Greub 2006, 2131

MATTHIAS HORN

Cri.bla.my.di.a.ce'ae. N.L. fem. n. *Criblamydia* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Criblamydiaceae* the *Criblamydia* family.

The family *Criblamydiaceae* currently contains a single genus, *Criblamydia*, comprising a single species, which grows in amoebae of the genus *Acanthamoeba* and shows highest 16S rRNA

sequence similarity to members of the *Parachlamydiaceae* (89%, Figure 154) (Thomas et al., 2006).

Type genus: Criblamydia Thomas, Casson and Greub 2006, 2131.

Genus I. **Criblamydia** Thomas, Casson and Greub 2006, 2131

MATTHIAS HORN

Crib.la.my'di.a. N.L. fem. n. *Cribia* arbitrary name derived from the abbreviation CRIB (Center for Research on Intracellular Bacteria); N.L. fem. n. *Chlamydia* taxonomic name of a bacterial genus; N.L. fem. n. *Criblamydia* arbitrary name intended to mean a *Chlamydia* named after CRIB.

Coccoid to pleomorphic, nonmotile, obligately intracellular bacteria, 0.5–1 µm in diameter. Cells show a **developmental cycle** with morphologically distinct stages and **grow within host-derived vacuoles**. Organisms are differentiated from all other chlamydiae by the **star-shaped elementary body** seen with transmission electron microscopy (Figure 162). The genus *Criblamydia* contains a single species, *Criblamydia sequanensis* (Figure 154), which has been recovered from a water sample from the river Seine (France) by co-cultivation with *Acanthamoeba castellanii* ATCC 30010 (Thomas et al., 2006).

Type species: Criblamydia sequanensis Thomas, Casson and Greub 2006, 2131.

Further descriptive information

The natural host of the sole *Criblamydia* strain known to date (CRIB-18) is not known. Like many chlamydiae, it grew well

in the free-living amoebae *Acanthamoeba castellanii* ATCC 30010 and *Acanthamoeba polyphaga* Linc-API, but could not propagate in *Hartmannella vermiformis* ATCC 50237 and *Dictyostelium discoideum* DH1-10, or mammalian cells (Thomas et al., 2006). In *Acanthamoeba castellanii*, *Criblamydia sequanensis* formed 1–10 large vacuoles within 72–96 h, which led to lysis of the amoeba host cell after 4–6 d. No bacteria were observed in amoeba cysts. The reticulate bodies (0.8–1.0 µm in diameter) possess a granular cytoplasm and a three-layer cell wall. The elementary bodies (0.5 µm in diameter) frequently contain electron-translucent oblong laminar structures, possess a five-layer cell wall, and show a star-like morphology with 3–7 branches in transmission electron micrographs, which possibly represents a fixation artifact due to some unique cell-wall properties (Thomas et al., 2006).

List of species of the genus *Criblamydia*1. ***Criblamydia sequanensis*** Thomas, Casson and Greub 2006, 2131.

sequ.a.nen'sis.L. n. *Sequana* Latin name of the river Seine (France); N.L. fem. adj. *sequanensis* of or belonging to *Sequana* from which the type strain was recovered.

The characteristics of the sole member of the genus and species are the same as that provided for the genus description. Its isolation by co-culture with amoebae in the presence of ampicillin and vancomycin suggests resistance to these antibiotics. The 16S rRNA-targeted oligonucleotide probe

SS-Crib-0064-a-A-20 (5'-GTTACCCAAATACTTCGTTTC-3') can be used for specific detection using fluorescence in situ hybridization (Thomas et al., 2006).

Type strain: CRIB-18, not yet deposited in a public culture collection.

Sequence accession no. (16S rRNA gene): DQ124300.

Family IV. **Parachlamydiaceae** Everett, Bush and Andersen 1999, 434^{VP}

MATTHIAS HORN

Pa.ra.chla.my.di.a.ce'ae. N.L. fem. n. *Parachlamydia* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Parachlamydiaceae* the *Parachlamydia* family.

The *Parachlamydiaceae* naturally thrive in free-living amoebae (Everett et al., 1999). The family currently contains three genera, *Parachlamydia*, *Neochlamydia*, and *Protochlamydia* (Figure 154). Further symbionts of acanthamoebae, which were identified as being related to the *Parachlamydiaceae* but which were

not described in greater detail, might represent additional genera within this family (Fritsche et al., 2000).

Type genus: Parachlamydia Everett, Busch and Andersen 1999, 435^{VP}.

Genus I. *Parachlamydia* Everett, Bush and Andersen 1999, 435^{VP}

MATTHIAS HORN

Pa.ra.chla.my'di.a. Gr. prep. *para* like, alongside of; N.L. fem. n. *Chlamydia* taxonomic name of a bacterial genus; N.L. fem. n. *Parachlamydia* resembling the genus *Chlamydia*.

Coccoid, nonmotile, obligate intracellular bacteria, 0.4–0.6 µm in diameter. Cells show a **developmental cycle** with morphologically distinct stages and **grow within host-derived vacuoles**. Organisms naturally infect free-living amoebae of the genus *Acanthamoeba*. The genus *Parachlamydia* currently contains but a single species, *Parachlamydia acanthamoebae* (Amann et al., 1997; Everett et al., 1999) (Figure 154). A number of additional symbionts of *Acanthamoeba* species closely related to *Parachlamydia acanthamoebae* have been identified but not described in greater detail (Amann et al., 1997; Collingro et al., 2005a; Heinz et al., 2007; Thomas et al., 2006).

Type species: Parachlamydia acanthamoebae Everett, Bush and Andersen 1999, 435^{VP}.

Further descriptive information

Two distinct morphological forms, almost similar in size (0.4–0.6 µm) and resembling the reticulate and elementary bodies of the *Chlamydiaceae*, have originally been observed inside the host-derived vacuoles in which the bacteria live (Michel et al., 1994). An inclusion typically contains many bacteria. In addition, a third developmental stage, the crescent body, has been proposed and was associated with prolonged co-incubation time of 6 d (Greub and Raoult, 2002a). The crescent body of *Parachlamydia acanthamoebae* has a crescent shape, shows a thickened cell wall similar to the elementary body, and is considered to represent an additional infective stage. Elementary and crescent bodies enter the amoeba host by phagocytosis and differentiate within inclusions in less than 8 h to reticulate bodies (Greub and Raoult, 2002a). All developmental stages except for crescent bodies have also been observed outside of inclusions (directly in the cytoplasm), although the inclusion seemed to be the preferred intracellular niche of *Parachlamydia acanthamoebae*. Bacteria are released from their host cells within vesicles or by lysis of the amoebae. The lytic activity of *Parachlamydia acanthamoebae* was dependent on temperature, showing low levels at temperatures below 30°C and reaching a maximum at temperatures of 32–37°C (Greub et al., 2003c). Infection of acanthamoebae largely inhibited cyst formation (Greub and Raoult, 2002a; Michel et al., 1994).

The *Parachlamydia* species strain OEW1, most closely related to *Parachlamydia acanthamoebae*, has been found naturally sharing its amoeba host cells with a second, betaproteobacterial symbiont related to “*Candidatus Procabacter*” (Heinz et al., 2007). Co-cultivation with amoebae has been a valuable and straightforward method to directly recover *Parachlamydia* species (and other chlamydiae) from complex environmental samples without the need to isolate the natural host (Collingro et al., 2005a; Thomas et al., 2006).

In addition to being found in free-living amoebae, in the laboratory *Parachlamydia acanthamoebae* is able to enter and (to a limited degree to) multiply in Vero cells, in human macrophages, pneumocytes, and lung fibroblasts (Casson et al., 2006; Collingro et al., 2005a; Greub et al., 2003d). In monocyte-derived

macrophages, *Parachlamydia acanthamoebae* trafficked through the endocytic pathway and replicated in a modified vacuole, which was acidic, Lamp-1 positive, and cathepsin negative (Greub et al., 2005). This is fundamentally different from the *Chlamydiaceae*, which bypass the endocytic pathway (Dautry-Varat et al., 2004).

In human macrophages, *Parachlamydia acanthamoebae* did not induce an oxidative burst or pro-inflammatory cytokine production, but showed a cytopathic effect, most likely due to apoptosis (Greub et al., 2003d, 2005a). In contrast, no cytopathic effect was observed on pneumocytes and lung fibroblasts, indicating that rather than macrophages, these or similar cell types might represent replicative niches for *Parachlamydia acanthamoebae* in humans (Casson et al., 2006).

Parachlamydia acanthamoebae, like other chlamydiae, uses an ATP/ADP translocase to thrive as an energy parasite within its host cell (Greub and Raoult, 2003; Schmitz-Esser et al., 2004).

Pathogenesis. Free-living amoebae are considered the natural hosts of *Parachlamydia* species, but there is also accumulating evidence for a potential pathogenicity of these bacteria for humans (extensively reviewed by Greub and Raoult, 2002b; Corsaro and Venditti, 2004; Corsaro and Greub, 2006). “Hall’s coccus”, later identified as a *Parachlamydia acanthamoebae* strain, was one of the first chlamydia-like organisms that has been implicated in human disease. It was originally found in an *Acanthamoeba* species isolated from the source of an outbreak of humidifier fever in Vermont, USA. In a separate study, approximately 1% of patients with pneumonia of undetermined cause showed elevated antibody titers against these bacteria (Birtles et al., 1997). To date, *Parachlamydia* species have primarily been associated with respiratory disease including community acquired pneumonia, bronchitis, and aspiration pneumonia, and also with atherosclerosis (Corsaro et al., 2002; Greub et al., 2003a, b, 2006; Marrie et al., 2001). These studies are purely based on serological (immunofluorescence assays) or molecular evidence (PCR, nested PCR, real-time PCR). *Parachlamydia acanthamoebae* has not yet been isolated from a patient, and Frederick’s and Relman’s revisions of Koch’s postulates for sequence-based identification of microbial pathogens have not yet been fulfilled (Fredericks and Relman, 1996). Considering the slow growth of *Parachlamydia acanthamoebae* in human macrophages, pneumocytes, and lung fibroblasts compared to the *Chlamydiaceae* or the intracellular pathogen *Legionella pneumophila* (a difference of three orders of magnitude), and taking into account evidence for *Parachlamydia acanthamoebae* infections in immunocompromised patients (Greub et al., 2003a; Marrie et al., 2001), *Parachlamydia acanthamoebae* might be an opportunistic respiratory pathogen.

All *Parachlamydia* strains tested were resistant to beta-lactam antibiotics and fluoroquinolones, but were susceptible to macrolides, tetracycline, and rifampicin (Casson and Greub, 2006; Maurin et al., 2002; Michel et al., 1994).

List of species of the genus *Parachlamydia*1. ***Parachlamydia acanthamoebae*** Everett, Bush and Andersen 1999, 435^{VP}

a.can.tha.mo.e'bae. N.L. n. *Acanthamoeba* taxonomic name of a genus of *Acanthamoebidae*; N.L. gen. n. *acanthamoebae* of (living in) members of the genus *Acanthamoeba*.

The characteristics of the sole member of the genus and species are the same as that provided for the genus description. The original host amoeba *Acanthamoeba* sp. Bn₉ was isolated from human nasal mucosa of a healthy volunteer in Germany (Michel et al., 1994). *Parachlamydia acanthamoebae* can also use other *Acanthamoeba* species as hosts.

The 16S rRNA-targeted oligonucleotide probe Bn₉658 (5'-TCCGTTTTCTCCGCCTAC-3') can be used for the detection of *Parachlamydia acanthamoebae* by fluorescence *in situ* hybridization (Amann et al., 1997), but this probe targets also members of the genus *Protochlamydia*.

Several *Parachlamydia acanthamoebae* strains have been described (Berg17, Bn9, "Hall's coccus", OEWI, Seine, UV7) showing nearly identical 16S rRNA gene sequences. The genome sequence of *Parachlamydia acanthamoebae* UV7 is currently being determined.

DNA G+C content (mol%): not available.

Type strain: Bn₉, ATCC VR 1476.

Sequence accession no. (16S rRNA gene): not available.

Genus II. ***Neochlamydia*** Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2001, 1229^{VP} (Effective publication: Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2000, 1236.)

MATTHIAS HORN

Ne.o.chla.my'di.a. Gr. pref. *neo-* (from. Gr. adj. *neos*) new; N.L. fem. n. *Chlamydia* name of a bacterial genus; N.L. fem. n. *Neochlamydia* a new *Chlamydia*, referring to the modest phylogenetic relationship to the *Chlamydiaceae*.

Coccioid, nonmotile, obligate intracellular bacteria, 0.4–0.6 µm in diameter. Bacteria show a **developmental cycle** with morphologically distinct stages and are **directly located in the host cell cytoplasm**. Organisms naturally **infect the amoeba *Hartmannella vermiformis***, but no other free-living amoebae including the *Acanthamoeba* species tested; the only exception was the social amoeba *Dictyostelium discoideum* Berg.₂₅. The genus *Neochlamydia* currently contains a single species, *Neochlamydia hartmannellae* (Figure 154) (Horn et al., 2000).

Type species: ***Neochlamydia hartmannellae*** Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2001, 1229^{VP} (Effective publication: Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2000, 1237.).

Further descriptive information

Two distinct morphological forms, representing different developmental stages, have been observed inside the amoeba *Hartmannella vermiformis* host. Reticulate bodies were irregularly spherical in shape (0.4–0.6 µm in diameter) and showed a granular cytoplasm similar to the reticulate bodies of members of the *Chlamydiaceae*. The coccioid elementary bodies were of similar size (0.5–0.6 µm in diameter). In contrast to all other chlamydiae known so far, *Neochlamydia hartmannellae* did not seem to be located within inclusions, but directly in the cytoplasm of its host cell, indicating that these organisms

possess an escape mechanism from the phagosome (Horn et al., 2000).

Infection of the amoeba *Hartmannella vermiformis* with *Neochlamydia hartmannellae* suppressed cyst formation and led to rapid lysis of the amoeba host within 5 d. This suggests a limited adaptation of host and parasite, possibly due to a relatively short evolutionary relationship, and might indicate the existence of alternative protist hosts for *Neochlamydia hartmannellae* in the environment (Horn et al., 2000).

Bacteriophage-like particles have been observed by electron microscopy in abnormal, enlarged *Neochlamydia hartmannellae* cells (up to 1.3 µm in diameter). This putative bacteriophage (Neo-Ph/1) is 68 nm in diameter, much larger than known chlamydia phages of the genus *Chlamydia microvirus* (Schmid et al., 2001).

Pathogenesis. *Neochlamydia hartmannellae* is primarily a parasite of amoebae. *Neochlamydia hartmannellae* has also been identified as possible causative agent of epitheliocystis in fish (Draghi et al., 2007; Meijer et al., 2006). In addition, there is preliminary molecular evidence for an association with feline ocular disease (von Bomhard et al., 2003). To date, there is no evidence for an association of *Neochlamydia hartmannellae* with disease in humans. *Neochlamydia hartmannellae* is resistant to the quinolone ciprofloxacin (Casson and Greub, 2006).

List of species of the genus *Neochlamydia*1. ***Neochlamydia hartmannellae*** Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2001, 1229^{VP} (Effective publication: Horn, Wagner, Müller, Schmid, Fritsche, Schleifer and Michel 2000, 1237.)

hart.man.nel'lae. N.L. gen. n. *hartmannellae*, of *Hartmannella* (taxonomic name of a genus of *Hartmannellidae*), referring to the name of the host amoeba, *Hartmannella vermiformis* strain A₁Hsp, in which the organism was first discovered.

The characteristics of the sole member of the genus and species are the same as that provided for the genus description. The original host amoeba (*Hartmannella vermiformis* A₁Hsp) of the type strain has been isolated from a water conduit system of a dental unit in Germany.

The 16S rRNA-targeted oligonucleotide probe S-S-ParaC-0658-a-A-18 (5'-TCCATTTCTCCGCTAC-3') can be used for the detection of *Neochlamydia hartmannellae* by

fluorescence *in situ* hybridization (Horn et al., 2000). This probe also targets two closely related symbionts of *Acanthamoeba* species (Fritsche et al., 2000).

DNA G+C content (mol%): not available.

Type strain: A₁Hsp, ATCC 50802.

Sequence accession no. (16S rRNA gene): AF177275.

Genus III. *Protochlamydia* Horn, gen. nov. (previously known as “*Candidatus Protochlamydia*” Collingro et al. 2005b)

MATTHIAS HORN

Pro.to.chla.my'di.a. Gr. adj. *protos* first, foremost; N.L. fem. n. *Chlamydia* name of a bacterial genus; N.L. fem. n. *Protochlamydia* first *Chlamydia*, referring to the similarity of these bacteria to the chlamydial ancestor.

Coccioid, nonmotile, obligately intracellular bacteria, 0.5–1 µm. Cells show a **developmental cycle** with morphologically distinct stages and **grow within host-derived vacuoles**. Organisms naturally **infect amoebae of the genus *Acanthamoeba***. The genus *Protochlamydia* currently contains a single species, *Protochlamydia amoebophila* (Figure 154) (Collingro et al., 2005b; Fritsche et al., 2000). A 16S rRNA gene sequence showing 97% similarity with the 16S rRNA gene of *Protochlamydia amoebophila* has been deposited at GenBank/EMBL/DDBJ (DQ632609). This sequence represents a second species within the genus *Protochlamydia*, tentatively named *Protochlamydia naegleriophila* (Casson, Michel, Goy, Müller and Greub, unpublished), but no further details have yet been published.

DNA G+C content (mol%): 35.8.

Type species: ***Protochlamydia amoebophila*** Horn, sp. nov. (previously known as “*Candidatus Protochlamydia amoebophila*” Collingro et al. 2005b).

Further descriptive information

The developmental stages of *Protochlamydia* species resemble those of the *Chlamydiaceae*. Elementary bodies are 0.5–0.8 µm in diameter; reticulate bodies are 0.7–1.0 µm in diameter. Bacteria are located inside inclusions, which, in contrast to *Parachlamydia acanthamoebae*, typically comprise only one or very few bacteria. No stages similar to persistent forms of the *Chlamydiaceae* have been observed (Collingro et al., 2005b; Fritsche et al., 2000).

Parachlamydia amoebophila had a cytopathic effect on its original host *Acanthamoeba* sp. UWE25, but also grows in various other *Acanthamoeba* strains, where its life cycle seems to be well coordinated with growth of the amoeba host. *Parachlamydia amoebophila* shows only marginal cytopathic effect on these host cells at temperatures around 20°C, but hampers their multiplication (Collingro et al., 2004). In contrast to *Neochlamydia hartmannellae* and *Parachlamydia acanthamoebae*, infection of *Acanthamoeba* species does not seem to inhibit cyst formation, and *Parachlamydia amoebophila* is occasionally also seen in *Acanthamoeba* cysts (Collingro et al., 2005a; Fritsche et al., 2000). *Parachlamydia amoebophila* is also able to use the social amoeba *Dictyostelium discoideum* as host (Skriwan et al., 2002).

The circular genome of the type strain, *Parachlamydia amoebophila* UWE25, is the largest chlamydial genome available to date (2.4 Mb), contains a low G+C content of 36 mol%, and encodes three rRNA operons (Horn et al., 2004). Based on comparative genome analysis, several metabolic pathways are truncated in *Parachlamydia amoebophila*, and therefore essential building blocks like nucleotides, many amino acids (except for glycine, alanine, serine, aspartic acid, glutamine, glutamic acid, and proline), and several cofactors (except for riboflavin, heme, folate, and menaquinone) need to be acquired from the host cell. Compared to the *Chlamydiaceae*, however, *Parachla-*

mydia amoebophila has generally greater metabolic capabilities. The *Parachlamydia amoebophila* genome, for example, encodes a complete tricarboxylic acid cycle and possesses a more versatile respiratory chain (Horn et al., 2006).

Like other intracellular bacteria, *Parachlamydia amoebophila* uses a variety of transport proteins to compensate for the lack of essential biosynthetic pathways. As an example, five nucleotide transporters are encoded in the *Parachlamydia amoebophila* genome, whose joint action catalyzes the import of RNA nucleotides and the cofactor nicotinamide adenine dinucleotide (Haferkamp et al., 2004, 2006; Schmitz-Esser et al., 2004). In addition, one of these transporters functions as an ATP/ADP translocase importing ATP from the amoeba host in exchange for bacterial ADP and thus serving to parasitize the host's ATP pool (Schmitz-Esser et al., 2004; Trentmann et al., 2007).

Parachlamydia amoebophila encodes a complete gene set for peptidoglycan biosynthesis and the cysteine-rich proteins OmcA and OmcB, but lacks a gene for the major outer-membrane protein OmpA. *Parachlamydia amoebophila* does not cross-react with antibodies against OmpA of members of the *Chlamydiaceae* or the *Chlamydia*-specific lipopolysaccharide epitope (Collingro et al., 2005b; Horn et al., 2004; Horn et al., 2006).

Several proteins that have been implicated in pathogenicity of the *Chlamydiaceae* are encoded in the *Parachlamydia amoebophila* genome. For example, *Parachlamydia amoebophila* possesses proteins targeted to the inclusion membrane (Inc) and expresses the *Chlamydia*-specific protease-like activity factor CPAF. *Parachlamydia amoebophila* also possesses a type three secretions system, distributed among several loci across the genome, which seems to be characteristic for the *Chlamydiae* in contrast to proteobacterial type three secretion systems, which are generally encoded on a plasmid or a single region on the chromosome (Horn et al., 2004; Hueck, 1998; Peters et al., 2007). On the other hand, many proteins considered important for host cell interaction of the *Chlamydiaceae* are missing in *Parachlamydia amoebophila*, e.g., polymorphic membrane proteins (Pmp). *Parachlamydia amoebophila* instead encodes several proteins potentially involved in host cell interaction but absent in the *Chlamydiaceae*, such as a number of leucine-rich repeat proteins and a type four secretion system encoded on a genomic island which has most likely been acquired by lateral gene transfer and might be involved in protein export or conjugative DNA transfer (Greub et al., 2004; Horn et al., 2004).

Phylogenetic analysis suggests that the last common ancestor of *Parachlamydia amoebophila* and the *Chlamydiaceae* lived at least 700 million years ago. This ancient microorganism had, at that time, most likely already lived within a eukaryotic host cell and used several basic mechanisms for host cell interaction which are conserved to date, and which most likely developed during interplay with ancient unicellular eukaryotes (Horn et al., 2004).

Pathogenesis. Free-living amoebae are considered the natural hosts of *Protochlamydia* species. The presence of *Parachlamydia amoebophila* increased the *in vitro* cytopathogenicity of

Acanthamoeba host cells on human fibroblasts (Fritsche et al., 1998). To date, there is no evidence for a direct pathogenic potential of *Parachlamydia amoebophila* for humans.

List of species of the genus *Protochlamydia*

1. ***Protochlamydia amoebophila*** Horn, sp. nov. (previously known as "*Candidatus Protochlamydia amoebophila*" Collingro, Toenshoff, Taylor, Fritsche, Wagner and Horn 2005b).

a.moe'bo.phi.la. N.L. n. *amoeba* an amoeba; N.L. adj. *philus-a-um* (from Gr. adj. *philos -ê-on*) friend, loving; N.L. fem. adj. *amoebophila* amoeba-loving, referring to the intracellular life style within amoebae.

The characteristics of the sole member of the genus and species are the same as that provided for the genus description. The original host amoeba *Acanthamoeba* species UWE25 was isolated from a soil sample in western Washington

State, USA; the current host is *Acanthamoeba* species UWC1 (Fritsche et al., 1993, 1998).

The 16S rRNA-targeted oligonucleotide probe Bn₉658 (5'-TCCGTTTTCTCCGCCTAC-3') can be used for the detection of *Protochlamydia amoebophila* by fluorescence *in situ* hybridization (Amann et al., 1997), but this probe also targets members of the genus *Parachlamydia*.

A complete genome sequence is available for the type strain *Protochlamydia amoebophila* UWE25 (Horn et al., 2004).

DNA G+C content (mol %): 35.8.

Type strain: UWE25, ATCC PRA-7.

Sequence accession no. (16S rRNA gene): AF083615.

Taxonomic note: the correct specific epithet should be *amoebiphila*.

Family V. "Candidatus Piscichlamydiaceae"

MATTHIAS HORN

Pi.sci.chla.my.di.a.ce'ae. N.L. fem. n. *Piscichlamydia* type genus of the family; *-aceae* ending to denote a family, N.L. fem. pl. n. *Piscichlamydiaceae* the *Piscichlamydia* family.

The family "Candidatus Piscichlamydiaceae" is to date solely based on 16S rRNA sequences distantly related to all other members of the *Chlamydiae* (80–83% sequence similarity; Figure 154). The family "Candidatus Piscichlamydiaceae" con-

tains a single genus, "Candidatus Piscichlamydia" (Draghi et al., 2004).

Type genus: "Candidatus Piscichlamydia" Draghi, Popov, Kahl, Stanton, Brown, Tsongalis, West and Frasca 2004, 5286.

Genus I. "Candidatus Piscichlamydia" Draghi, Popov, Kahl, Stanton, Brown, Tsongalis, West and Frasca 2004, 5286

MATTHIAS HORN

Pi.sci.chla.my'di.a. L. n. *piscis*, *-is* fish; N.L. fem. n. *Chlamydia* name of a bacterial genus; N.L. fem. n. *Piscichlamydia* *Chlamydia*-like organism affecting fish.

Coccioid to rod shaped, nonmotile, obligately intracellular bacteria, up to 1.8 µm in length.

Cells show a developmental cycle with morphologically distinct stages similar to those of the *Chlamydiaceae* and thrive inside a host vacuole. Organisms were found within gill lesions of fish and have not yet been obtained in cell culture.

Type species: "Candidatus Piscichlamydia salmonis" Draghi, Popov, Kahl, Stanton, Brown, Tsongalis, West and Frasca 2004, 5286.

Further descriptive information

Two distinct morphological forms, representing different developmental stages, have been observed inside the host-derived vacuole that surrounded the bacteria. The proposed reticulate bodies are elongate, oblong, or spherical (0.7–1.8 µm) with even, granular cytoplasm resembling the reticulate bodies of *Chlamydiaceae*. The second morphological stage was round

to oval (0.6–0.8 µm) with a central, condensed cytoplasm. Although these forms were proposed to represent intermediate bodies, they might in fact correspond to elementary bodies as no other stage resembling the elementary bodies of other chlamydiae has been observed (Draghi et al., 2004). Immunogold labeling experiments using antibodies against the *Chlamydia* genus-specific LPS epitope KDOp-(2–8)-KDOp-(2–4)-KDO suggested the presence of a similar trisaccharide in the LPS of "Candidatus Piscichlamydia salmonis" (Draghi et al., 2004).

Pathogenesis. "Candidatus Piscichlamydia salmonis" has been found infecting the gills of salmonid fish (Atlantic salmon, *Salmo salar*) in marine water, forming proliferative lesions and inclusions in hypertrophied epithelial cells at the tips of lamellae. "Candidatus Piscichlamydia salmonis" has been suggested to represent one possible etiological agent of epitheliocystis in fish from marine environments (Draghi et al., 2004).

List of tentative species of the genus “*Candidatus Piscichlamydia*”

1. “*Candidatus Piscichlamydia salmonis*” Draghi, Popov, Kahl, Stanton, Brown, Tsongalis, West and Frasca 2004, 5286
sal.mo'nis. L. n. *salmo*, -onis salmon; L. gen. n. *salmonis* of salmon (infecting fish of the genus *Salmo*).

The genus “*Candidatus Piscichlamydia*” is based on the description of “*Candidatus Piscichlamydia salmonis*” (Draghi et al., 2004) (Figure 154).

Sequence accession no. (16S rRNA gene): AY462244.

Reference

Characterization of “*Candidatus Piscichlamydia salmonis*” (order *Chlamydiales*), a chlamydia-like bacterium associated with epitheliocystis in farmed Atlantic salmon (*Salmo salar*). J. Clin. Microbiol. 42: 5286–5297.

Family VI. *Rhabdochlamydiaceae* fam. nov.

MATTHIAS HORN

Rhab.do.chla.my.di.a.ce'ae. N.L. fem. n. *Rhabdochlamydia* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Rhabdochlamydiaceae* the *Rhabdochlamydia* family.

Members of the family *Rhabdochlamydiaceae* have been found infecting arthropods, but can also thrive in amoebae and are moderately related to the *Simkaniaceae* (around 86% 16S rRNA sequence similarity; Figure 154). The family *Rhabdochlamydiaceae*

is a sister family of the *Simkaniaceae* and contains a single genus, *Rhabdochlamydia*.

Type genus: ***Rhabdochlamydia*** gen. nov.

Genus I. ***Rhabdochlamydia*** Horn, gen. nov. (previously known as “*Candidatus Rhabdochlamydia*” Kostanjšek, Štrus, Drobne and Avguštin 2004)

MATTHIAS HORN

Rhab.do.chla.my'di.a. Gr. fem. n. *rhabdos* stick, rod; N.L. fem. n. *Chlamydia* taxonomic name of a bacterial genus; N.L. fem. n. *Rhabdochlamydia* referring to the rod-like morphology of the elementary bodies of this genus.

Coccioid to rod shaped, nonmotile, obligately intracellular bacteria, 0.35–4 µm. Cells show a **developmental cycle** with morphologically distinct stages and **grow within host-derived vacuoles**. Organisms naturally **infect arthropods** and are differentiated from all other chlamydiae by the **rod-shaped elementary body**, which has a **five-layer cell wall** and shows one or two **electron-translucent oblong structures in the cytoplasm** (Figure 162). The genus *Rhabdochlamydia* is based on the description of “*Candidatus Rhabdochlamydia porcellionis*” and *Rhabdochlamydia crassificans* (Corsaro et al., 2007; Kostanjšek et al., 2004) (Figure 154).

Type species: ***Rhabdochlamydia crassificans*** Horn, gen. nov. (previously known as “*Candidatus Rhabdochlamydia*” Kostanjšek, Štrus, Drobne and Avguštin 2004).

Further descriptive information

Three distinct morphological forms, representing different developmental stages, have been observed inside the host-derived vacuoles in which the bacteria live. Reticulate bodies are spherical in shape (0.9–4 µm in diameter), show a granular cytoplasm, resemble the reticulate bodies of members of the *Chlamydiaceae*,

and have a three-layer cell wall. The elementary bodies are rod-shaped (0.25–0.7 µm long, with a diameter of 0.1–0.25 µm), electron-dense, possess a five-layer cell wall, and show one to two electron-translucent, elongate inclusions in the cytoplasm, generally at one pole (Corsaro et al., 2007; Kostanjšek et al., 2004). Transitional stages between reticulate and elementary bodies, intermediate bodies, have been observed, which largely resemble reticulate bodies, but are smaller in size (0.35–0.65 µm) and show an electron-dense central area (Kostanjšek et al., 2004). Elementary bodies with a similar morphology have previously been described for organisms classified as *Rickettsiella* species in spiders and scorpions (Morel, 1976; Weiss et al., 1984).

Pathogenesis. The *Rhabdochlamydia* species identified to date have been found in the hepatopancreas of the terrestrial isopod *Porcellio scaber* (Kostanjšek et al., 2004) and the fat body of the cockroach *Blatta orientalis*, respectively (Corsaro et al., 2007). These arthropods might represent the natural hosts for the respective *Rhabdochlamydia* species, which can co-exist with their hosts in an asymptomatic state, but which may also cause disease, e.g., abdominal swelling (Corsaro et al., 2007; Kostanjšek et al., 2004).

List of species of the genus *Rhabdochlamydia*

1. ***Rhabdochlamydia crassificans*** Corsaro, Thomas, Goy, Venditti, Radek and Greub 2005, 226
cras'si.fi.cans. L. adj. *crassus* thick; L. ending -*ficans* (from L. v. *facio facere* to make) making; N.L. adj. *crassificans* making thick, referring to the body swelling of cockroaches upon infection.

The characteristics are the same as for the genus, except noted. Reticulate bodies are about 0.9 µm in diameter;

elementary bodies are about 0.5 µm × 0.25 µm (Corsaro et al., 2007); two intermediate stages have been described resembling the elementary and the reticulate bodies, respectively (Radek, 2000).

Rhabdochlamydia crassificans was found infecting the cockroach *Blatta orientalis*. Infection occurred mainly in the fat body but also systemically, affecting gut epithelium,

Malpighian tubules, blood cells, and ovarioles (Radek, 2000). Cells infected with *Rhabdochlamydia crassificans* contained several small to large inclusions (7–50 µm in diameter with single vacuoles as large as 100 µm). Mycetocytes containing the primary cockroach symbiont *Blattabacterium* species were also observed to be co-infected with *Rhabdochlamydia crassificans* (Radek, 2000). Infection of *Blattabacterium orientalis* with *Rhabdochlamydia crassificans* caused severe abdominal swelling resulting in individuals unable to move and with a decreased life expectancy (Radek, 2000), but asymptomatic cockroaches were also found (Corsaro et al., 2007). On the population level, infection with *Rhabdochlamydia crassificans* led to stagnation of reproduction of *Blattabacterium orientalis* colonies. Transmission of *Rhabdochlamydia crassificans* may be transovarial or via feces.

Rhabdochlamydia crassificans can be grown in the amoeba *Acanthamoeba castellanii* ATCC 30010 (Casson et al., 2007).

Rhabdochlamydia crassificans has previously been classified as *Rickettsiella crassificans* (Radek, 2000).

Type strain: CRIB-01 (not yet deposited in a public culture collection).

Sequence accession no. (16S rRNA gene): AY928092.

2. “*Candidatus Rhabdochlamydia porcellionis*” Kostanjšek, Štrus, Drobne and Avguštin 2004, 548

por.cel.li.o'nis. L. n. *porcellio*, -onis a cheslip, woodlouse, sowbug, and also a zoological genus name (*Porcellio*); L. gen. n. *porcellionis* of *Porcellio* (infecting terrestrial isopods of the genus *Porcellio*).

Not yet obtained in cell culture. The characteristics are the same as for the genus, except as noted.

Reticulate bodies are 1–4 µm in diameter; intermediate bodies are 0.35–0.65 µm. Mature elementary bodies are 0.25–0.7 µm in length and 0.1–0.15 µm in diameter (Kostanjšek et al., 2004).

“*Candidatus Rhabdochlamydia porcellionis*” was found infecting the hepatopancreas of the terrestrial isopod (“woodlouse”) *Porcellio scaber*. Infection can be noted by characteristic, white spots (100–200 µm in diameter) along the glands, which represent enlarged epithelial cells with multiple smaller or a single large vacuole (up to 30 µm in diameter) containing different developmental stages of the bacteria, which are eventually released into the gland lumina. Infection of *Porcellio scaber* with “*Candidatus Rhabdochlamydia porcellionis*” leads to a reorganization of the structure and function of the digestive glands and possibly to death of the infected individuals although no differences in feeding rate has been observed between uninfected and infected individuals during a period of 5 d. Between 0 and 10% of individuals in natural *Porcellio scaber* populations are generally infected (Drobne et al., 1999; Kostanjšek et al., 2004).

“*Candidatus Rhabdochlamydia porcellionis*” has previously been classified as *Chlamydia isopodii* (Shay et al., 1985) or placed in the polyphyletic genus *Rickettsiella* (Drobne et al., 1999).

The 16S rRNA-targeted oligonucleotide probe S-S-RhaC-0992-a-A-20 (5'-GATGCTGTCCTTTGCATTTC-3') can be used for specific detection using fluorescence *in situ* hybridization (Kostanjšek et al., 2004).

Sequence accession no. (16S rRNA gene): AY223862.

Family VII. Simkaniaceae Everett, Bush and Andersen 1999, 435^{VP}

MATTHIAS HORN

Sim.ka.ni.a.ce'ae. N.L. fem. n. *Simkania* type genus of the family; -aceae ending to denote a family.
N.L. fem. pl. n. *Simkaniaceae* the *Simkania* family.

The family *Simkaniaceae* originally comprised but a single genus, the type genus *Simkania* (Everett et al., 1999). A second genus, *Fritschea*, based on the description of “*Candidatus Fritschea bemisiae*” and “*Candidatus Fritschea eriococci*” is added (Everett et al., 2005; Thao et al., 2003). The recently

identified endosymbiont of the enigmatic marine animal *Xenoturbella* constitutes a third genus within the family *Simkaniaceae*, but awaits formal description (Israelsson, 2007) (Figure 154). The 23S rRNA genes of all known members of the *Simkaniaceae* (including the *Xenoturbella* symbiont, but with the exception

of "*Candidatus Fritschea eriococci*") contain group I introns encoding a DNA endonuclease most similar to group I introns in the 23S rRNA of chloroplasts and mitochondria of algae.

The family *Simkaniaceae* is a sister family of the *Rhabdochlamydiaceae*.

Type genus: Simkania Everett, Bush and Andersen 1999, 435^{VP}.

Genus I. *Simkania* Everett, Bush and Andersen 1999, 435^{VP}

PATRIK M. BAVOIL, RICHARD S. STEPHENS, BERNHARD KALTENBOECK AND CHO-CHOU KUO

Sim.ká'ni.a. N.L. fem. n. *Simkania* arbitrary name formed from the personal name Simona Kahane, the discoverer of the type species.

Coccoid or slightly elongated, nonmotile, obligately intracellular organisms, 0.2–0.7 µm in diameter. Cells grow in the cytosolic compartment of eukaryotic host cells within membrane-bound vacuoles termed inclusions. Organisms are differentiated from members of the *Chlamydiaceae* by their resistance to penicillin, the infectivity of both replicating and proposed differentiated forms toward eukaryotic cells, and their infectivity of amoebae.

DNA G+C content (mol%): 42.5.

Type species: Simkania negevensis Everett, Bush and Andersen 1999, 435^{VP}.

Further descriptive information

Isolation, growth, cell morphology, and other characteristics. The expanding scientific literature is reviewed in which *Simkania* illustrates significant structural and biological differences from the *Chlamydiaceae*. First isolated as a contaminant of cell culture (Kahane et al., 1993), *Simkania negevensis* also grows in Vero cells, HeLa cells, and trophozoites of acanthamoebae, and survives in amoebal cysts (Kahane et al., 2001).

Rapid growth occurs in Vero cells for a period of 2–3 d followed by a "stationary" phase of 8 or more days (Kahane et al., 1999). Growing simkaniiae are characterized by replicating and proposed differentiated forms that are 0.2–0.3 and 0.3–0.7 µm in diameter, respectively; both forms are infectious (Kahane et al., 2002). Differentiated forms differ from chlamydial elementary bodies structurally in that they appear either as coccoid or slightly elongated with an electron-dense, eccentrically located nucleoid (Kahane et al., 2002). Replicating forms are more pleomorphic than their chlamydial counterparts and often appear elongated. Multiple *Simkania* inclusions are observed in each infected cell. The genome size of *Simkania negevensis* has been determined to be 1.7 Mbp.

Pathogenesis. Although a direct causal relationship has not been demonstrated, *Simkania negevensis* has been serologically associated with community-acquired pneumonia in adults (Lieberman et al., 1997), bronchiolitis in infants (Kahane et al., 1998), and acute exacerbation of chronic obstructive pulmonary disease (Lieberman et al., 2002). The species is resistant to penicillin (Kahane et al., 1993).

List of species of the genus *Simkania*

1. ***Simkania negevensis*** Everett, Bush and Andersen 1999, 435^{VP}
ne.ge.ven'sis N.L. fem. adj. *negevensis* of or pertaining to the Negev Desert in Israel.

The characteristics of the sole member of the genus and species are the same as that provided for the genus description.

DNA G+C content (mol%): 42.5 (T_m).

Type strain: Z, ATCC VR-1471.

Sequence accession no. (16S rRNA gene): U68460.

Genus II. "*Candidatus Fritschea*" Everett, Thao, Horn, Dyszynski and Baumann 2005

MATTHIAS HORN

Fri'tsche.a. N.L. fem. n. *Fritschea* named after Thomas R. Fritsche, an American physician and parasitologist, in honor of his contributions to our current knowledge on chlamydial diversity.

Coccoid to rod-shaped, nonmotile, obligately intracellular bacteria, up to 2.5 µm in length. Cells show a **developmental cycle** with morphologically distinct stages similar to those of the *Chlamydiaceae*. Organisms were found in whitefly and scale insects, but have not yet been obtained in cell culture. The genus is based on the description of "*Candidatus Fritschea bemisiae*" and "*Candidatus Fritschea eriococci*" (Everett et al., 2005; Thao et al., 2003) (Figure 154).

Type species: "Candidatus Fritschea bemisiae" Everett, Thao, Horn, Dyszynski and Baumann 2005, 1585.

Further descriptive information

Two distinct morphological forms, representing different developmental stages of "*Candidatus Fritschea bemisiae*", have

been observed inside bacteriocytes of the whitefly *Bemisia tabaci*, which also contained gammaproteobacterial primary and secondary symbionts (Costa et al., 1995). The intracellular niche of "*Candidatus Fritschea bemisiae*" has not yet been characterized in much detail; it is currently unclear whether "*Candidatus Fritschea bemisiae*" thrives directly in the cytoplasm or within a host-derived vacuole. The proposed reticulate bodies are elongate (0.7–2.5 µm in length and 0.7–0.8 µm in width) with even, granular cytoplasm resembling the reticulate bodies of *Chlamydiaceae*. Occasionally, filamentous structures can be seen in the cytoplasm of reticulate bodies. The second morphological stage is spherical, much smaller (0.2–0.25 µm in diameter), and very electron-dense (Costa et al., 1995). No morphological data are available for "*Candidatus Fritschea eriococci*".

List of species of the genus *Fritschea*

1. “*Candidatus Fritschea bemisiae*” Everett, Thao, Horn, Dyszynski and Baumann 2005, 1585.

be.mi'si.ae. N.L. gen. fem. n. *bemisiae* of *Bemisia*, discovered in whitefly insects of the genus *Bemisia*.

Not yet obtained in cell culture. The characteristics are the same as for the genus. “*Candidatus Fritschea bemisiae*” has so far only been found in the whitefly insect *Bemisia tabaci* (biotype A). “*Candidatus Fritschea bemisiae*” could not be detected in *Bemisia tabaci* biotypes B and Q (Chiel et al., 2007). A 16.6 kb genome fragment of “*Candidatus Fritschea bemisiae*” has been sequenced, indicating a genomic G+C content of 40 mol% and encoding six proteins most similar to proteins of *Protochlamydia amoebophila* and other chlamydial species (Thao et al., 2003). The 23S rRNA gene of “*Candidatus Fritschea bemisiae*” contains a group I intron similar to the group I intron found in the 23S rRNA of *Simkania negevensis*. The oligonucleotide 5'-GATGCTGTC-CTTTGCATTTTC-3' should be suited for specific detection

of “*Candidatus Fritschea bemisiae*” by fluorescence *in situ* hybridization (Thao et al., 2003).

Sequence accession no. (16.6 kb genome fragment including the rRNA operon): AY140910.

2. “*Candidatus Fritschea eriococci*” Everett, Thao, Horn, Dyszynski and Baumann 2005, 1586

e.ri.o.cocci. N.L. gen. masc. n. *eriococci* of *Eriococcus*, discovered in scale insects of the genus *Eriococcus*.

Not yet obtained in cell culture; no morphological data available. The rRNA genes of “*Candidatus Fritschea eriococci*” have been identified in the scale insect *Eriococcus spuriosus* during a screening of a collection of insects for *Fritschea* species (Thao et al., 2003). The 16S rRNA shows 97% sequence similarity with the 16S rRNA of “*Candidatus Fritschea bemisiae*”. “*Candidatus Fritschea eriococci*” is so far the only member of the family *Simkaniaceae* that does not contain a group I intron in the 23S rRNA gene.

Sequence accession no. (16S and 23S rRNA genes): AY140911.

Family VIII. **Waddliaceae** Rurangirwa, Dilbeck, Crawford, McGuire and McElwain 1999, 580^{VP}

THE EDITORIAL BOARD

Wadd'li.a'ce.ae. N.L. fem. n. *Waddlia* the type genus of the family; -aceae ending to denote family; N.L. fem. pl. *Waddliaceae* the *Waddlia* family.

The family *Waddliaceae* includes the sole genus, *Waddlia* (Rurangirwa et al., 1999) which are **obligately intracellular bacteria of cattle and possibly other animals**. The organisms are classified based upon 16S rRNA gene phylogeny.

DNA G+C content (mol%): not available.

Type genus: **Waddlia** Rurangirwa, Dilbeck, Crawford, McGuire and McElwain 1999, 580^{VP}.

Genus I. **Waddlia** Rurangirwa, Dilbeck, Crawford, McGuire and McElwain 1999, 580^{VP}

THE EDITORIAL BOARD

Wadd'li.a. N.L. fem. n. *Waddlia* arbitrary name derived from the abbreviation WADDL (Washington Animal Disease Diagnostic Laboratory).

Obligate intracellular bacteria in animals. Cells of the type strain were isolated from aborted fetuses of cattle.

DNA G+C content (mol%): not available.

Type species: **Waddlia chondrophila** Rurangirwa, Dilbeck, Crawford, McGuire and McElwain 1999, 580^{VP}.

Further descriptive information

Strains do not react with antisera from other species used for typing the chlamydiae or rickettsiae. The 16S rRNA genes are most closely related to that of the *Chlamydiaceae* because they exhibit 80–90% similarity to strains of that family.

List of species of the genus *Waddlia*1. **Waddlia chondrophila** Rurangirwa, Dilbeck, Crawford, McGuire and McElwain 1999, 580^{VP}

chon.dro'phi.la. Gr. n. *chondros* clump; N.L. fem. adj. *phila* (from Gr. fem. adj. *philē*), friend, loving; N.L. fem. adj. *chondrophila* liking clumps, in reference to the association of the bacterium with mitochondria (the noun mitochondria was coined in 1898 by the microbiologist Carl Benda, from Gr. *mitos* thread and Gr. *chondrion* little granule).

Gram-stain-negative, coccoid bacteria 0.2–0.5 µm in diameter which are **obligately intracellular parasites of cattle**. *Waddlia chondrophila* was isolated from the tissues of a bovine fetus, which was aborted in the first trimester. This organism's description is identical to that of "WSU 86-1044" that was reported by Dilbeck et al. (1990) and Kocan et al. (1990). The species includes only the type strain, WSU

86-1044^T (=ATCC VR 1470^T). The full-length 16S rRNA gene sequence is 15% different from that of *Chlamydiaceae* species. Furthermore, it is 12.8% different from *Parachlamydia acanthamoebae* and 15% different from *Simkania negevensis* thereby justifying its placement in a separate family of the *Chlamydiales* (Everett et al., 1999).

Cells can be grown in bovine turbinate cells (BT) where they produce multiple cytoplasmic vacuoles. BT infection is terminated with tetracycline or chloroform treatment. Cells divide by binary transverse fission. Two developmental cell forms are produced. The dense cell form is infective. The reticulate cell type, usually associated with mitochondria, divides by binary transverse fission.

DNA G+C content (mol%): not available.

Type strain: WSU 86-1044, ATCC VR-1470.

Sequence accession no. (16S rRNA gene): AF042496.

Other organism

1. "Waddlia malaysiensis"

ma.lay.si.en'sis. N.L. fem. adj. *malaysiensis* of or pertaining to Malaysia

Although there are no other validly published species in the genus *Waddlia*, a strain obtained from bats

has been reported. Based upon 16S rRNA gene sequence analyses it is most closely related to *Waddlia chondrophila*. A new species was proposed for the bat parasites, "*Waddlia malaysiensis*", but its name has not been validated (Chua et al., 2005).

NAOMI L. WARD

Planc.to.my.ce.ta.ce'ae. N.L. masc. n. *Planctomyces*, -*etis* type genus of the family; -*aceae* ending to denote a family; N.L. fem. pl. n. *Planctomycetaceae* the *Planctomyces* family.

Gram-stain-negative bacteria observed in, or isolated from, marine, brackish, freshwater and groundwater habitats, as well as soil, peat bog, compost, manure, sewage sludge, and animal (prawn, sponge, coral, lice, termite, human colon) tissues. The occurrence of planctomycetes in high temperature, hypersaline, acidic and alkaline environments has been reported. Some species reported to be associated with the occurrence of algal blooms. The use of 16S rRNA as a molecular marker has suggested that planctomycetes, like other previously obscure taxa such as the acidobacteria and verrucomicrobia, have a cosmopolitan distribution.

Mature cell shape may be tear-drop to pear-shaped, spherical to ovoid, or bulbiform. One species (*Isosphaera pallida*) is multicellular and filamentous. Mature cells may have major multifibrillar (i.e., nonprosthecae) appendages described as stalks, spikes, spines, fimbriae, or bristles. Stalks may be encrusted with iron or manganese oxide deposits; the mechanism (active oxidation or passive deposition) has not been determined. Holdfasts may be present either at the distal end of the stalk or at the narrow or pointed cell pole of mature cell. Formation of rosettes may occur. Crateriform structures and pili present either on reproductive pole of mature cell only, or scattered all over cell surface.

Reproduction, where observed, is by budding. Buds may be motile by means of a monotrichous flagellum inserted either close to the reproductive pole or opposite at the subsequent attachment pole. With regard to shape and distribution of crateriform structures, buds resemble the mother cell.

Relatively few strains have been obtained in pure culture, and the type species of the type genus has never been isolated. Most axenic cultures are aerobic or facultatively anaerobic chemoheterotrophs, with carbohydrates serving as prime sources of carbon for growth. Growth temperature optimum 20–41°C.

Cell envelope (in axenic cultures where analysis has been performed) lacks murein (peptidoglycan). Proteins, often rich in glutamate and cystine/cysteine, are the main cell envelope component. Main isoprenoid quinone is MK-6, a menaquinone, in species which have been analyzed.

Cells may exhibit different types of compartmentalization, unusual in the prokaryotic domains, where the nucleoid and RNA are separated from the remainder of the cell inside a compartment designated the pirellosome. This cell plan has recently been shown to be shared with members of the verrucomicrobia.

Phylogenetic analysis by means of 16S rRNA and other molecular chronometers suggests that the planctomycetes form a monophyletic group only distantly related to other members of the domain *Bacteria*. This distance is supported by the absence of certain otherwise universal oligonucleotides in planctomycete 16S rRNA genes. There is considerable evidence for a superphylum relationship between the planctomycetes, chlamydiae, and

verrucomicrobia; deeper relationships to other phyla are still unclear. Planctomycete 5S rRNA is shorter (109–111 nt) than the “minimal” length of 118 nt found in other prokaryotes, and uniquely lacks an insertion at position 66. Some species display unlinked organization of the *rm* operon.

DNA G+C content (mol%): 50–64.

Type genus: **Planctomyces** Gimesi 1924, 8^{AL}.

Key to the genera of the family *Planctomycetaceae* available in pure culture

1. Single ovoid to spherical cells or rosettes; stalks very common; single polar flagellum; crateriform structures distributed over entire cell surface or reproductive pole; pink to red pigmentation; no capsule; no growth at pH 5; growth at pH 8; no growth at 4°C; growth at 35°C.
→ Genus *Planctomyces*
2. Single ellipsoid cells; stalks short and rarely observed; nonpigmented; capsule present; growth at pH 5; no growth at pH 8; growth at 4°C; no growth at 35°C.
→ Genus *Schlesneria*
3. Single cells or rosettes; stalk absent; single polar flagellum; crateriform structures only on reproductive pole; single large pirellosome; nonpigmented; limited tolerance for saline conditions; cells contain spermidine.
→ Genus *Pirellula*
4. Single cells or rosettes; stalk absent; single large pirellosome; nonpigmented; requires high concentration of sodium chloride and calcium.
→ Genus *Blastopirellula*
5. Single cells or rosettes; stalk absent; single subpolar flagellum; multiple smaller pirellosome structures; pigmented; requires high concentration of sodium chloride and calcium; cells contain putrescine and cadaverine; possesses phosphatidylcholine.
→ Genus *Rhodopirellula*
6. Multicellular, filamentous; stalk absent; no flagellum; motile by gliding; phototactic; forms gas vesicles; crateriform structures distributed over entire cell surface; strictly aerobic; no growth at pH 4.5–5.5; no growth at 4°C; growth above 35°C; no C_{18:2} fatty acids; pink pigmented.
→ Genus *Isosphaera*
7. Single, paired, or shapeless aggregates of spherical cells; stalk absent; no gliding motility; not phototactic; aerobic or microaerophilic; growth at pH 4.5–5.5; growth at 4°C; no growth above 35°C; presence of C_{18:2} fatty acids.
→ Genus *Singulisphaera*
8. Single spherical to ovoid cells; no rosettes; stalk absent; flagellum is polar bundle; crateriform structures distributed

over entire cell surface; evidence for a membrane-bounded nuclear body; sterol synthesis; no growth below pH 5.0.

→ Genus *Gemmata*

9. Single ellipsoidal cells or rosettes; stalk present; single polar flagellum; crateriform structures distributed over entire cell surface; no sterol synthesis; growth below pH 5.0.

→ Genus *Zavarzinella*

Genus I. *Planctomyces* Gimesi 1924, 4^{AL}

NAOMI L. WARD, JAMES T. STALEY AND JEAN M. SCHMIDT

Planc.to.my'ces. Gr. adj. *planktos* wandering, floating; Gr. masc. n. *mukês* fungus; N.L. masc. n. *Planctomyces* floating fungus.

Cells are spherical, ovoid, ellipsoidal, teardrop-shaped, or bulbiform. Often relatively large (ignoring appendages and aggregations, individual vegetative cells range up to 3.5 µm in greatest dimension; immature buds smaller). Have at least one **major multifibrillar (nonprosthecate) appendage** (called a **spike, spire, fascicle, bristle, or stalk**) which does not always have the true stalk function of connecting the cell to a substratum. **Divide by budding.** A **holdfast** which is not always an easily visualized, discrete structure is often present at the distal end of an appendage or at one end of the cell. Often form **homologous aggregations, rosettes or bouquets**, by attachment at the holdfasts in natural habitats. Produce **crateriform surface structures** (surface pits 12 nm in diameter, circumscribed by a grommet with a 30–36 nm outside diameter) and **pili** in characteristic patterns. **Gram-stain-negative bacteria. Lack peptidoglycan. Resistant to β-lactam antibiotics. Divide by budding.** Some species have a **dimorphic life cycle: a sessile mother cell** buds; the bud develops into a **swarmer** that is **motile** by means of a **flagellum** (often **ensheathed**); after maturation, the swarmer loses its flagellum and becomes a sessile, budding mother cell. All cultivated species are aerobes or facultative anaerobes. Occur worldwide in both eutrophic and oligotrophic freshwaters, as well as in estuarine and marine habitats. Sometimes become **encrusted with iron and manganese oxides**. Often **associated** in nature with **algae** and **cyanobacteria**. Although several species have now been **isolated in pure culture**, the type species and various other rosette-forming species **have not been cultivated axenically**. **Carbohydrates** are reported to be the main carbon source for cultivated members of the genus, which are relatively **slow-growing**.

DNA G+C content (mol%): 50.5–57.7.

Type species: Planctomyces bekefii Gimesi 1924, 4^{AL} (*Blastocaulis sphaerica* Henrici and Johnson 1935, 84 (Hirsch 1972); morphotype Ia of the *Blastocaulis-Planctomyces* group (Schmidt and Starr 1980b, 1981).

Further descriptive information

Phylogenetic treatment. The three described *Planctomyces* species for which 16S rRNA gene sequences are available (*Planctomyces brasiliensis*, *Planctomyces limnophilus*, and *Planctomyces maris*), as well as several undescribed species isolated by Heinz Schlesner (Schlesner, 1994) form a phylogenetically coherent group that appears to share its most recent common ancestor with members of the genus *Pirellula* (Gripenburg et al., 1999; Ward et al., 1995). This relationship between the two genera is also reflected in analysis of the 23S rRNA gene (Ward et al., 2000), as well as that encoding the 70-kDa heat-shock protein HSP70 (Ward-Rainey et al., 1996). In contrast, a recent analysis of ribonuclease P RNA (Butler and Fuerst, 2004) does not appear to

support a closer relationship between *Planctomyces* and *Pirellula* than between either genus and the remaining cultivated planctomycete genera, *Isosphaera*, *Rhodopirellula*, *Blastopirellula*, and *Gemmata*.

Cell morphology. Members of the genus *Planctomyces* rank among the most morphologically distinctive of the *Bacteria*, with relatively large cells (up to 3.5 µm in greatest dimension) that assume a spherical, ovoid, ellipsoidal, teardrop-shaped, or bulbiform shape (Tables 169, 170). They exhibit a diversity of major multifibrillar non-prosthecate appendages, variously named spikes, spires, fascicles, bristles, and stalks. In some species, the appendage (stalk) connects the mature cell to its substratum via a holdfast structure, while in others the holdfast is located at the opposite pole of the cell. There are no reports of the stalk serving a reproductive function as found in, for example, the genus *Hyphomonas*. Several species, including the uncultivated *Planctomyces bekefii*, *Planctomyces guttaeformis*, and *Planctomyces stranskae*, form rosettes by adhering at the holdfasts, yielding a distinctive and visually appealing structure. Like other members of their family, *Planctomyces* species exhibit crateriform structures (surface pits 12 nm in diameter, circumscribed by a grommet with a 30–36-nm outside diameter) and pili on their cell surface; the distribution of these features can be diagnostic for the species.

Cell-wall composition. The absence of peptidoglycan as the principal cell-wall structural compound is a distinguishing hallmark of the planctomycetes (Giovannoni et al., 1987a; König et al., 1984; Liesack et al., 1986; Stackebrandt et al., 1986) and shared by all *Planctomyces* species for which cell-wall analysis has been performed. As is the case for other planctomycetes, the cell walls of *Planctomyces* species are proteinaceous, presumably strengthened by the disulfide bonds formed by large quantities of glutamate and cystine/cysteine residues (Liesack et al., 1986).

Lipid composition. Like other planctomycetes, members of the genus *Planctomyces* contain the ester-linked polar lipids characteristic of the *Bacteria* (Kerger et al., 1988). Cellular fatty acids include palmitic, palmitoleic, and oleic acids, as well as 18-carbon monounsaturated C_{18:1} ω9c and C_{18:1} ω11c fatty acids. *Planctomyces* strains tested possess hydroxy fatty acids of the 3-hydroxyeicosanoic acid (C_{20:0} 3-OH) type, but lack 3-hydroxyoctadecanoic acid (C_{18:0} 3-OH) (Sittig and Schlesner, 1993), a fatty acid profile which can be used to distinguish them from members of the genus *Pirellula*. Phospholipid composition has been found to vary between groups of related *Planctomyces* strains (Sittig and Schlesner, 1993).

Polyamine distribution. Gripenburg and coworkers (Gripenburg et al., 1999) demonstrated that polyamine distribution is a useful chemotaxonomic marker at and below the

TABLE 169. Characteristics differentiating species of the genus *Planctomyces*^a

Morphotype <i>sensu</i> Schmidt and Starr	Ia	IIIa	Va	IIIa	IIIb	Vb
Source/habitat	Eutrophic, aquatic, slightly alkaline	Salt pit	Eutrophic, aquatic	Freshwater lake	Marine	Eutrophic, aquatic

species level. *Planctomyces limnophilus* and related strains differ from other planctomycetes tested in containing large amounts of putrescine, rather than spermidine and *sym*-homospermidine, as the dominant polyamine component.

Fine structure. *Planctomyces maris* exhibits the cellular compartmentalization described as characteristic for members of the genus *Pirellula*, namely the presence of a single membrane which divides the cell into the pirellosome (containing the nucleoid and most of the RNA) and the paryphoplasm or polar cap region (Lindsay et al., 1997).

Life cycle. All species available in pure culture have a dimorphic life cycle, characterized by a budding mode of reproduction in which the cell envelope of the daughter bud is formed *de novo* (Staley, 1973; Tekniepe et al., 1981). The resulting daughter cells are motile, by means of a polar to subpolar flagellum, and initially lack stalks. Stalks eventually form during maturation of the daughter cell into its sessile adult form.

Nutrition and growth conditions. Carbohydrates are reported to be the main carbon source for cultivated members of the genus (Tables 169, 170), but *Planctomyces limnophilus* can also use gelatin, while *Planctomyces brasiliensis* utilizes both gelatin and starch (Hirsch and Müller, 1985; Schlesner, 1989). The use of selective carbon and nitrogen sources, e.g., *N*-acetylglucosamine, proved very successful for the isolation and maintenance of a large group of novel isolates (Schlesner, 1994).

Some species, e.g., *Planctomyces maris*, are obligate aerobes, while *Planctomyces limnophilus* and *Planctomyces brasiliensis* are facultative anaerobes, in the sense that they can ferment carbohydrates. As a group, planctomycete species are relatively slow-growing; the shortest recorded generation time is 13 h for *Planctomyces maris* (Bauld and Staley, 1976).

Metabolism and metabolic pathways. There have been virtually no studies of *Planctomyces* metabolism beyond the physiological information garnered for the purpose of species description.

Genetics. There is a limited amount of available information on genome organization in *Planctomyces limnophilus* (Ward-Rainey, 1996) which suggests a single circular molecule of approximately 5.2 Megabases. The same study confirmed the unlinked *rm* (rRNA) operon organization reported by Menke

and coworkers (Menke et al., 1991) and revealed duplicate copies of several housekeeping genes. Other genetic studies of *Planctomyces* species are few and far between: Leary and coworkers (Leary et al., 1998) cloned the *rpoN* gene, encoding alternative sigma factor δ^{54} , from *Planctomyces limnophilus* and demonstrated complementation in a *Salmonella typhimurium* mutant. The presence of this alternative sigma factor, involved in diverse metabolic functions such as nitrogen fixation, hydrogen metabolism, and degradation of aromatic compounds (Kustu et al., 1989), could catalyze future studies of genetic control mechanisms in planctomycetes. The introduction of foreign genes into *Planctomyces maris* from *Pseudomonas putida* has been accomplished (Dahlberg et al., 1998) but establishment of genetic systems for other planctomycetes lies in the future.

Bacteriophages and plasmids. There are only two reports of the presence of bacteriophages in *Planctomyces* species (Gliesche, 1980; Majewski, 1985) which describe the tailed bacteriophage PI-89 from the type strain of *Planctomyces limnophilus* as a member of the family Styloviridae morphogroup B1. The presence of plasmids in the type strain of *Planctomyces limnophilus* is suggested by the observation of a discrete band of high mobility when undigested chromosomal DNA from these strains is subjected to electrophoresis (Ward-Rainey, 1996).

Antibiotic sensitivity. As might be expected from the composition of the cell wall, there is a corresponding resistance of cultivated *Planctomyces* species (and species not yet available in pure culture for which enrichments have been obtained) to antibiotics targeting the synthesis of peptidoglycan, including both β -lactams and non- β -lactams such as D-cycloserine (König et al., 1984; Schmidt and Starr, 1982). β -Lactamase activity was tested and found to be absent in *Planctomyces maris* (as well as *Pirellula marina*) (Claus et al., 2000).

Ecology. *Planctomyces* species, like planctomycetes in general, are now known to be remarkably ubiquitous in their distribution, being found in freshwater and marine habitats, as well as non-aquatic environments such as soil and sewage sludge. Reported geographic locations include European, Asian, North American, South American, and Australian sites. Much of our knowledge of this wide distribution has arisen from molecular microbial ecology studies utilizing 16S rRNA as a marker gene,

but also from a handful of studies (Fuerst et al., 1991; Schlesner, 1994) in which novel isolation methodologies were applied. *Planctomyces* species have been observed in environments in all trophic states, with some reports of higher numbers occurring in association with eutrophic and polluted waters; other reports (Staley et al., 1980) indicated that the ratio of planctomycetes to total heterotrophs is independent of trophic state. In any case, algal or cyanobacterial blooms (often a response to eutrophication) are sometimes followed by increases in numbers of the rosette-forming planctomycetes (*Planctomyces bekefii*, *Planctomyces guttaeformis*, *Planctomyces stranskae*) (Granberg, 1969), perhaps due to the hydrogen sulfide and increased iron and manganese concentrations resulting from phytoplankton decomposition (Kristiansen, 1971). Many rosette-forming species have been reported to accumulate iron and/or manganese on the stalk surface (Schmidt and Starr, 1981, 1982); the mechanism by which these deposits are acquired (passive accumulation vs. active oxidation) is not known. Associations with invertebrates have also been reported; some isolates obtained from the giant tiger prawn *Penaeus monodon* are related to members of the genus *Planctomyces* (Fuerst et al., 1997), with the closest phylogenetic relationship to *Planctomyces brasiliensis*.

The ecological role of *Planctomyces* species is poorly understood, despite their ubiquity, in large part due to the paucity of isolates available in pure culture and the limited scope of physiological research into these strains. Most of the available physiological data were acquired for the purpose of taxonomic description. All available cultured members of the genus are chemoheterotrophs, with carbohydrates serving as the major carbon source.

Taxonomic comments

The genus *Planctomyces* Gimesi 1924 was originally established to accommodate the peculiar aquatic “fungus” observed by Gimesi (1924) in a pond (Lake Lágymányos) in Budapest, Hungary. Gimesi’s organism, named by him *Planctomyces bekefii*, has been reported many times from all over the world (Fott and Komarek, 1960; Heynig, 1961; Hortobágyi, 1965, 1968; Kristiansen, 1971; Olah and Hajdu, 1973; Parra, 1972; Schmidt and Starr, 1978; Teiling, 1942; Tell, 1975; Wawrik, 1952; Zavarzin, 1961).

The notion that this organism was a fungus persisted during the next half century; in fact, several additional species were assigned to this “fungal” genus *Planctomyces* (Hortobágyi, 1965; Skuja, 1964; Wawrik, 1952). This situation was not altered until Hirsch (1972) reported that a freshwater bacterium, described under the name “*Blastocaulis sphaerica*” (Henrici and Johnson, 1935), was identical with *Planctomyces bekefii*. Examination of material from the type localities of both organisms (Schmidt and Starr, 1979b) has provided conclusive evidence that the two organisms are indeed indistinguishable and that both are bacterial rather than fungal. Thus, a bacterial genus (“*Blastocaulis*” Henrici and Johnson 1935) has the dubious distinction of being an exact later synonym of a group which had, for some 50 years, been considered to be a “fungal” genus (*Planctomyces* Gimesi 1924).

Neither the type species (*Planctomyces bekefii*) nor several other species have ever been cultivated axenically, making it difficult to establish the limits of the genus *Planctomyces* solely on the basis of the cultivated members. Because of this taxonomic uncertainty, this rather heterogeneous assemblage has been treated in the past as morphotypes of the *Blastocaulis*–*Planctomyces* group

(Schmidt, 1978; Schmidt et al., 1981). It has been pointed out (Starr and Schmidt, 1989) that some organisms comprising the genus *Planctomyces* most likely do not fit within the boundaries of a single well-conceived bacterial genus. However, the paucity and fragmentary nature of existing knowledge about these bacteria, including unavailability of axenic cultures of the type species of the genus *Planctomyces* (as well as of other key organisms), presently precludes precise delineation of alternative genera. Hence, as in the previous edition of the *Manual* (Starr and Schmidt, 1989), all validly published members of this group are formally classified here as species of the genus *Planctomyces*, within a framework of the vernacular morphotype designations. Where later synonyms have been published, they are referenced here, although good definitive comparative studies are often lacking. Due to the fact that the available phenotypic information differs greatly for cultivated and non-cultivated species, we have presented comprehensive information on all species in Table 169, diagnostic information pertinent to all species in Table 170, and diagnostic information relevant only to cultivated species in Table 171.

Enrichment and isolation procedures

Of the five morphotypes originally described by Schmidt and Starr (1978, 1979a, b, 1981), only representatives of morphotypes III and IV have been isolated in axenic culture. Although they have not yet been isolated axenically, morphotypes I, II, and V have been substantially enriched in the laboratory.

Enrichment and axenic isolation of morphotypes III and IV. Morphotypes III and IV can be enriched (Schmidt, 1978; Schmidt and Starr, 1978, 1981) by adding a small amount of peptone (0.001–0.005%) to freshwater samples placed in beakers covered with clear plastic wrap and held for several days or weeks at room temperature (24–28°C). These budding and appendaged bacteria occur in the surface film, often closely associated with green algae and cyanobacteria. Exposure of the enrichment beakers to ambient light is usually accompanied by development of algae and cyanobacteria. Enrichment of morphotypes III and IV is improved by the presence of these phototrophs and, consequently, by incubation of the samples in the light rather than in the dark. Microscopic examination of the samples is done on a weekly basis by brief contact of a small coverslip with the surface film in the beaker; these preparations are then observed by phase-contrast microscopy, looking for ellipsoidal, ovoid, or spherical budding bacteria possessing a very thin, nonprosthecate major appendage. The appendage may be difficult to visualize by light microscopy, and it may be desirable to touch electron microscope grids to promising surface films and, after negative staining, examine these in the transmission electron microscope. Enrichment cultures containing such organisms in their surface films are suitable candidates for streaking on solid media as described below.

The water agar-coverslip technique (Hirsch et al., 1977) is another useful method for enrichment and isolation of morphotypes III and IV. Relatively nutrient-poor water samples are solidified with 1.8–2.0% agar without any additions (“water agar”); a layer 0.5–0.75 cm deep is placed in the bottom of a Petri dish 20 cm in diameter. In addition, coverslips are coated with the same water agar. Several such coated coverslips, as well as several uncoated ones, are inserted perpendicularly into the solidified layer of agar in the Petri dish. The water sample providing the inoculum is then added in a volume that almost fills

TABLE 171. Diagnostic characteristics of the cultivated species of the genus *Planctomyces*^a

^cData from Kölbl-Boelke et al. (1985).

the Petri dish, leaving only the top 2–3 mm of the coverslips not submerged. The dishes are incubated at room temperatures under ambient light to encourage development of phototrophs which, in turn, seem to enhance development of these budding bacteria. The coverslips that were not coated with water agar are monitored weekly or even more often, by examining them with a phase-contrast microscope for the occurrence of attached budding bacteria. When such bacteria are present, the agar-coated coverslips provide the inoculum for preparation of streak or dilution-spread plates. The locations at which the budding bacteria were observed microscopically to occur on the uncoated coverslips is used as a guide in selecting the regions of the agar-coated coverslips to be plated.

Isolation media. The media used for isolation of morphotypes III and IV are typically low in nutrients. Often the natural water sample itself, with 1.5–1.8% agar added, is suitable. Staley's (Staley, 1981a) MMB agar (0.15% peptone, 0.015% yeast extract, 0.1% glucose, 0.025% ammonium sulfate, 1.0% vitamin solution, 1–2% Hutner's vitamin-free mineral base, 1.5% agar, and distilled water) also is useful. A number of strains have been isolated by using Schmidt's (Schmidt, 1978) medium I (0.02% peptone, 0.01% yeast extract, 0.1% filter-sterilized glucose, 1.0% Hutner's vitamin-free mineral base, 1.0–1.5% agar, and distilled water) and Staley's (Staley, 1981b) PYG medium (0.025% peptone, 0.025% yeast extract, 0.025% glucose, 2.0% Hutner's vitamin-free mineral base, 1.0% vitamin solution, 1.5% agar, and distilled water or artificial sea water). Media with higher concentrations of organic nutrients may also be employed. Sometimes, isolations are facilitated by additions of 5 mM MgSO₄, 0.005 M Trizma buffer (pH 7.5–7.9; Sigma), and/or NaCl or artificial sea water (the latter is particularly desirable for isolations from brackish or marine sources). Use of solidifying agents other than agar may improve the chances of securing axenic cultures.

Direct streaking and spreading of diluted material are the most effective of the various routines used for inoculating the primary isolation plates. Morphotypes III and IV grow rather slowly in culture. Plates must be incubated for 2–5 weeks at room temperature; hence, precautions must be taken to avoid desiccation of the medium, such as sealing the Petri dishes with Parafilm or using plastic bags or boxes. Colonies are very small,

rather inconspicuous, usually quite adherent or cohesive, and white or pigmented (pink or light brown). Patch plates, prepared with the same medium used for the primary isolation, may then be used to produce enough material for microscopic examination and restreaking.

Enrichment of morphotype Ia. The enrichment of morphotype Ia, *Planctomyces bekefii*, the type species of the genus *Planctomyces*, has been facilitated by taking advantage of the considerable resistance of all members of this group to antibiotics which, in other bacteria, affect peptidoglycan integrity. Addition of a β-lactam antibiotic such as ampicillin (about 250 μg/ml) to pond water samples containing detectable but low amounts (1–5 × 10⁴/ml) of morphotype Ia rosettes results, within 3 d, in a 5–6-fold increase in the number of rosettes as determined by direct microscopic counts. This increase may have resulted from (a) release of nutrients or growth factors from other bacteria lysed by action of the antibiotic or (b) inhibition by the antibiotic of organisms antagonistic to the development of *Planctomyces bekefii* rosettes. The effect of β-lactam antibiotics appears to be dependent upon the types and numbers of other microbes present in the water samples. Many workers, including phycologists and limnologists, have reported that occurrence of planktonic morphotype Ia often coincides with occurrence of various algae and cyanobacteria. The dominant algae and cyanobacteria present during and immediately preceding *Planctomyces bekefii* blooms in natural aquatic environments may be useful as "helpers" to enhance growth of *Planctomyces bekefii* in co-cultivation trials in the laboratory. Axenic cultivation of *Planctomyces bekefii* (morphotype Ia), the type species of the genus *Planctomyces*, and the closely related "*Planctomyces crassus*" (morphotype Ib) remains a challenge. Some success has been achieved in enriching co-cultures of *Planctomyces bekefii* using dilute peptone media. The accompanying Gram-stain-negative bacterium could be purified but purification of *Planctomyces bekefii* using spent medium of the accompanying bacterium was unsuccessful (J. T. Staley, personal communication).

Enrichment of morphotype II. Morphotype II, an ovoid budding organism with a long multifibrillar stalk, occurs individually and in clusters ("bouquets") in pond water enrichments to which 0.001–0.005% peptone has been added. The pond waters in which this relatively uncommon organism occurs are

typically eutrophic. About 1 or 2 weeks after peptone is added to pond waters of this sort, these morphotype II organisms are found in the surface films. They have not been isolated axenically, nor have they been cultivated on any solid medium.

Attempted enrichment of morphotype V. *Planctomyces guttaeformis* (morphotype Va) and *Planctomyces stranskae* (morphotype Vb) are planktonic bacteria bulbiform in shape and characteristically occurring in multicellular rosettes in pond or lake waters where they accompany algal and/or cyanobacterial blooms. They seem not to be inhibited by addition of ampicillin (250 µg/ml); neither do they seem to be enriched by the presence of this antibiotic, as is *Planctomyces bekefii*. Additions of various organic nutrients (e.g., peptones, amino acid mixtures, individual amino acids, vitamin mixtures, and/or individual vitamins) to pond water samples containing easily detectable numbers of morphotype V have not provided any clue to specific enrichment conditions for these bacteria. Their natural aquatic habitats usually have a distinctly eutrophic character, and the number of rosettes of these bacteria often increases significantly (4–5-fold) in such water samples held in the collection bottle for a week or so in the laboratory without any additions (e.g., antibiotics, preservatives, or possible nutrients). No representative of morphotype V has been observed to grow on any solid medium.

Maintenance procedures

The existing axenic cultures, all belonging to morphotypes III and IV, have successfully been preserved by lyophilization of cell suspensions in skim milk. Addition of 10% (v/v) glycerol to liquid cultures of morphotypes III and IV, followed by freezing and

storage at -70°C , has satisfactorily preserved these strains for several months.

Acknowledgements

We gratefully acknowledge the use of text written by M.P. Starr and J.M. Schmidt for the chapter on the genus *Planctomyces* (Starr and Schmidt, 1989) contained in the previous edition of the *Manual*. The sections *Taxonomic comments*, *Enrichment and isolation procedures*, and *Maintenance procedures*, as well as the genus summary and all but one of the species descriptions, are used here virtually unaltered from the previous edition.

Differentiation of species of the genus *Planctomyces*

The species of *Planctomyces* can be differentiated from one another by the features listed in Table 169.

List of species of the genus *Planctomyces*

- 1. *Planctomyces bekefii*** Gimesi 1924, 4^{AL} (*Blastocaulis sphaerica* Henrici and Johnson 1935, 84 Hirsch 1972); morphotype Ia of the *Blastocaulis*–*Planctomyces* group (Schmidt and Starr 1980b, 1981)

be.ke'fi.i. N.L. gen. masc. n. *bekefii* of Békefi, named for Remigius Békefi (1858–1924), cultural historian, university professor, and abbot of the Hungarian Cistercian Order.

Gram-stain-negative, budding bacteria. Cellular shape is spherical. Mature cells are 1.4–1.7 µm in diameter. Each mature cell has a tubular, nonprosthecae stalk (Figure 163) 0.25–0.35 µm wide and varying in length from very short (<0.2 µm) to several micrometers. The tubular stalk is comprised of a regular array (Figure 163) of longitudinally aligned microtubules (12–13 nm in diameter) enmeshed in an osmophilic matrix (Figure 163). The distal end of each stalk is characteristically attached to several other distal stalk tips to form multicellular homologous rosettes (Figure 163), however, no distinctive or obvious holdfast structure can be discerned at the junction. Crateriform surface structures (Figure 163) are uniformly distributed over the entire cell. Numerous cephalotrichous, tapering, multifibrillar spires (Figure 163) emanate from the hemisphere of the cell opposite the site of attachment of the stalk. Pili are present over the entire cell.

Nonmotile. Divide by budding from a site precisely opposite to the pole from which the stalk originates. The

nonstalked and nonmotile daughter cells, after they are released from the mother cell, may associate with the center of the originating or another rosette and subsequently form a stalk, thus resulting in an increased number of stalked cells in a rosette. Stalks may be encrusted with manganese and/or iron oxides (Schmidt et al., 1982). Resistant to β-lactam antibiotics. Rosettes are planktonic, occurring in eutrophic freshwater lakes, ponds, and reservoirs, typically with waters of a slightly alkaline pH. Occurrence usually is concomitant with or subsequent to blooms of various algae and cyanobacteria, especially during the late summer in temperate climates. Mesophilic. Worldwide in distribution. Complete life cycle is unknown, however, nonstalked budding bacteria with morphological and ultrastructural features (shape, size, occurrence and distribution of crateriform surface structures and spires, distinctive cell envelopes) identical to those of *Planctomyces bekefii* occur in clusters in the same aquatic samples. Although the relationship of these nonstalked forms to *Planctomyces bekefii* has not yet been demonstrated conclusively, the circumstantial evidence is strong that they may be immature (i.e., nonstalked) forms of *Planctomyces bekefii*. *Planctomyces bekefii* has not been cultivated axenically; hence, archival (Gimesi, 1924) and modern (Schmidt and Starr, 1980a, b) descriptive type material from the type locality, a pond in the Lágymányos district of Budapest, Hungary, must suffice in place of a type culture.

FIGURE 163. Morphotype I of the *Blastocaulis*–*Planctomyces* group. (a) Morphotype Ia (*Planctomyces bekefii*) from the eutrophic man-made pond at The Lakes, Tempe, Arizona, USA; rosette with several budding cells. 1.0% uranyl acetate; $\times 3960$. (b) Budding cell of morphotype Ia (*Planctomyces bekefii*) from Lake Mendota, Madison, Wisconsin, USA. Note bud, spires, crateriform surface structures, and stalk substructure showing parallel fibrils. 1.0% uranyl acetate; $\times 40,135$. (c) Thin section of cell of morphotype Ia (*Planctomyces bekefii*) from the pond at The Lakes, Tempe, Arizona, showing a tangential section of the tubular stalk as well as a separate transverse section (arrow) of another stalk. Fixed by the acroleinglutaraldehyde procedure of Burdett and Murray (1974) (see also Schmidt and Starr, 1980a); $\times 36,000$. (d) Rosette of morphotype Ib “*Planctomyces crassus*” in a sample from the railroad-bridge pond, Budapest, Hungary, showing heavy metallic oxide encrustation of its stalks (Schmidt and Starr, 1981). 1.0% uranyl acetate; $\times 15,000$. Bars = 1.0 μm .

No species belonging to morphotype II has been validly published, nor has the axenic cultivation of any strain been reported, although substantial laboratory enrichment has been achieved (Schmidt and Starr, 1979a). The unmistakable arrangement into a bouquet of several stalked cells of a typical representative of morphotype II, as sketched by Henrici and Johnson (1935), is reproduced here in Figure 164. This organism was referred to as “*Blastocaulis* sp.” by these authors, with the remark that “specific names are withheld until further studies have been completed” (Henrici and Johnson, 1935). Unfortunately, no further publication about this organism by these authors seems to have appeared.

DNA G+C content (mol%): not determined.

FIGURE 164. Morphotype II of the *Blastocaulis*–*Planctomyces* group. (a) Several morphotype II cells, some with buds, arranged in a typical bouquet, from a dilute peptone enrichment of water from a lake near Hesteskodam, Hillerød, Denmark. These organisms can be found in the surface film or pellicle of such enrichments. $\times 1900$. (b) Drawing of “*Blastocaulis* sp.” (Henrici and Johnson, 1935). $\times 1900$. (c) Two morphotype II organisms, one with a bud and each with a long major appendage (a stalk) terminating in a holdfast (one holdfast is attached to detritus). Several cephalotrichous flagella and numerous crateriform surface structures are found on the budding (nonstalked) hemisphere. Dilute peptone enrichment of water sample from a highly eutrophic pond at the sewage works in Strandfontein, Republic of South Africa. 1.0% uranyl acetate; $\times 11,200$. (d) A budding cell of morphotype II with crateriform surface structures everted as cornicula, as they often do when stained with 1.0% uranyl acetate (Schmidt and Starr, 1979b); pili, several flagella, and the major appendage (a stalk) are evident. Dilute peptone enrichment of water sample from an ornamental fountain, University of the Witwatersrand, Johannesburg, Republic of South Africa. 1.0% uranyl acetate; $\times 51,300$. Bars = 5.0 μm for (a) and (b) and 1.0 μm for (c) and (d).

Type strain: description, not isolated in axenic culture.

Sequence accession no. (16S rRNA gene): not determined.

2. **Planctomyces brasiliensis** Schlesner 1990, 105^{VP} (Effective publication: Schlesner 1989, 161.)

bra.si.li.en'sis. N.L. masc. adj. *brasiliensis* pertaining to the country of Brazil.

Cells are spherical to ovoid, with a diameter of 0.7–1.8 µm. Colonies have a dry and rough surface and a yellow to ochre pigmentation. Growth is optimal between 27 and 35°C, the maximum temperature is less than 38°C. Nitrate is reduced to nitrite under anaerobic conditions. Carbon sources utilized are: D-cellobiose, D(+)-galactose, D(+)-glucose, maltose, D(+)-mannose, melibiose, rhamnose, ribose, trehalose, N-acetylglucosamine, and glucuronate. Carbon sources not utilized: D(-)-fructose, D-fucose, D(-)-lyxose, α-D-melezitose, raffinose, L(-)-sorbitol, D(+)-xylose, methanol, ethanol, glycerol, D(-)-mannitol, D(-)-sorbitol, acetate, fumarate, lactate, malate, pyruvate, succinate, L-glutamic acid, L-glutamine, L-serine, amygdalin, gluconate, and creatinine. Ammonia, nitrate, and N-acetylglucosamine are utilized as a nitrogen source; urea is not utilized. Gelatin and starch are hydrolyzed; DNA and Tween 80 are not. Catalase, cytochrome oxidase, and H₂S are produced. The molecular mass of genomic DNA (strain 1448^T) is 2.81 × 10⁹ Da.

DNA G+C content (mol%): 55.1–57.7 (*T_m*).

Type strain: ATCC 49424, DSM 5305, IFAM 1448, JCM 21570, NBRC 103401.

Sequence accession no. (16S rRNA gene): AJ231190, X81949, X85247.

3. **Planctomyces guttaeformis** (ex Hortobágyi 1965) Starr and Schmidt 1984, 473^{VP} [*Planctomyces guttaeformis* Hortobágyi 1965, 111 emend. Hajdú (Hortobágyi and Hajdú 1984)]; morphotype Va of the *Blastocaulis-Planctomyces* group (Schmidt and Starr 1979a; Starr and Schmidt 1984)

gut.ta.e.for'mis. L. n. *gutta*, -ae a drop; L. gen. n. *guttae* of a drop; L. suff. -*formis* in the form or shape of; N.L. masc. adj. *guttaeformis* drop-shaped.

Gram-stain-negative, budding bacteria. Mature cells are relatively large (2.9–3.0 µm in length, 1.15–1.3 µm for the diameter of the globose end, and 0.6–0.7 µm for the diameter of the cylindrical end). Bulbiform (bulb-shaped; in this case, a cylinder blending into a spherical terminal dilatation; shaped like a common screw-in incandescent lamp). A prominent multifibrillar appendage, a spike (Figure 165), extends from the globose end of the cell. Division is by budding, with a mirror-image bud (Figure 165) formed at the globose end of the cell; the bud is often slightly off center with respect to the longitudinal axis of the mother cell, whereas the spike is usually exactly polar. Numerous crateriform surface structures and fine pili occur on the globose end of the cell (Figure 165). Fine structure is that of a typical bacterium except for the rather thin cell envelope, the spike and its basal attachment site, and the crateriform surface structures. Cells are resistant to β-lactam antibiotics. Occur in rosettes (Figure 165) consisting of as many as a dozen cells attached via holdfasts located at the narrower ends of the several cells. Neither motility nor flagella have been observed. Common in eutrophic aquatic habitats, usually accompanying phototrophs (algae and cyanobacteria).

Species has not been cultivated axenically, though blooms occur in laboratory enrichments. Descriptive type material in Starr and Schmidt (1984). The type locality is a eutrophic man-made pond in a residential district (The Lakes) in Tempe, Arizona, USA. Frequently confused with *Planctomyces stranskae*, from which it can readily be distinguished on the basis of the characteristic cellular sizes and shapes, the presence of a multifibrillar spike in *Planctomyces guttaeformis* and its absence in *Planctomyces stranskae*, and the presence of numerous multifibrillar bristles in *Planctomyces stranskae* and their absence in *Planctomyces guttaeformis*.

DNA G+C content (mol%): not determined.

Type strain: description, not isolated in axenic culture.

Sequence accession no. (16S rRNA gene): not determined.

4. **Planctomyces limnophilus** Hirsch and Müller 1986, 355^{VP} (Effective publication: Hirsch and Müller 1985, 278.) (This taxon is based on two red-pigmented strains belonging to morphotype IIIA of the *Blastocaulis-Planctomyces* group; Schmidt and Starr, 1981. Synonymy is unclear, since direct comparisons of *Planctomyces limnophilus* with nonpigmented morphotype IIIa strains or with the earlier published *Gemmata obscuriglobus* Franzmann and Skerman (1984), a representative of morphotype IIIc of this group, seem not to have been made.)

lim.no'phi.us. Gr. n. *limnos* lake; Gr. masc. adj. *philos* loving; N.L. masc. adj. *limnophilus* lake-loving.

Gram-stain-negative, budding bacteria. Mature cells are spherical to ellipsoidal, 1.1–1.5 µm in diameter. Numerous crateriform structures and pili occur on the cell surface. Mature cells have a braided or twisted, multifibrillar, nonprosthecate stalk (a fascicle) extending from a pole exactly opposite the budding pole; the noncellular end of the fascicle serves as a “holdfast” device. Multiplication is by budding on the pole of the cell distal to the fascicle. Daughter cells are monotrichously and polarly or subpolarly flagellated; the flagellum is attached at or near the pole from which the stalk originates. Nonacidfast; colonies red; do not form endospores.

Temperature range: 17–39°C; optimum: 30–32°C. NaCl tolerance: <1% (w/v). pH tolerance: 6.2–8.0; pH optimum: 6.2–7.0.

The following substances are utilized as carbon sources (0.1% (w/v)): D-glucose, D-galactose, maltose, cellobiose, and N-acetylglucosamine. The following substances are not utilized as carbon sources (0.1% (w/v) except where different concentrations are noted): glucuronic acid, D-fructose, D-ribose, mannitol, starch, dextrin, inulin, salicin, pyruvate, citrate, α-oxoglutarate, succinate, fumarate, malate, formamide, methylamine hydrochloride (0.136%), formate (0.136%), urea (0.09%), methane (0.5%), methanol (0.4%), ethanol (0.4%), lactate, acetate, propionate, tartrate, glutarate, caproate, phthalate, glycerol (0.186%), L-arginine, L-aspartate, DL-alanine, L-glutamate, L-glycine, L-histidine, L-leucine, DL-phenylalanine, L-proline and L-serine. No aerobic acid formation from D-glucose, sucrose, D-fructose, maltose, D-galactose, or mannitol. Anaerobic acid formation from D-glucose, sucrose, maltose, or galactose; no anaerobic acid formation from D-fructose or mannitol. No anaerobic gas formation in the Hugh–Leifson tests.

The following substances are utilized as nitrogen sources at 0.1% (w/v) except where a different concentration is noted:

FIGURE 165. Morphotype V of the *Blastocaulis*-*Planctomyces* group. (a) Stained (Kodaka et al., 1982) preparation of a rosette of morphotype Va (*Planctomyces guttaeformis*), homologous as to cell type, showing the typical bulbiform cellular shape and the prominent spikes. $\times 1800$. (b) Bulbous end of morphotype Va (*Planctomyces guttaeformis*) cell, showing pili, crateriform surface structures, and basal portion of the spike. 1.0% uranyl acetate; $\times 25,200$. (c) Budding cell of morphotype Va (*Planctomyces guttaeformis*) from the pond at The Lakes, Tempe, Arizona, showing pili, crateriform surface structures, and base of the spike. The bud is a mirror image of the bulbiform mother cell. 1.0% uranyl acetate; $\times 27,333$. (d) Stained (Kodaka et al., 1982) preparation showing a rosette, homologous as to cell type, of morphotype Vb (*Planctomyces stranskae*). Note that this organism lacks the spikes typical of morphotype Va but does have a prominent halo of bristles with entrapped bacteria. $\times 1800$. (e) Globose hemisphere of a morphotype Vb (*Planctomyces stranskae*) cell from the pond at The Lakes, Tempe, Arizona, showing the typical multifibrillar bristles. Neither a spike nor the "socket" from which the spike emanates in morphotype Va is present. 1.0% uranyl acetate; $\times 45,000$. (f) Rosette of cells of morphotype Vb (*Planctomyces stranskae*) cells from the pond at The Lakes, Tempe, Arizona, one with a mirror-image bud. Note the numerous multifibrillar bristles on the globose hemispheres of each cell. 1.0% uranyl acetate; $\times 11,560$. Bars = 5.0 μm for (a) and (d); 1.0 μm for (b), (c) and (f); and 0.5 μm for (e).

$(\text{NH}_4)_2\text{SO}_4$ (0.05%), Bacto peptone, Bacto yeast extract, or Casamino acids (vitamin-free). The following substances are not utilized as nitrogen sources: NaNO_2 (0.2–0.69%), NaNO_3 (0.2–0.85%), methylamine hydrochloride (0.675%), and urea (0.46%).

Vitamins not required. The following reactions are positive: nitrate reduction (dissimilatory), gelatin liquefaction, H_2S formation, and tolerance to 30 vol% carbon monoxide. The following reactions are negative: decarboxylation of lysine and arginine, deamination of phenylalanine and lysine, oligocarbophilic growth, urease, nitrification, nitrate reduction (assimilatory), anaerobic gas formation with nitrate, formation of acetoin and indole, growth in or changes of litmus milk, tolerance to 50 vol% carbon monoxide, and extracellular DNase.

Genome size (strain 1008): $2.67 \pm 0.05 \times 10^9$ daltons.

Source: surface water of the freshwater lake Plüßee, Holstein, Germany.

DNA G+C content (mol%): 53.24 ± 0.59 .

Type strain: Mü 290, ATCC 43296, DSM 3776, IFAM 1008.

Sequence accession no. (16S rRNA gene): X62911.

- 5. *Planctomyces maris*** (ex Bauld and Staley 1976) Bauld and Staley 1980, 657^{VP} (morphotype IIIb of the *Blastocaulis*-*Planctomyces* group (Schmidt and Starr, 1981). Other names are sometimes encountered for organisms belonging to morphotype III; most of these names have no taxonomic standing. Two red-pigmented strains belonging to morphotype IIIA provided the basis for the description of the species *Planctomyces limnophilus* by Hirsch and Müller (1985).

A single morphotype IIIc strain is the basis of a description by Franzmann and Skerman (1984) of the genus *Gemmata* and its sole species *Gemmata obscuriglobus*. However, rigorous comparisons of these taxa with *Planctomyces maris* and/or with other presently unnamed representatives of morphotype III (Schmidt and Starr, 1978, 1981) remain to be made. *ma'ris*. L. gen. n. *maris* of the sea.

Gram-stain-negative, budding bacteria. Mature cells are spherical or ellipsoidal, 1.0–1.5 μm in major dimension. Numerous crateriform surface structures and pili (5–6 nm in diameter) are distributed randomly over the entire cell (Figure 166). In the budding process, the newly released daughter cells (0.4 μm in minimum diameter) are usually smaller than mature cells. Mature cells generally have a braided, multifibrillar, nonprosthecae stalk extending from a pole exactly opposite to the budding pole (Figure 166). Individual fibrils (5 nm in diameter) of the multifibrillar stalk, emanating from separate pores at the basal structure when anchored to the cell, are joined into a bundle (a fascicle) to form the stalk, which may be up to 5 μm long. The many finer fibrils, which extend from the distal tip of the stalk, may serve as a “holdfast” device (Figure 166); some stalked cells, joined by the distal tips of their stalks, are depicted here in Figure 166. The daughter cells are motile by a single, subpolar, sheathed flagellum which is attached to the cell at or near the pole from which the stalk originates.

Of marine origin, with an absolute requirement for 1.5–4.0% (w/v) NaCl. Heterotrophic, obligately aerobic, mesophilic (optimum temperature: 30–33°C). Colonies on marine agar (Difco) are white or slightly cream-colored, 2–4 mm in diameter, slightly mucoid, and glistening. Carbon sources utilized: *N*-acetylglucosamine, cellobiose, esculin, furanose, galactose, glucose, glucuronic acid, lactic acid, maltose, mannose, melibiose, pectin, rhamnose, trehalose, and xylose. Vitamins are not required, but colonies grow more rapidly in the presence of peptone and yeast extract than in the glucose-salt medium. Growth is relatively slow, with a minimum doubling time of 13 h at 30°C.

The DNA G+C content of ATCC 29201 is 50.5 mol% (Bauld and Staley, 1976) or 52.0 mol% (M. Mandel, personal communication, 1979) as determined by buoyant density.

Strains essentially identical to *Planctomyces maris* in morphological and ultrastructural features, and probably also related in other ways, have been isolated from freshwater samples originating in many parts of the world (Franzmann and Skerman, 1984; Gebers et al., 1985; Hirsch and Müller, 1985; Hirsch et al., 1977; Schmidt, 1978; Schmidt and Starr, 1978, 1981). With the exceptions of *Gemmata obscuriglobus* Franzmann and Skerman (1984), a taxon based upon a single morphotype IIIc strain not yet compared rigorously with other members of morphotype III, and *Planctomyces limnophilus* Hirsch and Müller (1985), a taxon based solely upon two red pigmented morphotype IIIa strains, none of these strains has as yet been validly named. They do not require 1.5% NaCl.

Genome sizes (renaturation kinetics) of the few strains examined ranged from 2.67–3.65 $\times 10^9$ Da (Kölbel-Boelke et al., 1985); to the extent examined, no peptidoglycan can be detected by chemical analysis (O. Kandler, personal communication, 1979–1980; König et al. (1984) or electron

FIGURE 166. Morphotype III of the *Blastocaulis–Planctomyces* group. (a) Several cells of *Planctomyces maris*, ATCC 29201, morphotype IIIb of the *Blastocaulis–Planctomyces* group. Stained with 1.0% potassium phosphotungstate following fixation with 0.5% glutaraldehyde. A braided, multifibrillar fascicle (a stalk) extends from a pole of each cell, and the distal ends of the fascicles are attached to each other. $\times 8960$. (b) Cell of a morphotype III organism from a freshwater enrichment (water sample from Old Main Fountain, Arizona State University, Tempe, Arizona, USA). The crateriform structures are scattered over most of the cell surface. Note the ellipsoidal cellular shape. The prominent, braided, multifibrillar fascicle with its electron-dense (i.e., heavily stained) holdfast is typical of morphotype III. 1.0% potassium phosphotungstate; $\times 35,100$. (c) Cell of morphotype III from an enrichment (water sample from Willow Springs Lake, northern Arizona), showing a very early state of budding (the tiny protuberance at the pole opposite to the stalk) as well as the typical braided stalk with electron-dense holdfast. 0.5% potassium phosphotungstate; $\times 28,700$. Bars = 1.0 μm for (a)–(c).

microscopy (König et al., 1984; Schmidt and Starr, 1978, 1981), thus correlating with the demonstrated resistance to β -lactam antibiotics (König et al., 1984; Schmidt and Starr, 1980b), existence of other characteristics atypical of ordinary eubacteria (Schmidt and Starr, 1981), and their postulated evolutionary origin (Stackebrandt et al., 1984). Some of these freshwater strains form pink or red colonies, though their colonies are more typically cream colored or white; some develop a brown (melanin-like) pigmentation after several days of growth. The single strain tested was not pathogenic to mice (Famurewa et al., 1983).

DNA G+C content (mol%): 50–52 (Bd).

Type strain: 534-30, ATCC 29201, DSM 8797.

Sequence accession no. (16S rRNA gene): AJ231184, X62910.

6. **Planctomyces stranskae** (ex Wawrik 1952) Starr and Schmidt 1984, 473^{VP} (*Planctomyces stranskae* Wawrik 1952, 448; morphotype Vb of the *Blastocaulis*–*Planctomyces* group (Starr and Schmidt, 1984)

stran'skae. N.L. fem. gen. n. *stranskae* of Stransky; named originally by F. Wawrik in honor of her biology teacher, M.L. Stransky.

Gram-stain-negative, budding bacteria. Mature cells are relatively large (3.0–3.5 µm in length, 1.5–1.7 µm for the diameter of the globose end, about 1.3–1.4 µm for the initial diameter of the conical end, and 1.0–1.1 µm for the diameter of the terminus of the cell). Bulbiform (i.e., bulb shaped; in this case, a truncated cone blending into a spherical terminal dilatation; shaped like a common screw-in incandescent lamp). Numerous multifibrillar appendages, termed bristles (Figure 165), extend from the globose end of the cell; many smaller bacteria are associated with the bristles, especially in preparations made directly from natural samples. Division is by budding, with a mirror-image bud (Figure 165) formed at the globose end of the cell. Numerous crateriform surface structures (Figure 165) occur on

the globose end of the cell; presence of pili is uncertain. Fine structure is that of a typical bacterium, except for a rather thin cell envelope, the crateriform surface structures, and the many multifibrillar bristles. Cells are resistant to β-lactam antibiotics. Occur in rosettes consisting of as many as a dozen cells attached via holdfasts at the narrower ends of the several cells. Neither motility nor flagella have been observed. Common in eutrophic freshwater habitats, usually accompanying phototrophs (algae and cyanobacteria). Metallic oxide encrustations of the cells have been observed in specimens from Austria and Arizona. Species has not been cultivated axenically, though blooms occur in laboratory enrichments. Descriptive type material in Starr and Schmidt (1984). The type locality is a eutrophic man-made pond in a residential district (The Lakes) in Tempe, Arizona, USA. Frequently confused with *Planctomyces guttaeformis*, from which it can readily be distinguished on the basis of the characteristic cellular sizes and shapes, the absence of a multifibrillar spike in *Planctomyces stranskae* and its presence in *Planctomyces guttaeformis*, and the presence of numerous multifibrillar bristles in *Planctomyces stranskae* and their absence in *Planctomyces guttaeformis*.

DNA G+C content (mol%): not determined.

Type strain: description, not isolated in axenic culture.

Sequence accession no. (16S rRNA gene): not determined.

Species *incertae sedis*

1. “**Planctomyces condensatus**” Skuja 1964, 16

Skuja (1964) stated that this organism differs from *Planctomyces bekefii* Gimesi “durch die viel kürzeren und sich zentralwärts nicht merklich verdickten Zellstielchen, die kleineren Kolonien, durch das gewöhnlich solitäre Vorkommen von terminalen Kugelzellen sowie die verhältnismässig mächtige und anscheinend immer auftretende zentrale Eisenhydroxykonkretion.” (“in its much shorter cell stalks which are not markedly thicker towards the center of the rosette; the smaller colonies; the typically solitary occurrence of terminal spherical cells, as well as the relatively heavy and always apparent concretion of the central ferric hydroxide or as well as the relatively heavy and always apparent concretion of iron hydroxide at the center of the rosette.”)

2. “**Planctomyces crassus**” Hortobágyi 1965, 111 (Morphotype Ib of the *Blastocaulis*–*Planctomyces* group; Schmidt and Starr, 1981)

In the German résumé of his paper, Hortobágyi (1965), using the mycological terminology then in vogue, stated that “*Planctomyces crassus*” was distinguished from all other species of the genus *Planctomyces* “durch die Ausbildung der Sporenträger und die aus den Armen hervorschiebenden Sporen” [“by the development of the conidiophores and the conidia which emerge from it”] - a view based on comparisons of the remarkably broad and tapering stalks (in the mycological terminology used by Hortobágyi, these are called “Sporenträger” or “conidiophores”) of “*Planctomyces crassus*” with the rather thin and uniformly dimensioned

stalks of *Planctomyces bekefii*, and of the spherical cells (“Sporen” or “conidia”) of “*Planctomyces crassus*” with the bulbiform cells of *Planctomyces guttaeformis*. Our examination (Schmidt and Starr, 1981) of this relatively uncommon bacterial form (Figure 163) supports the distinctions made by Hortobágyi (1965) and adds others concerning its bacterial nature, the fine structure of the stalk, and deposition of metallic oxides.

3. “**Planctomyces crassus subsp. maximus**” Hortobágyi 1980

Its author stated: “The subspecies differs from *Planctomyces crassus* Hortobágyi in its robust thallus similar to that of *Planctomyces condensatus* Skuja, but its shape is different[,] as is the development of reproductive cells.”

4. “**Planctomyces ferrimorula**” Wawrik 1956, 296

The entire description of this rare organism by Wawrik (1956) follows: “In einer zarten Gallerthülle lagern locker um eine zentrale Eisenoxyhydratausfällung von 1–8 µm diam., 1–100 und mehr farblose kugelige Zellen von 0.5–1.5 µm diam. Das Endstadium der Entwicklung ist ein morulaartiges Gebilde von 12–20 µm diam., in dem sich die Zellen nach allen Richtungen des Raumes dicht an die dunkelbraune Eisen-konkretion angelagert haben. Es wurden auch zusammengesetzte Kolonien beobachtet.” (“1–100 or more colorless spherical cells of 0.5–1.5 µm diameter are stored in a delicate slime layer around a central iron hydroxide deposit/precipitate of 1–8 µm diameter. The final stage of development is a morula-like object of 12–20 µm diameter, in which the cells have attached closely in all directions

around the dark-brown iron accretion. Compound colonies were also observed.”)

5. “*Planctomyces gracilis*” Hortobágyi 1965, 112

This unusual rosette-forming and filamentous organism (Figure 167) is not a member of the *Blastocaulis*–*Planctomyces* group (Starr and Schmidt, 1984).

6. “*Planctomyces hajdui*” Hortobágyi 1980

Its author stated “The species is nearest to *Planctomyces crassus* Hortobágyi but differs from it in its broad thallus and the projecting thinner stalks.”

7. “*Planctomyces kljasmensis*” (Razumov 1949) Hirsch 1972, 110

An accessible description of this organism has been presented by Zavarzin (1961) under the names “*Blastocaulis kljasmensis*” Razumov (1949) and “*Gallionella planctonica*” Krasil’nikov (1949). From Zavarzin’s description, this organism – except for its smaller cells (reported by Zavarzin as spherical and 0.3–0.5 µm in diameter, although he stated that “sometimes larger cells are encountered”) – seems to be similar to iron-encrusted *Planctomyces bekefi*.

FIGURE 167. Rosette of “*Planctomyces gracilis*” Hortobágyi (1965). Water sample from the pond at The Lakes, Tempe, Arizona, USA. This unusual rosette-forming and filamentous bacterium, which lacks crateriform surface structures and multifibrillar appendages, does not belong to the *Blastocaulis*–*Planctomyces* group (Starr and Schmidt, 1984). 1.0% uranyl acetate; ×6710; bar = 1.0 µm.

Genus II. **Blastopirellula** Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1578^{VP}

HEINZ SCHLESNER

Blas.to.pi.rel'lu.la. Gr. masc. n. *blastos* bud, shoot; N.L. fem. n. *Pirellula* name of a bacterial genus; N.L. fem. n. *Blastopirellula* a budding *Pirellula*.

Cells are ovoid, ellipsoidal or pear-shaped, occurring singly or in rosettes by attachment at the smaller cell pole. Cells divide by budding. Buds are produced directly from the broader cell pole of the mother cell; they may appear bean-shaped. **Crateriform structures and fimbriae are found in the upper cell region. Cells have an intracytoplasmic membranous structure (pirellulosome).** Gram-stain-variable. Buds may have a single flagellum inserted subpolarly at the proximal pole. Adult cells are immobile. Strictly aerobic. **Colonies are grayish to brownish white.** Mesophilic. Requires sea water for growth. Nonsporeforming. PHB is not stored. Chemoheterotrophic. Carbon and energy sources are mainly carbohydrates. Cl-compounds are not used. *N*-Acetylglucosamine serves as carbon and nitrogen source. Catalase- and cytochrome oxidase-positive. **The proteinaceous cell wall lacks peptidoglycan.** The major polyamine is *sym*-homospermidine. **The major menaquinone is MK-6.** The major phospholipid is phosphatidylglycerol. The major fatty acids present are C_{15:0}, C_{16:0} iso, C_{16:1} ω7, C_{16:0}, C_{17:1} ω8, C_{17:0}, C_{18:1} ω9, C_{18:1} ω7, C_{18:0}, C_{19:1} ω8, and C_{20:1} ω9.

DNA G+C content (mol%): 54–57 (HPLC).

Type species: ***Blastopirellula marina*** (Schlesner 1986) Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1578 (*Pirella marina* Schlesner 1986, 180; *Pirellula marina* Schlesner and Hirsch 1987, 441).

Further descriptive information

Blastopirellula marina is the only described species of *Blastopirellula*. Morphologically, it is characterized by a polar organization of the cells. The small cell pole (holdfast pole) excretes a sticky substance of still unknown composition which enables the cell to attach to surfaces or to form rosettes. The reproductive pole produces the bean-shaped bud. Crateriform structures are distributed over the entire cell surface of the buds, however, they

are only found around the reproductive pole of adult cells. In the same area, numerous fimbriae are found (Figures 168, 169).

Blastopirellula marina possesses a characteristic type of cell compartmentalization, in which a single membrane (the intracytoplasmic membrane) divides the cell into two separate regions, the pirellulosome and a polar cap region, later termed “the paryphoplasm” (Lindsay et al., 1997; Figure 170). The pirellulosome contains the nucleoid and most of the ribosomes. A structure analogous to the pirellulosome has also been reported in other genera of the *Planctomycetales* (Lindsay et al., 2001).

The cell wall lacks peptidoglycan and possesses a proteinaceous sacculus instead, as was found in all strains of *Planctomycetales* examined so far. This was first reported for several strains of *Planctomyces* and *Pirellula* (then *Pasteuria*; König et al., 1984).

The Gram reaction of untreated adult cells is positive; buds and swarmer cells react negatively. Adult cells also give the negative Gram reaction after washing. The reason might be a glycocalyx as was shown for *Rhodopirellula* and which may retain the dyes (refer to Figure 185).

Blastopirellula is a member of the attached living microflora and, like several other representatives of such immobile bacteria, it produces motile daughter cells, thus exhibiting a biphasic life cycle. After ripening, the bud separates from the mother cell and moves away till it attaches to a substratum. Then the flagellum is released (see Figure 186, below). When there is a high cell density, swarmer cells may form rosettes by contact with their holdfast poles (Figure 171).

The main carbon and energy sources are carbohydrates. Interestingly, *N*-acetylglucosamine, the monomer of chitin, serves as both carbon and nitrogen source. Chitinase activity, however, was not detected.

Though *Blastopirellula* is quite similar to *Pirellula* and *Rhodopirellula* in morphology and physiology, the 16S rRNA sequence

FIGURE 168. Bean-shaped swarmer cell of *Blastopirellula marina* strain SH106^T with single flagellum shows crateriform structures (cr) on the cell surface. Negatively stained with uranyl acetate. Bar = 0.5 μ m.

FIGURE 169. Mature cell of *Blastopirellula marina* strain SH106^T with bud. Crateriform structures (cr) and fimbriae (fi) are seen in the region of the reproductive pole. Negatively stained with phosphotungstic acid. Bar = 1 μ m.

analysis showed less than 90% similarity between the type strains of these genera (refer to Table 174, below). The length of the 5S rRNA of *Rhodopirellula baltica* strain SH1^T is in the range of that for other planctomycetae, i.e. 109–111 bases rather than 118 bases as for the majority of *Bacteria* and *Archaea* (Bomar et al., 1988). The analysis of sequences encoding 23S rRNA also separates the genera *Pirellula* and *Blastopirellula* (Ward et al., 2000). The sequences encoding the 70-kDa heat-shock protein (Ward-Rainey et al., 1997) and the β -subunit of ATP synthase (Rönner et al., 1991) were analyzed and compared to sequences of other bacteria and supported the findings of 16S rRNA analyzes that the planctomycetae were a phylogenetically diverse group within the *Bacteria* (Gripenburg et al., 1999; Ward et al., 1995). The comparison of elongation factor-Tu

proteins from *Blastopirellula marina* and *Isosphaera pallida* with numerous other bacteria (Jenkins and Fuerst, 2001) did not support a close relationship between planctomycetes and chlamydiae (the only other group bacteria with a cell wall lacking peptidoglycan) that had been proposed earlier as sister taxa (Weisburg et al., 1986).

The presence of an extrachromosomal element was detected by pulsed field gel electrophoresis (PFGE) of undi-

gested chromosomal DNA (Ward-Rainey, 1996). Physical mapping of the genome of *Blastopirellula marina* using probes for housekeeping genes indicated that the genes encoding 16S rRNA and 23S rRNA are separated in the genome and that more than one chromosomal locus exists for several of the genetic markers (Ward-Rainey, 1996). Unlinked *rrn* organization had been previously reported by Liesack and Stackebrandt (1989).

Blastopirellula marina can be considered as a marine bacterium as it does not grow in freshwater media. Essential components of artificial sea water were Ca^{2+} , Na^{+} , and Cl^{-} . Seven strains were isolated from the brackish water of Kiel Fjord and Schlei Fjord (both part of the Baltic Sea) over a period of 15 years, suggesting that these bacteria belong to the autochthonous microflora of this habitat (Schlesner et al., 2004).

Enrichment and isolation procedures

Adult cells are normally attached to surfaces and so mainly swarmer cells are sampled from the free water column. For this reason, an enrichment of cells is necessary before starting isolation attempts. Three methods of enrichment have been successfully used (Schlesner, 1986): (a) 100 ml samples with 0.05% glucose in 250 ml Erlenmeyer flasks with cotton plugs were kept aerobically at room temperature (20–23°C) in daylight, (b) as in (a) but the substrate was 0.1% *N*-acetylglucosamine + 100 µg/ml ampicillin, (c) the Petri-dish method (Hirsch et al., 1977; Schlesner, 1994): The bottom of a 20 cm diameter glass Petri dish was covered with a 2 cm layer of sterilized water agar before adding the water sample. Sterilized cover glasses with or without water agar coat were placed vertically and partially into the agar layer and monitored microscopically from time to time. As soon as the desired bacteria had appeared on such sample cover glasses, other cover glasses were taken out for agar streak isolations.

Streaks can be performed on media M13, M13a or M30. The addition of ampicillin and cycloheximide (0.2 mg/l each) reduces growth of ampicillin-sensitive bacteria and of fungi.

Medium 13 (Schlesner, 1986) (g/l or ml/l) contains: peptone, 0.25; yeast extract, 0.25; glucose, 0.25; artificial sea water (ASW; Lyman and Fleming, 1940, 250); vitamin solution no. 6 (Staley, 1968), 10; Hutner's basal salts medium (HBM; Cohen-Bazire

et al., 1957) 20; 0.1 M Tris/HCl pH 7.5, 50 ml; distilled water, 670. The recipes of the other media are given in the Genus *Rhodopirellula* chapter, below.

Maintenance procedures

Besides the media mentioned above, M13f is a suitable culture medium. Addition of ampicillin and cycloheximide is not necessary for pure cultures. The optimum incubation temperature is 30°C.

The strains grown on slants can be kept at 4–5°C for at least 3 months. They are easily revived from lyophilized cultures and can be stored at –70°C in a solution of 50% glycerol in the culture medium.

Differentiation of the genus *Blastopirellula* from other closely related taxa

Properties of the type strains of *Rhodopirellula baltica*, *Blastopirellula marina*, and *Pirellula staleyi* that allow differentiation of the three genera are summarized in Table 174.

oxygen as the terminal electron acceptor. **Colonies have pink pigmentation.**

Cell walls of the type species are proteinaceous and do not possess detectable peptidoglycan. **Crateriform structures on cell surface are uniformly distributed over the cell. In thin sections of chemically fixed or cryosubstituted cells and freeze-fracture replicas, nucleoids are surrounded by an envelope consisting of two closely apposed membranes** which are contained within a region of cell cytoplasm bounded in turn by an intracytoplasmic membrane. Via phase-contrast light microscopy, this nuclear region may appear as an inclusion of different phase refractility. Cells possess the shared planctomycete cell plan, i.e., cell is compartmentalized into a ribosome-free paryphoplasm and ribosome- and nucleoid-containing pirellulosome separated via a single intracytoplasmic membrane. **16S rRNA sequence has a characteristic insertion absent in other planctomycetes.**

DNA G+C content (mol%): 64.4 ± 1.0 (*T_m*).

Type species: Gemmata obscuriglobus Franzmann and Skerman 1985, 375^{VP} (Effective publication: Franzmann and Skerman 1984, 266.).

Further descriptive information

Cells reproduce by budding from one pole to produce a smaller daughter cell of similar shape attached via a narrow region to the mother cell (Figure 172).

Cells possess crateriform structures distributed uniformly over cell surface (Figure 173), multitrichous flagella (emerging as a tuft from one side of the coccus in *Gemmata obscuriglobus*), and may also possess fimbriae (Figure 174). Crateriform structures are retained in cell envelopes isolated after treatment with 10% sodium dodecyl sulfate, and the proteinaceous cell wall lacks peptidoglycan as indicated by the absence of muramic acid and diamino pimelic acid (Stackebrandt et al., 1986). Alignments

FIGURE 172. Phase-contrast micrograph of budding *Gemmata obscuriglobus* cells grown for 5 d in PYGV broth. Bar = 10 μm.

FIGURE 173. Transmission electron micrograph of cell of *Gemmata obscuriglobus* negatively stained with ammonium molybdate, showing crateriform structures with uniform distribution over the cell surface. Bar = 1 μm.

of the 16S rRNA sequence of *Gemmata obscuriglobus* and related strains display a characteristic insertion of at least ten bases between *Escherichia coli* position 998 and 999 relative to sequences of other strains due to a unique secondary structure bulge loop (Liesack and Stackebrandt, 1992; Wang et al., 2002). At least two distinct *Gemmata* strains, *Gemmata obscuriglobus* and *Gemmata* Wa1-1 (a strain with 93% 16S rRNA similarity to *Gemmata obscuriglobus* and therefore possibly a distinct species) are capable of synthesizing sterols including lanosterol and parkeol, via squalene monooxygenase and oxidosqualene cyclase (Pearson et al., 2003). Draft genome sequences exist for *Gemmata obscuriglobus* and for *Gemmata* strain Wa1-1. Genes involved in C₁ transfer mediated by methanopterin and methanofuran are present in *Gemmata obscuriglobus* and in another member of the clade of organisms clustering with *Gemmata obscuriglobus* in phylogenetic trees, *Gemmata* Wa1-1 (Chistoserdova et al., 2004).

FIGURE 174. Transmission electron micrograph of cell of *Gemmata obscuriglobus* negatively stained with ammonium molybdate, showing a multitrichous tuft of flagella emerging from a restricted region. Bar = 500 nm.

Enrichment and isolation procedures

The type strain was isolated from a freshwater inoculum (derived from Maroon Dam, southeast Queensland, Australia) using micromanipulation methods of Skerman (1968) using lake water agar (Franzmann and Skerman, 1981). Other strains have been isolated using a soil inoculum (Wang et al., 2002). Antibiotics inhibiting peptidoglycan synthesis and protein synthesis in other bacteria have been used effectively for *Gemmata* strain isolation, e.g., M1 isolation medium of Schlesner (1994) supplemented with the antifungals amphotericin B (0.25–0.5 µg/ml) or cycloheximide (20–100 µg/ml), ampicillin at 200 µg/ml or penicillin G at 500 µg/ml and streptomycin at 1000 µg/ml (Wang et al., 2002). Resistance to peptidoglycan-synthesis-inhibiting antibiotics forms the basis for selection, but resistance of at least some strains of *Gemmata* to the protein synthesis-inhibitor streptomycin also aids selectivity of this medium. For experimental studies or broth enrichment cultures, growth in PYGV broth (Staley, 1968) can avoid clumping and allow determination of exponential phase.

Maintenance procedures

Staley's complex medium (pH 7.2) (Staley, 1973) was used for maintenance of *Gemmata obscuriglobus* after initial isolation using lake water agar. Half-strength soil substitution equivalent agar (½ SSE) (Lindsay et al., 1995, 2001) and M1 agar (Schlesner, 1994) have also been used successfully for maintenance.

Frequent subculture (every 2 weeks) may be needed to prevent loss of viability. Cultures can be successfully preserved via freeze-drying and via 20% glycerol suspensions at –70 to –80°C.

Procedures for testing special characters

For the study of cell ultrastructure and the presence of double membrane envelopes enclosing the nucleoids, cryosubstitution is recommended as described by Lindsay et al. (2001).

FIGURE 175. Transmission electron micrograph of thin sectioned cell of *Gemmata obscuriglobus* prepared via high-pressure freezing and cryosubstitution, showing the double-membrane envelope surrounding a condensed fibrillar nucleoid, forming the nuclear body characteristic of *Gemmata obscuriglobus* and close relatives. Bar = 500 nm.

Differentiation of the genus *Gemmata* from other genera

Cells of *Gemmata obscuriglobus* and other *Gemmata*-like strains clustering with *Gemmata obscuriglobus* tend to be coccoid rather than ovoid or teardrop-shaped, so are similar to cells of *Planctomyces* and *Isosphaera* but differ from *Pirellula*. Unlike *Isosphaera pallida* which forms filaments exhibiting intercalary budding, *Gemmata* strains are usually single cells or occur with one bud. With respect to internal cell structure, *Gemmata* strains so far examined all display a double-membrane-bounded nucleoid (Figure 175) forming a nuclear body compartment surrounded by an envelope consisting of two membranes closely apposed to each other; this nuclear body is found within the riboplasm of the pirellosome (Fuerst and Webb, 1991; Lindsay et al., 2001; Wang et al., 2002). This double-membrane-bounded nuclear body has not been observed in the genera *Pirellula*, *Blastopirellula*, *Rhodopirellula*, or *Isosphaera* and also does not occur in at least *Planctomyces maris* within the genus *Planctomyces* (Lindsay et al., 2001). *Gemmata obscuriglobus*, at least, does not form a holdfast structure or, unlike *Planctomyces* species, a stalk. *Gemmata* forms a tuft of several flagella (Figure 174), unlike other planctomycetes such as *Pirellula* and *Blastopirellula* with single polar flagella, or *Isosphaera* which is a gliding bacterium not known to possess flagella. Unlike planctomycetes producing only motile swarmer buds, mother cells of *Gemmata* possess flagella and most cells in a young culture are motile whether budding or not.

Gemmata differs from *Pirellula* and *Blastopirellula* in the distribution of the dense circular pits called crateriform structures on its cell surface, which are uniformly distributed in the case of *Gemmata* unlike the polar distribution in *Pirellula*

and *Blastopirellula*, but similar to the uniform distribution in *Planctomyces*. *Gemmata obscuriglobus* possesses a higher DNA G+C content than species of *Pirellula* (56–59 mol%), *Blastopirellula* (53.6–57.4 mol%), *Rhodopirellula* (53–57 mol%), *Planctomyces* (50–58 mol%), and *Isosphaera* (62 mol%).

Taxonomic comments

The characteristic cell compartmentation of *Gemmata* and strains clustering phylogenetically in the *Gemmata* group, involving a double membrane-bounded region containing a fibrillar nucleoid, is found in all cultured strains of this group where this property has been examined via thin sections of cells prepared via cryosubstitution following cryofixation (e.g., via high pressure freezing); see Figure 175. This membrane-bounded structure has been termed a “nuclear body” (though some

confusion with a nonanalogous structure within the eukaryote nucleus with that name is possible if that term is used). It thus appears to be phylogenetically conserved within *Gemmata*-like strains, and it is diagnostic for the genus as it now stands. Double-membrane bounded nucleoids are not present in other planctomycete genera such as *Pirellula*, *Blastopirellula*, *Rhodopirellula*, or *Isosphaera*, or in anammox genera “*Candidatus* Kueningenia”, “*Candidatus* Brocadia”, or “*Candidatus* Scalindua”, and within the genus *Planctomyces* (at least not in *Planctomyces maris*, though the structures of *Planctomyces limnophilus* and *Planctomyces brasiliensis* are too complex to exclude such occurrence). The nucleoid in the other planctomycete genera appears to be enveloped only by the single intracytoplasmic membrane and lies within the ribosome-containing pirellosome compartment bounded by that membrane.

List of species of the genus *Gemmata*

1. ***Gemmata obscuriglobus*** Franzmann and Skerman 1985, 375^{VP} (Effective publication: Franzmann and Skerman 1984, 266.)

ob.scu.ri.glo'bus. L. adj. *obscurus* dark; L. n. *globus* a sphere; N.L. n. *obscuriglobus* a dark sphere.

Spherical to pear-shaped cells, 1.4–3.0 × 1.4–3.0 μm, which form new cells by budding through a narrow attachment site. Cells contain an inclusion of different phase density correlated with a DAPI stain- positive DNA-containing compartment. In thin sections of cryosubstituted cells via transmission electron microscopy, the condensed nucleoids appear surrounded by an envelope consisting of two closely apposed membranes. Gram-stain-negative. Cell wall is proteinaceous in composition and does not contain detectable markers for peptidoglycan such as muramic acid or for Gram-stain-negative peptidoglycan such as diaminopimelic acid. A discrete holdfast is not produced, and attachment to glass surfaces appears to be effected by secreted slime from

a broad area on the cell. Secreted stalks are not produced. Cells are motile by multitrichous flagella, and all cells in a motile population appear motile, not only buds. Colony color is pink or rose red. Generation time on Staley maintenance medium (Staley, 1973) at 24°C is about 13 h. Catalase-positive. Oxidase-negative. Glucose, galactose, mannose, xylose, ribose, rhamnose, melezitose, salicin, and starch are utilized as carbon sources but fructose, pyruvate, lactate, acetate, tartrate, propionate, phthalate, glycerol, mannitol, ethanol, methanol, adonitol, or a large number of amino acids are not. The temperature range for growth is 16–35°C.

DNA G+C content (mol%): 64.4 ± 1.0 (T_m).

Type strain: DSM 5831, ACM 2246 (originally designated UQM 2246 before reassignment of abbreviation for the relevant culture collection).

Sequence accession no. (16S rRNA gene): AJ231191, X54522, X56305, X85248.

Genus IV. ***Isosphaera*** Giovannoni, Schabtach and Castenholz 1995, 619^{VP} (Effective publication: Giovannoni, Schabtach and Castenholz 1987b, 283.)

RICHARD W. CASTENHOLZ

[*Isocystis* Borzi 1878 (cyanobacteria)]

I.so.spha.e'ra. Gr. adj. *isos* equal; L. fem. n. *sphaera* ball or sphere; N.L. fem. n. *Isosphaera* sphere of equal size.

Spherical cells 2.0–2.5 μm in diameter **forming chains** of indefinite length, often over 100 cells. Cell division by **budding**, intercalary or terminal. No branching occurs. Capsules are not present. Gas vesicles are usually present in all cells, mostly in one cluster (gas vacuole or “pseudovacule”). Resting cells are not known. Gram variable. **Motility by gliding**; pili present, no flagella. **Phototactic** on solid substrate. **Strictly aerobic**. Temperature range ~40–55°C in culture. Optimal pH range 7.8–8.8.

Chemoheterotrophic, aerobic respiratory metabolism. Glucose, ribose, and lactate utilized as carbon sources. Oligotrophic, i.e. D-glucose above 0.05% is inhibitory, as is ribose over 0.25%. Casamino acids tend to enhance growth, but not adequate as the sole carbon source. Carotenoids present; no chlorophyll or bacteriochlorophyll present. Cell envelopes are proteinaceous

with phospholipids containing beta-hydroxylated fatty acids in the lipopolysaccharide lipid A outer layer. Lipids are ester-linked.

Peptidoglycan is absent.

DNA G+C content (mol%): 62.2.

Type species: ***Isosphaera pallida*** (Woronichin 1927) Giovannoni, Schabtach and Castenholz 1995, 619 corrig. Euzéby and Kudo 2001, 1938 (Effective publication: Giovannoni, Schabtach and Castenholz 1987b, 283.) (*Isocystis pallida* Woronichin 1927 – as a cyanobacterium; *Torulopsidosira pallida* (Woronochin) Geitler 1963 – as a yeast).

Further descriptive information

Cell size is variable in actively growing cultures. Negatively stained specimens show no sign of capsules, although cells

sometimes appear capsulated under phase-contrast microscopy. No resting cells are known, but some cells appear refractile. Small refractile spheres may be seen in many cells. These are clusters of gas vesicles (Figure 176). Intercalary budding of cells may also be seen (Figure 176). Numerous pili are visualized by transmission electron microscopy (TEM) (Giovannoni et al., 1987b). Gliding motility is relatively slow ($\sim 0.05 \mu\text{m/s}$). Chains of cells and entire colonies are phototactic, the latter looking like pink “comets” (see Giovannoni et al., 1987b). Motility and phototaxis has been demonstrated on plates of 0.4% agarose, Gelrite, and 1.5% Bacto-agar.

Ultrastructure visualized by TEM has shown periodically spaced ring-shaped structures on the outer surface of the cell wall in negatively stained cells. TEM of thin sections of the cell envelope shows two electron-dense layers separated by an electron-transparent layer (Figure 177). Cytoplasmic staining with 4',6-diamidino-2-phenylindole has shown that the DNA is restricted to a distinct region of the cell, surrounded by an envelope-like structure resembling a nuclear membrane (Figure 178). Cell-wall and lipid composition has been characterized by Giovannoni et al. (1987a) and the polyamine pattern

by others (Gripenburg et al., 1999). The DNA G+C content is 62.2 mol% (Giovannoni et al., 1987b). At this point, only *Isosphaera* and *Gemmata* strains have contents of over 60 mol%; other members of the *Planctomycetales* have values lower than 60 mol% (Gripenburg et al., 1999).

As with other members of the order *Planctomycetales*, growth of *Isosphaera pallida* is not inhibited by penicillin G (2338 units/ml) or related antibiotics.

Ecological comments. Although the initial observations and recovery of *Isosphaera pallida* were from hot springs with relatively mild temperatures (~ 37 – 55°C) and TDS of less than 2 ppt, mixed *Isosphaera*/cyanobacterial cultures were also collected

FIGURE 176. Phase-contrast photomicrographs of *Isosphaera pallida*. (a) Exponential-phase cells of strain IS1B isolated from Kah-nee-ta Hot springs, Oregon. Arrows indicate pair of buds forming between adjacent cells. Spherical white bodies are gas vacuoles (clusters of gas vesicles). (b). Field specimen from Mammoth Hot Springs, Yellowstone National Park. The tightly coiled filament (trichome) is a species of the cyanobacterium, *Spirulina*. Again, the light spots showing in some cells of *Isosphaera* are gas vacuoles. Bars = 10 μm .

FIGURE 177. Transmission electron micrograph of a thin section of *Isosphaera pallida* showing wall ultrastructure. Bar = 0.5 μm .

FIGURE 178. Transmission electron micrograph of a thin section of *Isosphaera pallida* showing a late stage bud (center cell). Also note dark boundary around nuclear area in two of the cells. Bar = $\sim 0.8 \mu\text{m}$.

from a slightly saline hot spring in Utah (~13 ppt), USA, but isolation attempts failed. More recently, *Isosphaera*-like isolates and environmental sequences that also cluster with *Isosphaera* have been identified from nonthermal environments such as leakage water from a compost heap (Wang et al., 2002) and also from a municipal wastewater treatment plant (Chouari et al., 2003). In the former case, isolates could be grown at 28°C without supplemental CO₂. The original six isolates from various hot springs and pools in Wyoming (including Yellowstone National Park) produced gas vesicles in discreet clusters (Giovannoni et al., 1987b). Since O₂ is in lower concentrations in warm waters, the gas vesicles of this aerobic bacterium may be an adaptation that allows a buoyant ascent from bottom mats toward surface waters where O₂ is higher. Little more is known of the ecology of *Isosphaera* species.

Enrichment and isolation procedures

Isosphaera pallida has been seen microscopically and isolated from numerous North American hot springs including Mammoth Hot Springs and Lower Geyser Basin, both in Yellowstone National Park, (Wyoming), Thermopolis hot springs, Wyoming, and Kah-nee-ta Hot Springs, Oregon, as well as other hot springs in North America and Europe (Anagnostidis and Rathsack-Künzenbach, 1967; Giovannoni et al., 1987b).

It invariably occurs in association with cyanobacteria in neutral to alkaline hot springs within the temperature range of 35–55°C. It is generally a minor component, but can be identified easily by light microscopy. Since it is a chemoheterotroph, it is presumably dependent on products released from the cyanobacterial primary producers.

Isosphaera pallida may be isolated by streaking dilute samples onto plates of IMC medium (Table 173) and incubated in the dark at 45°C under a filter-sterilized mixture of 5% CO₂ and 95% air. Under these conditions, the bicarbonate/CO₂ buffer system maintains a pH of ~7.9. Small (1–2 mm) pink circular colonies appear after 1–2 weeks. Colonies are firm and nonviscous.

Maintenance in culture

Isosphaera cultures have been maintained by monthly transfer on agar slants of IMC medium at 45°C in an atmosphere of 5% CO₂ (Table 173). These slants may also be stored (after substantial growth has occurred) at room temperature in air (cotton-plugged) for 1 month without losing viability. Viability may also be conserved in sealed tubes at –80°C.

Differentiation of the genus *Isosphaera* from other genera

Size and morphological shape are adequate for preliminary identification. If in growth phase, the budding of cells may be seen in addition to the small glistening spheres that are the clusters of gas vesicles (Figure 176). A possible exception are some cyanobacteria that form chains of spherical cells (e.g., *Nostoc* spp.), but normally can be distinguished by blue-green to greenish color that reflects their content of chlorophyll *a* and blue or red phycobilin pigments. The presence of these pigments can also be confirmed by autofluorescence under an epifluorescent microscope. There are still some biologists who believe that the original “*Isocystis pallida*” (described as a cyanobacterium), from which *Isosphaera pallida* was renamed, still exists as a cyanobacterium with the identical morphotypic characteristics of *Isosphaera* (e.g., Hindak, 2001), but the cyanobiologists Komárek and Anagnostidis (2005) have left this possibility open. It is obvious from physiological data, lack of chlorophyll, and the 16S rRNA sequences, that *Isosphaera* is definitely related to the Planctomycetales and not to the cyanobacteria. Colonies of *Isosphaera* are pale pink, but filaments show no color under a light microscope unless en masse. *Gemmata*, *Pirellula*, and *Planctomyces* comprise the other cultured members of this order. None of these three genera bear a resemblance to *Isosphaera* morphologically and none are filamentous, but they do have in common a membrane-like boundary around the nucleoid.

Taxonomic comments

The 16S rRNA gene sequence (1460 bp) of the original strain IS1B of *Isosphaera pallida* from Kah-nee-ta Hot Springs is available

TABLE 173. Composition of *Isosphaera* medium IMC

Solution/medium	Ingredient	Concentration/quantity
Solution A ^a	CaCl ₂ ·2H ₂ O	0.32 g/l
	MgSO ₄ ·7H ₂ O	0.40 g/l
	KCl	0.50 g/l
	NaCl	1.00 g/l
	(NH ₄) ₂ SO ₄	0.50 g/l
	KH ₂ PO ₄	0.30 g/l
	FeCl ₃	0.292 mg/l
	Micronutrient solution ^b	10 ml/l (make up with 1 l distilled H ₂ O), then autoclave
Solution B	NaHCO ₃	42 g/l (sterilize by autoclaving, followed by sparging with sterile CO ₂ for 1 h)
IMC medium	Solution A (sterile)	250 ml
	Distilled H ₂ O (sterile)	650 ml, then add:
	Sterile solution B	100 ml, plus
	D-Glucose (final conc.)	0.025% (filter-sterilized)
	Casamino acids (final conc.)	0.025% (filter-sterilized)
	Vitamin mix ^c	0.5 ml/l (filter-sterilized)

^aAdjust solution A to pH 7.6 with NaOH (store at 4°C until autoclaved).

^bUse any commonly used micronutrient solution (see Castenholz, 1988).

^cThe vitamin solution contains (per ml) nicotinic acid, 2 mg; thiamine HCl, 1 mg; *p*-aminobenzoic acid, 0.2 mg; biotin, 0.02 mg; and B₁₂, 0.02 mg.

from GenBank (accession no. X64372). A partial sequence (2779 bp) of the 23S rDNA of another culture strain is also available, as well as 16S rDNA sequences of other strains and of the translational elongation factor-Tu (*tuf*) gene. Phylogenetic trees place *Isosphaera pallida* and other *Isosphaera*-like relatives distinctly within the order *Planctomycetales* but only distantly related to other members of the order such as *Gemmata*, *Pirellula*, and *Planctomyces* (Chouari et al., 2003; Wang et al., 2002). A comparative analysis of ribonuclease P RNA of the cultured members of the *Planctomycetes* was completed by Butler and Fuerst (2004). The tRNA processing endonuclease ribonuclease P contains a highly conserved and required RNA molecule (RNase P RNA) that is the catalytic subunit of the enzyme. They were able to show how the secondary structures of RNase P RNA differed in *Isosphaera pallida* (and a related *Isosphaera*-like isolate) from isolates of *Pirellula*, *Planctomyces*, *Gemmata*, and *Gemmata*-like strains.

"*Isocystis pallida*" Woronichin 1927 was described as pale blue-green in color, but otherwise morphologically the same as *Isosphaera pallida*. The original collection was from warm springs in the Caucasus. Because of the budding nature of the cells, Geitler (1963) reclassified "*Isocystis pallida*" and other species

of "*Isocystis*" as yeasts (thereby conceding they were nonphotosynthetic). Anagnostidis and Rathsack-Kunzenbach (1967), who were very familiar with these same morphotypes from hot springs in Greece, concluded that "*Isocystis pallida*" was a cyanobacterium. A weak red epifluorescence was seen in some of their collections. This fluorescence was not seen in the North American collections and cultures. If their collections were mixed with highly fluorescent cyanobacteria, there is commonly a "spill-over" that appears to give fluorescence to nonfluorescent cells.

List of species of the genus *Isosphaera*

1. ***Isosphaera pallida*** (Woronichin 1927) Giovannoni, Schabtach and Castenholz 1995, 619^{VP} corrig. Euzéby and Kudo 2001, 1938 (Effective publication: Giovannoni, Schabtach and Castenholz 1987b, 283.) (*Isocystis pallida* Woronichin 1927 – as a cyanobacterium; *Torulopsidosira pallida* (Woronichin) Geitler 1963 – as a yeast)
pal'li.da L. fem. adj. *pallida* pale.

Only one species has been isolated and described in detail. Therefore, the characteristics are those described for the genus above. Other strains have been isolated but not systematically. Some probably represent other species of this genus (Gripenburg et al., 1999; Wang et al., 2002).

DNA G+C content (mol%): 62.2 (Bd).

Type strain: IS1B, ATCC 43644, DSM 9630.

Sequence accession no. (16S rRNA gene): AJ231195, X64372.

Genus V. *Pirellula* Schlesner and Hirsch 1987, 441^{VP} emend. Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1577

JOHN A. FUERST AND MARGARET K. BUTLER

Pi.rel'lu.la. L. n. *pirum* pear; L. fem. dim. ending -*ella*; L. fem. dim. ending -*ula*; N.L. fem. n. *Pirellula* very small pear, referring to the shape of the bacterium.

Pear or teardrop-shaped cells with one pointed attachment pole, 0.5–3.0 × 1.0–5.0 μm. Gram-stain-negative. **Cells do not possess a stalk**, but may form a fibrillar holdfast. **Frequently form rosettes** by attachment with the pointed cell pole. The holdfast occurs on one pole of the cell (the narrow pole of ovoid cells) and facilitates attachment to other cells to form rosettes. **Crateriform structures are distributed at one pole only. Reproduction is solely by bud formation.** Buds are formed at or near the opposite, wider pole which thus constitutes the reproductive pole. Newly formed buds are motile by **polar to subpolar monotrichous flagella**. When thin sectioned cells prepared via cryosubstitution are examined via electron microscopy, they display a **characteristic organization including a major cell compartment, the pirellosome, in which ribosomes and a condensed nucleoid are enclosed by an intracytoplasmic membrane, and a ribosome-free paryphoplasm region between this intracytoplasmic membrane and the closely apposed cytoplasmic membrane and cell wall.** Chemoorganotrophic; obligately aerobic. The original description was emended following the description of *Rhodopirellula* and *Blastopirellula* to include more recent data (Schlesner et al., 2004). **The major polyamine is sym-homospermidine.** The major respiratory lipoquinone present is

MK-6. The major phospholipid present is phosphatidylglycerol. A number of other lipids are present that have characteristic R_f values, but whose structures are not currently known. **The lipid pattern is characteristic. The major fatty acids present are C_{14:0}⁷, C_{16:1}⁰⁷, C_{16:0}⁹, C_{18:1}⁰⁹, C_{18:1}⁰⁷, C_{18:0}⁹, and C_{20:1}⁰¹¹.**

DNA G+C content (mol%): 56.4 ± 0.4 to 59.0 (T_m , Bd).

Type species: ***Pirellula staley*** Schlesner and Hirsch 1987, 441^{VP} emend. Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1577.

Further descriptive information

Cells of *Pirellula staley* share with *Rhodopirellula baltica* and *Blastopirellula marina* a similar compartmentalized cell structure when thin sections of cells prepared via cryosubstitution are viewed by transmission electron microscopy (Lindsay et al., 2001). The condensed nucleoid and ribosome-like particles are contained within a single intracytoplasmic membrane forming a pirellosome organelle. A ribosome-free paryphoplasm region lies between the intracytoplasmic membrane and the cytoplasmic membrane closely apposed to the cell wall, often forming a ribosome-free polar cap at one end of the cell (Figure 179). Crateriform structures, electron-dense pits on the

FIGURE 179. Transmission electron micrograph of thin sectioned cryosubstituted cell of *Pirellula staleyi* ATCC 27377 showing pirellulosome (PI) containing condensed nucleoid (N) and ribosome-like particles, surrounded by a single intracytoplasmic membrane (ICM), and the ribosome-free paryphoplasm (P) surrounding the pirellulosome and forming a polar cap at one end of the cell. Bar = 0.1 μm .

FIGURE 180. Transmission electron micrograph of negatively stained *Pirellula* strain ATCC 35122 showing polar distribution of crateriform structures on same pole as fimbriae appendages. Bar = 0.5 μm .

cell surface of planctomycetes, are distributed over one pole only (Figure 180), and in *Pirellula staleyi* appear to extend over only less than half the cell surface in contrast to *Blastopirellula*. The cell wall, as in other planctomycetes which have been examined, is proteinaceous, with amino acids accounting for 82%

FIGURE 181. Transmission electron micrograph of thin section of cryosubstituted cell of *Pirellula* strain ATCC 35122, showing internal pirellulosome containing a condensed nucleoid surrounded by single intracytoplasmic membrane and polar cap, and hump-like prosthecae protrusions of wall and paryphoplasm on both sides of the cell. Bar = 200 nm.

of isolated cell-wall dry weight in the type strain ATCC 27377 (Liesack et al., 1986). Unlike *Rhodopirellula baltica*, the polar cap region in *Pirellula staleyi* does not appear to possess further small membrane-bounded ribosome containing regions. Both the type strain ATCC 27377 and the strain ATCC 35122 (which shares 100% 16S rRNA identity with the type strain) display one or two pointed-humplike protrusions that are opposite each other on the cell in the case where two are visible, constituting prosthecae visible at the electron microscope level (Figure 181). The type strain ATCC 27377 and another closely related strain ATCC 35122 attach to glass surfaces when grown in broth, consistent with potential habitat as periphyton.

Of the type strains of the three "*Pirellula*-group" genera, *Pirellula staleyi*, *Rhodopirellula baltica*, and *Blastopirellula marina*, only *Rhodopirellula baltica* is pigmented pink to red. However, it is possible that pigmented strains of *Pirellula* occur, as ICPB 4232 (a so-called "morphotype IV" strain of freshwater planctomycete cultures) from which ATCC 35122 with 100% identity in 16S rRNA sequence to ATCC 27377 was derived as a nonpigmented subclone, was reported to produce brown colonies (Tekniepe et al., 1981).

Enrichment and isolation procedures

Pirellula staleyi was originally isolated from freshwater (Lake Lansing, Michigan, USA) by adding 100 ml of freshwater sample to a sterile 150 ml beaker containing 10 mg peptone and incubating at room temperature (Staley, 1973). After approximately a month incubation, 0.1 ml of a 1:100 dilution of this enrichment was spread onto a peptone yeast extract medium (0.025% each of peptone, yeast extract, and glucose in a vitamin mineral salts medium) and incubated for 3 weeks, after

which light yellow pigmented colonies containing budding bacteria appeared and were restreaked on the same medium. *Pirellula staley*-like organisms have also been isolated from freshwater sources such as Campus Lake, Baton Rouge, Louisiana (Tekniepe et al., 1981), the source of ATCC 35122 which shares 100% 16S rRNA sequence identity with ATCC 27377. These organisms were isolated by streaking and patch-plating of colonies appearing only after 5–7 d on Medium II agar of Schmidt and Starr containing 0.04% peptone, 0.02% yeast extract, 5–10 mM MgCl₂, and Hutner's vitamin-free mineral base (Schmidt and Starr, 1981).

These approaches can be combined with a selective one employing peptidoglycan synthesis-inhibiting antibiotics such as ampicillin and/or protein-synthesis inhibiting antibiotics such as streptomycin as used for planctomycete isolation by Schlesner (1994) and Wang et al. (2002). *Pirellula*-like strains including nonpigmented ones were isolated from freshwater sources by Schlesner (1994) using *N*-acetylglucosamine (2.0 g/l) as sole carbon and nitrogen source and ampicillin and cycloheximide (0.002% each) as selective agents against other bacteria and fungi, respectively.

Maintenance procedures

The type strain, ATCC 27377, can be maintained for at least 6 months at ca. 4°C on a medium (Staley, 1968; Van Ert and Staley, 1971) containing 0.5% Bacto-peptone, 0.05% yeast extract, vitamin and mineral salts solutions, and 1.5% Difco agar (Staley, 1973). It has been preserved via freeze-drying and at -70°C in Protect (Technical Service Consultants, Ltd) commercial vials. It grows well on Caulobacter tap water agar (ATCC Medium 36 – Caulobacter medium) at 26–28°C. ATCC 35122 can be grown on Caulobacter tap water agar or M1 agar (Schlesner, 1994) at 26–28°C. Cells are weakly inhibited by artificial light at 2400 lx.

Differentiation of the genus *Pirellula* from other genera

Features distinguishing *Pirellula* from the morphologically similar *Blastopirellula* and *Rhodopirellula* are summarized in Table 174. For example, *Pirellula staley* has only limited tolerance to artificial sea water and hydrolyzes casein, unlike *Blastopirellula* and *Rhodopirellula*, and the major fatty acid composition is characteristic (e.g., relatively high percentage of C_{20:1} ω11). *Pirellula* can be distinguished from *Planctomyces* and *Gemmata* on the basis of its mature cell shape as teardrop to pear-shaped (rather than spherical to ovoid) with the attachment pole slightly pointed, the absence of a stalk (relative to *Planctomyces*), and the presence of crateriform structures on one cell pole only (claimed to be the reproductive cell pole) (Schlesner and Hirsch, 1984) relative to *Planctomyces* and *Gemmata* where these are distributed uniformly over the cell surface. *Pirellula* can be distinguished from *Gemmata* on the basis of the absence in thin sections of cryosubstituted cells of any double membrane-bounded nuclear body within

the pirellosome of *Pirellula*, but it shares this simple type of pirellosome with *Blastopirellula* and *Rhodopirellula*. *Pirellula* is distinguished from *Blastopirellula* and *Rhodopirellula* on the basis of the high sodium chloride and calcium requirements of the latter (12–175% and 12–200% artificial seawater, respectively) relative to the limited tolerance (0–50% artificial sea water) of *Pirellula staley* to artificial sea water (Schlesner et al., 2004). Colonies of *Rhodopirellula* are pink to red, but those of *Pirellula* are unpigmented. DNA base composition is of limited value in distinguishing *Pirellula* from *Blastopirellula* and *Rhodopirellula*. *Pirellula staley* type strain has a DNA G+C content varying with author from 56 to 59 mol% (Schlesner and Hirsch, 1984), and this overlaps with those of *Rhodopirellula baltica* (53–57 mol%) (Schlesner et al., 2004) and *Blastopirellula marina* (53.6–57.4 mol%) (Schlesner, 1986).

16S rRNA gene sequence similarity values are of significance in delineating this genus, but the extent cannot be defined at present, since strains with less than 95% sequence similarity to members of this genus should probably be placed in separate genera (Schlesner et al., 2004).

Taxonomic comments

The type strain ATCC 27377, originally isolated from Lake Lansing, Michigan, had been assigned to *Pasteuria ramosa* on the basis of a morphological resemblance to a bacterial parasite of cladoceran invertebrates in the genus *Daphnia* isolated by Metchnikoff in the nineteenth century (Staley, 1973). Again on the basis largely of morphological characteristics, ATCC 27377 was reassigned (Starr et al., 1983) to the genus *Planctomyces* as *Planctomyces staley*, and then, on the basis of 16S rRNA oligonucleotide analysis and DNA base composition, to the genus *Pirella* (Schlesner and Hirsch, 1984). *Pirella* was later rejected as a name (Schlesner and Hirsch, 1987) due to homonymy with the name of a fungus *Pirella* Bainier 1883, therefore ATCC 27377 was proposed as the type strain of the new genus *Pirellula*, initially including *Pirellula staley* and *Pirellula marina*. Finally, the genus *Pirellula* was emended by Schlesner et al. (2004) following the description of the two new genera *Blastopirellula* to include the former *Pirellula marina* and *Rhodopirellula* to include the new species *Rhodopirellula baltica*. *Pirellula staley* is thus now the only described species of the genus.

Strain ATCC 35122 was isolated (designated ICPB 4362) as a “white” nonpigmented subclone of ICPB 4232, originally isolated from freshwater Campus lake, Baton Rouge, Louisiana, which tended to form brown colonies with age (Tekniepe et al., 1981). It displays 100% 16S rRNA sequence identity with ATCC 27377 (Butler et al., 2002) and shares crateriform structure distribution, ultrastructural compartmentalization features, and hump-like protrusions with ATCC 27377 (Butler et al., 2002), forming a second culture collection reference culture of a member of genus *Pirellula*.

List of species of the genus *Pirellula*

1. ***Pirellula staley*** Schlesner and Hirsch 1987, 441^{VP} emend. Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1577

staley. N.L. gen. masc. n. *staley* of Staley, named after James T. Staley, who isolated strain ATCC 27377, under the name *Pasteuria ramosa*.

The description is the same as the genus. Glucose, galactose, mannose, xylose, ribose, fucose, rhamnose, cellobiose,

melzitose, inulin, salicin, starch, dextrin, glucuronic acid, *N*-acetylglucosamine, pyruvate, pectin, lactose, maltose, melibiose, raffinose, sucrose, and trehalose are utilized as carbon sources. The maximum salt tolerance is 50% artificial seawater.

DNA G+C content (mol%): 56.4 ± 0.4–59.0 (*T_m*, Bd).

Type strain: ATCC 27377, DSM 6068.

Sequence accession no. (16S rRNA gene): AJ231183, X81946.

Genus VI. **Rhodopirellula** Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1577^{VP}

HEINZ SCHLESNER

Rho.do.pi.rel'lu.la. Gr. neut. n. *rhodon* a rose; N.L. fem. n. *Pirellula* name of a bacterial genus; N.L. fem. n. *Rhodopirellula* a red *Pirellula*.

Cells are ovoid, ellipsoidal, or pear-shaped, occurring singly or in rosettes by attachment at the smaller cell pole. Cells divide by budding. Buds are produced directly from the broader cell pole of the mother cell. Crateriform structures and fimbriae are found in the upper cell region. Cells have intracytoplasmic membranous structures. Gram-stain-variable. Buds may have a single flagellum inserted subpolarly at the proximal pole. Adult cells are immobile. Strictly aerobic. Colonies are pink to red in color. Mesophilic. Requires seawater for growth. Nonspore-forming. PHB is not stored. Chemoheterotrophic. Carbon and energy sources are mainly carbohydrates. C1-compounds are not used. *N*-acetylglucosamine serves as carbon and nitrogen source. Catalase- and cytochrome oxidase-positive. The proteinaceous cell wall lacks peptidoglycan. The major polyamines are putrescine, cadaverine, and *sym*-homospermidine. The major menaquinone is MK-6. The major fatty acids are C_{16:1} ω7, C_{16:0}, C_{17:1} ω8, C_{17:0}, C_{18:1} ω7, C_{18:1} ω9, and C_{18:0}. The major phospholipids are phosphatidylcholine and phosphatidylglycerol.

DNA G+C content (mol%): 53–57 (HPLC).

Type species: **Rhodopirellula baltica** Schlesner, Rensmann, Tindall, Gade, Rabus, Pfeiffer and Hirsch 2004, 1577^{VP}.

Further descriptive information

Rhodopirellula baltica is the only described species of *Rhodopirellula*. Morphologically, it is characterized by a polar organization of the cells. The small cell pole (“holdfast pole”) excretes a sticky substance of still unknown composition (Figure 182) to enable the cell to attach to surfaces or to form rosettes (see Figure 171 in the chapter Genus *Blastopirellula*). The reproductive pole produces the bud which grows to a smaller mirror

FIGURE 182. *Rhodopirellula baltica* strain SH1^T. Cell with extensive holdfast (h) production. Crateriform structures (cr) are restricted to the reproductive cell pole. Bar = 0.5 μm. Negatively stained with phosphotungstic acid.

image of the mother cell. Crateriform structures are distributed over the entire cell surface of the buds, however, they are only found around the reproductive pole of adult cells. In the same area, numerous fimbriae are found. Studies of electron microscopical images suggest, that the fimbriae originate from the crateriform structures (Figure 183).

Thin cryosubstituted sections of cells showed membranous structures surrounding the nuclear material and the majority of the ribosomes. Analysis of cross-sections of strain SH 1^T as well as SH 796 (Gade et al., 2004) revealed several small structures in addition to a large central one (Figure 184; Schlesner et al., 2004). This microscopic appearance differs from that of the pirellulosome structure described for *Pirellula staleyi* and *Blastopirellula marina* (Lindsay et al., 1997, 2001).

Adult cells excrete a glycocalyx (Figure 185) which might be responsible for the positive Gram reaction of adult cells as it may retain the dyes. Buds and swarmer cells react negatively, and even adult cells give the negative Gram reaction after washing.

The cell wall lacks peptidoglycan and possesses a proteinaceous sacculus instead as has been found in all strains of *Planctomycetales* examined so far. This was first reported for several strains of *Planctomyces* and *Pirellula* (then *Pasteuria*; König et al., 1984). A more detailed study of the cell-wall composition

FIGURE 183. *Rhodopirellula baltica* strain SH143. Fimbriae (fi) originate from crateriform structures (cr). Bar = 0.5 μm. Negatively stained with phosphotungstic acid.

FIGURE 185. *Rhodopirellula baltica* strain SH165 negatively contrasted with India ink demonstrates slime formation.

included the type strain of *Rhodopirellula baltica* (Liesack et al., 1986).

Rhodopirellula is a member of the attached living microflora and, in common with several other representatives of such immobile bacteria, it produces motile daughter cells, thus exhibiting a biphasic life cycle. After ripening, the bud separates from the mother cell and moves away till it attaches to a substratum. Then the flagellum is released (Figure 186). In case of high cell densities, swarmer cells may form rosettes by contact with their holdfast poles.

Carbohydrates are the main substrates as carbon and energy sources. Interestingly, *N*-acetylglucosamine, the monomer of

chitin, serves as carbon and nitrogen source; chitinase activity, however, was not detected.

Though *Rhodopirellula* is quite similar to *Pirellula staleyi* and *Blastopirellula marina* in morphology and physiology, the 16S rRNA sequence analysis showed less than 90% similarity between the type strains of these genera (Table 174). The length of the 5S rRNA of *Rhodopirellula baltica* strain SH1^T is in the range of that for other planctomyceta, i.e. 109–111 bases rather than 118 bases as for the majority of *Bacteria* and *Archaea* (Bomar et al., 1988).

An unusual characteristic seems to be the large genome size. Initial investigations of genome sizes of budding bacteria were performed using DNA renaturation kinetics and indicated that the type strain of *Rhodopirellula baltica* had a considerably larger genome than most of the other strains of budding bacteria (belonging to the genera *Hyphomicrobium*, *Hyphomonas*, *Filomicrobium*, and *Pedomicrobium*) (Kölbel-Boelke et al., 1985). Recently, the complete genome sequence of the type strain has been determined (Glöckner et al., 2003) (GenBank accession no. BX119912). With a size of 7.145 Mb, it is one of the largest circular bacterial genomes known to date. The genome contains unexpected genes, e.g., 110 genes possibly encoding sulfatases (Glöckner et al., 2003) or archaea-like genes for C1-transfer enzymes (Bauer et al., 2004). It could be speculated that growth with chondroitin sulfate, as was recently

found (Schlesner et al., 2004), may require the activity of a specific sulfatase that liberates the carbohydrate moiety. Although the organism has a proteinaceous cell-wall, remnants of genes for peptidoglycan synthesis were found. Genes for lipid A biosynthesis and homologs to the flagellar L- and P-ring protein indicate a former Gram-negative type of cell wall. Genomic and proteomic studies have also identified genes involved in *N*-acetylglucosamine metabolism (Rabus et al., 2002) which may be a key process in marine systems where *Rhodopirellula*, *Blastopirellula*, and *Planctomyces* species are abundant (Glöckner et al., 1999; Lobet-Brossa et al., 1998; Schlesner, 1994).

In proteomic analysis of carbohydrate catabolism and regulation, almost all enzymes of glycolysis and TCA cycle were identified, and almost all enzymes of the oxidative branch of the pentose phosphate cycle were detected (Gade et al., 2005a, c).

Growth phase dependent changes of protein composition were quantitatively monitored. Results indicated an opposing regulation of TCA and oxidative pentose phosphate cycle, down regulation of several enzymes involved in amino acid biosyntheses, and an up regulation of the alternative sigma factor σ^H in stationary phase (Gade et al., 2005b).

Rhodopirellula baltica can be considered a marine bacterium as it does not grow in freshwater media. Essential components of artificial seawater were Ca^{2+} , Na^+ , and Cl^- . The majority of the 25 strains of the species were isolated from the brackish water of the Kiel Fjord (Baltic Sea) over a period of 25 years, suggesting that these bacteria belong to the autochthonous microbial community of the habitat (Schlesner et al., 2004). Interestingly, two strains were isolated from the Mediterranean sponge *Aplysina aerophoba* (Gade et al., 2004), indicating the widespread occurrence of the species. In addition, DeLong et al. (1993) obtained molecular clones of 16S rRNA gene sequences with high similarity to *Rhodopirellula baltica* from marine snow (Pacific Ocean).

Enrichment and isolation procedures

Adult cells are normally attached to surfaces and so mainly swarmer cells are sampled from the free water column. For this reason, an enrichment of cells is necessary before starting isolation attempts. A method successfully applied is to keep 100 ml samples in cotton-plugged 250 ml Erlenmeyer flask over a sediment of 10 g chitin in the laboratory at room temperature (20–23°C) for 3 weeks before streaking over agar-solidified media. The use of *N*-acetylglucosamine as sole carbon and nitrogen source (M30) will reduce the number of upcoming colonies considerably. Further reduction can be achieved by adding filter-sterilized antibiotics affecting the development of peptidoglycan, e.g., ampicillin (0.002%, w/v), to the medium after autoclaving. Addition of 0.002% cycloheximide reduces the growth of fungi. Incubation temperature should not exceed 28°C. Upcoming pigmented colonies are examined microscopically. This is conveniently done by the tooth-pick procedure (Hirsch et al., 1977; Schlesner, 1994). A colony is touched with a sterile tooth-pick and transferred to a master plate (Petri dish with a grid on the backside and filled with the same solidified medium) and then to a labeled glass slide.

If microscopic observation of the slide reveals cells morphologically similar to *Rhodopirellula* species, the inoculum on the master plate is labeled, cultivated, and purified by subsequent streaks on solidified medium. Suitable media are M13a*, M13f†, or M30‡.

Maintenance procedures

The strains grown on slants can be kept at 4–5°C for at least 3 months. They are easily revived from lyophilized cultures and can be stored at –70°C in a solution of 50% glycerol in the culture medium.

Differentiation of the genus *Rhodopirellula* from other genera

Major differentiating properties are shown in Table 174.

Genus VII. **Schlesneria** Kulichevskaya, Ivanova, Belova, Baulina, Bodelier, Rijpstra, Sinninghe Damsté, Zavarzin and Dedysh 2007, 2685^{VP}

SVETLANA N. DEDYSH, IRINA S. KULICHEVSKAYA AND GEORGE A. ZAVARZIN

Schles.ne'ri.a. N.L. fem. n. *Schlesneria* named after the German microbiologist Heinz Schlesner in recognition of his work on planctomycete diversity and ecology.

Ellipsoid-shaped cells, occurring singly, in pairs, or in rosettes. **Free cell poles are covered with crateriform surface structures** and possess **an unusual spur-like projection**. Encapsulated. **Reproduce by budding**. Gram-stain-negative. Adult cells are immobile. Daughter cells are motile by means of two subpolar flagella. No resting stages known. **Stalk-like structures are short and rarely observed**. Chemoorganotrophic aerobes. Capable of growth in microaerobic conditions. Colonies are small and nonpigmented. Various carbohydrates or *N*-acetylglucosamine are the preferred substrates. No growth factors are required. Organic nitrogen compounds, ammonium, nitrate, and some amino acids serve as nitrogen sources. **Possess hydrolytic capabilities. Oxidase- and catalase-positive**. Urease-negative. Dissimilatory nitrate reduction is positive. Mesophilic and **moderately acidophilic bacteria** growing in the pH range of 4.2–7.5, with an optimum at pH 5.0–6.2. **Sensitive to NaCl**. This genus is a member of the phylum *Planctomycetes*, order *Planctomycetales*, family *Planctomycetaceae*. Acidic wetlands are the main habitat.

DNA G+C content (mol%): 54.4–56.5.

Type species: Schlesneria paludicola Kulichevskaya, Ivanova, Belova, Baulina, Bodelier, Rijpstra, Sinninghe Damsté, Zavarzin and Dedysh 2007, 2686^{VP}.

Further descriptive information

A single species, *Schlesneria paludicola*, has been described based on characterization of three independent isolates (Kulichevskaya et al., 2007). These strains possess ellipsoidal cells that occur singly or in pairs or are arranged in rosettes (Figure 187). Mature cells are 0.6–1.5 µm × 1.3–2.1 µm; they are immobile and reproduce by budding. After separation from the mother cells, the buds display high motility due to possession of subpolar flagella. In most cases, two flagella per cell are observed. Thin sections reveal a characteristic type of cell organization in which a single membrane separates the cytoplasm into two major compartments. The nucleoid and most ribosomes are located in one of these compartments. Examination of negatively stained cells using electron microscopy shows the presence of crateriform pits which display a polar distribution and cover approximately one-third of the cell surface (Figure 187). An unusual spur-like projection is located on one pole of the cell which gives a cell shape somewhat similar to a lemon. In addition, the cell surface is covered with numerous, 4–8 nm thick, fimbria-like fibrillar structures and 10–15 nm thick fibrillar appendages. Some cells in cultures are connected to each other by means of stalk-like

FIGURE 187. (a, b) Phase-contrast micrographs of mature and budding single cells (a) and rosettes (b) of *Schlesneria paludicola*. (c) Electron micrograph of negatively stained cells displaying crateriform surface structures with polar distribution and a polar lemon-shaped cell projection. C, Crateriform structures; SP, spur-like projection. Bars = 10 μm (a and b) and 0.5 μm (c). [(c) Printed with permission of Olga I. Baulina.]

structures, which resemble the bundles of twisted fibrils. However, these structures are short, rarely observed, and cannot be discerned by observation with the phase-contrast microscope.

On agar media, visible growth of *Schlesneria paludicola* appears after 2–3 weeks of incubation at 24°C. Colonies are small and uncolored. Members of the genus *Schlesneria* are aerobic chemoorganotrophs. Best growth is observed on media with carbohydrates or *N*-acetylglucosamine. All strains are also capable of slow growth on media with various biopolymers. Representatives of *Schlesneria paludicola* are able to reduce nitrate to nitrite. They are moderately acidophilic (pH range of 4.2–7.5) and mesophilic (temperature range of 4–32°C) organisms. High sensitivity to NaCl reflects adaptation of these bacteria to dilute environments such as ombrotrophic peat bogs.

Cells of *Schlesneria paludicola* contain menaquinone-6 (MK-6) as the predominant isoprenoid quinone. The major fatty acids are C_{16:0} (43.5–49.6%) and C_{16:1} ω 7c (40.3–46.8%); the major neutral lipids are *n*-C₃₁ polyunsaturated alkenes, *n*-C₂₆-2,25-diols, and *n*-C₂₄-2,23-diols.

Enrichment and isolation procedures

Microbial biofilms enriched with cells of *Schlesneria paludicola* and other peat-inhabiting planctomycetes can be obtained by using the water agar-coverslip technique developed by Hirsch et al. (1977). Sterile glass coverslips are inserted vertically into a sterile water agar layer in Petri dishes. The plates are then inoculated with 10–15 ml of peat water and incubated in the dark at 15–24°C for 1–2 months. Periodically, a few coverslips are taken out and subjected to examination by means of fluorescence *in situ* hybridization (FISH) with oligonucleotide probes specific for the *Planctomycetes* (Neef et al., 1998) to monitor development of the target bacteria as described by Dedysh et al. (2006) and Kulichevskaya et al. (2006). When good growth of planctomycetes is observed on these coverslips, replicates are taken out for agar streak isolation. The latter is performed using agar medium M31 (modification of medium 31 described by Staley et al., 1992) containing (g per liter of distilled water) KH₂PO₄, 0.1; Hutner's basal salts, 20 ml; *N*-acetylglucosamine, 1.0; Na-ampicillin, 0.2; peptone, 0.1; yeast extract, 0.1; agar-agar (Difco), 18, pH 5.5–5.8. Incubation is at 20–24°C for 1–2 months. The colonies appearing on the plates are

randomly picked for FISH-based identification and examination by phase microscopy for the presence of ellipsoidal cells arranged in pairs or in rosettes. This procedure is continued until individual colonies of target bacteria are ultimately identified and obtained in pure culture.

Maintenance procedures

Strains can be maintained on agar medium M31 by subculturing once in 2–3 months. Alternatively, they can be kept in liquid medium M31 with 10% glycerol at –70°C or stored by lyophilization.

Differentiation of the genus *Schlesneria* from other genera

Table 176 lists characteristics of *Schlesneria* that differentiate it from other aerobic budding bacteria that lack peptidoglycan. Cell shape and formation of rosettes makes *Schlesneria* different from *Isosphaera*, *Singulisphaera*, and *Gemmata*. High sensitivity to NaCl distinguishes it from *Pirellula*, *Blastopirellula*, and *Rhodopirellula*. With the only exception of *Singulisphaera*, the capability to grow at pH below 5.0 distinguishes *Schlesneria* from all other currently known planctomycetes. Finally, the absence of long stalks and minor amounts of C_{18:1} ω 9c in the fatty acid profile helps to differentiate *Schlesneria* from *Planctomyces*.

Taxonomic comments

Comparative sequence analysis of the 16S rRNA gene shows that *Schlesneria paludicola* is a member of the phylum *Planctomycetes* and belongs to a phylogenetic lineage defined by the genus *Planctomyces*. Highest 16S rRNA gene sequence relatedness (87%) is displayed with *Planctomyces limnophilus* (Hirsch and Müller, 1985). Other validly described cultured species of the genus *Planctomyces*, i.e. *Planctomyces maris* (Bauld and Staley, 1976) and *Planctomyces brasiliensis* (Schlesner, 1989), show lower levels of 16S rRNA gene relatedness (84–86%).

Three taxonomically described strains of *Schlesneria paludicola* were isolated from acidic *Sphagnum*-dominated boreal wetlands of northern Russia. Two other phylogenetically related (97.5–97.8% 16S rRNA gene sequence similarity) but taxonomically uncharacterized planctomycetes, strains Schlesner 638 and 642, were isolated from compost leakage water (Schlesner, 1994).

List of species of the genus *Schlesneria*

1. ***Schlesneria paludicola*** Kulichevskaya, Ivanova, Belova, Baulina, Bodelier, Rijpstra, Sinninghe Damsté, Zavarzin and Dedysh 2007, 2686^{VP}

pa.lu.di.co'la. L. n. *palus*, *-udis* a marsh, bog; L. suff. *cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *paludicola* a bog-dweller.

Description as for the genus with the following additional information. Colonies are circular, smooth, raised, opaque, uncolored, 1–3 mm in diameter. Carbon sources (0.05%, w/v) include glucose, *N*-acetylglucosamine, cellobiose, maltose, sucrose, trehalose, fucose, and salicin. Capable of hydrolyzing fucoidan, laminarin, esculin, pectin, chondroitin sulfate, pullulan, gelatin, and xylan. Nitrogen sources (0.05%, w/v)

are ammonia, nitrate, *N*-acetylglucosamine, Bacto peptone, Bacto Yeast Extract, alanine, aspartate, glutamine, and threonine. Growth factors are not required, but yeast extract slightly increases the growth rate. Members of this species are resistant to ampicillin, streptomycin, chloramphenicol, lincomycin, and novobiocin, but are sensitive to neomycin, kanamycin, and gentamicin. Optimal growth occurs at pH 5.0–6.2 and at temperatures 15–26°C. NaCl inhibits growth at concentrations above 0.5% (w/v).

DNA G+C content (mol%): 54.4–56.5 (T_m).

Type strain: MPL7, ATCC BAA-1393, VKM 2452.

Sequence accession no. (16S rRNA gene): AM162407.

Genus VIII. ***Singulisphaera*** Kulichevskaya, Ivanova, Baulina, Bodelier, Sinninghe Damsté and Dedysh 2008, 1191^{VP}

SVETLANA N. DEDYSH AND IRINA S. KULICHEVSKAYA

Sin.gu.li.spha.e'ra. L. adj. *singuli* single, separate; L. fem. n. *sphaera* sphere; N.L. fem. n. *Singulisphaera* a single spherical cell.

Spherical cells, up to 3–4 µm in diameter, occurring **singly**, in pairs, or in shapeless aggregates. **Crateriform structures** are scattered **over the whole cell surface**. Encapsulated. Immobile. Reproduce by budding. **Stalk-like structures are absent**. Attach to surfaces by means of **amorphous holdfast material**. Gram-stain-negative. Chemoorganotrophic aerobes. Capable of growth in microaerobic conditions. Colonies are opaque and nonpigmented. Various carbohydrates or *N*-acetylglucosamine are the preferred substrates. No growth factors are required. **Possess hydrolytic capabilities**. Organic nitrogen compounds, ammonium, and some amino acids serve as nitrogen sources. **Nitrate is not utilized**. Catalase, oxidase, and urease positive. Dissimilatory nitrate reduction is negative. Mesophilic and **moderately acidophilic bacteria** growing in the pH range of 4.2–7.5, with an optimum at pH 5.0–6.2. **Sensitive to NaCl**. This genus is a member of the phylum *Planctomycetes*, order *Planctomycetales*, family *Planctomycetaceae*. Acidic wetlands are the main habitat.

DNA G+C content (mol%): 57.8–59.9.

Type species: ***Singulisphaera acidiphila*** Kulichevskaya, Ivanova, Baulina, Bodelier, Sinninghe Damsté and Dedysh 2008, 1191^{VP}.

Further descriptive information

A single species, *Singulisphaera acidiphila*, has been described based on characterization of four independent isolates (Kulichevskaya et al., 2008). Mature cells of this species vary in size from 1.6 to 2.6 µm (Figure 188), but some cells in old cultures are up to 3–4 µm in diameter (Figure 188). No stable cell chains or filaments are present in cultures of *Singulisphaera acidiphila*. Examination of old cultures grown on agar plates shows the presence of an amorphous holdfast substance excreted from the cell poles (Figure 188). Thin sections show the pattern of cell compartmentalization typical for *Isosphaera*-like planctomycetes (Figure 188) (Fuerst, 2005; Giovannoni et al., 1987b; Lindsay et al., 2001). The cell wall consists of two electron-dense layers separated by an electron-transparent layer; the total wall thickness is about 12 nm. Crateriform structures with a diameter of 25 nm are scattered over the whole cell surface. An enlarged view of the cross-section of one of these pit-like structures shows

that it represents a cell-wall invagination, which is connected to underlying paryphoplasm (Figure 188). The intracytoplasmic membrane compartmentalizes the cell to produce irregularly shaped membrane-bounded regions. The paryphoplasm in cells of *Singulisphaera acidiphila* is invaginated in a way to form a central region and numerous peripheral regions which are filled with an electron-dense substance. Nucleoid and electron-dense ribosome-like particles are located in the central part of the cell.

On agar media, *Singulisphaera acidiphila* forms raised, opaque, uncolored, circular colonies with an entire edge and a smooth surface. One-month-old colonies are 1–4 mm in diameter. Members of the genus *Singulisphaera* are obligately aerobic chemoheterotrophs, however, they grow well in microaerobic conditions. Most sugars and *N*-acetylglucosamine are the preferred growth substrates, but good growth occurs also on media with various biopolymers. Organic acids are either not utilized or poorly utilized by some of the strains. Representatives of *Singulisphaera acidiphila* are moderately acidophilic (pH range of 4.2–7.5) and mesophilic (temperature range of 4–33°C). High sensitivity to NaCl reflects adaptation of these bacteria to dilute environments such as ombrotrophic peat bogs. Growth inhibition of 50–80% occurs in the presence of NaCl in the medium at concentrations of 0.2–0.5% (w/v), and NaCl at concentrations above 0.5% (w/v) completely inhibits growth.

Cells of *Singulisphaera acidiphila* contain menaquinone-6 (MK-6) as the predominant isoprenoid quinone. The major fatty acids are C_{16:0} (23.9–36.6%), C_{18:1} ω9c (23.5–46.7%), and C_{18:2} ω6,12c (13.8–25.6%); the latter is genus-characteristic. The neutral lipids are dominated by an *n*-C_{31:9} hydrocarbon; squalene, diplopterol, and 3-methyl-diplopterol are also present.

Enrichment and isolation procedures

Enrichment strategy and the medium used for isolation procedure (M31) are the same as for members of the genus *Schlesneria* (above). The colonies appearing on the plates are subjected to examination by phase microscopy for the presence of spherical cells that occur singly or in shapeless aggregates.

FIGURE 188. (a) Phase-contrast micrographs of cells of *Singulisphaera acidiphila* grown in liquid culture and (b) on agar medium; black arrows show amorphous holdfast substance excreted by the cells grown on agar medium. (c) Electron micrograph of an ultrathin section of a cell of *Singulisphaera acidiphila*; CW, cell wall; ICM, intracytoplasmic membrane; P, paraphoplasm; R, ribosome-like particles; N, nucleoid. Black arrow indicates pit-like invagination of a cell wall [enlarged view is shown in (d)]. Bars = 10 μm [(a) and (b)] and 0.2 μm [(c) and (d)]. [(c) and (d), Printed with permission of Olga I. Baulina.]

Maintenance procedures

Strains can be maintained on agar medium M31 by subculturing once in 2–3 months. Alternatively, they can be kept in liquid medium M31 with 10% glycerol at -70°C or stored by lyophilization.

Differentiation of the genus *Singulisphaera* from other genera

Table 176 gives characteristics of *Singulisphaera* that differentiate it from other aerobic budding bacteria that lack peptidoglycan. Spherical cell shape makes *Singulisphaera* different from *Schlesneria*, *Planctomyces*, *Pirellula*, *Blastopirellula*, and *Rhodopirellula*. Absence of cell filaments, pigmentation, and gliding motility differentiate *Singulisphaera* from *Isosphaera*. High sensitivity to NaCl distinguishes it from *Pirellula*, *Blastopirellula*, and *Rhodopirellula*.

The ability to grow at pH below 5.0 distinguishes it from all other currently known planctomycetes with the only exception being *Schlesneria*. Finally, the presence of $\text{C}_{18:2}$ fatty acids is a genus-characteristic feature of *Singulisphaera* that is unique among other planctomycetes.

Taxonomic comments

Comparative sequence analysis of the 16S rRNA gene shows that *Singulisphaera acidiphila* is a member of the order *Planctomycetales* and belongs to a phylogenetic lineage defined by the genus *Isosphaera*. The 16S rRNA gene sequence identity between the *Isosphaera pallida* (Giovannoni et al., 1987b) and representatives of the *Singulisphaera acidiphila* is about 90%.

Four taxonomically described strains of *Singulisphaera acidiphila* were obtained from acidic *Sphagnum*-dominated boreal wetlands of northern Russia.

List of species of the genus *Singulisphaera*

1. *Singulisphaera acidiphila* Kulichevskaya, Ivanova, Baulina, Bodelier, Sinnighe Damsté and Dedysch 2008, 1191^{VP}

a.ci.di'phi.la. N.L. n. *acidum* acid from L. adj. *acidus* sour; N.L. adj. *philus*-a-um (from Gr. adj. *philos*-ê-on), friend, loving; N.L. fem. adj. *acidiphila* acid-loving.

Description as for the genus with the following additional information. Carbon sources (0.05%, w/v) include glucose, fructose, galactose, lactose, cellobiose, maltose, mannose, melibiose, rhamnose, ribose, trehalose, saccharose, xylose, leucrose, *N*-acetylglucosamine, and salicin. Ability to utilize fucose, lactate, and pyruvate is variable. Capable of hydrolyzing laminarin, pectin, chondroitin sulfate, esculin, gelatin, pullulan, lichenan, and xylan. Shows the following enzyme activities: alkaline and acid phosphatase, esterase, esterase lipase, leucine arylamidase, cystine arylamidase, valine

arylamidase, phosphohydrolase, *N*-acetyl- β -glucosaminidase, and β -galactosidase. Nitrogen sources (0.05%, w/v) are ammonia, *N*-acetylglucosamine, Bacto Peptone, Bacto Yeast Extract, alanine, aspartate, arginine, glutamine, threonine, tryptophan, and glycine. Some strains can also utilize asparagine, isoleucine, lysine, phenylalanine, proline, and valine. Nitrate or nitrite are not utilized. Vitamins are not required. Resistant to ampicillin, streptomycin, chloramphenicol, lincomycin, kanamycin, and novobiocin, but sensitive to neomycin and gentamicin. Optimal growth occurs at pH 5.0–6.2 and at temperatures 20–26°C. NaCl inhibits growth at concentrations above 0.5% (w/v).

DNA G+C content (mol%): 57.8–59.9 (T_m).

Type strain: MOB10, ATCC BAA-1392, DSM 18658, VKM B-2454.

Sequence accession no. (16S rRNA gene): AM850678.

Family I. "*Candidatus Brocadiaceae*" fam. nov.

MIKE S.M. JETTEN, HUUB J.M. OP DEN CAMP, J. GIJS KUENEN AND MARC STROUS

Bro.ca.di.a.ce'ae. N.L. fem. n. [*Candidatus*] *Brocadia* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Brocadiaceae* the family of "*Candidatus Brocadia*".

Cocoid cells, generally 0.7–1.1 × 1.1–1.3 µm. Depending on the growth conditions, anammox cells occur singly or in aggregates. Phenomenologically "Gram-stain-negative". No endospores are formed. Ultrastructure similar to that of the Planctomycetales, with typical membrane-bound riboplasm and parhyphoplasm. An internal organelle (the anammoxosome), the locus of anammox metabolism, is present in the cytoplasm.

Nonmotile. Obligately anaerobic. **Facultatively chemolithoautotrophic on ammonium and nitrite**. Nitrite (which is converted to nitrate) is the electron donor for autotrophic CO₂-fixation. Electron transport is cytochrome-based with nitrate, nitrite, Mn(IV), or Fe(III) as terminal electron acceptor. **Hydrazine is produced from ammonium and hydroxylamine**. Nitrate: nitrite oxidoreductase activity is present. Catalase- and hydrogen

peroxidase-positive. **Media supporting an autotrophic lifestyle, containing ammonium, nitrite, and bicarbonate, are required.** Optimum growth temperature for enriched species 15–40°C. Very slow growth with doubling times of 2–3 weeks.

Type genus: "Candidatus Brocadia" Strous et al. 1999a; Kuenen and Jetten 2001.

Taxonomic comments

The family "Candidatus Brocadiaceae" contains the bacteria responsible for anaerobic oxidation of ammonium (anammox). So far all anammox bacteria identified on the basis of 16S rRNA gene sequencing comprise a monophyletic cluster within the *Planctomycetes* lineage of descent (Jetten et al., 2005b; Quan et al., 2008; Schmid et al., 2005; Woebken et al., 2008). Although knowledge on the microbiology of the anammox bacteria is steadily increasing, at this point the information is still too limited to describe the five recognized genera of the family "Candidatus Brocadiaceae" separately (Strous and Jetten, 2004). As isolation of pure cultures using traditional methods has so far not been successful, all type species have the *Candidatus* status (Kartal et al., 2007b, 2008; Kuenen and Jetten, 2001; Quan et al., 2008; Schmid et al., 2001, 2003; Strous et al., 1999a; Woebken et al., 2008). Highly purified cultures have been obtained by physical separation. The genome of one of the anammox bacteria "Candidatus Kuenenia stuttgartiensis" has been sequenced (Strous et al., 2006).

Further descriptive information

Phylogeny and detection. Comparative 16S rRNA gene sequence analysis shows more than 15% sequence difference between the anammox bacteria and cultivated members of the

Planctomycetales (Figure 189). The similarity of the five anammox genera is well below the 97% threshold value typically used to separate species. The deep monophyletic branching of the anammox bacteria has been confirmed by analysis of large datasets of concatenated ribosomal proteins and genes (Strous et al., 2006). Since the anammox bacteria have several features in common with members of the order *Planctomycetales*, notably its compartmentalized ultrastructure, it is not surprising that the oligonucleotide probe S-P-Planc-0046-a-A-18 (Table 177; Neef et al., 1998) also hybridizes with all five genera of anammox bacteria. Most of the initial probes designed for anammox bacteria targeted only "Candidatus Brocadia anammoxidans" (Table 177; Schmid et al., 2005; Strous et al., 1999a). However, probe S*-Amx-0820-a-A-22 also hybridized with "Candidatus Kuenenia stuttgartiensis". "Candidatus Kuenenia" and "Candidatus Brocadia" can be distinguished by fluorescence *in situ* hybridization (FISH) microscopy using the probes S-S-Kst-0157-a-A-18 and S-S-Ban-0162-a-A-18 (Table 177; Schmid et al., 2005). Probe S*-Kst-1275-a-A-20 (Table 177) is specific for "Candidatus Kuenenia stuttgartiensis". The genus "Candidatus Scalindua" can be detected by probes S-G-Sca-1309-a-A-21, S*-Scabr-1114-a-A-22 and S*-BS-820-a-A-22 (Table 177). Specific probes for the genera "Candidatus Anammoxoglobus" and "Candidatus Jettenia" have recently become available (Kartal et al., 2007b; Quan et al., 2008). The 23S rRNA targeting probe L*-Amx-1900-a-A-21 was designed to detect "Candidatus Brocadia" and "Candidatus Kuenenia" (Schmid et al., 2001). Recently the intergenic spacer and large parts of the 23S ribosomal gene of the five different anammox genera have become available to design new probes (Quan et al., 2008; Woebken et al., 2008).

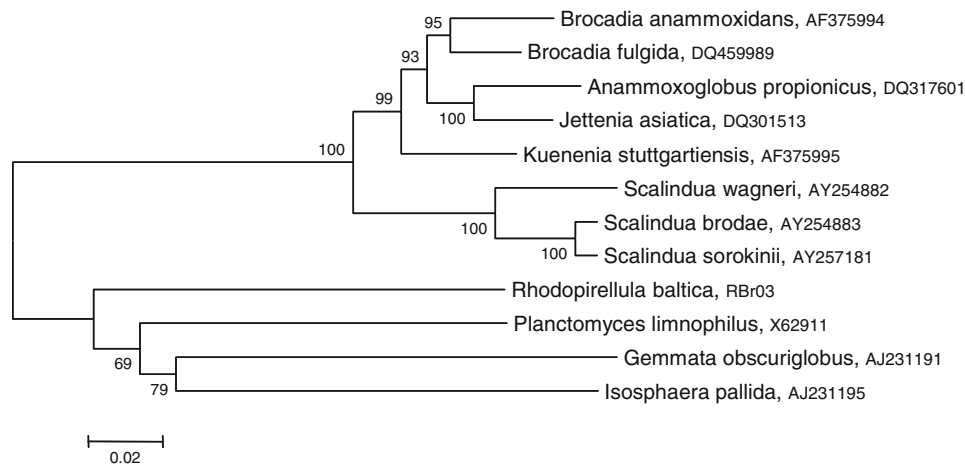

FIGURE 189. Phylogenetic affiliation of the *Brocadiales* to the *Planctomycetales*, based on 16S rRNA gene analysis. The evolutionary history was inferred using the neighbor-joining method (Saitou and Nei, 1987). The optimal tree with the sum of branch length = 0.93 is shown. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (500 replicates) is shown next to the branches (Felsenstein, 1985). The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary distances were computed using the maximum composite likelihood method (Tamura et al., 2004) and are expressed as the number of base substitutions per site. All positions containing alignment gaps and missing data were eliminated only in pairwise sequence comparisons (pairwise deletion option). There were a total of 1633 positions in the final dataset. Phylogenetic analyses were conducted in MEGA4 (Tamura et al., 2007). Accession numbers are given after the species names.

Symbols: +, greater than 90% of strains positive; ++, high activity; -, less than 10% positive; nd, not determined.

Cell-wall composition. Peptidoglycan appears to be absent and electron microscopy shows a visible proteinaceous S-layer (van Niftrik et al., 2008a, b). The absence of a complete peptidoglycan biosynthesis route was confirmed by genomic analysis of *Kuenenia stuttgartiensis* (Strous et al., 2006).

Ultrastructure. Like the cells of other planctomycetes, anammox bacteria possess the shared planctomycete cell plan involving a single-membrane-bounded compartment containing the nucleoid and ribosomes, as well as a paryphoplasm region surrounding the outer rim of the cell (Fuerst, 2005). Within the riboplasm, however, members of the family "Candidatus Brocadiaceae" possess another single membrane-bounded compartment, the anammoxosome, unique to these bacteria. The anammoxosome harbors at least one specialized enzyme, a hydrazine/hydroxylamine oxidoreductase functional in the mechanism of anaerobic ammonium oxidation (Lindsay et al., 2001; Schalk et al., 2000; Shimamura et al., 2007, 2008; van Niftrik et al., 2008a, b). The anammoxosome is wrapped in a single-membrane envelope possessing unique cyclobutane-containing ladderane lipids which may confer relatively high density and reduced permeability to the anammoxosome membrane.

Ladderane lipids, fatty acids, and sterols. The main components in the membrane lipids of anammox bacteria were shown to be so-called "ladderane lipids" (Damste et al., 2002, 2005). These lipids are comprised of three-to-five linearly concatenated cyclobutane moieties with *cis* ring junctions, which occur as fatty acids, fatty alcohols, alkyl glycerol monoethers, dialkyl glycerol diethers, and alkyl acyl glycerol ether/esters (Damste et al., 2005). The internal membrane surrounding the anammoxosome organelle is nearly exclusively composed of ladderane

lipids as a barrier against diffusion of protons and intermediates (van Niftrik et al., 2004). The most abundant fatty acids of anammox bacteria are 14-methylpentadecanoic acid (C₁₆), 10-methylhexadecanoic acid, and 9,14-dimethylpentadecanoic acid. In addition, the anammox bacteria also contain squalene, and a number of hopanoids (hop-22[29]-ene, diplopterol, 17β,21β(H)-bis-homohopanoic acid, 17β,21β(H)-32-hydroxy-trishomohopanoic acid, 22,29,30-trisnor-21-oxo-hopane; Damste et al., 2004). Recently the intact phospholipids of anammox bacteria containing phosphoethanolamine and phosphocholine headgroups have been investigated and compared to each other (Boumann et al., 2006; Rattray, 2008).

Nutrition and growth conditions. A medium sustaining a chemolithoautotrophic lifestyle on ammonium, nitrite, and carbon dioxide in the absence of oxygen is required for growth of anammox bacteria (Jetten et al., 2005a; van de Graaf et al., 1995, 1996). Furthermore, a continuous flow reactor set up with very efficient biomass retention is required to maintain optimal conditions for (exponential) growth (Strous et al., 1998, 2002; van der Star, 2008a). A sequencing fed-batch reactor has been proven to be very suitable for the enrichment and maintenance of a growing anammox culture. Recently, also a membrane reactor was described to produce high quality single cells (van der Star, 2008b).

The basic mineral medium contains (in g/l): KHCO₃, 1.25; NaH₂PO₄, 0.05; CaCl₂·2H₂O, 0.3; MgSO₄·7H₂O, 0.2; FeSO₄, 0.00625; EDTA, 0.00625; trace element solution, 1.25 ml/l. The trace element solution contains (g/l): EDTA, 15; ZnSO₄·7H₂O, 0.43; CoCl₂·6H₂O, 0.24; MnCl₂·4H₂O, 1.0; CuSO₄·H₂O, 0.25; NaMoO₄·2H₂O, 0.22; NiCl₂·6H₂O, 0.19; NaSeO₄·10H₂O, 0.21; H₃BO₃, 0.014; NaWO₄·2H₂O, 0.050. For the enrichment of

marine "*Candidatus Scalindua*" species an appropriate seawater medium should be composed (Kartal et al., 2006; Nakajima et al., 2008; van de Vossenberg, 2008; Windey et al., 2005). The genus "*Candidatus Anammoxoglobus*" and "*Candidatus Brocadia fulgida*" obtain a competitive advantage when using propionate and acetate, as an additional energy source, respectively. Thus propionate or acetate can be added to the ammonium-nitrite enrichment medium in a C/N ratio of 1/6 (Guvén et al., 2005; Kartal et al., 2007b, 2008).

The medium concentrations of NaNO_2 , $(\text{NH}_4)_2\text{SO}_4$, and NaNO_3 are initially set to 5, 5, and 10 mM each. Suitable starting material for the enrichment of anammox bacteria is activated sludge from a treatment plant with a long sludge age, or anoxic sediments which receive a continuous supply of ammonium and nitrate (Dapena-Mora et al., 2004; Fujii et al., 2002; Kartal et al., 2007b, 2008; Schmid et al., 2000, 2003; Toh et al., 2002; van de Vossenberg, 2008; van der Star et al., 2007; Zhang et al., 2007). The biomass concentration in the enrichment cultures should stay above 1 g dry wt per liter to prevent loss of activity. The inflowing ammonium and nitrite concentrations can be increased gradually (to a maximum of 45 mM each) as long as the nitrite is completely consumed. Successful enrichments often have a reddish, pink, or brownish appearance due to the high cytochrome content of the anammox bacteria. In these enrichments anammox bacteria comprise about 80–85% of the community as determined by specific oligonucleotide probes using FISH. Purified cells can be obtained via physical separation using density centrifugation (Kartal et al., 2007a, 2008; Strous et al., 1999a, 2002).

Antibiotic sensitivity. Penicillin G can be added to the media at 0.1 mg/ml to suppress growth of undesirable contaminants (van de Graaf et al., 1995). Whether the insensitivity of anammox bacteria to Penicillin G is caused by lack of peptidoglycan or the growth in aggregates remains to be established.

Ecology. Anammox bacteria were first discovered in wastewater treatment systems and most successful enrichments have used inocula from such environments (Jetten et al., 2005a, b; Schmid et al., 2000, 2003). However, it is now clear that the occurrence of anammox bacteria is practically ubiquitous. Many studies have detected the presence and activity of anammox bacteria in more than 30 natural freshwater and marine ecosystems all over the world (Francis et al., 2007; Op den Camp et al., 2006; Penton et al., 2006; Tsushima et al., 2007). The detection and quantification of the anammox bacteria in these ecosystems was based on a combination of different techniques: enrichment cultures, nutrient profiles, ^{15}N labeling incubations with sediments or water samples, ladderane lipid analysis, FISH microscopy, or 16S rRNA gene sequencing (Dalsgaard et al., 2005; Egli et al., 2001; Kuypers et al., 2003, 2005; Pynaert et al., 2003; Rich et al., 2008; Risgaard-Petersen et al., 2004; Rysgaard and Glud, 2004; Schubert et al., 2006; Tal et al., 2005; Thamdrup and Dalsgaard, 2002). As the anammox bacteria require the simultaneous presence of ammonium and nitrite for growth, they are typical interface organisms, thriving in sediments, biofilms, and stratified waterbodies. In anoxic sediments with low organic carbon content, the anammox bacteria can account for 20–79% of total N_2 production. Studies in the anoxic water columns of the Black Sea and the Golfe Dulce showed that anammox bacteria were responsible

for 20–50% of the total N_2 production (Dalsgaard et al., 2003; Kuypers et al., 2003; Thamdrup et al., 2004). Anammox bacteria are also mainly responsible for nitrogen loss in the oxygen minimum zone (OMZ) that are most productive regions of the world oceans (Hamersley et al., 2007; Kuypers et al., 2005; Thamdrup et al., 2006). The strong N-deficit in the OMZ was until now attributed to denitrification, but recent studies showed unequivocally that the anammox bacteria are responsible for the majority of nitrogen transformation in the OMZs. Based on these observations, it is likely that anammox also plays an important role in other OMZ waters and sediments of the ocean.

In various ecosystems, anammox bacteria will be dependent on the activity of aerobic ammonium-oxidizing bacteria especially when the oxygen supply is limited for example in biofilms or aggregates (Schmidt et al., 2002). In these oxygen-limited environments, the ammonium-oxidizing bacteria would oxidize ammonium to nitrite and keep the oxygen concentration low, while anammox bacteria would convert the produced nitrite and the remaining ammonium to dinitrogen gas (Strous et al., 1997; Third et al., 2001, 2005). Such conditions have been established in many different man-made ecosystems (Schmidt et al., 2002). FISH analysis and activity measurements showed that aerobic as well as anammox bacteria were present and active, but aerobic nitrite oxidizers (i.e., *Nitrobacter* or *Nitrospira*) were not detected (Third et al., 2001, 2005). It seems likely that under these conditions anaerobic and aerobic ammonium oxidizers form a quite stable community. The cooperation of ammonium-oxidizing bacteria is not only relevant for wastewater treatment, but might play an important role in natural environments at the oxic/anoxic interface (Kindaichi et al., 2007; Kuypers et al., 2005; Lam et al., 2007; Nielsen et al., 2005; Woebken et al., 2007).

Ecophysiology. The anammox bacteria have a relatively well-studied ecophysiology (Strous et al., 1999b). The anammox bacteria grow very slowly. This is caused by a low maximum substrate conversion rate, rather than by a low biomass yield. The K_s values of anammox bacteria for ammonium and nitrite are below the detection level ($<5 \mu\text{M}$). Anammox bacteria are reversibly inhibited by very low levels ($<1 \mu\text{M}$) of oxygen and irreversibly inhibited by high nitrite ($>10 \text{ mM}$), low methanol ($<0.5 \text{ mM}$), and acetylene concentrations (Guvén et al., 2005; Jensen et al., 2007; Strous et al., 1999b; Third et al., 2005). All anammox bacteria investigated so far produce hydrazine from hydroxylamine and ammonium (Kartal et al., 2007b; van de Graaf et al., 1997; van der Star, 2008a). Anammox bacteria may be able to use organic acids as additional electron donors (Table 177) for nitrate reduction to nitrite and nitrite reduction to ammonium (Guvén et al., 2005; Kartal et al., 2007a, b, 2008; van de Vossenberg, 2008). The genome sequence (4.2 Mb) of "*Candidatus Kuenenia stuttgartiensis*" has been assembled from community bacterial artificial chromosome (BAC), fosmid, and shotgun libraries (Strous et al., 2006). Genomic evidence, confirmed by CO dehydrogenase enzyme assays, points to the acetyl-CoA pathway for CO_2 fixation. This is consistent with the observed carbon discrimination and the presence of very ^{13}C -depleted (-70%) lipids in anammox bacteria (Schouten et al., 2004). The presence of cytochrome *c*-based respiration of nitrate and nitrite could also be confirmed by analysis of the genome assembly.

Isolation procedures. Owing to the long generation time of 2–3 weeks and the cell density-dependent activity, anammox organisms are most likely incompatible with any currently existing isolation protocol. However, anammox cells can be purified and separated from other organisms present in the community using a density-gradient centrifugation (Strous et al., 1999a, 2002). For this procedure, anammox aggregates are washed in HEPES buffer pH 7.8 containing 5 mM bicarbonate. Subsequently, the anammox cells are mildly sonicated. After centrifugation, the larger aggregates form a light red pellet on top of the dark red pellet of the single cells. The aggregates are removed, the single cells are resuspended in the HEPES/bicarbonate buffer, and Percoll is added. This mixture is centrifuged and anammox cells form a red band at the lower part of the gradient (density 1.107–1.138 g/l). After extraction of the band, the Percoll is removed by washing with HEPES/bicarbonate buffer. The resulting cell suspension contains usually only one contaminating organism for every 200–800 target organisms. The anammox activity of purified cells can be tested after addition of hydrazine, ammonium, and nitrite (Strous et al., 1999a).

Differentiation of the anammox bacteria

As stated in the introduction, information is too limited to separately describe the five recognized genera of the family "Candidatus Brocadiaceae". In Table 177, the most prominent features of the five different anammox genera are listed. After enrichment of the anammox bacteria on ammonium and nitrite media, sequencing of the 16S rRNA gene, and FISH analysis with specific probes are most indicative to determine which anammox species has been obtained. Higher concentrations of phosphate may favor enrichment of "Candidatus Kuenenia" species, whereas inclusion of higher concentrations of salt might favor the marine anammox species. The addition of propionate or acetate results in the enrichment of "Candidatus Anammoxoglobus propionicus" or "Candidatus Brocadia fulgida", respectively.

List of genera of the family "Candidatus Brocadiaceae"

1. "**Candidatus Brocadia**" Strous et al. 1999a; Kuenen and Jetten 2001
 Bro.ca'di.a. N.L. fem. n. *Brocadia* named after place of discovery at the Gist-Brocades factory in Delft, the Netherlands, and the gaudy brocade color of the bacteria.
 Currently the genus includes "Candidatus Brocadia anammoxidans" and "Candidatus Brocadia fulgida".
2. "**Candidatus Anammoxoglobus**" Kartal et al. 2007b
 A.nam.mo.xo.glo'bus. N.L. n. *anammox* abbreviation of anaerobic ammonium oxidation (arbitrary name); L. masc. n. *globus* sphere referring to the spherical shape; N.L. masc. n. *Anammoxoglobus*.
 Currently the genus includes "Candidatus Anammoxoglobus propionicus".
3. "**Candidatus Jettenia**" Quan et al. 2008
 Jet.te'ni.a. N.L. fem. n. *Jettenia* named after Mike S.M. Jetten.

Currently the genus includes "Candidatus Jettenia asiatica".

4. "**Candidatus Kuenenia**" Schmid et al. 2001
 Ku.e.ne'ni.a. N.L. fem. n. *Kuenenia* named in honor after Johannes Gijbrecht Kuenen for his contribution as founding father of anammox research.
 Currently the genus includes "Candidatus Kuenenia stuttgartiensis".
5. "**Candidatus Scalindua**" Schmid et al. 2003; Kuypers et al. 2003; Woebken et al. 2008
 Sca.lin'du.a. L. fem. n. *scala* ladder; L. v. *induo* to dress out or fit with; N.L. fem. n. *scalindua* intended to mean dressed out with ladders, referring to the presence of unique ladderane lipids.
 Currently the genus includes "Candidatus Scalindua brodae", "Candidatus Scalindua sorokinii", "Candidatus Scalindua wagneri", and "Candidatus Scalindua arabica".

Index of scientific names of *Archaea* and *Bacteria*

Key to the fonts and symbols used in this index:

Nomenclature

Lower case, Roman

Genera, species, and subspecies of bacteria. Every bacterial name mentioned in the text is listed in the index. Specific epithets are listed individually and also under the genus.*

CAPITALS, ROMAN:

Names of taxa higher than genus (tribes, families, orders, classes, divisions, kingdoms).

Pagination

Roman:

Pages on which taxa are mentioned.

Boldface:

Indicates page on which the description of a taxon is given.†

* Intrasubspecific names, such as serovars, biovars, and pathovars, are not listed in the index.

† A description may not necessarily be given in the *Manual* for a taxon that is considered as *incertae sedis* or that is listed in an addendum or note added in proof; however, the page on which the complete citation of such a taxon is given is indicated in boldface type.

Index of scientific names of *Archaea* and *Bacteria*

- aalborgi (*Brachyspira*), 10, 472, 531–534, 537, **538**, 539–541

Mycoplasma, 10, 11, 23, 488, 568, 571, 574, 575, 576–581, 583–585, 587, 640, 641, 644, 645, 647, 650, 654, 656, 658, 660, 667, 669, 688–690, 693, 698, 702, 719–721, 723
Mycoplasma adleri, 11, 582, 584, 587
Mycoplasma agalactiae, 11, 569, 578, 579, 582, 584, 587, 590
Mycoplasma agassizii, 11, 582, 584, 587
Mycoplasma alkalescens, 11, 582, 584, 587, 588
Mycoplasma alligatoris, 11, 577, 582, 584, 588
Mycoplasma amphoriforme, 11, 583, 584, 588, 610
Mycoplasma anatis, 11, 582, 584, 588, 589
Mycoplasma anseris, 11, 109, 584, 589
Mycoplasma arginini, 11, 580, 582, 584, 588, 589
Mycoplasma arthritis, 11, 569, 578–580, 582, 584, 589
Mycoplasma auris, 11, 582, 584, 589
Mycoplasma bovigenitalium, 11, 582, 584, 589, 590
Mycoplasma bovirhinis, 11, 578, 582, 584, 590
Mycoplasma bovis, 11, 578, 579, 582, 584, 587, 590
Mycoplasma bovovuli, 11, 582, 584, 590
Mycoplasma buccale, 582, 584, 590
Mycoplasma buteonis, 582, 584, 591
Mycoplasma californicum, 11, 582, 584, 591
Mycoplasma canadense, 11, 582, 584, 591
Mycoplasma canis, 11, 582, 584, 591
Mycoplasma capricolum, 11, 579, 581, 591, 592
Mycoplasma capricolum subsp. *capricolum*, 569, 579, 584, 587, 592, 602
Mycoplasma capricolum subsp. *capripneumoniae*, 579, 581, 584, 592, 602
Mycoplasma caviae, 11, 582, 584, 592
Mycoplasma cavipharyngis, 11, 583, 584, 592
Mycoplasma citelli, 11, 582, 584, 592, 593
Mycoplasma cloacale, 11, 582, 584, 593
Mycoplasma coccoides, 11, 572, 583, 584, 611, 641
Mycoplasma collis, 11, 582, 584, 593
Mycoplasma columbinasale, 11, 582, 584, 593, 597
Mycoplasma columbinum, 11, 582, 584, 593
Mycoplasma columborale, 11, 582, 584, 593
Mycoplasma conjunctivae, 11, 569, 582, 584, 593, 594
Mycoplasma corogypsi, 11, 582, 584, 594
Mycoplasma cottewii, 11, 584, 594
Mycoplasma cricetuli, 11, 582, 584, 594
Mycoplasma crocodyli, 11, 582, 584, 594
Mycoplasma cynos, 11, 582, 584, 594
Mycoplasma dispar, 11, 582, 584, 594, 595
Mycoplasma edwardii, 11, 582, 584, 595
Mycoplasma elephantis, 11, 582, 584, 595
Mycoplasma ellychniae, 646, 647
Mycoplasma equigenitalium, 11, 582, 584, 595, 647
Mycoplasma equirhinis, 11, 582, 584, 595
Mycoplasma falconis, 11, 582, 584, 595
Mycoplasma fastidiosum, 11, 583, 584, 595, 596, 613
Mycoplasma faucium, 11, 582, 584, 596
Mycoplasma laefaucium, 11, 582, 584, 596
Mycoplasma feliminutum, 11, 581, 584, 596, 690
Mycoplasma felis, 11, 582, 584, 596
Mycoplasma fermentans, 11, 578–580, 582, 584, 596, 597
Mycoplasma flocculare, 11, 578, 582, 584, 597
Mycoplasma gallinaceum, 11, 582, 584, 597
Mycoplasma gallinarum, 11, 582, 584, 597
Mycoplasma gallisepticum, 11, 569, 577–579, 583, 584, 588, 597, 598, 601, 602, 610
Mycoplasma gallopavonis, 11, 582, 584, 598
Mycoplasma gateae, 11, 582, 584, 598
Mycoplasma genitalium, 11, 569, 576, 578, 579, 581, 583, 585, 598, 599, 607, 616, 659
Mycoplasma glycophilum, 11, 582, 584, 599
Mycoplasma gypsi, 11, 582, 585, 599
Mycoplasma haematoparvum (*Candidatus*), 586, 611
Mycoplasma haemobos (*Candidatus*), 611
Mycoplasma haemocanis, 11, 579–580, 583, 585, 599, 642, 643
Mycoplasma haemodidelphidis (*Candidatus*), 586, 612
Mycoplasma haemofelis, 11, 579, 583, 585, 599, 612, 642–643
Mycoplasma haemolamae (*Candidatus*), 586, 612
Mycoplasma haemominutum (*Candidatus*), 586, 612
Mycoplasma haemomuris, 11, 583, 585, 599, 600, 642
Mycoplasma haemotarandirangiferis (*Candidatus*), 612
Mycoplasma hominis, 11, 569, 572, 577–580, 582, 583, 585, 600, 613, 614
