Family II. Chitinophagaceae fam. nov. Kämpfer, Lodders and Falsen 2010

PETER KÄMPFER

Chi.ti.no.pha.ga.ce'a.e. N.L. fem. n. *Chitinophaga* type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. *Chitinophagaceae* the *Chitinophaga* family.

This family is defined in part on the basis of sequence similarities of 16S rRNA gene sequences. The main properties are described in the description of the order *Sphingobacteriales*. Cells are often thin, rod-shaped and usually nonmotile. Swarming motility may occur. Aerobic or facultatively anaerobic. Limited fermentative capabilities are observed in some members. Menaquinones are of the MK-7 type, and a fatty acid pattern containing C_{15:0} iso, C_{17:0} iso 3-OH, and C_{15:1} iso G are the most important components and characteristics. The family comprises two genera, *Chitinophaga* (Sangkhobol and Skerman, 1981) and *Terrimonas* (Xie and Yokota, 2006) in addition to the

recently described genera *Niastella* (Weon et al., 2006), *Segetibacter* (An et al., 2007), *Niabella* (Kim et al., 2007), *Flavisolibacter* (Yoon and Im, 2007), *Sediminibacterium* (Qu and Yuan, 2008), *Parasegetibacter* (Zhang et al., 2009), *Lacibacter* (Qu et al., 2009), *Ferruginibacter* (Lim et al., 2009), *Filimonas* (Shiratori et al., 2009), *Flaviumibacter* (Zhang et al., 2010) and *Hydrotalea* (Kämpfer et al., 2010), which also share the main properties of the order *Sphingobacteriales*.

Type genus: Chitinophaga Sangkhobol and Skerman 1981, 288^{VP}.

Genus I. *Chitinophaga* Sangkhobol and Skerman 1981, 285^{VP} emend. Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2225^{VP}

THE EDITORIAL BOARD

Chi.ti.no'pha.ga. N.L. n. *chitinum* chitin; Gr. v. *phagein* to devour, to eat; N.L. fem. n. *Chitinophaga* chitin eater, chitin destroyer.

Flexible rods with rounded ends, 0.5–0.8 × ~40 µm when fully developed. Occur singly. **A resting stage (microcyst), 0.8–0.9 µm in diameter, is formed but is not highly refractile.** Macroscopic fruiting bodies are not formed. **Motility by gliding is possessed by some, but not all species.** Gram-stain-negative. Aerobic. Optimum temperature, 23–24°C; maximum, 37–40°C; minimum: 10–12°C. Optimum pH, 7; maximum, 8–10; minimum, 4. Chemo-organotrophic. **Oxidative or fermentative.** Acid but no gas produced from some carbohydrates. **Some species hydrolyze chitin and some hydrolyze cellulose. Agar is not hydrolyzed.** Congo red is not absorbed. Cell masses are yellow. The major fatty acids are C_{16:1} ω5c and C_{15:0} iso. C_{14:0} is not present. In those species that have been analyzed, the **quinone system is MK-7** and the **major polyamine is homospermidine.**

DNA G+C content (mol%): 43–46.

Type species: Chitinophaga pinensis Sangkhobol and Skerman 1981, 285^{VP}.

Enrichment and isolation procedures

Most strains of *Chitinophaga* can be isolated by inoculating water samples from the littoral zones of freshwater lakes and creeks onto a medium prepared by adding 1.5% of an optically clear agar to lake water which has been freed of optically visible particles by filtration through a membrane filter (pore size 0.45 µm) (Skerman, 1989). The pH is not adjusted. The medium is sterilized at 121°C for 15 min. The medium contains adequate nutrients for the development of microcolonies of most of the organisms that constitute the resident populations of freshwaters. Supplementation tends to produce overgrowth that makes isolation more difficult. Although a chitin-supplemented medium might enhance

development of chitin-hydrolyzing species of *Chitinophaga*, it could also enhance the growth of other chitin-hydrolyzing bacteria at the expense of the slower-growing *Chitinophaga* cells.

The medium is inoculated by allowing ~0.05 ml to flow across the face of the medium and then removing excess surface moisture by incubating the medium for 10 min in a sterile chamber at 22°C. Petri dish cultures are examined periodically from 8 to 24 h by using a 10× phase-contrast objective. Typical gliding filaments are isolated with a microloop (Skerman, 1989) before overgrowth of colonies of other microorganisms occurs. Selected cells are transferred to a lake-water agar supplemented with 0.01% peptone (Difco) and 0.01% yeast extract (Difco), which supports more luxuriant growth.

Chitinophaga skermanii was isolated from the feces of the millipede *Arthrosphaera magna* collected in India. The organism was cultured on nutrient agar (Kämpfer et al., 2006).

Strains of *Chitinophaga arvensicola* were isolated from peat samples collected from a *Sphagnum* peat bog in West Siberia (Pankratov et al., 2006). Aerobic cellulolytic communities were enriched using 120-ml serum bottles containing strips of filter paper immersed in 30 ml of 0.2× diluted liquid mineral medium ST5 (Stanier, 1942). Cell suspensions of the resulting enrichments were spread-plated onto the surface of the dilute ST5 solidified with agar and containing various supplements, such as 0.1% starch, 1% peat extract, or gellan gum.

Chitinophaga japonensis was isolated on a starch-casein agar plate from a soil sample (Fujita et al., 1996). *Chitinophaga ginsengisegitidis* and *Chitinophaga ginsengisoli* were isolated from a ginseng field in South Korea (Lee et al., 2007). *Chitinophaga terrae* was isolated from soil from a field in South Korea.

Maintenance procedures

Cultures can be preserved by lyophilization or by liquid nitrogen storage. For lyophilization, cultures grown on CYEA for 48 h at 22°C are suspended in *Mist Desiccans* [which contains (per liter of distilled water) Bacto peptone (Difco), 12 g, and glucose, 30 g; Greaves (1956)], freeze-dried, and stored in ampoules under oxygen-free nitrogen at 4°C. For liquid nitrogen storage, cells from CYEA are suspended to a density of 10⁹ cells/ml in filtered lake water containing 10% glycerol. This suspension, distributed and sealed in 0.5-ml amounts in 0.7-ml ampoules is precooled to -20°C for 2 h before storage in liquid nitrogen.

Differentiation of the genus *Chitinophaga* from other genera of unicellular gliding organisms

The ability to hydrolyze *p*-nitrophenyl (*p*NP)-phosphorylcholine, 2-deoxythymidine-5'-*p*NP phosphate, L-glutamate- γ -3-carboxy-*p*-nitroanilide (NA) and L-proline-*p*-NA can differentiate *Chitinophaga* species from *Terrimonas* species (Kämpfer et al., 2006); however, results for *Chitinophaga terrae*, *Chitinophaga ginsengisegetis*, and *Chitinophaga ginsengisoli* have not been reported in this regard.

Taxonomic comments

On basis of 16S rRNA gene sequence analysis and menaquinone analysis of *Cytophaga* species, Nakagawa and Yamasato (1993) concluded that the genus *Cytophaga* was so heterogeneous that it should be divided into several genera in accordance with

phylogenetic relationships. Sly et al. (1999) reported that *Chitinophaga pinensis* and *Flexibacter filiformis* formed a distinct lineage based on 16S rRNA gene sequencing that also included *Flexibacter sancti* and *Cytophaga arvensicola*; later, *Flexibacter japonensis* was also added (Nakagawa et al., 2002). Kämpfer et al. (2006) proposed transferring all of these species to the genus *Chitinophaga* on the basis of phylogenetic and phenotypic data. Although the similarities of the 16S rRNA gene sequences were low (88.5–96.4%), there was no evidence for clear phenotypic differences between these organisms that would justify assignment to different genera. Kämpfer et al. (2006) also added a new species to the genus *Chitinophaga*, *Chitinophaga skermanii*.

16S rRNA gene sequence analysis by Lee et al. (2007) indicated that *Chitinophaga ginsengisegetis* had 96.5% similarity to *Chitinophaga arvensicola*, 94.5% to *Chitinophaga japonensis*, 93.4% to *Chitinophaga sancti*, 93.4% to *Chitinophaga filiformis*, 92.0% to *Chitinophaga skermanii*, and 91.9% to *Chitinophaga pinensis*. These values indicated that *Chitinophaga ginsengisegetis* was a distinct species within the genus *Chitinophaga*. *Chitinophaga ginsengisoli* exhibited 00.6% similarity to *Chitinophaga filiformis*, which suggested that they might belong in a single species; however, the two species had a DNA–DNA relatedness value of only 38%, indicating that they were separate species.

16S rRNA gene sequence analysis indicated that *Chitinophaga terrae* belonged to *Chitinophaga*, but the 16S rRNA gene sequence similarities between *Chitinophaga terrae* and established *Chitinophaga* species ranged from 90.3 to 95.7% (Kim and Jung, 2007), indicating that *Chitinophaga terrae* was a distinct species.

List of species of the genus *Chitinophaga*

1. ***Chitinophaga pinensis*** Sangkhobol and Skerman 1981, 285^{VP}
pi'nen.sis L. n. *pinus* a pine, pine-tree; N.L. fem. adj. *pinensis* pertaining to pines.

The characteristics are as given for the genus and as listed in Tables 81 and 82, with the following additional features. Rods 0.5–0.8 \times ~40 μ m, with rounded ends. Microcyst diameter, 0.8–0.9 μ m. The cell mass is yellow. Motile by gliding motility. Temperature range, 10–40°C; optimum, 23–24. pH range, 4–8; some strains can grow at pH 10. NaCl tolerance, 0–1%; some strains can grow at 2%. Catalase-positive. Oxidase-negative. Chitin, gelatin, urea, casein, and Tweens 20, 40, and 80 are hydrolyzed but not cellulose, starch, alginate, or agar. Nitrate is not reduced. Phenylalanine deaminase and tryptophan deaminase activity is not present. In the O-F test for glucose catabolism, some strains are slowly oxidative while others are fermentative.

DNA G+C content (mol%): 43–46 (T_m).

Type strain: ATCC 43595, DSM 2588, IFO (now NBRC) 15968, LMG 13176, UQM 2034.

Sequence accession no. (16S rRNA gene): AF078775.

2. ***Chitinophaga arvensicola*** (Oyaizu, Komagata, Amemura and Harada 1983) Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2225^{VP} emend. Pankratov, Kulichevskaya, Liesack and Dedysh 2006, 2764^{VP} (*Cytophaga arvensicola* Oyaizu, Komagata, Amemura and Harada 1983, 438^{VP}; effective publication: Oyaizu, Komagata, Amemura and Harada 1982, 385.) ar.ven'si.co'la. N.L. adj. *arvensis* (from L. n. *arvum* a field) belonging to or living in the fields; L. suff. *-cola* from L. n. *incola* inhabitant; N.L. n. *arvensicola* an inhabitant of the fields.

The characteristics are as described for the genus and as listed in Tables 81 and 82, with the following additional features. Rod-shaped cells 0.4–0.5 \times 10–40 μ m. Motile by gliding (Pankratov et al., 2006); nonmotile by gliding (Kämpfer et al., 2006). Cells undergo a cyclic shape change in the course of culture development. Young cultures contain long and agile thread cells. On ageing, long cells divide into several nonmotile shorter (0.5–0.7 \times 1.5–5 μ m) cells. Old cultures consist of short rods (0.5–0.7 \times 0.7–2 μ m). Colonies are yellow-pigmented, irregularly shaped, with non-entire edges and flat. Produces flexirubin. Chemo-organotrophic. Aerobic or microaerobic. Growth occurs at temperatures between 4 and 37°C and at pH values between 4.5 and 8.0. NaCl inhibits growth at concentrations above 3% (w/v). Major fatty acids are C_{15:0} iso, C_{16:1} ω 5c, and C_{17:0} iso 3-OH. Nitrate reduction is variable. Mannitol, D-sucrose, D-cellobiose, D-rhamnose, D-galactose, inositol, D-xylose, D-glucose, and D-maltose are utilized, but not sorbitol, acetate, citrate, D-arabinose, or dulcitol. Casein, esculin, gelatin, gellan gum, and laminarin are hydrolyzed. Some strains are also capable of hydrolyzing xylan, starch, and agar. Cellulose, carboxymethylcellulose, pectin, chitin, and Tweens 20, 40, and 80 are not hydrolyzed. Acid is produced from D-glucose, D-xylose, D-cellobiose, D-maltose, D-sucrose, D-rhamnose, and D-galactose.

Source: Soils and acidic wetlands. The type strain was from soil of Osaka Prefecture, Japan.

DNA G+C content (mol%): 42.8–46.4 (Bd, T_m)

Type strain: M64, ATCC 51264, CIP 104804, DSM 3695, IAM 12650, JCM 2836, NBRC 14973.

Sequence accession no. (16S rRNA gene): AM237311.

3. ***Chitinophaga filiformis*** (Reichenbach 1989) Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2225^{VP} [*Flexibacter filiformis* (Solntseva 1940) Reichenbach 1989, 2067; *Myxococcus filiformis* Solntseva 1940, 221; *Flexibacter elegans* Soriano 1945, 93, non Lewin 1969, 200]

fi.li.for'mis. L. neut. n. *filum* a thread; L. suff. *-formis* like, of the shape of; N.L. fem. adj. *filiformis* thread-shaped.

The characteristics are as given for the genus and as listed in Tables 81 and 82, with the following additional features. Gliding motility is present. The organisms exhibit a cyclic shape change. Cell populations are usually highly pleomorphic. In young cultures are found long and very flexible

thread cells with tapering ends, 0.4–0.5 × 30–80 µm, sometimes even longer. Later, the thread cells fragment so that even shorter cells appear when the culture ages. Finally, only short, often curved, sometimes almost coccoid rods are present which are clearly fatter and, under phase-contrast, darker than the thread cells, measuring 0.5–0.6 × 0.7–1.0 µm or less. The short cells may still continue to grow and divide as such. Usually they grow out into thread cells again when brought into fresh medium. The morphological cycle is controlled by environmental factors, particularly nutrients and temperature, and may be manipulated experimentally. On agar plates, particularly on media that allow swarming,

the different morphological forms are, as a rule, found within one (usually the same) colony, with the longer cells near the edge of the swarm. The thread cells have no, or very few cross-walls, 10–30 μm apart, recognizable with the electron microscope. Each compartment appears to contain several nucleoids. The thread cells are extremely agile, gliding, bending, and twisting, but those shorter than about 6 μm are completely nonmotile. On solid media with a low nutrient content (e.g., 0.01% yeast extract) or on yeast agar (e.g., VY/2 agar; Reichenbach and Dworkin, 1981), the colonies are fast-spreading delicate swarms. On VY/2 agar the colonies have a characteristic surface pattern of circular or elongated flat mounds. On agar media with peptone concentrations above 0.3%, the colonies become more and more compact, with a convex surface and a smooth edge. Such colonies often contain only short rods. On yeast agar the cell mass is usually pale yellow, whereas on peptone media it is intensely golden yellow. This color changes quickly into purple or red-brown when alkali (e.g., 20% KOH solution) is added, and it returns to bright yellow when acid (e.g., 10% HCl) is added. The color reaction is due to the presence of flexirubin pigments, which are the main pigments of the organism. Many strains also contain substantial quantities of the bright yellow carotenoid, zeaxanthin. Very pale or totally nonpigmented strains are rarely found.

Catalase-negative. Oxidase-positive. Nitrate is not reduced. No growth occurs on seawater media. The highest NaCl concentration tolerated is 0.3%.

Peptones or a simpler organic nitrogen compound, NH_4^+ or NO_3^- , can serve as the sole source of nitrogen. Various sugars are used as carbon and energy sources and are usually metabolized with the production of acids. Acetate produced in this way is reused later; other organic acids, however, are not utilized. An acidic reaction occurs with glucose. In litmus milk, there is no acid production or coagulation; litmus is reduced and casein is hydrolyzed. Gelatin, casein, chitin, and yeast cells (in VY/2 agar) are hydrolyzed, but not starch or DNA. Indole and H_2S are not produced.

Strictly aerobic. Optimum temperature, $\sim 35^\circ\text{C}$; this organism still grows well at 38°C . Optimum pH, ~ 7 .

Source: Soil, decaying plant material, dung of herbivorous animals, and freshwater habitats in many different places. Its occurrence is rather common. The neotype strain was isolated in 1966 from soil collected on the island of Upolu, Samoa.

DNA G+C content (mol%): 45–47 (Bd, T_m).

Type strain: Fx e1 Reichenbach, ATCC 29495, CCUG 12809, CIP 106401, DSM 527, HAMBI 1966, NBRC 15056.

Sequence accession no. (16S rRNA gene): M58782.

4. ***Chitinophaga ginsengisegetis*** Lee, An, Im, Liu, Na, Cho, Jiun, Lee and Yang 2007, 1398^{VP}

gin.seng.i.se.ge'tis. N.L. n. *ginsengum* ginseng; L. n. *seges, segetis* a field; N.L. gen. n. *ginsengisegetis* of a ginseng field, the source of the organism.

The characteristics are as given for the genus and as listed in Tables 81 and 82, with the following additional features. Cells are $0.4\text{--}0.6 \times 1.1\text{--}1.3 \mu\text{m}$ on R2A agar after 3 d. Colonies grown on R2A agar for 3 d are smooth, circular, convex, transparent, and yellowish. Growth occurs well at $15\text{--}42^\circ\text{C}$ and at pH 5.5–8.5; slow growth occurs 4°C . Growth occurs in the absence of NaCl and in the presence of 2.0% (w/v) NaCl, but not in the

presence of 3% (w/v) NaCl. Nitrate is not reduced. Anaerobic growth does not occur. DNA, chitin, and xylan are not hydrolyzed. *N*-Acetyl-D-glucosamine, arabinose, L-fucose, glucose, maltose, mannose, D-melibiose, L-proline, rhamnose, salicin, D-sorbitol, and sucrose are utilized as sole carbon sources. Positive results for the utilization of L-alanine, gluconate, histidine, inositol, and L-serine are found after 7 d. Utilization of 5-ketogluconate and malate is positive after 14 d. The following compounds are not utilized: acetate, adipate, caprate, citrate, glycogen, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, 2-ketogluconate, itaconate, L-lactate, malonate, mannitol, phenylacetate, propionate, D-ribose, D-sorbitol, suberate, and valerate. The following enzyme activities are produced (API ZYM gallery): *N*-acetyl- β -glucosaminidase, acid phosphatase, alkaline phosphatase, cystine arylamidase, esterase (C4), α -fucosidase, α -galactosidase, β -glucosidase, leucine arylamidase, trypsin, and valine arylamidase, but not chymotrypsin, esterase lipase (C8), β -galactosidase, β -glucuronidase, β -glucuronidase, lipase (C14), α -mannosidase, or naphthol-AS-BI-phosphohydrolase. According to the API 20 NE gallery, the following tests are positive: arginine dihydrolase, β -galactosidase, and urease; glucose fermentation and gelatin hydrolysis are weakly positive. Negative results are obtained for nitrate reduction and tryptophan degradation. Flexirubin pigmentation is positive. $\text{C}_{15:0}$ iso and $\text{C}_{16:1}$ $\omega 5c$ are the predominant cellular fatty acids.

Source: soil of a ginseng field in Pocheon province, South Korea.

DNA G+C content (mol%): 47.1 (HPLC).

Type strain: Gsoil 040, KCTC 12654, DSM 18108.

Sequence accession no. (16S rRNA gene): AB264798.

5. ***Chitinophaga ginsengisoli*** Lee, An, Im, Liu, Na, Cho, Jiun, Lee and Yang 2007, 1399^{VP}

gin.sen.gi.so'li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of the organism.

The characteristics are as given for the genus and as listed in Tables 81 and 82, with the following additional features. Cells are $0.6\text{--}0.8 \times 1.2\text{--}1.6 \mu\text{m}$ on R2A agar after 3 d. Colonies grown on R2A agar for 3 d are smooth, circular, convex, transparent, and yellowish. Growth occurs at $15\text{--}42^\circ\text{C}$ and at pH 5.5–8.5. Growth occurs in the absence of NaCl and in the presence of $<1.0\%$ (w/v) NaCl. Nitrate is not reduced. Anaerobic growth does not occur. Chitin but not DNA or xylan is hydrolyzed. The following compounds are utilized as sole carbon sources: acetyl-D-glucosamine, arabinose, glucose, maltose, mannose, D-melibiose, L-proline, salicin, D-sorbitol, and sucrose. Positive results are also found for gluconate, inositol and rhamnose after 7 d, and for L-fucose and 5-ketogluconate after 14 d. The following are not utilized: acetate, adipate, L-alanine, caprate, citrate, glycogen, histidine, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, itaconate, 2-ketogluconate, L-lactate, malate, malonate, mannitol, phenylacetate, propionate, D-ribose, L-serine, D-sorbitol, suberate, or valerate. The following enzymes are present (API ZYM gallery): *N*-acetyl- β -glucosaminidase, acid phosphatase, alkaline phosphatase, cystine arylamidase, esterase (C4), esterase lipase (C8), α -fucosidase, α -galactosidase, β -galactosidase, α -glucosidase, leucine arylamidase, trypsin, and valine arylamidase. Weakly positive utilization of chymotrypsin and β -glucuronidase occurs. Negative for β -glucuronidase, lipase (C14),

naphthol-AS-BI-phosphohydrolase, and α -mannosidase. The following tests are positive (API 20NE gallery): arginine dihydrolase, β -galactosidase, gelatin hydrolysis, glucose fermentation, and urease, but not for nitrate reduction and tryptophan degradation. Flexirubin pigmentation is positive. $C_{15:0}$ iso and $C_{16:1}$ $\omega 5c$ are the predominant cellular fatty acids.

Source: soil of a ginseng field in Pocheon province, South Korea.

DNA G+C content (mol%): 48.4 (HPLC).

Type strain: Gsoil 052, KCTC 12592, DSM 18017.

Sequence accession no. (16S rRNA gene): AB245374.

6. **Chitinophaga japonensis** (Fujita, Okamoto, Kosako and Okuhara 1997) Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2225^{VP} (*Flexibacter japonensis* Fujita, Okamoto, Kosako and Okuhara 1997, 601^{VP}; effective publication: Fujita, Okamoto, Kosako and Okuhara 1996, 2.)

ja.po.nen'sis. N.L. fem. adj. *japonensis* pertaining to Japan, the source of the soil from which the organism was isolated.

The characteristics are as given for the genus and as listed in Tables 81 and 82, with the following additional features. Long, slender rods or sometimes filaments. Gliding motility is present. Colonies are translucent, orange yellow, and flat with irregular edges on nutrient agar. Microcysts are not formed. No growth occurs under anaerobic condition on nutrient agar. Temperature range, 17–44°C. The following tests are positive: catalase; oxidase; nitrate reduction; hydrolysis of gelatin, esculin, and DNA; growth in the presence of 2.0% NaCl; acid production from D-glucose, D-xylose, D-galactose, sucrose, lactose, and maltose; and utilization of glycerol, D-xylose, adonitol, D-fructose, rhamnose, salicin, and inulin. The following tests are negative: Voges-Proskauer; hydrolysis of casein, chitin and starch; acid production from D-fructose, D-mannitol, D-sorbitol, inositol, and salicin; and utilization of D-mannitol, gentiobiose, and D-turanose. MK-7 is the major menaquinone, and MK-6 is a minor menaquinone.

DNA G+C content (mol%): 49.8 (HPLC).

Type strain: 758, CIP 105790, DSM 13484, JCM 9735, NBRC 16041.

Sequence accession no. (16S rRNA gene): AJ971483.

7. **Chitinophaga sancti** (Lewin 1969) Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2225^{VP} (*Flexibacter sancti* Lewin 1969, 199^{AL})

sanc'ti. L. n. *sanctus* a saint; L. gen. n. *sancti* of a saint, perhaps named in honor of Santos Soriano, from whose laboratory the type strain was supplied (etymology is not clear).

The characteristics are as described for the genus and as listed in Table 81, with the following additional features. Rods with slightly tapering ends, 0.5 \times 2–5 μ m; some strains may be up to >15 μ m in length. The cell mass on peptone agar is golden yellow, reportedly due to the carotenoid, zeaxanthin (Lewin, 1969), but it turns instantly purple-red when alkali is added, so that, supposedly, flexirubin type pigments are present. On yeast agar (e.g., VY/2 agar), delicate swarms develop, and, yeast cells are attacked. On solid media, a tough sticky slime is produced. Grows with peptones, Casamino acids or NO_3^- but not with glutamate as sole nitrogen source. Various sugars are metabolized, with the production of acid. Degrades carboxymethylcellulose (CMC), starch, and gelatin. Catalase-negative. Reduces NO_3^- . Not halotolerant. Maximum tem-

perature, 35°C. Stated to resemble *Cytophaga johnsonae* in most respects, except that it does not degrade chitin (Lewin, 1969).

Source: soil (or similar material) in Argentina and the USA.

DNA G+C content (mol%): 46–47.

Type strain: ATCC 23092, DSM 784, HAMBI 1988, LMG 8377, NBRC 15057, VKM B-1428.

Sequence accession no. (16S rRNA gene): M62795.

8. **Chitinophaga skermanii** Kämpfer, Young, Sridhar, Arun, Lai, Shen and Rekha 2006, 2226^{VP}

sker.ma'ni.i. N.L. gen. masc. n. *skermanii* of Skerman, in honor of Victor B.D. Skerman, an Australian microbiologist, in recognition of his numerous contributions to the taxonomy of micro-organisms.

The characteristics are as described for the genus and as listed in Tables 81 and 82, with the following additional features. No gliding motility occurs. Aerobic. Oxidase-positive. Good growth occurs after 48 h on nutrient agar, tryptic soy agar, and MacConkey agar at 30–40°C. No growth occurs at 5 or 42°C. Colonies on nutrient agar are smooth, orange, circular, translucent, and shiny with entire edges, becoming mucoid. Orange pigmentation is non-diffusible and nonfluorescent; it turns to cherry red upon the addition of 20% KOH and retains its original color on addition of HCl. Growth occurs at pH 5.5–10 and in the presence of 7% (w/v) NaCl. The detailed fatty acid profile has been given by Kämpfer et al. (2006). The following tests are positive: β -galactosidase, acetoin production, gelatinase, and oxidation of glucose, mannitol, and melibiose. The following tests are negative: arginine dihydrolase, lysine decarboxylase, citrate utilization, H_2S production, urease, tryptophan deaminase, indole production, oxidation of inositol, sorbitol, rhamnose, sucrose, amygdalin, and arabinose, and oxidase. The following compounds are utilized as sole carbon sources (tested with the Biolog GN system): α -cyclodextrin, dextrin, Tweens 40 and 80, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, cellobiose, L-fucose, gentiobiose, α -D-glucose, α -D-lactose, lactulose, maltose, D-mannose, D-melibiose, methyl β -D-glucoside, D-raffinose, sucrose, D-trehalose, turanose, monomethyl succinate, acetic acid, D-galacturonic acid, α -hydroxybutyric acid, α -ketobutyric acid, DL-lactic acid, succinic acid, DL-alanine, L-alanyl-glycine, L-asparagine, L-aspartic acid, L-glutamic acid, glycy-L-aspartic acid, glycy-L-glutamic acid, L-proline, L-serine, L-threonine, and glycerol. The following carbon sources are not utilized as sole carbon sources: D-arabitol, propionic acid, citric acid, glycogen, adonitol, L-arabinose, iso-erythritol, D-fructose, D-galactose, myo-inositol, D-mannitol, D-psi-cose, L-rhamnose, D-sorbitol, xylitol, pyruvic acid methyl ester, cis-aconitic acid, formic acid, D-galactonic acid lactone, D-glucosaminic acid, D-gluconic acid, D-gluconic acid, β - and γ -hydroxybutyric acids, *p*-hydroxyphenylacetic acid, itaconic acid, α -ketoglutaric acid, malonic acid, D-saccharic acid, sebacic acid, bromosuccinic acid, quinic acid, succinamic acid, L-pyroglutamic acid, α -ketovaleric acid, glucuronamide, L-alaninamide, D-alanine, L-histidine, hydroxy-L-proline, D-serine, L-leucine, L-ornithine, L-phenylalanine, inosine, uridine, thymidine, DL-carnitine, γ -aminobutyric acid, urocanic acid, phenylethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, DL- α -glycerol phosphate, glucose 1-phosphate and glucose 6-phosphate. The following enzyme activities are present: alkaline phosphatase, butyrate esterase, caprylate

esterase, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α -galactosidase, α -glucosidase, β -glucosidase, and *N*-acetyl- β -glucosaminidase. No enzyme activities are present for myristate esterase, α -chymotrypsin, β -galactosidase, β -glucuronidase, α -mannosidase, and α -fucosidase.

Source: feces of the millipede *Arthrosphaera magna*.

DNA G+C content (mol%): 40.7 (HPLC).

Type strain: CC-SG1B, CCUG 52510, CIP 109140.

Sequence accession no. (16S rRNA gene): AJ971483.

9. *Chitinophaga terrae* Kim and Jung 2007, 1723^{VP}

ter'rae. L. gen. n. *terrae* of the earth.

The characteristics are as described for the genus and as listed in Tables 81 and 82, with the following additional features. Nonmotile. Rods are 0.3–0.5 \times 0.6–0.8 μ m on R2A agar after 3 d. Colonies grown on LB agar for 3 d are smooth, circular, convex, and yellowish. Growth occurs at 15–42°C and at pH 6.0–9.0; slow growth occurs at 42°C and pH 9.0. Nitrate is reduced to nitrite but not to N₂. The following enzymes are produced: *N*-acetyl- β -glucosaminidase, acid

phosphatase, alkaline phosphatase, α -chymotrypsin, cystine arylamidase, esterase (C4), esterase (C8), α -fucosidase, α -galactosidase, α -glucosidase, β -galactosidase, β -glucosidase, leucine arylamidase, α -mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase. No production occurs of arginine dihydrolase, β -glucuronidase, lipase (C14), protease (gelatin hydrolysis), and urease. The following compounds are assimilated: L-arabinose, L-fucose, D-glucose, maltose, D-mannose, D-melibiose, L-rhamnose, sucrose, *N*-acetyl-D-glucosamine, and salicin. No assimilation occurs of acetate, adipate, caprate, citrate, gluconate, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, itaconate, 2-ketogluconate, 5-ketogluconate, lactate, L-malate, malonate, phenylacetate, propionate, suberate, *n*-valerate, D-ribose, *myo*-inositol, D-mannitol, D-sorbitol, L-alanine, L-histidine, L-proline, L-serine, and glycogen. C_{15:0} iso, C_{16:1} ω 5c, and C_{17:0} iso 3-OH are the predominant cellular fatty acids.

Source: soil from a field near Daejeon, South Korea.

DNA G+C content (mol%): 46.3 (HPLC).

Type strain: KP01, KCTC 12836, LMG 24015.

Sequence accession no. (16S rRNA gene): AB278570.

Genus II. *Terrimonas* Xie and Yokota 2006, 1120^{VP}

THE EDITORIAL BOARD

Ter.ri.mo'nas. L. n. *terra* soil; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Terrimonas* soil monad.

Rods, occurring singly. Nonmotile. No gliding motility. Gram-stain-negative. **Aerobic.** Growth is inhibited by >1.0% NaCl. Oxidase-positive. Catalase weakly positive. Positive for gelatin liquefaction, Voges–Proskauer test, and nitrate reduction. Negative for urease production and chitin degradation. Major cellular fatty acids are C_{15:0} iso, C_{15:1} iso, C_{17:0} iso 3-OH, and summed feature 3. The predominant menaquinone is MK-7; MK-6 is a minor component. The major cellular fatty acids are C_{15:0} iso, C_{15:1} iso, C_{17:0} iso 3-OH, and summed feature 3 (comprised of C_{15:0} iso 2-OH and/or C_{16:1} ω 7c). Isolated from soil.

DNA G+C content (mol%): 47.2–48.9 (HPLC).

Type species: *Terrimonas ferruginea* Xie and Yokota 2006, 1120^{VP} [*Flavobacterium ferrugineum* Sickles and Shaw 1934, 429^{AL}; *Pseudobacterium ferrugineum* (Sickles and Shaw 1934) Krasil'nikov 1949, 234; *Empedobacter ferrugineum* (Sickles and Shaw 1934) Prévot 1961, 181].

Further descriptive information

Terrimonas strains grow well in nutrient broth (Difco), IAM medium 802*, and the nitrogen-free medium[†] of Xie and Yokota (2005) at 29°C. Although they can grow well on the latter medium, the organisms appear to be incapable of fixing N₂, based on failure to reduce acetylene and to amplify the *nifH* gene (Xie and Yokota, 2006).

Differentiation of the genus *Terrimonas* from related genera

The lack of swimming and gliding motility, and the occurrence of single cells rather than filamentous cells, and the occurrence

of MK-7 as the major menaquinone, differentiates *Terrimonas* from the genus *Flavobacterium*. Lack of gliding motility and the occurrence of single cells rather than filamentous cells, differentiates *Terrimonas* from the genus *Flexithrix*. *Terrimonas* can be differentiated from the nongliding, nonfilamentous species *Chitinophaga arvensicola* by its ability to liquefy gelatin and to grow at 37°C. It can be distinguished from the nongliding, nonfilamentous species *Chitinophaga skermanii* by the higher mol% G+C of its DNA (47–49 vs. 41).

Taxonomic comments

Xie and Yokota (2006) isolated a bacterial strain called DY from garden soil in Japan. Sequence analysis of the 16S rRNA gene and the GyrB protein revealed that the closest relative of strain DY was the type strain of *Flavobacterium ferrugineum* Sickles and Shaw (1934), with 94.8 and 90.1% similarity, respectively. The two strains had menaquinone 7 as the major respiratory quinone, mol% G+C of the DNA (47–49), and a similar fatty acid composition.

Comparison of the 16S rDNA sequences with those of other organisms indicated that *Terrimonas* strains were most closely related to *Chitinophaga* species, sharing less than 92% sequence similarity with *Chitinophaga arvensicola*, *Chitinophaga japonensis*, *Chitinophaga sanctii*, *Chitinophaga filiformis*, and *Chitinophaga pinensis*. Consequently, Xie and Yokota (2006) reclassified *Flavobacterium ferrugineum* in a new genus, *Terrimonas*, as *Terrimonas ferruginea*, and they added their DY as a second species, *Terrimonas lutea*.

Differentiation of species of the genus *Terrimonas*

Table 83 lists characteristics that differentiate *Terrimonas ferruginea* from *Terrimonas lutea*.

*IAM medium 802 contains (g/l): polypeptone (Nihon Pharmaceutical Co.), 10; yeast extract, 2.0; and MgSO₄·7H₂O, 1.0.

[†]The nitrogen-free medium of Xie and Yokota (2005) contains (g/l): glucose, 10.0; CaCl₂·2H₂O, 0.1; MgSO₄·7H₂O, 0.1; K₂HPO₄, 0.9; KH₂PO₄, 0.1; CaCO₃, 5.0; FeSO₄·7H₂O, 0.01; Na₂MoO₄·2H₂O, 0.005; pH 7–3.

TABLE 83. Characteristics differentiating the species of the genus *Terrimonas*^{a,b}

Characteristic	<i>T. ferruginea</i>	<i>T. lutea</i>
<i>Colony pigmentation:</i>		
Salmon-red	+	-
Yellow	-	+
<i>Acid production from:</i>		
Rhamnose, melibiose	+	-
Raffinose, sucrose, galactose, fructose	-	+
<i>Assimilation of:</i>		
Arabinose, trehalose	-	+
D-Xylose	+	-
Methyl- α -D-mannoside, N-acetylglucosamine, melibiose, sucrose, gentiobiose	-	+

<i>Enzymic activities (API ZYM system):</i>		
β -Galactosidase, α -chymotrypsin	+	-
α -Fucosidase	w	-

^aSymbols: +, 90% or more percent of strains are positive; -, 90% or more of strains are negative; w, weak reaction.

^bData taken from Xie and Yokota (2006).

List of species of the genus *Terrimonas*

1. ***Terrimonas ferruginea*** Xie and Yokota 2006, 1120. (*Flavobacterium ferrugineum* Sickles and Shaw 1934, 429^{Al}; *Pseudobacterium ferrugineum* (Sickles and Shaw 1934) Krasil'nikov 1949, 234; *Empedobacter ferrugineum* (Sickles and Shaw 1934) Prévot 1961, 181)

fer.ru.gi'ne.a. L. fem. adj. *ferruginea* rust-colored.

The characteristics are as described for the genus, with the following additional features. Cells are single rods, 0.3–0.5 \times 1–3 μ m. Colonies are circular, nonspreading, and about 1 mm in diameter. Growth occurs at 10–37°C; optimum, 25–32°C. Colonies are salmon red on nutrient agar and IAM medium 802. No hydrolysis of chitin and chitosan occurs. Acid is produced from glucose, cellobiose, maltose, mannose, melibiose, rhamnose, and xylose, but not from sucrose, dulcitol, glycerol, inositol, mannitol, sorbitol, raffinose, fructose, or galactose. The following carbon sources are utilized: glucose, mannose, esculin, xylose, maltose, cellobiose, rhamnose, lactose, 5-ketogluconate, starch, and glycogen. Sucrose, trehalose, dulcitol, arabinose, galactose, fructose, glycerol, inositol, mannitol, methyl- α -D-mannoside, raffinose, sorbitol, and gentiobiose are not utilized. Activity of the following enzymes is strongly positive: β -galactosidase, alkaline phosphatase, leucine arylamidase, valine arylamidase, acid phosphatase, α -chymotrypsin, naphthol phosphohydrolase, C4 esterase, C8 esterase lipase, and N-acetyl- β -glucosaminidase. Weakly positive activity is exhibited for cystine arylamidase, trypsin, α -glucosidase, and α -fucosidase. No activity occurs for α -galactosidase, β -glucuronidase, β -glucosidase, α -mannosidase, or C14 lipase.

Source: soil from an unknown locality.

DNA G+C content (mol%): 48.9 (HPLC).

Type strain: ATCC 13524, CCUG 33443, DSM 30193, IAM 15098, JCM 21559, LMG 4021, NBRC 14992.

Sequence accession no. (16S rRNA gene): M62798.

2. ***Terrimonas lutea*** Xie and Yokota 2006, 1120^{VP}

lu.te'a. L. fem. adj. *lutea* golden-yellow.

The characteristics are as described for the genus, with the following additional features. Cells are single rods, 0.3–0.5 \times 1–3 μ m. Colonies are circular, non-spreading, and about 1 mm in diameter. Growth occurs at 10–37°C; optimum 25–32°C. Colonies are yellow on nutrient agar and IAM medium 802. Chitin and chitosan are not hydrolyzed. Acid is produced from glucose, cellobiose, maltose, mannose, fructose, galactose, raffinose, and sucrose, but not from dulcitol, glycerol, inositol, mannitol, melibiose, rhamnose, xylose, or sorbitol. The following carbon sources are utilized: glucose, mannose, esculin, maltose, lactose, 5-ketogluconate, arabinose, galactose, fructose, methyl- α -D-mannoside, cellobiose, N-acetylglucosamine, sucrose, raffinose, gentiobiose, and melibiose. Starch, D-xylose, glycogen, glycerol, inositol, mannitol, sorbitol, rhamnose, and dulcitol are not utilized. Activity of the following enzymes is strongly positive: alkaline phosphatase, leucine arylamidase, valine arylamidase, acid phosphatase, naphthol phosphohydrolase, C4 esterase, C8 esterase lipase, and N-acetyl- β -glucosaminidase. Weak activity is exhibited for C14 lipase, cystine arylamidase, α - and β -glucosidases, and trypsin. No activity occurs for β -glucuronidase, α - and β -galactosidases, α -mannosidase, α -chymotrypsin, and α -fucosidase.

Source: garden soil in Japan.

DNA G+C content (mol%): 47.2 (HPLC).

Type strain: DY, CCTCC AB205006, IAM 15284, JCM 21735.

Sequence accession no. (16S rRNA gene): AB192292.

Family III. Saprospiraceae fam. nov.

THE EDITORIAL BOARD

Sa.pro.spi.ra.ce'a.e. N.L. fem. n. *Saprospira* type genus of the family; suff. *-aceae* ending to denote family; N.L. fem. pl. n. *Saprospiraceae* the *Saprospira* family.

The family *Saprospiraceae* was circumscribed for this volume on the basis of phylogenetic analysis for the 16S rDNA sequences; the family contains the genera *Saprospira* (type genus), *Haliscomenobacter*, *Lewinella*, and *Aureispira*. The organisms are Gram-stain-negative rods that form long filaments; two genera form helical filaments. Flagellar motility is absent. Three genera exhibit gliding motility (*Saprospira*, *Lewinella*, and *Aureispira*).

Two genera consist of helical gliding organisms (*Saprospira* and *Aureispira*). Nonphototrophic. Nonsporeforming. Aerobic. The color of the cell mass is pink, yellow, or orange. Found in freshwater and/or marine environments. The mol% G+C content of the DNA ranges from 33 to 53.

Further differences among the genera are listed in Table 84. Type genus: **Saprospira** Gross 1911, 202^{AL}.

TABLE 84. Distinguishing characteristics for genera of the family *Saprosspiraceae*^{a,b}

^d The G+C content of the type species is 45 mol%.

Genus I. *Saprospira* Gross 1911, 202^{AL}

RALPH A. LEWIN

Sap.ro.spi'ra. Gr. adj. *sapros* rotten, putrid; L. fem. n. *spira* a spiral; N.L. fem. n. *Saprospira* spiral associated with decaying matter.

The following generic description is modified from Reichenbach (1989). **Helical filaments 10–500 µm long and 0.5–3 µm wide, multicellular**, unbranched, without sheaths. **Cells 1.5–3.5 µm in length**. Gram-stain-negative. Non-flagellate. **Move by gliding** in either longitudinal direction at speeds up to 180 µm/min, simultaneously rotating around their long axes. Resting stages not known. **Colonies on agar surfaces are spreading; they may exhibit a regular pattern of stripes. Strictly aerobic organotrophs** requiring amino acids. Pigmentation is by carotenoids – pink, yellow, orange, or red. Aquatic, marine, or freshwater, on surfaces or in bottom sediments.

DNA G+C content (mol%): 33–48 (Bd, T_m).

Type species: *Saprospira grandis* Gross 1911, 202^{AL}.

Further descriptive information

The saprospiras are versatile microbes. They are not rare; they are nevertheless all too little studied, perhaps because they apparently include no pathogens. Their characteristic gliding motility can be seen in the film by Reichenbach (1980). They move on solid surfaces where they can hope to find potentially nutrient substrates or prey bacteria, but how they move is still under investigation (Aizawa, 2005). The filaments are multicellular, and it is not known how the cells are coordinated to push all in one direction or the other. What induces filaments to reverse their direction, or to break is unknown.

Saprospiras are typically helical, but the function of this shape is not understood. A helical form might facilitate wriggling around particles, but experimental evidence is lacking.

All saprospiras in culture are colored, due to different kinds of carotenoids (Lewin and Fox, 1963). Since the organisms are not photosynthetic, the function of the pigments is not known. Whether saprospiras are phototactic or chemotactic is also not known.

Within the past few years the biological knowledge of *Saprospira*, and perhaps of other flexibacteria too, has taken on a new twist since the discovery that these microbes are not merely saprophytes, but that some, at least, are in effect predatory. Certain strains of marine and freshwater *Saprospira* spp., like other flexibacteria, produce extracellular toxins that can kill diatoms, cyanobacteria, and other microbes, from which essential nutrients (including predominantly amino-acids; Lewin, 1972) can be absorbed (Ashton and Robarts, 1987; Sakata et al., 1991; Sangkhobol and Skerman, 1981). Some can even catch prey organisms, by a process called ixotrophy, before killing and digesting them (Lewin, 1997). Their slime, normally used in some way for their gliding motion, serves as a kind of adhesive “fly paper” with a specific affinity for the flagella of prey bacteria, notably some strains of *Vibrio*. When these unfortunate microbes are caught, they can be moved to and fro on the *Saprospira* surface until eventually killed by exotoxins and subjected to enzymic activity, whereby nutrients are liberated to supplement solutes in the medium.

Saprospiras require some or all of the so-called “essential” amino acids that animals do, and presumably for the same reason. It is unnecessary to biosynthesize essential molecules when one can obtain them ready-made by digesting food proteins. Many saprospiras are even more like animals, living by predation on other microbes, including diatoms and dinoflagellates as well as bacteria. In some, the mucilage tracks that they employ for motility have been pre-adapted to be sticky and thereby to catch bacterial prey, notably species of *Vibrio*, by their flagella (Lewin, 1997). Then an ixotrophic saprospira can kill the prey by extracellular toxins and digest them by extracellular enzymes, thereby liberating the amino acids that are needed for growth. The natures of the sticky mucilage, and of those toxins and enzymes, need to be further studied.

The first marine lytic bacteriophage was found in a saprospira (Lewin et al., 1964), but not all saprospiras succumb to it. Some saprospiras, perhaps all, contain rhabdosomes, which look like long bacteriophage tails (Reichle and Lewin, 1968). These are hollow cylinders with protruding central axes, and are liberated in large numbers when the saprospira cells lyse. Their origin and functions are unknown.

Enrichment, isolation, and maintenance procedures*

Gross (1911) originally enriched *Saprospira grandis* and "*Saprospira nana*" by filling large dishes with bottom sand and seawater from the Mediterranean and floating cover glasses on the water surface. Overnight, the saprospiras attached themselves firmly to the glass surface. R.A. Lewin (personal communication) collected them on glass slides immersed at a depth of 1000 m off the coast of California. Other specific enrichment techniques for *Saprospira* species are not known. To isolate these organisms, samples from bottom sediments from the seacoast, rivers, or lakes are placed as streaks or spots on the surface of dry low-nutrient agar plates, e.g., seawater agar, perhaps with 0.1% NH₄Cl and 0.002% sodium acetate or with 0.03% casein peptone and 0.01% yeast extract. Corresponding media may be used for freshwater species. The crude cultures are incubated at room temperature or 30°C and checked under a dissecting microscope from time to time for spreading colonies. *Saprospira* colonies may easily be recognized by their stripes. *Saprospira grandis* grows in a very wide temperature range, and it may be favorable to incubate the plates at 6°C. The desired organism grows still reasonably well at this temperature, while the development of contaminants is much restricted. Transfers are made from the crude cultures to increasingly rich media, and finally pure cultures may be obtained by plating of cell suspensions. By that time, other gliding bacteria and agar liquefiers (a serious problem with marine samples) should be eliminated, for otherwise well-separated colonies are not easily obtained. More details about isolation procedures and composition of suitable media may be found in Lewin (1962, 1965b) and in Reichenbach and Dworkin (1981).

Cultures of *Saprospira grandis* die within a few days (30°C) or weeks (at room temperature). *Saprospira grandis*, "*Saprospira toviformis*" (Lewin and Mandel, 1970), and some strains of "*Saprospira thermalis*" (Lewin, 1965a) could be preserved in liquid nitrogen for 1 year; in most cases, addition of 10% glycerol has been essential; "*Saprospira flammula*" (Lewin, 1965a) and "*Saprospira albida*" (Lewin, 1962) did not survive (Sanfilippo and Lewin, 1970). *Saprospira grandis* strain Sa gl [ATCC 49590, DSM 2844] survives for at least 2 years when stored at -80°C in peptone-yeast extract medium (e.g., SP5 liquid medium) (Reichenbach and Dworkin, 1981). The same strain did not survive drying in skim milk.

Differentiation of the genus *Saprospira* from other genera

Helical multicellular filaments and gliding motility distinguish *Saprospira* from all other genera.† Should uncoiled, nonmotile

strains, as observed in culture, also occur in nature, they would not be recognizable as saprospiras. Straight but gliding filaments from marine habitats, classified as *Microscilla marina*, are perhaps identical with *Saprospira grandis* (Lewin, 1962). From pure cultures of *Saprospira grandis*, stable variants have also been isolated that no longer form filaments but grow as 1–4-celled segments (Lewin, 1962).‡

Taxonomic comments

The problems involved in the taxonomy of *Saprospira* are like those now facing us for almost all microbes and many other kinds of organisms. We have somehow to resolve disagreements between classifications based solely on visual, biochemical, and physiological characters and those based essentially on molecular biology (MB) data. Since we as humans are primarily seeing organisms, we have no difficulty in recognizing a giraffe and assigning it to a genus. So when we look down a microscope and see helical bacteria, we naturally would like to assign them in the same way to named genera. However, whereas the shapes and sizes of giraffes are controlled by many thousands of genes, and their generations are many years long, those of microbes, with generations some ten orders of magnitude shorter, are controlled by only a handful of genes, and even these tend to be mutable. Natural selection may induce a filamentous bacterium to mutate and persist as a helix; conversely, a helical bacterium in culture may straighten spontaneously. Then what price is helicity as a key determinant for *Saprospira*? The same arguments might apply to considerations of gliding ability (Reichenbach et al., 1986). Furthermore, on the basis of present MB data, different *Saprospira*-like microbes may exhibit affinities with microbes from other diverse genera, indicative of considerable phylogenetic diversity within the named genus.

Although we cannot reconcile visual and MB classifications, we can at least make some workable arrangements. We must, if we need to name things. If we have to depend solely on what we can see under the microscope, then the broad generic name, *Saprospira*, is all we can use. But when objective MB data indicate otherwise, I think we will have to reassign – and rename – the diverse groups accordingly.

Following a proposition of Lewin (1962), nonphototrophic, helical, multicellular, filamentous bacteria with gliding motility were classified in the genus *Saprospira*. The genus had been defined earlier by Gross (1911), and his *Saprospira grandis* is very probably identical with Lewin's strains. Only the "spore" formation described by Gross and included in the species definition of *Saprospira grandis* has not been observed again and had to be discarded from the description. The present taxa are based, of course, on Lewin's more recent and more detailed investigations and his neotype strain. Lewin later described several other species, viz., "*Saprospira thermalis*" (freshwater; Lewin, 1965a), "*Saprospira flammula*" (freshwater; Lewin, 1965a) and "*Saprospira toviformis*" (marine; Lewin and Mandel, 1970), and revived another old species, "*Spirulina albida*" Kolkwitz (1909), as "*Saprospira albida*" (freshwater;

*Taken from Reichenbach (1989).

†The genus *Aureispira* is similar to *Saprospira* but exhibits differences in trypsin activity, acid phosphatase activity, naphthol-AS-BI-phosphohydrolase activity, and also large differences in cellular fatty acid composition (Hosoya et al., 2006).

‡Further details and differential characteristics of seven putative *Saprospira* spp. are summarized in a table in Reichenbach (1989).

Lewin, 1962). Although the assumption is supported by correspondences in several morphological and physiological characteristics, it was not certain whether all these organisms are really related to one another, as no molecular taxonomic data were available. The mol% G+C range of 35–48 would at least not rule out a relatively close relationship. Unfortunately, except for *Saprospira grandis*, the type strains of all species have been lost, so that these species were not included in

the Approved Lists of Bacterial Names. However, the organisms have been fairly well characterized, and there is no doubt that they really exist; their characteristics are given in detail by Reichenbach (1989).*†

Acknowledgements

I am grateful to S. Aizawa and X. Mayali for their useful suggestions.

List of species of the genus *Saprospira*

1. *Saprospira grandis* Gross 1911, 202, emend. Lewin 1962, 560^{AL}

gran'dis. L. fem. adj. *grandis* large.

The description is that given by Reichenbach (1989). Helical flexible filaments of constant width, 0.8–0.9 (to 1.2) µm depending on the strain, but variable in length; usually shorter in plate cultures (15–130 µm) than in liquid media (20–500 µm). The pitch and width of the screws may vary considerably even in one (the same) culture. The filaments may even uncoil entirely during culture. Stable variants have also been reported that grow as single cells or 2–4-celled segments (Lewin, 1962). The filaments are composed of cylindrical cells, 1–5.5 µm long depending on the strain and the culture; within one filament the longest cells are twice as long as the shortest ones. The cross-walls may be difficult to distinguish in young cultures but become well recognizable in old and drying filaments. End cells of the filaments are rounded (see photomicrographs in Reichenbach (1989).

Colonies on poor media are thin and spreading and remain relatively small, often with a pattern of parallel fine stripes (Figure 60). Colonies on rich media are round, convex,

thick, and slimy, relatively small, and deep orange to red (Figures 61 and 62). In liquid media, *Saprospira grandis* grows in homogeneous suspension; upon shaking, the cultures show a silky appearance. In peptone-yeast extract medium, the generation time is 2–2.8 h (at 30°C) (Lewin, 1962, 1972). The cell mass is orange to red, due to carotenoids, mainly saproxanthin (Aasen and Liaaen-Jensen, 1966).

Grows on peptones, Casamino acids and defined amino acid mixtures; in addition, unknown growth factors, e.g., with yeast extract, have to be supplied. Glucose, galactose, sucrose, and acetate are growth stimulatory for some strains. Gelatin is liquefied. Starch, agar, alginate, and carboxymethylcellulose are not decomposed. In litmus milk, coagulation occurs, but acid is not produced, the curd is usually not digested, and litmus is not reduced. Tyrosine is degraded to colored products. H₂S is not produced from cysteine-containing media. Nitrate is not reduced to nitrite. Catalase-negative. Strictly aerobic.

DNA G+C content (mol%): 46–48 (Bd, T_m).

Type strain: ATCC 23119, JCM 21750, LMG 10407.

Sequence accession no. (16S rRNA gene): M58795.

Genus II. *Aureispira* Hosoya, Arunpairojana, Suwannachart, Kanjana-Opas and Yokota 2006, 2933^{VP} emend. Hosoya, Arunpairojana, Suwannachart, Kanjana-Opas and Yokota 2006, 1950^{VP}

THE EDITORIAL BOARD

Au.re.i.spí'ra. L. adj. *aureus* golden; L. fem. n. *spira* a spiral; N.L. fem. n. *Aureispira* golden spiral.

Cells are 0.8–1.2 × 1.5–2.5 µm, forming **flexible, unbranched, helical filaments** up to 100 µm long. Helix width is 1.5–2.0 µm; helix pitch is 4–9 µm. **Motile by gliding**. Gram-stain-negative. Colonies are yellow or yellowish-orange. Chemo-organotrophic. **Aerobic. Seawater is required for growth**. Positive for alkaline phosphatase and acid phosphatase. Oxidase and catalase are variable. The predominant fatty acid is C_{20:4} ω6c (arachidonic acid); other characteristic fatty acids are C_{16:0} and C_{17:0} iso. The respiratory quinone is MK-7.

DNA G+C content (mol%): 38–39.

Type species: *Aureispira marina* Hosoya, Arunpairojana, Suwannachart, Kanjana-Opas and Yokota 2006, 2933^{VP}.

Further descriptive information

The genus belongs to the family *Saprospiraceae* in the phylum *Bacteroidetes*.

Until recently, the genus *Saprospira* was thought to be the only validly published genus of helical, nonphototrophic, gliding bacteria. However, Hosoya et al. (2006) isolated three gliding bacterial strains of helical bacteria from marine sponges and algae in Thailand and showed that these organisms represented a new genus distinct from *Saprospira*.

Enrichment and isolation procedures

Isolation can be achieved on SWG medium, consisting of seawater (filtered to remove large particles), 0.1% sodium glutamate,

*Modified from Reichenbach (1989).

†On the basis of analysis of 16S rRNA gene sequences, Sly et al. (1998) reported that *Saprospira grandis* is closely related to the *Haliscomenobacter* (Sly et al., 1998). Hosoya et al. (2006) reported that *Saprospira grandis* was related to *Haliscomenobacter* and *Lewinella*, and also found it closely related to their new genus *Aureispira*. Thus, the family *Saprospiraceae* would presently contain four genera - *Saprospira*, *Haliscomenobacter*, *Lewinella*, and *Aureispira*.

FIGURE 60. *Saprospira grandis* striped colonies. (a) Spreading colony, survey picture. The gliding filaments preferentially follow scratches in the agar surface produced by the inoculation loop. Oblique illumination. Bar = 250 μm . (b) Central part of a large colony. Brightfield illumination. Bar = 125 μm . (c) At high magnification the strict alignment of the filaments becomes recognizable. Phase-contrast. Bar = 25 μm .

FIGURE 61. *Saprospira grandis* compact colonies on agar medium with "high" peptone content (0.1% peptone from casein + 0.02% yeast extract). Plating of an enrichment culture with *Saprospira grandis* (small smooth colonies) and a spirillum (large colonies with concentric rings). Bar = 1200 μm .

FIGURE 62. *Saprospira grandis* spreading colony on agar medium with "low" peptone content (0.03% peptone from casein + 0.01% yeast extract). Enrichment culture; the round dark colonies are contaminants. Bar = 1200 μm .

and 1.5% agar; pH 7.2. A drop from undiluted samples collected from marine sponges, algae, and coastal woody materials are allowed to flow in a narrow band (slightly off-center) across the surface of each agar plate. After drying the agar surface by incubating at 22°C for 10 min, the plates are incubated 25°C for 3–4 d and then examined by low-power phase microscopy to observe microcolony development. Purification of the gliding bacteria is performed using the micromanipulation technique of Skerman (1968) as described by Sly and Arunpairojana (1987).

Strains can be cultured and maintained on Sap2 medium, which has the following composition (g/l): tryptone, 1.0; yeast extract, 1.0; agar, 15.0. The ingredients are dissolved

in 0.5× artificial seawater, having the following composition (g/l distilled water): NaCl, 15; KCl, 0.35; MgCl₂·6H₂O, 5.4; MgSO₄·7H₂O, 2.7; CaCl₂·2H₂O, 0.5.

Differentiation of the genus *Aureispira* from other genera

Aureispira marina and *Saprospira grandis* are similar in many ways, but unlike *Saprospira grandis*, *Aureispira marina* is negative for trypsin, positive for acid phosphatase and naphthol-AS-BI-phosphohydrolase, has yellowish-orange colonies instead of reddish orange, and has a mol% G+C of 38–39 instead of 49.8. In addition, *Aureispira marina* contains C_{20:4} ω6c (arachidonic acid), whereas *Saprospira grandis* does not.

List of species of the genus *Aureispira*

1. ***Aureispira marina*** Hosoya, Arunpairrojana, Suwannachart, Kanjana-Opas and Yokota 2006, 2933^{VP}

ma.ri'na. L. fem. adj. *marina* of or belonging to the sea, marine.

The characteristics are as given for the genus, with the following additional features. Optimal growth temperature, 25–30°C; no growth occurs at 8 or 37°C. pH range for growth, 6.0–8.0. Colonies are yellowish-orange. Growth occurs in artificial seawater ranging from 0.2 to 1.5× full-strength. The following tests are positive: esterase (C4); esterase lipase (C8); leucine arylamidase; naphthol-AS-BI-phosphohydrolase; degradation of casein, gelatin, and Tweens 20, 40, 60, and 80, and degradation of tyrosine to colored products. The following tests are negative: nitrate reduction; production of acetoin, H₂S, and indole; hydrolysis of agar, alginate, carboxymethylcellulose, citrate, DNA, and starch; lipase (C4); valine arylamidase; cystine arylamidase; trypsin; chymotrypsin; α-galactosidase; β-galactosidase; β-glucuronidase; α-glucosidase; β-glucosidase; N-acetyl-β-glucosamidase; α-mannosidase; α-fucosidase; acid production from arabinose, cellobiose, dulcitol, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, raffinose, rhamnose, sorbitol, sucrose, trehalose, and xylose.

Habitat: marine plant debris, marine sponges, and marine algae.

DNA G+C content (mol%): 38–39 (HPLC).

Type strain: 24, IAM 15389, JCM 23197, TISTR 1719.

Sequence accession no. (16S rRNA gene): AB245933

Taxonomic comments

Analysis of 16S rDNA sequences of the type strain of *Aureispira marina* indicated a similarity value of 86% similarity to the type strain of *Saprospira grandis* and 78–80% to the type strains of *Lewinella cohaerens* and *Haliscomenobacter hydrossis* (Hosoya et al., 2006).

A second species, *Aureispira maritima*, was added by Hosoya et al. (2007). The DNA–DNA relatedness between the type strain of *Aureispira marina* and that of *Aureispira maritima* was less than 5%. *Aureispira maritima* can be differentiated from *Aureispira marina* by lacking C4 esterase; by producing valine arylamidase, cystine arylamidase, and trypsin; by degrading carboxymethylcellulose and DNA; and by having a slightly lower mol% G+C content (38.7 vs. 39.4).

2. ***Aureispira maritima*** Hosoya, Arunpairrojana, Suwannachart, Kanjana-Opas and Yokota 2006, 1950^{VP}

ma.ri'ti.ma. L. fem. adj. *maritima* of the sea, marine, inhabiting marine environments.

The characteristics are as given for the genus, with the following additional features. Cells are 0.7–0.8 × 3–6 μm. The cells are helices 1.5–2.0 μm × 20–90 μm, with a wavelength of 4–5 μm. Optimal growth temperature, 30°C; no growth at 17 or 37°C. pH range for growth, 6.0–8.0. Growth occurs at seawater concentrations of 20–150% (w/v). Colonies are yellow. Flexirubin pigments are not detected. The following tests are positive: esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, and naphthol-AS-BI-phosphohydrolase, and for the degradation of casein, carboxymethylcellulose, DNA, gelatin, and Tweens 20, 40, 60 and 80. Tyrosine is degraded. Agar, alginate, citrate and starch are not attacked. Nitrate is not reduced. The following tests are negative: acetoin, H₂S and indole production; esterase (C4), lipase (C4), chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase; acid production from arabinose, cellobiose, dulcitol, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, raffinose, rhamnose, sorbitol, sucrose, trehalose, and xylose.

Habitat: marine barnacle debris.

DNA G+C content (mol%): 38.7 (HPLC).

Type strain: 59SA, IAM 15439, TISTR 1726.

Sequence accession no. (16S rRNA gene): AB278130.

Genus III. ***Haliscomenobacter*** van Veen, van der Kooy, Geuze and van der Vlies 1973, 213^{AL} (*Streptothrix* Cohn 1875, 186, *sensu* Mulder and Van Veen 1974, 133)

PETER KÄMPFER*

Ha.lis.co.me.no.bac'ter. Gr. v. *haliskomai* to fall into the hands of the enemy, to be imprisoned; N.L. masc. n. *bacter* a rod or staff; N.L. masc. n. *Haliscomenobacter* imprisoned rod.

Thin rods, 0.4–0.5 × 3–5 μm, usually **in chains, enclosed by a narrow, hardly visible hyaline sheath. No ferric or manganic oxides have been detected so far as depositions** in or on the sheaths. Sometimes **branching of the filaments** incidentally occurs in stationary cultures. The branching cells disrupt the sheath and form a new sheath outside the envelope. Com-

pared with the main filaments, the lateral branches are short. Cells outside the sheaths are rarely visible; **no flagellation** or motility has been observed. Gram-stain-negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the

*Updated from Mulder (1989).

until now (Krul, 1977; Mulder, 1989; Mulder and Deinema, 1981; van Veen et al., 1973; Ziegler et al., 1990). Krul (1977) reported that D-glucose together with some components from trypticase soy broth could be useful as energy sources. Mulder and Deinema (1981) reported that D-glucose but not glycerol and lactate can be used as carbon sources, which is in accordance with the study of Kämpfer (1995). In contrast, Krul (1977) reported sucrose utilization, but this could not be confirmed by Kämpfer (1995). In addition, Mulder (1989) listed glucosamine and lactose, and to a lesser extent mannitol, as carbon and energy sources. The utilization of lactose and D-mannitol was not observed for any isolate by Kämpfer (1995). As already mentioned above, isolates of the genus *Haliscomenobacter* are difficult to cultivate. A detailed study on the nutritional requirements of these isolates showed that D-glucose and D-fructose were good substrates for the cultivation of *Haliscomenobacter* (Kämpfer et al., 1995). In addition, the presence of calcium, magnesium, and phosphate in the media was required for growth of all isolates, and high ammonia concentrations (>2 g/l) inhibited their growth. Furthermore, *Haliscomenobacter* preferred a distinct range of phosphorus concentration (0.05–0.2 g/l), and a very low concentration of yeast extract and peptone (Kämpfer et al., 1995).

Since isolation and cultivation of these organisms is difficult and time consuming, the use of specific 16S rRNA targeted oligonucleotide probes as reported earlier (Kämpfer, 1997; Schauer and Hahn, 2005; Wagner et al., 1994) can be very useful for *in situ* detection and identification of *Haliscomenobacter*.

Haliscomenobacter hydrossis is often found in activated sludge. It is one of those filamentous bacteria that sometimes occur in large numbers in sludge (Eikelboom, 1975; Fourest et al., 2004; Pernelle et al., 2001; Schauer and Hahn, 2005). They make the sludge flocs voluminous, while many trichomes, like tiny straight needles, protrude into the surrounding water. Both phenomena are responsible for the slow settling of the flocs (bulking). There are only a few indications that the organism occurs in large masses in certain sludges. Pernelle et al. (2001) and Gaval and Pernelle (2003) reported a clear stimulation of growth of *Haliscomenobacter hydrossis* along with high amounts of easily assimilable substrates and oxygen deficiency. *Haliscomenobacter hydrossis* is not able to store polyhydroxyalkanoate under these conditions (Dionisi et al., 2002).

Under laboratory conditions, *Haliscomenobacter hydrossis* grows slowly. van Veen et al. (1982) reported maximum specific growth rates in continuous culture of approximately 0.05/h and 0.09/h for two different strains, corresponding to minimum doubling times of 14 and 9 h, respectively. These values are below those of most known bacteria occurring in wastewater and activated sludge (van Veen et al., 1982). The maintenance coefficients of these strains were low, 20 and 21 mg of glucose/g biomass/h, respectively. These values are far below those of most known bacteria and may contribute to the competitive ability of the organisms. The maximum yield coefficients (Y_c) found are 0.59 and 0.42 g of biomass/g of glucose, respectively. These observations were confirmed by Kämpfer et al. (1995), who found different carbon sources, nutrient addition, and inorganic growth factors significantly affected the growth of *Haliscomenobacter hydrossis*.

Enrichment and isolation procedures

Most often, bulking activated sludge, which upon microscopic examination is found to contain large masses of typical *Haliscomenobacter* filaments (Figure 64), can be used as enrichment

material. The following isolation procedure was recommended by Mulder and Deinema (1981). A sample of 0.1–0.5 ml of sludge is pipetted into tubes containing 10 ml of sterile tap water. The contents of the tubes are stirred for several minutes using a tube mixer, whereupon the flocs are allowed to settle. During moderate agitation of the floc suspensions, fragments of the threads are severed from the protruding filaments and will be seen in the supernatant. If upon microscopic observation insufficient amounts of separate filaments and free cells are present, the whole procedure is repeated. After settling of the flocs, a small amount of the supernatant is directly streaked on previously dried agar plates of the following composition (per liter of distilled water): glucose, 150 mg; $(\text{NH}_4)_2\text{SO}_4$, 50 mg; $\text{Ca}(\text{NO}_3)_2$, 10 mg; K_2HPO_4 , 50 mg; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 50 mg; KCl, 50 mg; CaCO_3 , 100 mg; $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, 5 mg; $\text{MnSO}_4 \cdot \text{H}_2\text{O}$, 2.5 mg; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 0.1 mg; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 0.1 mg; $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.05 mg; $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 0.05 mg; thiamine, 0.4 mg; vitamin B_{12} , 0.01 mg; agar (Oxoid), 10 g. After incubation for some weeks at 17–20°C, small filamentous colonies may develop that are difficult to recognize, even when viewed under a stereomicroscope. Low magnification ($\times 150$) phase-contrast microscopy facilitates detection. Sterile capillary tubes are used to transfer cells to agar plates of the following composition (in grams per liter of distilled water) (S.C.Y. agar): sucrose, 1.0; casitone (Difco), 0.75; yeast extract (Difco), 0.25; trypticase soy broth without glucose (BBL), 0.25; thiamine, 4×10^{-4} ; vitamin B_{12} , 10^{-5} ; agar (Oxoid), 10. Ziegler et al. (1990) investigated several additional isolation methods for filamentous bacteria and recovered most of the *Haliscomenobacter* isolates after a 1:10 dilution of the sample with MSV (Williams and Unz, 1985) and subsequent washing and centrifugation at 200 g for 5 min. I-medium

TABLE 85. Characteristics that differentiate the genus *Haliscomenobacter* from *Saprospira grandis* and the genus *Lewinella*^{a,b}

Characteristic	<i>Haliscomenobacter</i>	<i>S. grandis</i>	<i>Lewinella</i>
Length of cells (µm)	3–5	1–5.5	2–3
Diameter of filaments (µm)	0.4–0.5	0.8–1.2	0.5–1.5
Length of filaments (µm)	10–300	6–500	5–150
Gliding motility	–	–	+
Seawater as source of essential growth factors	–	+	+
Starch degraded	+	–	–
Predominant cellular polyamine	Spermidine	Agmatine	Spermidine
Color of cell mass	Pink	Orange-red	Orange-yellow
DNA G+C content (mol%)	49	46–48	45–53
Habitat	Wastewater, sewage	Marine	Marine

^aSymbols: +, 90% or more of strains are positive; –, 90% or more of strains are negative.

^bData from Hamana and Nakagawa (2001), Reichenbach (1989), and Sly et al. (1998).

(van Veen et al., 1973) and GMBN medium (Kämpfer, 1995) were recommended for initial isolation.

Maintenance procedures

Stock cultures on the previously described S.C.Y. agar slopes, with 3 ml of sterile tap water added on the surface of the agar, are inoculated and kept at 20–25°C until turbid growth in the liquid layer. The organism remains viable during 3 months

storage at 4°C and can be preserved for longer periods by common lyophilization techniques.

Differentiation of the genus *Haliscomenobacter* from other genera

A number of characteristics, summarized in Table 85, differentiate the genus *Haliscomenobacter* from the phylogenetically most closely related species *Saprospira grandis* and genus *Lewinella*.

List of species of the genus *Haliscomenobacter*

1. ***Haliscomenobacter hydrossis*** van Veen, van der Kooy, Geuze and van der Vlies 1973, 213^{AL} (*Streptothrix hyalina* Migula 1895, 38, *sensu* Mulder and Van Veen 1974, 133)

hydrossis. Gr. n. *hudôr* water; *Oss* town in the Netherlands; N.L. gen. n. *hydrossis* from water of Oss.

Most of the characteristics are the same as those given for the genus. Electron micrographs revealing details of cell structure (e.g., Figure 65) have been presented by Deinema et al. (1977). Polysaccharides, not poly-β-hydroxybutyrate, serve as the reserve material of this organism. Extensive continuous-culture experiments have been carried out with *Haliscomenobacter hydrossis* growing in a complex medium (trypticase soy, yeast extract, and glucose) at different dilution rates (Krul, 1977). Owing to the pronounced proteolytic activity

of the organism, complex nitrogen compounds were readily degraded. Amino acids from these compounds were used as both nitrogen and energy sources in the presence of glucose. Of these amino acids, glutamic acid, glycine, methionine, tryptophan, lysine, and arginine were relatively easily taken up. The remaining amino acids accumulated in the free state at relatively high dilution rates, apparently owing to suppression of this uptake by glucose. At dilution rates below 0.015/h, all the amino acids were taken up more or less completely. In addition to these details from continuous culture experiments, more details on the physiological properties can be obtained from Kämpfer (1995) and Kämpfer et al. (1995).

DNA G+C content (mol%): 49 (*T_m*).

Type strain: ATCC 27775, DSM 1100, LMG 10767.

Sequence accession no. (16S rRNA gene): M58790.

Genus IV. *Lewinella* Sly, Taghavi and Fegan 1998, 735^{VP}

LINDSAY I. SLY AND MARK FEGAN

Le.win.el'la. L. fem. dim. ending *-ella*; N.L. fem. dim. n. *Lewinella* named after Ralph Lewin, who first isolated these organisms.

Unbranched, flexible rods or filaments 0.5–1.5 × 5–150 µm or longer (up to several mm) consisting of individual cells 2–3 µm long. **Ensheathed**, although sheaths may be difficult to visualize. Filament breakage or cell lysis results in empty ends or spaces (necridia). Resting stages not known. **Motile by gliding**. Gram-stain-negative. Produce **orange or yellow carotenoid pigments**. Chemo-organotrophic. **Aerobic**, having a respiratory type of metabolism with oxygen as the terminal electron acceptor. Gelatin is hydrolyzed but not cellulose, chitin, or starch. **Seawater is required for growth**. Isolated from marine environments.

DNA G+C content (mol%): 44.9–53.1.

Type species: ***Lewinella cohaerens*** (Lewin 1970) Sly, Taghavi and Fegan 1998, 735^{VP} (*Herpetosiphon cohaerens* Lewin 1970, 518^{AL}).

Further descriptive information

The species assigned to the genus *Lewinella* have not been studied extensively since their description by Lewin (1970). The descriptions below are based on data and taxonomic considerations from Mandel and Lewin (1969), Lewin (1970), Holt (1989), Reichenbach (1992), Sly et al. (1998), and Hamana and Nakagawa (2001).

FIGURE 65. *Haliscomenobacter hydrossis* branched filament with thin hyaline sheath. Electron micrograph. Bar = 1 μm . (Reproduced with permission from Mulder and Deinema 1981.)

Enrichment and isolation procedures

According to Holt (1989), seawater agar (1.0–1.5% agar) without added nutrients can often be used. Sample material from a natural marine habitat is placed in the center or in a single streak on

the plate. *Lewinella* organisms will glide away from the point of inoculation and form a characteristic rough, swirled swarm. Isolation can be achieved by selecting material from the leading edge of the swarm while viewing under low power magnification.

Differentiation of the genus *Lewinella* from other genera

The characteristics which differentiate *Lewinella* from other members of the family *Saprospiraceae* are listed in the introduction to the family Table 84. The most important features are flexible but non-helical, sheathed, unbranched filaments with gliding motility, requirement for seawater, inability to hydrolyze starch, and spermidine as the major polyamine.

Taxonomic comments

The species in this genus were originally assigned to the genus *Herpetosiphon*. However, analysis of 16S rRNA gene sequences from *Herpetosiphon* species indicated heterogeneity within that genus (Sly et al., 1998). The cluster of the three marine species of *Herpetosiphon* – *Herpetosiphon cohaerens*, *Herpetosiphon nigricans*, and *Herpetosiphon persicus* – exhibited affinities to *Saprospira* and *Haliscomenobacter* and was only distantly related to the type species of *Herpetosiphon*. Thus these three species were reassigned to a new genus, *Lewinella*, within the *Saprospiraceae* (Sly et al., 1998). Figure 66 shows the phylogenetic relationship of *Lewinella* species to other members of the family. The genus *Lewinella* forms a well-supported lineage with *Saprospira grandis* and *Haliscomenobacter hydrossis* within the *Saprospiraceae*. The 16S rRNA gene sequences of the three species have similarity values to one another of 86–88%, indicative of their separate species status (Sly et al., 1998).

Editorial note: Since the acceptance of this treatment of *Lewinella*, four new species, *Lewinella agarilytica* (Lee, 2007), *Lewinella antarctica* (Oh et al., 2009), *Lewinella lutea* (Khan et al., 2007), and *Lewinella marina* (Khan et al., 2007) have been described, and the genus and other species descriptions emended (Khan et al., 2007). Readers are referred to these papers for further information.

List of species of the genus *Lewinella*

1. ***Lewinella cohaerens*** (Lewin 1970) Sly, Taghavi and Fegan 1998, 735^{VP} (*Herpetosiphon cohaerens* Lewin 1970, 518^{AL})

co.hae'rens. L. part. adj. *cohaerens* cohering, uniting together.

The characteristics are as given for the genus, with the following additional features. Unbranched, flexible, sheathed rods or filaments 0.7 μm in diameter (1.0 μm including sheath) and 60–150 μm or more in length. Cell masses have an orange pigment believed to be the carotenoid saxopyxanthin. Growth is promoted by glucose and sucrose but not acetate, galactose, glycerol, or lactate. Nitrogen sources include tryptone and glutamate but not nitrate. Although no acid is produced in litmus milk, the milk is coagulated and the litmus is reduced. Tyrosine and dihydroxyphenylalanine are not degraded. Growth factors are not required. Seawater (one-half to double-strength) is required for growth.

Habitat: beach sand at Biarritz, France.

DNA G+C content (mol%): 44.9 (Bd).

Type strain: II-2, ATCC 23123, NBRC 102661, NCIMB 12855.

Sequence accession no. (16S rRNA gene): AF039292.

2. ***Lewinella nigricans*** (Lewin 1970) Sly, Taghavi and Fegan 1998, 736^{VP} (*Herpetosiphon nigricans* Lewin 1970, 518^{AL})

ni'gri.cans. L. part. adj. *nigricans* blackening.

Unbranched, flexible, sheathed rods or filaments 0.5 μm (1.0 μm including sheath) and 5–50 μm in length. Cell masses have a yellow pigment believed to be the carotenoid zeaxanthin. Glucose is a suitable carbon source. Growth is promoted by sucrose and galactose but not acetate, glycerol, or lactate. Nitrogen sources include Casamino acids, tryptone, glutamate, and nitrate. Although acid is not produced in litmus milk, the milk is coagulated and digested, and the litmus is reduced. Tyrosine is degraded with the formation of a pigmented product. Dihydroxyphenylalanine is not degraded. Growth factors are not required. Seawater (one-half to double-strength) is required for growth.

Habitat: beach sand near Lagos, Nigeria.

DNA G+C content (mol%): 53.1 (Bd).

Type strain: SS-2, ATCC 23147, NBRC 102662, NCIMB 1420.

Sequence accession no. (16S rRNA gene): AF039294.

3. ***Lewinella persica*** (Lewin 1970) Sly, Taghavi and Fegan 1998, 735^{VP} (*Herpetosiphon persicus* Lewin 1970, 518^{AL})

per'si.ca. L. fem. adj. *persica* Persian (of fruit = peach), i.e., peach-colored.

Unbranched, flexible, sheathed rods or filaments 0.7 μm (1.0 μm including sheath) and 30–150 μm or more in length.

Class IV. *Cytophagia* class. nov.

YASUYOSHI NAKAGAWA

Cy.to.pha'gi.a. N.L. fem. n. *Cytophaga* type genus of the type order *Cytophagales*; suff. *-ia* ending proposed by Gibbons and Murray and by Stackebrandt et al. to denote a class; N.L. neut. pl. n. *Cytophagia* the class of *Cytophagales*.

Cells are short or long rods and sometimes filaments. Some genera form rings, coils, vibroids or S-shaped cells. **Spores or other resting cells are not found** except for the genus *Sporocytophaga*. **Motile by gliding or flagella, or nonmotile.** Flagella are found in only the genus *Balneola*. **Stain Gram-negative.** Growth is usually strictly aerobic, but microaerobic to anaerobic growth occurs in a few members. **Chemo-organotrophic. Colonies are usually pigmented,** and cell masses are yellow, orange, pink, or red owing to carotenoids, flexirubin-type pigments, or both. Widely distributed in nature. Some genera are marine organisms that require seawater salts for growth. Most species are mesophilic, but psychrophilic and thermophilic members exist.

Type order: *Cytophagales* Leadbetter 1974, 99^{AL}.

Taxonomic comments

The class *Cytophagia* is circumscribed for this volume on the basis of the phylogenetic analyses of the 16S rRNA sequences. The class includes the order *Cytophagales* and some other deep phylogenetic groups that are treated as orders *incertae sedis*.

Leadbetter, E.R. 1974. Order II. *Cytophagales* nomen novum. In *Bergey's Manual of Determinative Bacteriology*, 8th edn (edited by Buchanan and Gibbons). Williams & Wilkins, Baltimore, pp. 99–122.

Order I. *Cytophagales* Leadbetter 1974, 99^{AL}

YASUYOSHI NAKAGAWA

Cy.to.pha.ga'les. N.L. fem. n. *Cytophaga* the type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Cytophagales* the *Cytophaga* order.

Cells are short or long rods and sometimes filaments. Some genera form rings, coils, vibroids or S-shaped cells. **Spores or other resting cells have not been found** except for the genus *Sporocytophaga*. **Motile by gliding or nonmotile.** Flagella are usually absent. **Stain Gram-negative.** Growth is usually strictly aerobic, but microaerobic to anaerobic growth occurs in a few members. **Chemo-organotrophic.** Most species are able to degrade one or several kinds of organic macromolecules such as proteins (e.g., casein, gelatin), lipids (e.g., Tweens) and esculin, starch, pectin, agar, chitin, carboxymethylcellulose or cellulose. **Colonies are usually pigmented** and cell masses are yellow, orange, pink or red owing to carotenoids, flexirubin-type pigments, or both. Widely distributed in nature. Some genera are marine organisms requiring seawater salts for growth. Most species are mesophilic, but a few species and genera are psychrophilic. The major respiratory quinone is MK-7, as far as it has been investigated. Most genera contain branched, unsaturated, or hydroxy fatty acids as predominant fatty acids.

Type genus: *Cytophaga* Winogradsky 1929, 577^{AL} emend. Nakagawa and Yamasato 1996, 600.

Taxonomic comments

The order *Cytophagales* that was established by Leadbetter (1974) accommodated three families *Cytophagaceae*, *Flavobacteriaceae*, and *Bacteroidaceae*, and some genera in the 1st edition of the *Systematics* (Reichenbach, 1989). The order is circumscribed

for this volume to encompass the three families *Cytophagaceae*, *Cyclobacteriaceae*, and *Flammeovirgaceae*, based on 16S rRNA sequences. The families *Flavobacteriaceae* and *Bacteroidaceae* are reassigned to the classes *Flavobacteriia* and *Bacteroidia*, respectively. The families *Cyclobacteriaceae* and *Flammeovirgaceae* were not described in previous editions of the manual. Because the three families belonging to the order *Cytophagales* share many phenotypic characteristics, they are difficult to differentiate based solely on phenotype. The major quinone is MK-7, as far as it has been investigated. The G+C contents of the DNA of the families *Cytophagaceae*, *Cyclobacteriaceae*, and *Flammeovirgaceae* are 34–65, 35–45, and 31–45 mol%, respectively.

Family I. **Cytophagaceae** Stanier 1940, 630^{AL}

YASUYOSHI NAKAGAWA

Cy.to.pha.ga'ce.ae. N.L. fem. n. *Cytophaga* the type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. *Cytophagaceae* the *Cytophaga* family.

Cells are short or long rods and sometimes filaments. Some genera form rings, coils, vibroids or S-shaped cells. **Spores or other resting cells** are absent except for the genus *Sporocytophaga*. **Motile by gliding, or nonmotile.** Flagella are usually absent. **Stains Gram-negative.** Growth is usually strictly aerobic, but microaerobic to anaerobic growth occurs in members of a few genera. **Chemo-organotrophs.** Members of most species are able to degrade one or several kinds of organic macromolecules such as proteins (e.g., casein, gelatin), lipids (e.g., Tweens) and esculin, starch, pectin, agar, chitin, carboxymethylcellulose or cellulose. **Colonies are usually pigmented** and cell masses are yellow, orange, pink or red owing to carotenoids, flexirubin-type pigments, or both. Widely distributed in nature. Some genera are marine organisms requiring sea water salts for growth. Most species are mesophilic, but a few species and genera are psychrophilic. The major respiratory quinone is MK-7 as far as investigated. Predominant fatty acids in most genera are branched, unsaturated or hydroxy fatty acids such as C_{15:0} iso, C_{16:1}, C_{17:1}, C_{15:0} iso 2-OH and/or C_{17:0} iso 3-OH.

DNA G+C content (mol%): 34–65.

Type genus: **Cytophaga** Winogradsky 1929, 577 emend. Nakagawa and Yamasato 1996, 600^{AL}.

Taxonomic comments

The family *Cytophagaceae* was established to accommodate one genus, *Cytophaga*, by Stanier (1940) and expanded to encompass six more genera, *Capnocytophaga*, *Chitinophaga*, *Flexibacter*, *Flexithrix*, *Microscilla*, and *Sporocytophaga* in the 1st edition of this *Manual* (Reichenbach, 1989c). Since then, many new genera have been described in the phylum *Bacteroidetes* and 16S rRNA sequence data have become available. In light of this new information, the family is delineated again in this volume. The genera *Capnocytophaga*, *Chitinophaga*, and *Flexithrix* are excluded from the family *Cytophagaceae* and reassigned to the families *Flavobacteriaceae*, *Chitinophagaceae*, and *Flammeovirgaceae*, respectively. Since 13 other genera have been added to the family *Cytophagaceae*, it now contains 17 genera. The major respiratory quinone of all genera belonging to the family is MK-7 as far as has been determined. This character is useful for differentiating the family *Cytophagaceae* from the family *Flavobacteriaceae*, which is characterized by MK-6 (Bernardet et al., 2002).

Although phenotypic differentiation of the 17 genera belonging to the family is difficult, some differential characteristics are summarized in Table 86.

Genus I. **Cytophaga** Winogradsky 1929, 577^{AL} emend. Nakagawa and Yamasato 1996, 600^{VP}

YASUYOSHI NAKAGAWA

Cy.to'pha.ga. Gr. n. *cytos* vessel, container, and in biology a cell; Gr. v. *phagein* to eat; N.L. fem. n. *Cytophaga* devourer of cell; intended to mean devourer of cell wall, cellulose digester.

Moderately long flexible rods 0.3–0.5 µm wide and 2–10 µm long with slightly tapering ends. **Motile by gliding.** Nonspore-forming. Resting stages are absent. Gram-stain-negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Chemo-organotrophic. Cell mass is yellow to orange owing to carotenoids, flexirubin-type pigments, or both. Oxidase-positive. Catalase-negative. Terrestrial organisms, common in soil. The optimum pH for growth is 7. Crystalline cellulose (filter paper) and carboxymethyl cellulose are degraded. The major respiratory quinone is MK-7. The major polyamine is homospermidine.

DNA G+C content (mol%): 37–42.

Type species: **Cytophaga hutchinsonii** Winogradsky 1929, 578^{AL}.

Enrichment and isolation procedures

Standard procedures to isolate cellulose-degrading organisms can be applied. Media in which filter papers have been placed on mineral salts agar or immersed in a mineral salt solution are used. After incubation for several days to 1 month, yellow to orange spots will appear on the surface of the filter papers. Cellulose powders or carboxymethylcellulose can be used instead of filter paper. Detailed protocols have been described by Reichenbach (1989c, 1992a).

Maintenance procedures

Cultures of *Cytophaga* strains can be preserved by freezing at temperatures lower than –80°C. For freezing, cells are suspended in a suitable liquid medium containing 10% glycerol or 7% DMSO. *Cytophaga* strains are rather sensitive to drying; however, they can be preserved by the liquid drying method using a protective medium such as SM1* (Sakane et al., 1996) or by freeze drying.

Differentiation of the genus *Cytophaga* from other genera

Phylogenetic analysis shows that the genus *Cytophaga* is a phylogenetically independent genus in the phylum *Bacteroidetes* (see Figure 74 of the chapter *Flexibacter*). When the genus was emended (Nakagawa and Yamasato, 1996), the key characteristics to differentiate the genus from the related taxa were the possession of MK-7 as the major quinone and the ability to degrade cellulose. Menaquinone types can be used to differentiate the genus from the family *Flavobacteriaceae*, which is characterized by MK-6 (Bernardet et al., 2002; Nakagawa and Yamasato, 1993). Since then, a number of new genera have been proposed,

*SM1 (Sakane et al., 1996) consists of: monosodium glutamate monohydrate, 30 g; adonitol, 15 g; L-(–)-cysteine-HCl, 0.5 g; and 0.1 M phosphate buffer (pH 7.0), 1000 ml.

^cNot determined for all members of the genus.

making it very difficult to differentiate the genus *Cytophaga* from other related genera only by phenotypic characteristics. When additional strains are isolated, other chemotaxonomic, physiologic, and biochemical characteristics of the genus *Cytophaga* will be found.

Taxonomic comments

The genus *Cytophaga* was first described by Winogradsky (1929) for aerobic, cellulolytic, soil bacteria with probable gliding motility. Stanier (1940, 1941, 1942, 1947) investigated Gram-stain-negative bacteria that could move by gliding and degrade cellulose, agar, and/or chitin, and suggested that the gliding motility and the ability to degrade biomacromolecules were indispensable characters for the genus. These generic concepts were accepted in principle in the 1st edition of this *Manual* by Reichenbach (1989c); however, he stated that the genus is “a rather heterogeneous assembly of organisms which certainly do not belong to one single genus”. In addition, several taxonomic investigations described in the reviews by Callies and Mannheim (1978), Christensen (1977), Hayes (1977), Oyaizu and Komagata (1981), and Shewan and McMeekin (1983) revealed considerable overlapping of phenotypic and chemotaxonomic characteristics between members of the genera *Cytophaga* and *Flavobacterium*. Only gliding motility could be regarded as a distinguishing feature for the two genera, but this feature is sometimes not easy to discern (Henrichsen, 1972; McMeekin and Shewan, 1978; Perry, 1973). Accordingly the two genera were called the *Flavobacterium-Cytophaga* complex. These developments are described in detail in the 1st edition of this *Manual* (Reichenbach, 1989c).

Of the 23 validly published *Cytophaga* species, 20 were recognized in the 1st edition of this *Manual*. 16S rRNA sequencing analysis showed great biological diversity within the genus *Cytophaga* (Nakagawa and Yamasato, 1993). They also showed that *Cytophaga* species were characterized by either MK-6 (*Cytophaga aquatilis*, *Cytophaga aurantiaca*, *Cytophaga columnaris*, *Cytophaga flevensis*, *Cytophaga johnsonae*, *Cytophaga latercula*, *Cytophaga lytica*,

Cytophaga marina, *Cytophaga marinoflava*, *Cytophaga pectinovora*, *Cytophaga psychrophila*, *Cytophaga saccharophila*, *Cytophaga succinicans*) or MK-7 (*Cytophaga agarovorans*, *Cytophaga aprica*, *Cytophaga arvensicola*, *Cytophaga diffluens*, *Cytophaga fermentans*, *Cytophaga heparina*, *Cytophaga hutchinsonii*, *Cytophaga salmonicolor*). The types of major menaquinones correlated well with the phylogenetic relationships. Some of the species possessing MK-6 were closely related to *Flavobacterium aquatile*, the type species of the genus *Flavobacterium*. The understanding and acceptance of the diversity of the genus have led to several reclassifications and descriptions of new genera as summarized in Table 87 and described below.

Nakagawa and Yamasato (1996) emended the genus *Cytophaga* to contain only two species, *Cytophaga hutchinsonii* and *Cytophaga aurantiaca*. These are the only two species that are, based on 16S rRNA sequencing analysis, justifiably members of the genus *Cytophaga*. *Cytophaga agarovorans* and *Cytophaga salmonicolor*, which are facultatively anaerobic, usually pink-colored marine organisms, formed a distinct cluster in the class *Bacteroides* and were transferred in the new genus *Marinilabilia* (Nakagawa and Yamasato, 1996). Later, *gyrB* sequence analyses and DNA–DNA hybridization studies showed that *Marinilabilia salmonicolor* (basonym *Cytophaga salmonicolor*) and *Marinilabilia agarovorans* (basonym, *Cytophaga agarovorans*) should be unified in a single species, and the name *Marinilabilia salmonicolor* biovar. *agarovorans* was proposed for it (Suzuki et al., 1999). Eight species possessing MK-6 – *Cytophaga aquatilis*, *Cytophaga columnaris* (synonym, *Flexibacter columnaris*), *Cytophaga flevensis*, *Cytophaga johnsonae*, *Cytophaga pectinovora*, *Cytophaga psychrophila* (synonym, *Flexibacter psychrophilus*), *Cytophaga saccharophila*, and *Cytophaga succinicans* – were closely related to the genus *Flavobacterium* and therefore transferred to the genus *Flavobacterium*. The family *Flavobacteriaceae* was emended to accommodate MK-6 organisms (Bernardet et al., 1996, 2002). Accordingly, the genus *Flavobacterium* now includes both gliding-motile and non-motile organisms. This means that gliding motility is not a significant taxonomic characteristic for differentiation of genera.

<i>C. psychrophila</i>	<i>Flavobacterium psychrophilum</i>	Bernardet et al. (1996)
<i>C. saccharophila</i>	<i>Flavobacterium saccharophilum</i>	Bernardet et al. (1996)
<i>C. salmonicolor</i>	<i>Marinilabilia salmonicolor</i>	Nakagawa and Yamasato (1996); Suzuki et al. (1999)
<i>C. succinicans</i>	<i>Flavobacterium succinicans</i>	Bernardet et al. (1996)
<i>C. uliginosa</i>	<i>Zobellia uliginosa</i>	Bowman (2000); Barbeyron et al. (2001)

Two marine agarolytic organisms, *Cytophaga aprica* and *Cytophaga diffluens*, were transferred to the new genera *Flammeovirga* and *Persicobacter*, respectively (Nakagawa et al., 1997). A heparin-degrading species, *Cytophaga heparina* was initially transferred to the genus *Sphingobacterium*, because it contained sphingolipids (Takeuchi and Yokota, 1992), and then was reclassified in the new genus *Pedobacter* as *Pedobacter heparinum*, together with other heparinase-producing organisms (Steyn et al., 1998). *Cytophaga lytica* and *Cytophaga uliginosa* – marine species possessing MK-6 – were classified in the new genus *Cellulophaga* (Bowman, 2000; Johansen et al., 1999); later, *Cellulophaga uliginosa* was transferred to the new genus *Zobellia* (Barbeyron et al., 2001). A marine fish pathogen, *Cytophaga marina* (heterotypic synonym, *Flexibacter maritimus*) was reclassified as *Tenacibaculum maritimum* (Suzuki et al., 2001). *Cytophaga marinostrava* was assigned to the genus *Leeuwenhoekella* (Nedashkovskaya et al., 2005d). The genus *Stanierella* was established to accommodate *Cytophaga latercula*; however, this new genus was eventually subsumed into another genus, *Aquimarina*, proposed in the same paper (Nedashkovskaya et al., 2005b, 2006). *Cytophaga arvensicola*, together with three other misclassified *Flexibacter* species – *Flexibacter filiformis*, *Flexibacter japonensis*, and *Flexibacter sancti* – was classified in the genus *Chitinophaga* (Kämpfer et al., 2006). At present, two of 23 validated species of the genus *Cytophaga* – *Cytophaga fermentans* and *Cytophaga xylanolytica* – remain to be reclassified. *Cytophaga fermentans* is a marine facultative anaerobe that possesses MK-7

and was closely related to the class *Bacteroides* based on the 16S rRNA sequence analysis (Nakagawa and Yamasato, 1993, 1996). *Cytophaga xylanolytica* is anaerobic gliding bacterium degrading xylan (Haack and Breznak, 1993). Only three partial 16S rRNA sequences (lengths, 287, 290, 350 bases, respectively) of this species are currently available; however, they show that *Cytophaga xylanolytica* is related to the class *Bacteroides*. Thus, *Cytophaga fermentans* and *Cytophaga xylanolytica* should not be included in the genus *Cytophaga*.

Differentiation of species of the genus *Cytophaga*

Table 88 lists characteristics that distinguish *Cytophaga* species from one another.

TABLE 88. Characteristics differentiating the species of the genus *Cytophaga*^{a,b}

^bData from Reichenbach (1989c) and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

List of species of the genus *Cytophaga*

1. *Cytophaga hutchinsonii* Winogradsky 1929, 578^{AL}

hut.chin.so'ni.i. N.L. masc. gen. n. *hutchinsonii* of Hutchinson, named in honor of English microbiologist, H. B. Hutchinson.

The characteristics are as described for the genus with the following additional features taken from *Bergey's Manual of Determinative Bacteriology* (9th edition) and the 1st edition of this *Manual*. Cells are flexible rods, 0.3–0.5 µm wide and 2–10 µm long or longer. The cell mass is bright yellow. Optimum growth temperature is 30°C. Oxidase-positive. Catalase-negative or very weakly positive. Cellulose (filter paper) and carboxymethyl cellulose are degraded, but not agar, chitin, pectin, or starch. Peptones, Casamino acids, several amino acids including aspartic and glutamic acids, NO₃⁻, and NH₄⁺ serve as sole nitrogen source. Cellulose, cellobiose, and glucose are used, but arabinose, fructose, galactose, mannitol, mannose, sodium pyruvate, and xylose are not. Growth does not occur in seawater media. A flexirubin type pigment is present.

Source: unclear but assumed to be from soil (Reichenbach, 1989c).

DNA G+C content (mol%): 39 (Bd) to 40 (*T_m*).

Type strain: ATCC 33406, CIP 103989, DSM 1761, JCM 20678, LMG 10844, NBRC 15051, NCIMB 9469.

Sequence accession no. (complete genome): CP000383, NC008255; (*16S rRNA gene*): M58768.

2. *Cytophaga aurantiaca* (ex Winogradsky 1929) Reichenbach 1989c, 2036^{VP} (*Cytophaga aurantiaca* Winogradsky 1929, 597) au.ran.ti'a.ca. N.L. fem. adj. *aurantiaca* orange colored.

The characteristics are as described for the genus with the following additional features taken from *Bergey's Manual of Determinative Bacteriology* (9th edition) and the 1st edition of this *Manual*. Cells are flexible rods, 0.3–0.4 µm wide and 2–8 µm long or longer. The cell mass is bright orange. Optimum growth temperature is 20–25°C. Oxidase-positive. Catalase-negative. Cellulose (filter paper) and carboxymethyl cellulose are degraded, but not agar, casein, or starch. Peptones, NO₃⁻, and NH₄⁺ serve as nitrogen sources. Cellulose, cellobiose, and glucose are used. Growth does not occur in seawater media. A flexirubin type pigment is absent.

It is suggested that the type strain of *Cytophaga aurantiaca* is identical with Bortels's strain *Cytophaga aurantiaca* 51, which is isolated from soil of the swampy edge of a pond in Germany (Bortels, 1956; Reichenbach, 1989c).

DNA G+C content (mol%): 37–42 (Bd).

Type strain: ATCC 12208, DSM 3654, JCM 8511, NBRC 16043, NCIMB 8628.

Sequence accession no. (16S rRNA gene): D12658.

Other species

No species listed below should be included in the genus *Cytophaga*, because they are not closely related to the type species of the genus based on 16S rRNA sequence analysis.

1. *Cytophaga fermentans* Bachmann 1955, 549^{AL} fer.men'tans. L. part. adj. *fermentans* fermenting.

The descriptions include characteristics described in *Bergey's Manual of Determinative Bacteriology* (9th edition) and the 1st edition of this *Manual*. Cells are flexible rods, 0.3–0.7 µm wide and 8–50 µm long or longer. Motile by gliding. Nonsporeforming. Resting stages are absent. Gram-stain-negative. The cell mass from aerobic cultures is bright yellow on peptone media, and from anaerobic cultures, it is unpigmented on minimal media. Colonies are thin spreading films with yellow blobs in shallow craters. Facultatively anaerobic. Optimum growth temperature is 30°C. Agar and starch, but not alginate, cellulose (filter paper), or chitin are degraded. Peptones, asparagine, glutamine, and NH₄⁺ serve as nitrogen sources, but not NO₃⁻ or urea. Arabinose, cellobiose, fructose, glucose, lactose, maltose, mannitol, mannose, raffinose, starch, sucrose, and xylose are used, but acetate, agar, alginate, cellulose, chitin, dulcitol, ethanol, galactose, glycerol, rhamnose, trehalose, and sorbose are not. Glucose is fermented with production of acetate, propionate, and succinate. Growth does not occur in seawater media. Nitrate is not reduced. Marine organism, requiring elevated salt concentrations.

This species is related to the class *Bacteroides* based on the 16S rRNA sequence analysis (Nakagawa and Yamasato, 1996).

DNA G+C content (mol%): 39 (Bd) to 42 (*T_m*).

Type strain: ATCC 19072, CIP 104805, DSM 9555, JCM 21142, NBRC 15936.

Sequence accession no. (16S rRNA gene): M58766.

2. *Cytophaga xylanolytica* Haack and Breznak 1993, 14^{VP}

xylan.o.ly'ti.ci. N.L. n. *xylanum* xylan (a xylose-containing heteropolysaccharides in plant cell walls); N.L. fem. adj. *lytica* (from Gr. fem. adj. *lytikē*), able to loosen, able to dissolve; N.L. fem. adj. *xylanolytica* xylan-dissolving.

The characteristics are as described by Haack and Breznak (1993). Cells are flexible rods, 0.4 µm wide and 3–24 µm long or longer. Motile by gliding. Nonsporeforming. Resting stages are absent. Gram-stain-negative. The cell mass is orange to salmon due to the presence of carotenoids. Aeroduric anaerobe. No growth occurs under conventional aerobic conditions with or without CO₂ enrichment of the atmosphere. Growth occurs at 19–37°C; optimum is 30–32°C. Growth occurs at pH 6.1–8.7; optimum 7.2–8.2. Oxidase-negative. Catalase weakly positive. Sulfide is used as the sole sulfur source. Peptones, glutamine, and NH₄⁺ serve as nitrogen sources, but not NO₃⁻, N₂, or glutamate. Xylan, laminarin, lichenin, cellobiose, lactose, glucose, galactose, mannose, xylose, and arabinose are fermented as energy sources for growth, but not cellulose, carboxymethyl cellulose, arabinogalactan, mannan, chitin, *N*-acetylglucosamine, sorbose, ribose, or rhamnose. Acetate, propionate, and succinate are the major products of xylan, xylose, and glucose fermentation. NO₃⁻ and SO₄²⁻ are not used as terminal electron acceptors during anaerobic growth. O₂ is not used as terminal electron acceptor (type strain). Growth occurs in the presence of up to 3% NaCl. Marine organism, requiring elevated salt concentrations. A flexirubin type pigment and a sulfonolipid are present. The major cellular fatty acids are C_{15:0} anteiso, C_{15:0}^o and C_{15:0} 3-OH.

Analysis of partial 16S rRNA sequences indicates a close relationship between this species and the class *Bacteroides*.

DNA G+C content (mol%): 45.5 (Bd).

Type strain: XM3, ATCC 51429, DSM 6779.

Sequence accession no. (three partial 16S rRNA in lengths 287, 290, 350 bases): AH001617.

Genus II. *Adhaeribacter* Rickard, Stead, O'May, Lindsay, Banner, Handley and Gilbert 2005, 827^{VP}

PETER GILBERT* AND ALEXANDER H. RICKARD

Ad.haer'i.bac.ter. L. v. *adhaereo*, *adhaere* to ADHERE to, to stick fast; N.L. masc. n. *bacter* from Gr. n. *baktron* rod; N.L. masc. n. *Adhaeribacter* sticky rod.

Rods, about 0.9–1.7 by 2.8–4.1 µm. In batch culture, mean size is dependent upon the phase of growth. During exponential growth, the rods occur singly, in aggregates, and in chains of up to approximately 4 cells in length. In the stationary phase, the cells occur singly. Cells are Gram-stain-negative, non-sporulating, nonflagellated, and nonmotile. Growth occurs in liquid and on solid interfaces. Strictly aerobic. **Chemoheterotrophic**. Temperature range for growth, 4–37°C; optimum, 30°C. Limited **NaCl tolerance**; growth occurs between 0–4.0% (w/v) NaCl.

Habitat: within freshwater, multi-species biofilm communities developed on a stainless-steel surface exposed to potable water at a shear rate of 305/s.

DNA G+C content (mol%): 40.0.

Type species: *Adhaeribacter aquaticus* Rickard, Stead, O'May, Lindsay, Banner, Handley and Gilbert 2005, 827^{VP}.

Further descriptive information

Based on 16S rRNA analysis, *Adhaeribacter* represents a separate and distinct lineage within the family *Cytophagaceae* of the *Cytophaga-Flavobacterium-Bacteroides* group (Figure 67).

Colonies are pink, round, and mucoid on R2A medium (Reasoner and Geldreich, 1985) and are not easily emulsified in sterile water or phosphate buffered saline. Growth does not occur on peptone water agar or other media commonly used for the isolation of freshwater bacteria. The growth rate on agar is improved in a moist atmosphere. Cells grown in liquid R2A do not pellet tightly when centrifuged at <3500 g, which may be a consequence of the production of extracellular polymeric substances.

Cells that are in exponential and stationary phase are completely covered with a dense fibrillar matrix, possibly composed of extracellular polysaccharide as well as other polymeric substances (Figure 68). Bundles of fibrils exist close to the cell surface, and individual thin fibers radiate away from each cell. Furthermore, the addition of the acidic dye nigrosin reveals an extensive capsule surrounding the cells. During late exponential

*Deceased.

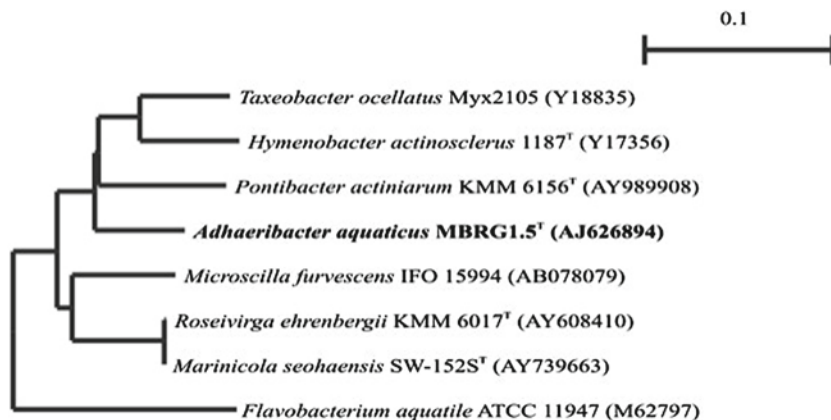

FIGURE 67. Neighbor-joining 16S rRNA phylogenetic dendrogram showing the position of *Adhaeribacter aquaticus* in relation to other closely related genera from the order *Cytophagales*. Bar represents 1 nucleotide change in every 10.

FIGURE 68. Electron micrographs of a typical negatively stained cell of *Adhaeribacter aquaticus* harvested after 72 h from batch culture. Cells were stained with 1.5% (w/v) methylamine tungstate. Cells are rod-shaped and surrounded by bundles of fibrils (BF). Each cell possesses a clearly visible electron dense "halo" (EDH). Blebbing (BL) is evident, and an inner membrane (IM) that has shrunk away from the outer membrane can be seen. Bar represents 1.0 μm .

phase and stationary phase, a large proportion of the cells plasmolyse, and blebbing and shrinkage of the inner membrane from the outer membrane occurs (Figure 68). The cause for such extensive plasmolysis is not known.

Many species of bacteria live together within biofilms (Costerton et al., 1995). *Adhaeribacter aquaticus* was isolated from a multi-species biofilm community on a stainless steel surface of a concentric cylinder reactor (Rickard et al., 2004). This device was used to demonstrate that species composition of multi-species biofilm communities is dependent upon the

imposed hydrodynamic shear forces. *Adhaeribacter aquaticus* was only isolated from biofilms exposed, for 3 months, to the highest imposed shear forces (305/s). The ability of this organism to form biofilms and reside on surfaces exposed to such extreme shear rates is likely related to the copious amounts of adhesive fibrillar material that is produced by *Adhaeribacter aquaticus*.

Enrichment and isolation procedures

There is currently no known method for selective enrichment of *Adhaeribacter aquaticus* from a mixed-species freshwater community. In general, following isolation, growth of *Adhaeribacter aquaticus* is best at 30°C in aerobic liquid R2A medium or on R2A agar in a humid atmosphere. Maximum growth rates are at 30°C, and incubation at this temperature will generate visible colonies after 3 d.

Maintenance procedures

For short-term storage, *Adhaeribacter aquaticus* can be maintained on R2A agar for approximately 1 month. For long-term storage, *Adhaeribacter aquaticus* can be stored at -70°C in 50% (v/v) glycerol.

Differentiation of the genus *Adhaeribacter* from other genera

Adhaeribacter aquaticus can be phylogenetically differentiated from other genera within the order *Cytophagales* and, indeed, within the family *Cytophagaceae* by comparison of the 16S rRNA gene sequences. The validly published species *Pontibacter actiniarum* gen. nov., sp. nov. (Nedashkovskaya et al., 2005c) is the closest relative to *Adhaeribacter aquaticus*, with 89.1% 16S rRNA gene sequence similarity (Figure 67). Phenotypically, cells from no other related genera have been reported to exhibit such a high degree of plasmolysis and produce such conspicuous amounts of extracellular polymeric substances. In addition, the profile of identifiable cellular fatty acids of *Adhaeribacter aquaticus* is significantly different from that of phylogenetically related strains.

Acknowledgements

We are grateful to P.S. Handley for assistance in preparing the TEM micrograph.

Genus III. ***Arcicella*** Nikitin, Strömpl, Oranskaya and Abraham 2004, 683^{VP} (*Arcocella* Nikitin, Oranskaya, Pitryuk, Chernykh and Lysenko 1994, 152)

WOLF-RAINER ABRAHAM, ALEXANDRE J. MACEDO, HEINRICH LÜNSDORF AND DENIS I. NIKITIN

Ar.ci.cel'la. L. masc. n. *arcus* the arc; L. fem. n. *cella* a store-room, and in biology a cell; N.L. fem. n. *Arcicella* arc-shaped cell.

Vibrioid, stretched spirals, or S-shaped cells 2.5–3.0 by 0.5–0.75 μm . Colonies on solid media are mucoid and light orange. Growth occurs between 4 and 40°C; optimum, 28–30°C. Optimum pH, ~7. Growth occurs in the presence of NaCl concentrations between 0.5 and 6.0% (w/v); no growth occurs above 6% or in the absence of NaCl. Aerobic. Growth occurs on a wide range of carbohydrates (monosaccharides are preferred) but not on C_1 compounds, amino acids, or salts of organic acids. Ammonium salts and nitrate can be used as nitrogen sources. Nitrate is not reduced to nitrite or N_2 . Biopolymers are not hydrolyzed. The main polar lipids are 2-*N*-(2'-hydroxyisopentadecanoyl)amino-3-hydroxyisoheptadeca-4(*E*)-ene-1-(2''-aminoethyl)-phosphate and its 3-hydroxyoctadeca-4(*E*)-ene homologs, phosphatidylethylamine, 2-*D*-(2'-*D*-hydroxyisopentadecanoyl)amino-3-*D*-hydroxyisoheptadecane-1-sulfonic acid, and 2-*N*-(2''-hydroxyisopentadecanoyl)amino-3-hydroxyisoheptadeca-4(*E*)-ene-1-hydroxycarbonyl-6-deoxy-6-amino-mannopyranoside. The major fatty acids are $C_{16:0}$, $C_{14:0}$, $C_{18:1}$ $\omega 6$ and $C_{18:0}$. Lives in freshwater habitats.

DNA G+C content (mol%): 34.

Type species: ***Arcicella aquatica*** Nikitin, Strömpl, Oranskaya and Abraham 2004, 683^{VP} (*Arcocella aquatica* Nikitin, Oranskaya, Pitryuk, Chernykh and Lysenko 1994, 152).

Further descriptive information

The cells are vibrioid, stretched spirals, or S-shaped, morphologically similar to the ring-forming cells of *Flectobacillus major* and, to a lesser degree, *Spirosoma linguale*.

The phospholipid and fatty acid composition of *Arcicella* and related organisms is given in Table 89.

Electron microscopic studies of *Arcicella aquatica*, in either whole mount preparations shadow-casted with Pt (Figure 69) or embedded ultrathin sections (Figure 69), revealed Gram-stain-negative cell wall architecture (Figure 69). Often the organism

was found engulfed within a slimy matrix (Figure 69) and the outermost layer of the outer membrane appeared intensely stained with thorium dioxide (Figure 69). Correspondingly, protuberances of the outer membrane were coated by thorium, indicating that these surfaces are negatively charged (Lünsdorf et al., 2006). However, the outermost slime layer (Figure 69) was free from colloidal stain, which is indicative of the neutral and/or positive charge state of the slime matrix. Cells were irregular in length (2.49–6.79 μm), and width (0.54–0.76 μm), with a mean of $0.66 \pm 0.05 \mu\text{m}$ ($n = 33$). Under actual growth conditions, intracellular inclusion bodies (ib) were often found (Figure 69), which often showed a weak hexagonal contour in cross-section, similar to that of polyhedral bodies. These cytoplasmic inclusions were 110–268 nm in diameter, with a mean of $183.4 \pm 41.8 \text{ nm}$ ($n = 17$). Fast Fourier Transform analysis of individual inclusions revealed a few ordered spots (Figure 69), indicative of an ordered arrangement of constituents and reflective of the regular arrangement of particles in the inclusion bodies (Figure 69). These features may be linked to the metabolic activities of diverse enzymes (see below) and thus the inclusions may represent so-called “metabolosomes” (Brinsmade et al., 2005).

Nutritional requirements were studied on a mineral medium of the following composition (g/l of distilled water): KH_2PO_4 , 0.01; K_2HPO_4 , 0.1; $(\text{NH}_4)_2\text{HPO}_4$, 0.2; MgSO_4 , 0.03; NaCl, 0.01; CaCl_2 , 0.01; MnSO_4 , trace amounts; FeSO_4 , trace amounts; yeast extract, 0.005%; pH, 7.2. The concentration of the carbon sources was 0.1%. Growth occurred on glucose, fructose, lactose, maltose, rhamnose, galactose, arabinose, ribose, sucrose, cellobiose, and inulin. Some growth occurred on mannitol, sorbitol, acetate, and aspartate, but no growth occurred on sorbose, dulcitol, ethanol, methanol, formate, propionate, pyruvate, monomethylamine, citrate, oxalate, succinate, and malate, or on amino acids, with the exception of aspartate.

TABLE 89. Phospholipid and fatty acid composition of *Arcicella* and related organisms^{a,b}

Species	Individual phospholipid (% of total)			Individual fatty acids (% of total)							
	PE	PG	AAPG ^c	14:0	15:1	15:0	16:0	16:1	17:1	18:0	18:1

^bData from Nikitin et al. (1994).

^cThe main AAPGs of *Arcicella aquatica* are 2-*N*-(2'-hydroxyisopentadecanoyl)amino-3-hydroxyisoheptadeca-4(*E*)-ene-1-(2''-aminoethyl)-phosphate and 2-*N*-(2'-hydroxyisopentadecanoyl)amino-3-hydroxyoctadeca-4(*E*)-ene-1-(2''-aminoethyl)-phosphate.

FIGURE 69. Electron micrographs of *Arcicella aquatica* (for details, see text; cm, cytoplasmic membrane; om, outer membrane; omt, outer membrane tubular extensions; m, murein. White arrows indicate direction of shadow casting.

No growth on meat infusion media is observed. Growth in liquid media at a carbon source concentration of 0.01% is characterized by a prolonged lag phase (up to 24 h) and slow growth, which proceeds for 48–72 h. Upon reaching the stationary phase, the culture retains the achieved optical density for as long as 21 d.

Strains can be cultivated on PYG medium, which has the following composition (g/l of distilled water): peptone (enzymic hydrolysate, Type I; from meat), 1.0; yeast extract (“Sigma” Y-4000), 1.0; glucose, 1.0. For agar plates, 20 g of agar is added; pH is 6.8–7.2. The medium is sterilized 120°C for 30 min. Strains grow within 4–5 d at 28°C.

Cells display high activity of alkaline phosphatase, leucine and valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, catalase and *N*-acetyl-β-glucosaminidase; weak activity of esterase lipase (C_8), α-chymotrypsin, α-galactosidase,

β-glucosidase and α-fucosidase; and no activity of lipase (C_{14}), α-glucuronidase, or α-mannosidase.

The genome size of *Arcicella aquatica* is 2.9×10^9 Da.

The type strain came from a neuston — a film composed of organisms found on top of or attached to the underside of the surface film of water — in the central part of Lake Trostenskoe near Zvenigorod, Moscow region.

Enrichment and isolation procedures

The type strain was isolated on a medium consisting of (g/l of distilled water): peptone, 1.0; yeast extract, 1.0; glucose, 1.0; agar (Difco), 15.0; pH 7.0–7.2. On solid media the colonies are ~3 mm in diameter, mucoid, and light orange.

Differentiation of the genus *Arcicella* from other genera

Table 90 lists some characteristics that differentiate the genus *Arcicella* from other ring-forming genera.

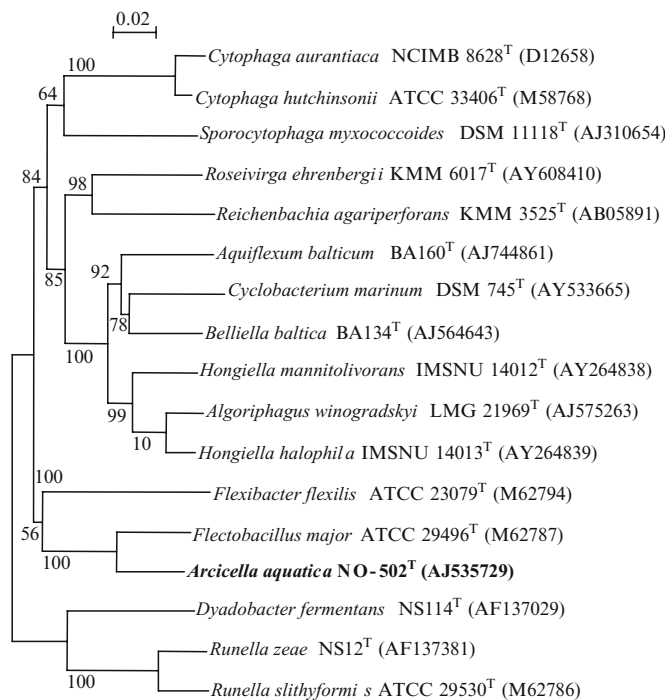

FIGURE 70. Unrooted neighbor-joining dendrogram of the phylogenetic relationships between *Arcicella aquatica* and type species of closely related genera based on a distance matrix analysis of the 16S rRNA gene sequences. Accession numbers are given in parentheses. Bootstrap percentages are indicated at tree branching points and the scale bar represents substitutions per nucleotide.

Taxonomic comments

The 16S rRNA gene sequence similarity between the type strain of *Arcicella aquatica* and the most similar published sequence of an organism with a validly published name, *Flectobacillus major*, is 93.52% (Nikitin et al., 2004) (Figure 70). This

similarity value, and the differences in the polar lipids, the cellular fatty acids, and biochemical and physiological characteristics between *Flectobacillus major* and the type strain of *Arcicella aquatica*, together with the differences in the mol% G+C content of their DNA, all support the separate generic status of *Arcicella*.

List of species of the genus *Arcicella*

1. ***Arcicella aquatica*** Nikitin, Strömpl, Oranskaya and Abraham 2004, 683^{VP} (*Arcocella aquatica* Nikitin, Oranskaya, Pitryuk, Chernykh and Lysenko 1994, 152)

a.qua.ti'ca. L. fem. adj. *aquatica* aquatic.

The characteristics are as given for the genus with the following additional features. Main phospholipids are 2-*N*-(2'-hydroxyisopentadecanoyl)amino-3-hydroxyisoheptadeca-4(*E*)-ene-1-(2''-aminoethyl)-phosphate, 2-*N*-(2'-hydroxyisopentadecanoyl)amino-3-hydroxyoctadeca-4(*E*)-ene-1-(2''-aminoethyl)-phosphate, 1-pentadecanoyl-2-hexadecenoylphosphatidyl-2'-ethylamine, 1,2-bis-hexadecenoylphosphatidyl-2'-ethylamine and 1-hexadecanoyl-2-hexadecenoylphosphatidyl-2'-ethylamine. Cells display high activities of alkaline phosphatase, leucine, and valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naph-

thol-AS-BI-phosphohydrolase, β -galactosidase, α -glucosidase, catalase and *N*-acetyl- β -glucosaminidase, weak activities of esterase lipase (C8), α -chymotrypsin, α -galactosidase, β -glucosidase, and α -fucosidase, and no activities of lipase (C₁₄), α -glucuronidase, or α -mannosidase. Growth occurs on glucose, fructose, lactose, maltose, rhamnose, galactose, arabinose, ribose, sucrose, cellobiose, and inulin; some growth occurs on mannitol, sorbitol, acetate, and aspartate; no growth occurs on sorbose, dulcitol, ethanol, methanol, formate, propionate, pyruvate, monomethylamine, citrate, oxalate, succinate, malate, or amino acids, with the exception of aspartate.

DNA G+C content (mol%): 34 (*T_m*).

Type strain: NO-502, CIP 107990, LMG 21963.

Sequence accession no. (16S rRNA gene): AJ535729.

Genus IV. ***Dyadobacter*** Chelius and Triplett 2000, 755^{VP}, emend. Reddy and Garcia-Pichel 2005, 1298^{VP}

GUNDLAPALLY S. N. REDDY AND FERRAN GARCIA-PICHEL

Dy.a.do.bac' ter. G. n. *dyas* two in number, pair; N.L. masc. n. *bacter* from the Gr. n. *baktron* rod or staff; N.L. masc. n. *Dyadobacter* rod or staff occurring in pairs.

Rods, 0.75–2 μ m in length, **in straight to curved arrangements, occurring in pairs** (Figure 71) **in young cultures and forming chains of coccoid cells in old cultures**. Nonmotile. Nonsporeforming. Gram-stain-negative. Aerobic, chemoorganoheterotrophs, unable to hydrolyze cellulose or starch or gelatin. Oxidase- and catalase-positive. **Cells produce a non-diffusible, yellow, flexirubin-like pigment. The major fatty acids are C_{15:0} iso, C_{16:1} ω 5c and C_{16:1} ω 7c.**

Type species: ***Dyadobacter fermentans*** Chelius and Triplett 2000, 756^{VP}.

FIGURE 71. Scanning electron micrograph showing the arrangement of cells of *Dyadobacter*.

Further descriptive information

The genus belongs to the family *Cytophagaceae* in the order *Cytophagales* of the phylum *Bacterioidetes*, and presently contains six species, *Dyadobacter fermentans* (Chelius and Triplett, 2000), *Dyadobacter crusticola* (Reddy and Garcia-Pichel, 2005), *Dyadobacter hamtensis* (Chaturvedi et al., 2005), *Dyadobacter ginsengisoli* (Liu et al., 2006), *Dyadobacter beijingensis* (Dong et al., 2007), and *Dyadobacter koreensis* (Baik et al., 2007a).

Dyadobacter species grown in trypticase soy agar (TSA) or R2A medium¹ contain C_{15:0} iso (19–30%), C_{16:1} ω 5c (8–20%), and C_{16:1} ω 7c (14–40%) as major fatty acids, with 20–60% of all fatty acids being the unsaturated fatty acids [C_{16:1} ω 5c and C_{16:1} ω 7c]. The minor fatty acids common to all strains are C_{16:0} and C_{16:0} 3-OH. Inasmuch as C_{16:1} ω 5c is present as a major fatty acid only in the species of the genus *Dyadobacter*, it can be readily used as a signature molecule to differentiate the genus *Dyadobacter* from other genera of the *Cytophagaceae*. Fatty acid profiles can also be used to differentiate among *Dyadobacter* species. C_{17:0} iso 3-OH, for example, is absent from *Dyadobacter crusticola* but the most abundant fatty acid in the other five species. C_{14:0} is absent from *Dyadobacter fermentans* and *Dyadobacter ginsengisoli* but present in the other four, as is C_{15:1} iso. Similarly, C_{15:0} iso 3-OH is absent in *Dyadobacter hamtensis* but present in all the other strains, and more significantly the fatty acid C_{15:0} iso 2-OH is present only in *Dyadobacter beijingensis* and not in others.

All the species of *Dyadobacter* are yellow due to a non-diffusible flexirubin-like pigment with absorption maxima at around 428, 452, and 476 nm (Figure 72; wavelengths of peak absorption may vary slightly among species) and with a characteristic bathochromic shift (from yellow to orange and then to red) upon reaction with alkali that distinguishes them from carotenoids (Reddy and Garcia-Pichel, 2005; Weeks, 1981). These flexirubin-like pigments are not very common among bacteria and are therefore of considerable chemotaxonomic value.

FIGURE 72. A typical absorption spectrum of flexirubin-like pigment of *Dyadobacter crusticola* in ethanol (solid line) and alkaline ethanol (dotted line).

The six species of the genus *Dyadobacter* grow well on R2A solid medium at room temperature, forming visible colonies in 24–48 h. However, their physiological adaptation to extreme conditions of temperature, pH, and salinity varies widely. For instance, the type strains of *Dyadobacter fermentans*, *Dyadobacter hamtensis*, and *Dyadobacter beijingensis* can grow from 4 to 37°C, with an optimum growth temperature of 28°C and pH 7. *Dyadobacter crusticola*, *Dyadobacter ginsengisoli*, and *Dyadobacter koreensis*, by contrast, can grow from 4 to 30°C, pH 6–8, and can tolerate a salt concentration of 1%, with a temperature optimum of 25°C and pH 7. Among the six species, only *Dyadobacter crusticola*, *Dyadobacter ginsengisoli*, and *Dyadobacter koreensis*, can grow at 5°C, albeit slowly, and thus can be deemed psychrotolerant. *Dyadobacter hamtensis* is clearly halotolerant, growing in NaCl concentration up to 11.6%, whereas *Dyadobacter koreensis* can tolerate a pH of 11, indicating that it is alkali tolerant. All the strains can grow on various rich organic media such as nutrient agar, TSA, and R2A, and type strains of *Dyadobacter fermentans* and *Dyadobacter hamtensis* can grow on Ayer's agar and peptone water as well (other species were not tested for growth on above two media). As shown in Table 91, differences in the metabolic versatility of the six species are substantial, ranging from the rather restricted capabilities of *Dyadobacter crusticola* to the wide array of carbon sources used by *Dyadobacter hamtensis*.

So far, there seems to be no unifying theme to the ecological habitat or role of *Dyadobacter* species. *Dyadobacter* could be a genus of adventitious, generalist bacteria, but, with only a few species isolated, it is probably too early to infer such a pattern. The six species originate from disparate habitats and show widely different carbon use profiles and even divergent physiological ranges for growth Table 91. The single available strain of *Dyadobacter fermentans* was isolated from internal tissue of *Zea mays* (i.e., surface-sterilized plant stems), but because the authors could demonstrate neither a beneficial nor a detrimental effect of the bacterium on the plants, its true habitat and role remain unclear. Interestingly, putative members of *Dyadobacter* have been isolated from surface-sterilized soil nematode cysts on plates of rich media (Nour et al., 2003). *Dyadobacter crusticola* was isolated from biological soil crusts (BSCs; Garcia-Pichel, 2002) where it is thought that cyanobacterial exudates serve as a source of carbon and nitrogen, and exopolysaccharide production contributes to crusting of the soil. However, extensive surveys of soil crust environments using cultivation-independent, DNA-based methods have

not yet detected *Dyadobacter* (Nagy et al., 2005; Reddy and Garcia-Pichel, 2006; Smith et al., 2004), indicating that they are not a major heterotrophic component of these communities; thus, their role remains to be clarified as well. *Dyadobacter hamtensis* was isolated from melt water from a Himalayan glacier and *Dyadobacter koreensis* was isolated from fresh water. By contrast, *Dyadobacter ginsengisoli* and *Dyadobacter beijingensis* were isolated from soil and rhizosphere-associated soil, respectively. The ecological role of all the above species too was not directly studied.

Enrichment and isolation procedures

Species of *Dyadobacter* have been isolated by directly plating on agar-solidified, relatively rich media (such as R2A or BG11-PGY) and incubated at ambient temperature in the dark for up to 15 d. Their yellow pigmentation and the typical cell shape and cell aggregation patterns that are readily observable under the compound microscope in a wet or dry mount, provide an easy system for preliminary identification on enrichment cultures. Repeated streaking of single colonies usually yields axenic, clonal strains with a few iterations. Inocula used successfully include surface sterilized maize stems, surface sterilized soil nematode cysts, biological soil crusts from arid lands, glacier melt waters, soil, rhizosphere-associated soil, and fresh water.

Maintenance procedures

Stock cultures of *Dyadobacter* species can be maintained under aerobic conditions on a suitable medium such as R2A or 10× PGY or nutrient agar by monthly transfer onto fresh plates. Cultures also can be stored as glycerol stocks (18% glycerol) at –80°C. However, the best method of storing for many years is lyophilization and freezing at –80°C, which they tolerate with high recovery.

Procedures for testing special characters

Colonies of *Dyadobacter* are colored yellow due to the presence of flexirubin-like pigment, and the presence of flexirubin, a characteristic feature of the genus, can be tested directly (and differentiated from carotenoid pigments) by adding a drop of 20% KOH onto colonies of *Dyadobacter*. This will cause change in the color of the pigment from yellow to orange and then to red (Reddy and Garcia-Pichel, 2005; Weeks, 1981). This alkali-driven shift can be also carried out on ethanolic extracts and quantified spectroscopically (Figure 72). Carotenoid-like absorption maxima at 428, 452, and 478 nm broaden upon addition of 1% KOH (final concentration) and an additional peak appears around 330 nm.

Differentiation of the genus *Dyadobacter* from other genera of the family *Cytophagaceae*

The phylogenetically closest genera *Runella* and *Spirosoma* (Figure 73) can be differentiated from *Dyadobacter* on the basis of pigment, cell morphology, and its variation during the growth cycle as well as fatty acid composition. For instance, unlike *Dyadobacter*, *Runella* has salmon colored colonies, no flexirubin, no cell morphology variation during the growth cycle, and lacks the fatty acid C_{16:1} ω5c. *Spirosoma* has no cell morphology variation during the growth cycle, degrades gelatin and starch, contains the fatty acids C_{16:1} and C_{17:0} iso, and lacks C_{15:0} iso, C_{16:1} ω5c, and C_{16:1} ω7c. Within the *Cytophagaceae*, variable cell morphology is

a hallmark of *Dyadobacter*, but it is also a trait of *Flectobacillus*. The latter genus, however, is pink-pigmented, not yellow, and does not contain flexirubin. The genus *Dyadobacter* can further be differentiated from *Flectobacillus* on the basis of fatty acid composition: members of *Dyadobacter* contain C_{16:1} ω5c and C_{16:1} ω7c as major fatty acids and lack C_{17:0} iso (Table 92). Besides

Dyadobacter, five other genera contain flexirubin-like pigments. However, compared to other genera, *Dyadobacter* is in the only one that contains the fatty acid C_{16:1} ω5c and varies in morphology and aggregation during its growth cycle (Table 92). Other genus-specific characteristics that differentiate *Dyadobacter* from closely related genera are listed in Table 92.

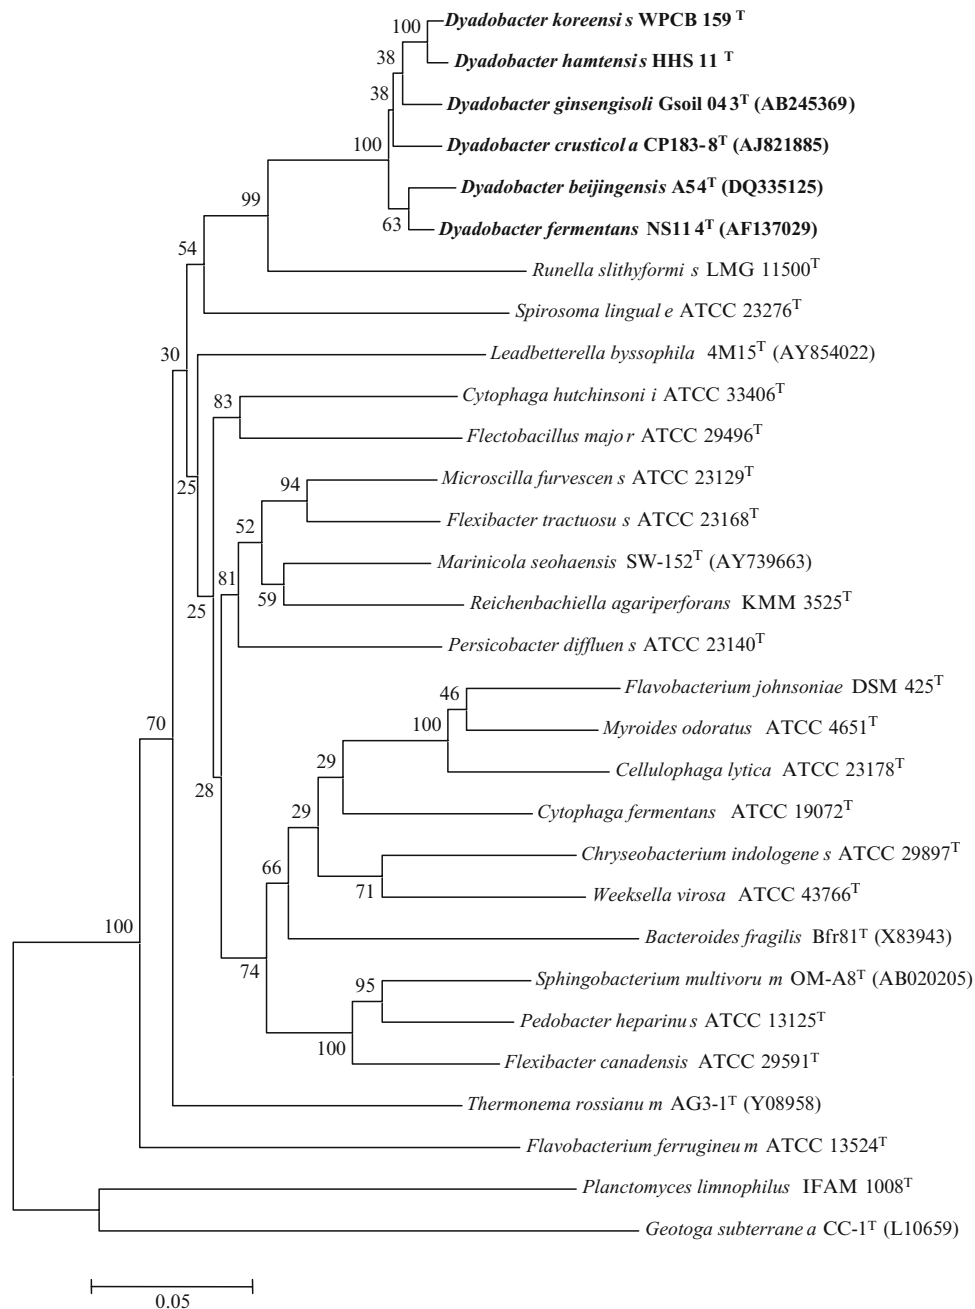

FIGURE 73. Neighbor-joining (NJ) tree based on 16S rRNA gene sequence (1337 nucleotides) showing the phylogenetic relationship between *Dyadobacter* and other related genera of the phylum *Bacteroidetes*. Bootstrap values (expressed as percentages of 1000 replicates) greater than 40% are given at nodes.

Taxonomic comments

The genus *Dyadobacter* was established to accommodate the bacteria that are straight to curved, occur in pairs in young cultures and produce a non-diffusible, yellow, flexirubin-like pigment (Chelius and Triplett, 2000). The six currently known species (*Dyadobacter fermentans*, *Dyadobacter crusticola*, *Dyadobacter hamtensis*, *Dyadobacter ginsengisoli*, *Dyadobacter beijingsensis*, and *Dyadobacter koreensis*) possess the above characteristics and, therefore, can be grouped within the genus. All six species have a 16S rRNA gene sequence similarity of 94.4–98.0%. The high-

est similarity of 98.0% was between *Dyadobacter hamtensis* and *Dyadobacter koreensis*, followed by *Dyadobacter fermentans* and *Dyadobacter beijingsensis* (a similarity of 97.4%). Since their similarity was >97.0%, DNA–DNA hybridization was performed between *Dyadobacter hamtensis* vs *Dyadobacter koreensis* and *Dyadobacter fermentans* vs *Dyadobacter beijingsensis*, and showed DNA–DNA similarities of 19.4 and <25%, respectively. Thus, according to the criteria set for discriminating species (Stackebrandt and Goebel, 1994), they all are distinctly new species. Although their number is small (six), these species, interestingly, seem

to have a kind of habitat relationship. For instance, the species *Dyadobacter fermentans* and *Dyadobacter beijingensis* have been isolated from closely related habitats – the root nodules or rhizosphere-associated soil – and exhibit a 16S rRNA gene sequence similarity of 97.4%. Similarly, *Dyadobacter hamtensis* and *Dyadobacter koreensis* were isolated from water samples and share a 16S rRNA gene sequence similarity of 98.0%.

Phylogenetic analysis based on 1337 nucleotides of the 16S rRNA gene sequence (base positions 47–1418 using *Escherichia coli* numbering, accession number J01695) indicate that species of the genus *Dyadobacter*, in accordance with their generic status, form a deeply rooted, monophyletic, and statistically very well supported clade (Figure 73). The species of *Dyadobacter* share a 16S rRNA gene sequence similarity of 94.0–98.0%, but it is less than 87% with other genera of the family *Cytophagaceae*. They share a sequence similarity of 86–87% with members of the genus *Rumella* and ca. 83% with those of *Spirosoma*, these two genera being the genera most closely related to *Dyadobacter*.

According to Reddy and Garcia-Pichel (2005), three variable regions (region I: 182–207, region II: 590–649, and region III: 835–848) contribute most to the 16S rRNA gene sequence variability among known *Dyadobacter* strains. Analysis of these regions alone is sufficient to differentiate at the species level.

Differentiation of the species of the genus *Dyadobacter*

The six *Dyadobacter* species are biochemically and physiologically divergent, exhibiting very significant and easily recognizable differences, particularly in carbon utilization patterns and temperature and pH ranges for growth. Temperature, pH, and NaCl tolerance are particularly useful in differentiating *Dyadobacter crusticola*, *Dyadobacter koreensis*, and *Dyadobacter hamtensis* from other species. The pattern of sugar and amino acid utilization can also be easily used to distinguish among the species. An extensive list of differentiating tests and traits is presented in Table 91.

List of species of the genus *Dyadobacter*

1. *Dyadobacter fermentans* Chelius and Triplett 2000, 756^{VP} fermen'tans. L. part. adj. *fermentans* causing fermentation.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. Colonies of *Dyadobacter fermentans* are yellow pigmented and can grow to a diameter of 2–3 mm. Growth occurs at 15–37°C, 0–1.5% NaCl, and pH 6–8, with an optimum temperature of 28°C and optimum pH of 7. No hydrolysis of agar,

gelatin, starch, and cellulose occurs. Growth occurs on starch, fumarate, 5-ketogluconate, malate, malonate, sucrose, erythritol, D- and L-xylose, β-methylxyloside, D-glucose, methyl α-D-mannoside, methyl α-D-glucoside, N-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, sucrose, trehalose, melezitose, D-raffinose, xylitol, gentiobiose, D-turanose, D-tagatose, and D- and L-fucose. *Dyadobacter fermentans* can ferment glucose and sucrose and produce acid from ribose. The principal fatty acids are (for cultures on

R2A medium) C_{15:0} iso (22.9%), C_{16:1} ω5c (14.3%), C_{16:1} ω7c (28.6%), C_{16:0} (5.7%), C_{16:0} 3-OH (2.9%), and C_{17:0} iso 3-OH (22.9%).

Source: surface-sterilized *Zea mays* (cv. Mo17) stem.

DNA G+C content (mol%): 48 (HPLC).

Type strain: NS114, ATCC 700827, CIP 107007.

Sequence accession no. (16S rRNA gene): AF137029.

2. **Dyadobacter beijingensis** Dong, Guo, Zhang, Qiu, Sun, Gong and Zhang 2007, 864^{VP}

beijing.en.sis. N.L. masc. adj. *beijingensis* pertaining to Beijing.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. Colonies on R2A agar are yellow, mucoid, flaky, convex, and smooth. The pigment present is of the flexirubin type, with absorption maxima at 428, 452, and 478 nm. Growth occurs at 4–35°C (optimum 28°C) but not at 37°C. Growth occurs at pH 6–8 (optimum pH 7) and in the presence of up to 1.5% NaCl. Growth occurs in peptone water, on Luria-Bertani (LB) medium, and R2A medium. No hydrolysis occurs of urea, gelatin, casein, cellulose, and starch. H₂S is not produced. The methyl red, indole, and Voges–Proskauer tests are negative. Acid is produced from D-galactose and D-rhamnose. The following substrates are utilized as sole carbon sources: erythritol, methyl β-D-xylopyranoside, D-glucose, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, arbutin, citrate, salicin, D-cellobiose, D-maltose, D-lactose, D-melibiose, sucrose, D-trehalose, D-melezitose, D-raffinose, gentiobiose, and D-fucose. No utilization occurs of glycerol, *myo*-inositol, *N*-acetylglucosamine, amygdalin, xylitol, D-turanose, D-lyxose, L-fucose, D-arabitol, L-arabitol, glycogen, D-tagatose, starch, potassium gluconate, potassium 2-ketogluconate, potassium 5-ketogluconate, and methanol. Cells are sensitive to (μg/disc) acetylspiramycin (100), carbenicillin (100), cephalothin (30), norfloxacin (10), penicillin (10), and spectinomycin (10), but are resistant to levofloxacin (100). The principal fatty acids are (culture grown on R2A medium) C_{14:0} (0.6%), C_{15:1} iso (0.5%), C_{15:0} iso (19.2%), C_{15:0} anteiso (1.0%), C_{16:1} ω5c (10.3%), C_{16:1} ω7c (17.5%), C_{16:0} (2.9%), C_{15:0} iso 2-OH (23.4%), C_{15:0} iso 3-OH (2.6%), C_{16:0} 3-OH (3.1%), C_{17:0} iso 3-OH (12.4%), and unknown (2.1%).

Source: the rhizosphere of turf grasses.

DNA G+C content (mol%): 49.2 (*T_m*).

Type strain: A54, CGMCC 1.6375, JCM 14200.

Sequence accession no. (16S rRNA gene): DQ335125.

3. **Dyadobacter crusticola** Reddy and Garcia-Pichel 2005, 1298^{VP} crus.ti.co.la. L.n. *crusta* crust; L. suff. *-cola* (from L. n. *incola*), dweller; N.L. n. *crusticola*, a dweller of crust.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. The colonies of *Dyadobacter crusticola* are mucoid, convex, round, and smooth and can grow to a size of 2–3 mm in diameter. Growth occurs at 5–30°C, 0–1.0% NaCl, and pH 6–8, with an optimum temperature of 25°C and pH of 7. Cells are positive for β-galactosidase but negative for urease, DNase, arginine decarboxylase, ornithine decarboxylase, phenylalanine deaminase, arginine dihydrolase, methyl red

test, Voges–Proskauer test, indole production, and Simmons' citrate test. Casein and cellulose are not hydrolyzed. H₂S is not produced. Acid is produced from D-fructose but not from D-galactose, lactose, D-mannitol, D-sorbitol, and D-xylose. L-Arabinose, D-galactose, D-maltose, and D-xylose are fermented, but not D-fructose, lactose, D-mannose, and D-sorbitol. D-Cellobiose, glucose, lactose, D-fructose, D-raffinose, sucrose, and D-trehalose are used as sole carbon sources but not citrate, ethanolamine, fumaric acid, pyruvate, succinate, adenine, cytosine, guanine, thymidine, nicotinic acid, oxalate, tartaric acid, indole, and phenanthrene. Cells are sensitive to (μg/disc): carbenicillin (100), doxycycline (30), and polymyxin B (300), but are resistant to azithromycin (15), aztreonam (30), bacitracin (10), ceftriaxone (30), cephalothin (30), ethambutol (50), nitrofurantoin (150), penicillin (10), sulfisoxazole (300), and sulfathiazole (300). The pigment present is a flexirubin type with absorption maxima at 428, 452, and 478 nm. The polar lipids present are phosphatidylserine, phosphatidylglycerol and diposphatidylglycerol (cardiolipin). The principal fatty acids are (culture grown on R2A medium) C_{14:0} (0.7%), C_{15:1} iso (0.5%), C_{15:0} iso (28.2%), C_{16:1} ω5c (15.5%), C_{16:1} ω7c (39.4%), C_{16:0} (13.6%), C_{16:0} 3-OH (0.5%), C_{18:0} (1.9%), and C_{18:1} (0.3).

4. **Dyadobacter ginsengisoli** Liu, Im, Lee, Yang and Lee 2006, 1941^{VP}

gin.sen.gi.so.li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of the soil of a ginseng field.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. Cells are 0.6–0.8 × 3.0–6.0 μm after 2 d on R2A agar. Colonies on R2A agar for 2 d are smooth, circular, transparent, and yellowish. Growth occurs at 4–30°C and at pH 5.5–8.5; no growth occurs at 37°C. Growth occurs in the absence of NaCl and in the presence of 1.0% NaCl, but not with 2% NaCl. Anaerobic growth does not occur. DNA, chitin, and xylan are not hydrolyzed. D-Lyxose, *N*-acetylglucosamine, salicin, D-lactose, D-maltose, and D-melibiose are utilized as sole carbon sources, but not D-fucose, ethanol, L-xylose, pyruvic acid, formic acid, propionate, 3-hydroxybutyrate, valerate, caprate, maleic acid, phenylacetate, benzoic acid, 3-hydroxybenzoate, 4-hydroxybenzoate, malate, succinic acid, glutaric acid, itaconate, adipate, suberate, oxalic acid, gluconate, xylitol, amygdalin, methanol, or glycogen. Cells are resistant to (μg/disc), carbenicillin (100) and hygromycin (100) but sensitive to streptomycin (100). The predominant menaquinone is MK-7. The principal fatty acids are (culture grown on R2A medium) C_{15:0} iso (23.0%), C_{16:1} ω5c (7.9%), C_{16:1} ω7c (44.6%), C_{16:0} (11.0%), C_{15:0} iso 2-OH (3.9%), C_{15:0} iso 3-OH (2.3%), and C_{17:0} iso 3-OH (7.6%).

5. **Dyadobacter hamtensis** Chaturvedi, Reddy and Shivaji 2005, 2116^{VP}

ham.ten'sis. N.L. masc. adj. *hamtensis* pertaining to the glacier Hamta.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. Colonies on nutrient agar are round, 2–3 mm in diameter, and light yellow. Growth occurs at 10–37°C and pH 6–8, but not at pH 10. The optimum temperature and pH for growth are 22°C and pH 7. The organisms are positive for arginine decarboxylase and β-galactosidase, but negative for urease, arginine dihydrolase, citrate utilization, H₂S production, methyl red test, indole test, and Voges–Proskauer test. Acid is not produced from D-ribose, D-galactose, L-rhamnose, D-lactose, and D-mannose. The following compounds are utilized as sole carbon sources: sucrose, N-acetylglucosamine, methyl α-D-mannoside, methyl α-D-glucoside, L-fucose, melezitose, D-cellobiose, sucrose, D-trehalose, D-lactose, D-raffinose, amygdalin, dextran, glycogen, arbutin, salicin, D-erythritol, citrate, malonate, citric acid, 2-ketogluconate, inulin, sodium formate, sodium fumarate, sodium malate, sodium tartrate, polyethylene glycol, and L-creatinine, but not D-maltose, gluconate, hydroxybutyric acid, sodium succinate, sodium pyruvate, thioglycolate, starch, methanol, and agar. Cells are sensitive to (μg/disc): cefoperazone (75), cefotaxime (10), doxycycline (30), sulfamethoxazole (50), nalidixic acid (30), norfloxacin (10), lomefloxacin (30), tobramycin (15), and amikacin (30), but resistant to co-trimoxazole (25), nitrofurantoin (300), penicillin (10), cefuroxime (20), cefazolin (30), and bacitracin (10). The principal fatty acids are (culture grown on R2A medium) C_{14:0} (1.2%), C_{15:1} iso (3.7%), C_{15:0} iso (24.7%), C_{16:1} ω5c (19.8%), C_{16:1} ω7c (14.8%), C_{16:0} (8.6%), C_{16:0} 3-OH (2.5%), C_{18:1} (2.5%), and C_{17:0} iso 3-OH (22.2%).

6. **Dyadobacter koreensis**. Baik, Kim, Kim, Kim and Seong 2007a, 1228^{VP}

ko.re.en'sis. N.L. masc. adj. *koreensis* pertaining to Korea.

The characteristics are as described for the genus and as listed in Tables 91 and 92, with the following additional features. Cells grow best on media such as R2A, plate count agar (PCA), and trypticase soy agar (TSA), but weakly on nutrient agar (NA). Colonies on TSA are circular, low-convex, entire margin, smooth, translucent, light yellow, and approximately 3.0 mm in diameter after 5 d at 25°C. Growth occurs at pH 5–11 (optimum pH 7) and at 4–30°C (optimum 25°C). Negative for gelatinase, arginine dihydrolase, urease, ornithine decarboxylase, and tryptophan deaminase. β-Galactosidase is present. H₂S and indole are not produced. Glucose and salicin are utilized as sole carbon and energy sources. Cells are sensitive to (μg/disc): amikacin (30), sulbactam (20), cefotaxime (30), imipenem (10), piperacillin (100), teicoplanin (30), and isepamicin (30), but resistant to aztreonam (30), clavulanic acid (20/10), bacitracin (10), cefepime (30), cefmetazole (30), ceftazidime (30), ciprofloxacin (5), moxalactam (30), oxacillin (1), piperacillin/tazobactam (100), and tobramycin (10). The major fatty acids are (culture grown on R2A medium) C_{14:0} (0.7%), C_{15:0} iso (24.2%), C_{16:1} ω5c (11.0%), C_{16:1} ω7c (34.8%), C_{16:0} (9.4%), C_{15:0} iso 3-OH (2.8%), C_{16:0} 3-OH (2.5%), and C_{17:0} iso 3-OH (9.5%).

Genus V. **Effluviibacter** Suresh, Mayilraj and Chakrabarti 2006, 1706^{VP}

THE EDITORIAL BOARD

Ef.flu.vi.i.bac'ter. L. neut. n. *effluvium* outflow; N.L. masc. n. *bacter* rod; N.L. masc. n. *Effluviibacter* rod from an outflow, referring to the source of isolation of the first strain.

Irregular rods 0.3–0.5 × 1.0–3.0 μm. Nonmotile. **No gliding motility.** Nonsporeforming. Gram-stain-negative. **Obligate aerobes.** Colonies are deep pink. Oxidase- and catalase-positive. **Starch and casein are hydrolyzed. Fructose and lactose are utilized. Acid is produced from glucose.** The major respiratory quinone is MK-7. The predominant whole-cell fatty acids are C_{17:1} iso I/anteiso B (36.7%), C_{15:0} iso (15.8%), and C_{17:0} iso 3-OH (10.3%).

DNA G+C content (mol%): 59.5.

Type species: **Effluviibacter roseus** Suresh, Mayilraj and Chakrabarti 2006, 1706^{VP}.

Enrichment and isolation procedures

A sample of muddy water was serially diluted in physiological saline (0.9% NaCl) and plated onto nutrient agar. After prolonged incubation at 30°C, a small, pink, mucoid colony was selected and purified.

Differentiation of the genus *Effluviibacter* from other genera

Effluviibacter roseus cells are irregular rods, whereas *Pontibacter actiniarum*, *Adhaeribacter aquaticus*, and *Hymenobacter roseosalivarius* cells are uniform in shape. *Effluviibacter roseus* does not exhibit gliding motility, whereas *Pontibacter actiniarum* does. In contrast to *Pontibacter actiniarum*, *Effluviibacter roseus* hydrolyzes casein and starch, utilizes fructose and lactose, produces acid from glucose, grows at 4°C but not at 42°C, exhibits sensitivity to gentamicin and streptomycin, and has a higher mol% G+C of its DNA (59.5 vs 48.7). *Effluviibacter roseus* differs from *Adhaeribacter aquaticus* by growing in the presence of 8.0% NaCl, hydrolyzing starch, producing acid from glucose, utilizing lactose but not adonitol and *myo*-inositol, and by having a higher mol% G+C of its DNA (59.5 vs 40.0). *Effluviibacter roseus* differs from *Hymenobacter roseosalivarius* by growing in the presence of 8.0% NaCl, utilizing fructose, and having a higher mol% G+C of its DNA (59.5 vs 56.0) (Suresh et al., 2006).

Taxonomic comments

Phylogenetic analysis based on 16S rRNA gene sequences indicate that the nearest neighbor of *Effluviibacter roseus* is

Pontibacter actiniarum (95.5% similarity), followed by *Adhaeribacter aquaticus* (89.0%) and *Hymenobacter roseosalivarius* DSM 11622^T (88.9%) (Suresh et al., 2006).

List of species of the genus *Effluviibacter*1. *Effluviibacter roseus* Suresh, Mayilraj and Chakrabarti 2006, 1706^{VP}

ro'se.us. L. masc. adj. *roseus* rose-colored, pink.

The characteristics are as described for the genus, with the following additional features. Colonies on nutrient agar are dark pink, circular, convex, smooth, and 2–3 mm in diameter after incubation for 6–8 d. Growth occurs at 4–37°C but not at 42°C. Growth occurs at pH 6.0–10.0. NaCl is tolerated up to a concentration of 8%. The following tests are positive: methyl red, amylase, protease, lysine decarboxylase, ornithine decarboxylase, and gelatin hydrolysis. Negative tests include: indole production, citrate utilization, H₂S production, arginine dihydrolase, Voges–Proskauer, urease, hydrolysis of esculin and Tween 20, and reduction of nitrate to nitrite. D-Fructose, D-galactose, D-glucose, lactose, raffinose, and sucrose are utilized as sole carbon sources, but not acetate, adonitol,

arabinose, citrate, fumarate, lactate, *myo*-inositol, salicin, sorbitol, and succinate. Histidine, L-isoleucine, L-lysine, ornithine, L-proline, and glycine are utilized as sole nitrogen sources, but not L-arginine, DL-alanine, and L-methionine. Acid is produced from D-glucose but not from lactose or sucrose. Susceptibility occurs toward vancomycin, lincomycin, streptomycin, gentamicin, and chlortetracycline, but not toward penicillin and tobramycin. The fatty acid profile is dominated by unsaturated and hydroxy fatty acids, including C_{17:1} iso I/anteiso B (36.7%), C_{15:0} iso (15.8%), and C_{17:0} iso 3-OH (10.3%). The phospholipids present are phosphatidylglycerol, diphosphatidylglycerol, and an unknown phospholipid.

Source: muddy water from an occasional drainage system in Chandigarh, India.

DNA G+C content (mol %): 59.5 (*T_m*).

Type strain: SRC-1, DSM 17521, MTCC 7260.

Sequence accession no. (16S rRNA gene): AM049256.

Genus VI. *Emticicia* Saha and Chakrabarti 2006, 993^{VP}

THE EDITORIAL BOARD

Em.ti.ci.ci.a. N.L. fem. n. *Emticicia* arbitrarily formed from the acronym MTCC for Microbial Type Culture Collection and GenBank, where this investigation was carried out.

Rods, usually 0.3–0.4 × 2–5 μm; in an aged culture, some cells may be longer. Cells occur singly and sometimes in pairs. Non-motile. **No gliding motility**. Gram-stain-negative. Oxidase-positive. Catalase weakly positive. **Growth does not occur on most of the common nutritionally rich culture media but does occur on 100-fold dilutions of these media. Salt tolerance is <1% NaCl.** Colonies are light pink. **Flexirubin pigments are not produced. Nitrate is reduced to nitrite. Urease-positive.** The predominant whole-cell fatty acids are C_{15:0} iso, C_{17:0} iso 3-OH, C_{15:0} anteiso, summed feature 3 (C_{15:0} iso 2-OH and/or C_{16:1} ω7*c*), C_{15:0} iso 3-OH, and C_{15:1} ω6*c*.

DNA G+C content (mol %): 36.9.

Type species: *Emticicia oligotrophica* Saha and Chakrabarti 2006, 993^{VP}.

Further descriptive information

Emticicia oligotrophica does not grow on most of the common nutritionally rich culture media such as tryptic soy broth, tryptic soy agar, yeast extract agar, plate count agar, nutrient broth, nutrient agar, Luria–Bertani agar, Mueller–Hinton agar, Zobell marine agar, etc. It does grow on modified R2A agar* and on

marine agar, etc. It does grow on modified RZA Agar and on 100-fold dilutions of all the above-mentioned media. Agarose (1.5%) is used to solidify the diluted media.

Enrichment and isolation procedures

Emticicia oligotrophica was isolated from spring water on TSBA100 medium (normal strength tryptic soy broth diluted 100 times and solidified with 1.5% agarose) by dilution plating, with incubation at 37°C.

Differentiation of the genus *Emticicia* from other genera

Emticicia oligotrophica differs from *Leadbetterella byssophila* by the light pink color of its colonies (vs orange for *Leadbetterella byssophila*), reduction of nitrate, hydrolysis of urea, inability to degrade tyrosine, lack of flexirubin pigments, inability to grow on undiluted tryptic soy agar or other rich media, a relatively higher amount of C_{15:0} anteiso fatty acid (12.2% of total fatty acids vs 0.4%), and a higher mol% G+C value (36.0 vs 33.0).

Taxonomic comments

Analysis of 16S rRNA gene sequences by Saha and Chakrabarti (2006) indicated that the nearest cultured neighbor of *Emticicia oligotrophica* was *Leadbetterella byssophila* (87.8% sequence similarity). Sequence similarities with other members of the phylum *Bacteroidetes* were less than 85%.

*Modified R2A (MR2A) agar contains (g/l): casamino acids, 0.025; yeast extract, 0.05; peptone, 0.075; glucose, 0.05; soluble starch, 0.05; K₂HPO₄, 0.03; MgSO₄·7H₂O, 0.0024; sodium pyruvate, 0.03; and agar, 1.5; pH 7.2.

List of species of the genus *Emticia*1. *Emticia oligotrophica* Saha and Chakrabarti 2006, 993^{VP}

o.li.go.tro'phi.ca. Gr. adj. *oligos* few; Gr. adj. *trophikos* nursing, tending or feeding; N.L. fem. adj. *oligotrophica* eating little, referring to a bacterium living on low-nutrient media.

The characteristics are as described for the genus, with the following additional features. Colonies on 0.01 × tryptic soy agar after 2 d at 37°C are round, mucoid, light pink, and convex with almost entire margins; with prolonged incubation, the colony color deepens, it produces slime and appears glistening. Temperature range for growth, 15–42°C; pH range for growth, 5.0–11.0. Methyl red positive, Voges–Proskauer negative. Gelatin, starch, and Tween 60 are hydrolyzed, but not casein, *o*-nitrophenol- β -D-galactoside (ONPG), hypoxanthine, chitin, cellulose [carboxymethyl cellulose (CMC) or filter paper], xylan, tyrosine, or Tween 20, 40, or 80. The following compounds are utilized as sole carbon sources: D-cellobiose, D-lactose, D-melezitose, D-raffinose, and arbutin; weak utilization occurs of L-arabinose, L-arabitol, D-amygdalin, D-fructose, D-galactose, D-glucose, glycerol, *myo*-inositol,

D-melibiose, and sucrose. No utilization occurs of adonitol, dulcitol, D-mannitol, D-sorbitol, L-sorbose, or xylitol. Acid is produced from arbutin, D-cellobiose, D-glucose, D-lactose, methyl α -D-glucoside, salicin, D-trehalose, and D-xylose. Weak acid production occurs from D-galactose, D-maltose, D-mannose, D-melibiose, D-melezitose, and sucrose. No acid is produced from adonitol, D-amygdalin, L-arabinose, L-arabitol, dulcitol, esculin, erythritol, D-fructose, D- or L-fucose, glycerol, glycogen, *myo*-inositol, inulin, 2-ketogluconate, D-mannitol, D-raffinose, D-ribose, D-sorbitol, L-sorbose, or xylitol. Sensitivity is exhibited toward ampicillin, bacitracin, chloramphenicol, erythromycin, gentamicin, kanamycin, lincomycin, neomycin, novobiocin, norfloxacin, penicillin G, polymyxin B, rifampin, streptomycin, sulfasomidine, and tetracycline.

Source: a warm spring water sample from Assam, India.

DNA G+C content (mol%): 36.9 (T_m).

Type strain: GPTSA100-15, DSM 17448, MTCC 6937.

Sequence accession no. (16S rRNA gene): AY904352.

Genus VII. *Flectobacillus* Larkin, Williams and Taylor 1977, 152^{AL} Emend. Raj and Maloy 1990, 346^{VP}

THE EDITORIAL BOARD

Flec.to.ba.cil'lus. L. v. FLECTO to curve; L. masc. n. *bacillus* a little staff, rod; N.L. masc. n. *Flectobacillus* little curved rod.

Curved, nonflexible rods with variable degrees of curvature from cell to cell. **Most cells of *Flectobacillus major* are shaped like the letter C** (wide-open rings), and **sometimes cell ends touch or overlap** (closed rings). Coils are less common, and spiral forms are rare. The outer ring diameter is 5–10 μ m, and the cell width is 0.6–2.0 μ m. The ends of the cells are tapered or rounded or both. **Cells of *Flectobacillus lacus* are almost straight rods**. Gram-stain-negative. **Nonflagellated and nonmotile**. Colonies are 2–6 mm in diameter with a **pale pink or rose-color due to a water-insoluble pigment**. No growth occurs in media containing seawater or 3.0% NaCl. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Oxidase-positive**. Chemo-organotrophic but not methylotrophic. The natural habitats are freshwater lakes and eutrophic ponds.

DNA G+C content (mol%): 38.3–40.3.

Type species: *Flectobacillus major* (Gromov 1963) Larkin, Williams and Taylor 1977, 155^{AL} (*Microcycilus major* Gromov 1963, 733).

Further descriptive information

Much of this chapter is taken from the excellent treatment by Larkin and Borrall (1984a) in the 1st edition of *Bergey's Manual of Systematic Bacteriology*. It has been updated when information that is more recent was needed.

Cells of *Flectobacillus major* typically appear as curved rods whose degree of curvature varies from nearly straight to crescent or horseshoe shaped, to rings (see Figure 3.3 in Larkin and Borrall, 1984a). An individual cell may be bent in more than one plane. Regular and irregular coils and helices as well as long sinuous filaments are rarely produced.

Colonies on MS agar (0.1% peptone, 0.1% yeast extract, 0.1% glucose, and 1.5% agar) produce a pink, water-insoluble, nonfluorescent pigment. The colonies are circular and convex with an entire margin. *Flectobacillus major* does not grow on eosin methylene blue agar, phenol red mannitol salt agar, phenylethyl alcohol agar, MacConkey agar, bismuth sulfite agar, or Salmonella-Shigella agar. Abundant growth occurs on MS agar, peptonized milk agar, yeast extract-acetate-tryptone agar, and nutrient agar (Larkin et al., 1977).

Flectobacillus is chemo-organotrophic and produces an acid reaction from a wide variety of carbohydrates including pentoses, hexoses, and disaccharides when incubated aerobically in the medium of Hugh and Leifson (1953). Acidification does not occur with any sugar alcohols. Casein, cellulose, and chitin are not hydrolyzed. Gelatin, tributyrin, and starch are hydrolyzed. Litmus milk is unchanged. *Flectobacillus* is not known to be pathogenic.

Isolation procedures

Flectobacillus major can be isolated by repeated streaking of samples onto MS agar with incubation at room temperature for up to 2 weeks. The pink pigmentation of the colonies aids detection.

Flectobacillus lacus was isolated from a surface sample from a highly eutrophic pond. The sample, at ambient temperature, was brought back to the laboratory within 15 min; 10–100 μ l of sample was spread on plates containing the R2A agar medium*

*R2A agar contains (g/l of distilled water): yeast extract, 0.5; peptone, 0.5; Casamino acids, 0.5; glucose, 0.5; starch, 0.5; sodium pyruvate, 0.3; K_2HPO_4 , 0.3; $MgSO_4$, 0.05; and agar, 15.0.

of Reasoner and Geldreich (1985) and incubated at 20°C for 1 week. Colonies were randomly selected and subsequently purified four times on R2A agar at 20°C.

Maintenance procedures

Strains of *Flectobacillus major* are grown on MS or nutrient agar. Incubation is at room temperature (25°C) for several days to allow abundant growth. The cultures will then survive refrigeration at 4°C for at least 3 weeks. They may also be preserved indefinitely by lyophilization.

Flectobacillus lacus can be maintained at -80°C in R2A broth supplemented with 30% (v/v) glycerol.

Procedures for testing special characters

For utilization of single carbon sources, the following medium (g/l) is used: MgSO₄, 0.2; (NH₄)₂HPO₄, 1.0; KH₂PO₄, 0.5; NaCl, 1.0; carbon source, 2.0; bromthymol blue, 0.08; agar, 20.0. The appearance of growth through four successive subcultures is considered positive even in the absence of a color change in the pH indicator (Larkin et al., 1977).

Differentiation of the genus *Flectobacillus* from other genera

Table 93 lists characteristics that differentiate the genus *Flectobacillus* from other morphologically similar organisms.

^bData taken from Larkin and Borrall (1984a, c); Gosink et al. (1998); Chelius and Triplett (2000), Chelius et al. (2002); Raj and Maloy (1990); Xin et al., 2004; Staley and Konopka (1984); Vancanneyt et al. (2006), and Hwang and Cho (2006).

^cIn contrast to the original description, NaCl is not required for growth (Nedashkovskaya et al., 2005a).

^dIndicated as positive by Larkin and Borrall (1984a), slowly positive by Raj and Maloy (1990), and negative by Chelius and Triplett (2000).

^eSugar media acidification may be slow, taking up to 3 weeks (Larkin and Borrall, 1984a).

^fIndicated as positive by Larkin and Borrall (1984a) but negative by Vancanneyt et al. (2006).

^gIndicated as negative by Larkin and Borrall (1984a) and Raj and Maloy (1990) but positive by Chelius and Triplett (2000).

^hIndicated as positive by Larkin and Borrall (1984a) but negative by McGuire et al. (1987).

ⁱStems of *Zea mays*.

^jRoots of *Spartina anglica*.

Taxonomic comments

In the 1st edition of *Bergey's Manual of Systematic Bacteriology*, the genus contained two species – *Flectobacillus major* and *Flectobacillus marinus*. The latter species had been described by Raj (1976) as a species of *Microcyclus*, “*Microcyclus marinus*”. In many features it resembled *Flectobacillus major*, and after studying both species Borrall and Larkin (1978) assigned it to the genus *Flectobacillus* as *Flectobacillus marinus*. Raj (1979) reported that *Flectobacillus major* and *Flectobacillus marinus* were sufficiently distinct to warrant classifying *Flectobacillus marinus* in a separate genus. The name “*Cyclobacterium marinus*” was suggested (H.D. Raj, cited by Larkin and Borrall, 1984a). Larkin and Borrall (1984a, c) believed that it would be best to retain the organism in the genus *Flectobacillus* because of the similarity in the mol% G+C content of the DNA (38–40) and because the DNA–DNA hybridization value between the type strains of *Flectobacillus marinus* and *Flectobacillus major* was 71%, using the renaturation rate method of DeLey et al. (1970). However, Raj and Maloy (1990) noted that analysis of the oligonucleotide sequences of the 16S rRNAs of these organisms (Woese et al., 1990) indicated that a relatively large evolutionary distance (ca. 20%) occurred between *Flectobacillus major* and *Flectobacillus marinus* (Woese, 1987), supporting the idea that *Flectobacillus marinus* should be separated from *Flectobacillus major* at the genus level. Consequently, Raj and Maloy (1990) reclassified *Flectobacillus marinus* as *Cyclobacterium marinus* (later corrected to *marinum* by Euzéby (1998)).

Organisms similar in appearance to *Flectobacillus* have been seen in fresh waters (Larkin et al., 1977). Metcalf and Krueger (cited by Larkin and Borrall, 1984a) located two shallow lakes near Sacramento, California, that had relatively large populations of *Flectobacillus major*. Counts on MS agar ranged from zero to several thousand per ml, and more than 60 isolates were obtained from separate samplings. The isolates were strikingly similar to the type strain of *Flectobacillus major* in their morphological and physiological characteristics, but differed from it in being unable to hydrolyze urea or gelatin.

A new species of *Flectobacillus*, *Flectobacillus glomeratus*, was described by McGuire et al. (1987) from Antarctic marine environments. The cells of the strains were vibrioid to highly coiled; however, Gosink et al. (1998) found *Flectobacillus glomeratus* to be phylogenetically distinct from *Flectobacillus major* by 16S rRNA gene sequence analysis. Although the cells were curved and lacked gas vacuoles, *Flectobacillus glomeratus* did have a close phylogenetic relationship to a group of filamentous or irregularly shaped, gas-vacuolated rods isolated from sea ice and water from the Arctic and Antarctic. Consequently, Gosink et al. (1998) reclassified *Flectobacillus glomeratus* together with these rods in a new genus, *Polaribacter*.

In 2006, Hwang and Cho described a new species, *Flectobacillus lacus*, isolated from a highly eutrophic pond located within the campus of Seoul National University, Korea. From 16S rRNA gene sequence analysis, the species was closely related to *Flectobacillus major* (95.7% sequence similarity).

Differentiation of the species of the genus *Flectobacillus*

Flectobacillus major cells are shaped like the letter C, and sometimes cell ends touch or overlap, forming closed rings. Cells of *Flectobacillus lacus* are almost straight rods and do not form rings. *Flectobacillus major* also differs from *Flectobacillus lacus* by being urease positive, by using succinate as a sole carbon source, and by forming acid from arabinose and rhamnose.

Hwang and Cho (2006) reported that, in their studies, the type strain of *Flectobacillus lacus* differed from the type strain of *Flectobacillus major* in the following ways: acid was produced from D-arabitol and 5-ketogluconate but not from D- or L-arabinose, D-xylose, L-rhamnose, amygdalin, arbutin, D-lyxose, and L-fucose; adipate was assimilated but not L-arabinose, D-mannose, N-acetylglucosamine, D-maltose, and gluconate; DL-cysteine and succinate were not used as sole carbon sources; and no growth occurred on media containing as little as 0.5% NaCl.

List of species of the genus *Flectobacillus*

1. ***Flectobacillus major*** (Gromov 1963) Larkin, Williams and Taylor 1977, 155^{AL}. (*Microcyclus major* Gromov 1963, 733) *major*. L. masc. comp. adj. *major* larger.

The characteristics are as described for the genus and as listed in Table 93, with the following additional features. Optimum growth occurs at 20–25°C. Growth occurs in the presence of 1.5% NaCl (Hwang and Cho, 2006). Catalase is weakly positive. Esculin, gelatin, starch, tributyrin, and urea are hydrolyzed, but not agar, casein, cellulose, or chitin. β-Galactosidase and phosphatase are present. The following tests are negative: acetoin production (Voges–Proskauer), H₂S production from peptone, indole production (Hwang and Cho, 2006, report the type strain as positive), lecithinase, lysine decarboxylase, nitrate reduction, ornithine decarboxylase, and phenylalanine deaminase. Acid is produced oxidatively from arabinose, cellobiose, dextrin, fructose, galactose, glucose, lactose, maltose, mannose, melibiose, α-methyl-D-glucoside, raffinose, rhamnose, salicin, sucrose, trehalose, and xylose. Acid production from inulin differs among strains. No acid is produced from dulcitol, erythritol,

glycerol, mannitol, ribose, sorbitol, and sorbose. Succinate is utilized as a sole carbon source, but not acetate, benzoate, citrate, formate, malonate, propionate, or tartrate.

DNA G+C content (mol%): 39.5–40.3 (*T_m*).

Type strain: ATCC 29496, DSM 103, LMG 13163, VKM B-859.

Sequence accession no. (16S rRNA gene): M62787.

2. ***Flectobacillus lacus*** Hwang and Cho 2006, 1200^{VP}

lacus. L. gen. n. *lacus* of a lake or pond, referring to the isolation of the type strain.

The characteristics are as described for the genus and as listed in Table 93, with the following additional features. Cells are approximately 0.3–0.6 × 4.7–10.0 μm. Colonies on R2A agar are pale pink to rose in color, round, 2–6 mm in diameter, convex and smooth with entire margins. Growth occurs at 10–35°C and pH 6–9; optimal temperature and pH for growth are 25–30°C and pH 7, respectively. Growth occurs on R2A and nutrient agar without NaCl or with 0.1% (w/v) NaCl; no growth occurs in the presence of ≥0.5% (w/v)

NaCl. Grows on R2A medium and nutrient medium, but not on MacConkey medium. Flexirubin pigments are absent. Positive for catalase, gelatinase, and amylase. Negative in the Voges–Proskauer test. Positive for α -galactosidase, β -galactosidase, esculin hydrolysis, alkaline phosphatase, acid phosphatase, esterase (C4), esterase lipase (C8), leucine, valine and cystine arylamidases, trypsin, α -chymotrypsin, naphthol-phosphohydrolase, α -glucosidase, β -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase. Negative

for indole production, arginine dihydrolase, lipase (C14), and β -glucuronidase. The major fatty acids are C_{16:1} ω 5c (26.9 \pm 10.8%), C_{15:0} iso 2-OH and/or C_{16:1} ω 7c (19.2 \pm 2.3%), and C_{15:0} iso (12.1 \pm 1.3%).

Source: a highly eutrophic pond, Gongdae Pond, located in the campus of Seoul National University, Korea.

DNA G+C content (mol%): 38.3 (HPLC).

Type strain: CL-GP79, JCM 13398, KCCM 42271.

Sequence accession no. (16S rRNA gene): DQ112352.

Genus VIII. *Flexibacter* Soriano 1945, 92^{AL}

YASUYOSHI NAKAGAWA

Flex.i.bac'ter. L. part. adj. *flexus* bent, winding; N.L. masc. n. *bacter* from Gr. neut. n. *baktron* little stick or rod; N.L. masc. n. *Flexibacter* intended to mean flexible rod.

Slender rod-shaped cells of variable length, 0.2–0.6 μ m wide and typically 10–50 μ m long, flexible, and with tapering or rounded ends. **Gliding**, but nonmotile stages may occur. In some species, there is a (cyclic) change in cell morphology. The cell mass is usually pigmented **yellow to orange**, but sometimes vary pale or even colorless. The pigments are cell-bound and often are **carotenoids and/or of the flexirubin type**. **Chemo-organotrophs**. Strictly aerobic or facultatively anaerobic. Peptones and amino acid mixtures serve as nitrogen sources. Various sugars are utilized. Cellulose and agar are not attacked, but chitin and starch are often hydrolyzed.

DNA G+C content (mol%): 37–47.

Type species: *Flexibacter flexilis* Soriano 1945, 92^{AL}.

Further descriptive information

The major quinone of *Flexibacter canadensis*, *Flexibacter flexilis*, *Flexibacter elegans*, *Flexibacter filiformis*, *Flexibacter japonensis*, *Flexibacter litoralis*, *Flexibacter polymorphus*, *Flexibacter roseolus*, *Flexibacter ruber*, *Flexibacter sancti*, and both type strains of *Flexibacter aggregans* and *Flexibacter tractuosus* is MK-7, whereas MK-6 is the major quinone of *Flexibacter aurantiacus*, *Flexibacter columnaris* (synonym, *Cytophaga columnaris*), *Flexibacter maritimus* (heterotypic synonym, *Cytophaga marina*), *Flexibacter ovolyticus*, *Flexibacter psychrophilus* (synonym, *Cytophaga psychrophila*) (Kämpfer et al., 2006; Nakagawa and Yamasato, 1993, 1996); Nakagawa, unpublished). The major polyamine of *Flexibacter flexilis*, the type species of the genus is homospermidine (Hosoya and Hamana, 2004).

Enrichment and isolation procedures

No enrichment media have been designed for isolation of *Flexibacter* strains. Standard procedures to isolate soil and freshwater bacteria can be applied. Low nutrient media are preferable. Colonies of *Flexibacter* are usually orange yellow. Detailed protocols have been described by Reichenbach (1989a, b, 1992a). *Flexibacter* strains have been isolated from various environments at widely separated sites (Lewin, 1969; Lewin and Lounsbury, 1969). The type strains of *Flexibacter flexilis* came from a pond in San José, Costa Rica.

Maintenance procedures

Cultures of most *Flexibacter* strains can be preserved by freezing at temperatures lower than -80°C . For freezing, cells are suspended in the suitable liquid media containing 10% glycerol

or 7% DMSO. *Flexibacter* strains are rather sensitive to drying; however, they can be preserved in a protective medium SM1 (see the chapter on *Cytophaga* for formulations) for the terrestrial organisms, or SM2 or SM3 for marine species (see the chapter on *Flammeovirga* for formulations) using a liquid drying method. The organisms can also be preserved by freeze-drying. One marine species, *Flexibacter polymorphus*, is very fastidious and is difficult to preserve by freezing -80°C or drying. Its cultures autolyze within a few days at 25°C ; however, it can be successfully preserved by freezing at temperatures lower than -140°C in liquid nitrogen (LN₂) tanks.

Differentiation of the genus *Flexibacter* from other genera

Phylogenetic analysis based on 16S rRNA sequences shows that *Flexibacter flexilis* - the type species of the genus *Flexibacter* - is phylogenetically independent in the phylum *Bacteroidetes* (Figure 74). However, because few taxonomic characteristics have been investigated since the original descriptions, it is impossible to discriminate the genus *Flexibacter* from other related genera only by phenotypic characteristics. It is hoped that chemotaxonomic, physiologic, and biochemical characteristics of the genus *Flexibacter* will be investigated.

Taxonomic comments

The genus *Flexibacter* was created by Soriano (1945) to accommodate five species of gliding organisms; however, the original definition of the genus was vague and his original strains have been lost. In addition, the genus *Microscilla* proposed by Pringsheim (1951) could not be distinguished from the genus *Flexibacter*. Lewin (1969) reisolated morphologically similar organisms and redefined both genera by classifying marine organisms with longer filaments (20–100 μ m) in the genus *Microscilla*. These definitions were not included in the *Bergey's Manual of Determinative Bacteriology*, 8th edition (Leadbetter, 1974). The inability to degrade polysaccharides such as agar, alginate, cellulose, and chitin was adopted in the genus definition of *Flexibacter*, and the genus *Microscilla* was grouped with the genus *Flexibacter*. However, *Flexibacter flexilis* is known to hydrolyze other polymers such as starch, and *Flexibacter filiformis* is a potent chitin decomposer. Later, Reichenbach (1989a, b) tried to define the genus *Flexibacter* on the basis of cell morphology, DNA G+C content, and habitat. He classified marine organisms with G+C contents above 37 mol% in the genus *Microscilla*. However, he also stated that the genus *Flexibacter* is probably still heterogeneous and will

have to be subdivided when data on the molecular taxonomy are accumulated. Those histories are described in detail in the first edition of this *Manual* (Reichenbach, 1989a, b).

Seventeen *Flexibacter* species have been approved or validly published to date. Three species, *Flexibacter flexilis* (the type species of the genus), *Flexibacter elegans*, and *Flexibacter filiformis* were recognized as belonging to *Flexibacter* in the 1st edition of this *Manual*.

16S rRNA sequencing analysis of the genera *Flexibacter* and *Microscilla* have shown great biological diversity within the genus *Flexibacter* (Nakagawa et al., 2002). Forty strains of 17 species of *Flexibacter* diverged into 20 phylogenetic groups. Four groups were located in the family *Flavobacteriaceae*, while others – including the type species *Flexibacter flexilis* – were not. Some *Flexibacter* strains were closely related to strains of the genus *Chitinophaga*, *Microscilla*, or *Flexithrix*. A phylogenetic tree of *Flexibacter*, *Flexithrix*, and *Microscilla* strains belonging to the classes *Cytophagia* and *Sphingobacteriia* is shown in Figure 74. It can be seen that *Flexibacter flexilis*, the type species of the genus *Flexibacter*, is isolated from the other species, which suggests that the genus *Flexibacter* should be restricted to the type species. All strains in this species clustered together except for one non-validated subspecies, “*Flexibacter flexilis* subsp. *pelliculosus*”, which was unrelated to the other known taxa.

Flexibacter aggregans was assigned the name “*Microscilla aggregans*” in the 1st edition of this *Manual* (Reichenbach, 1989a, b) because it is a marine organism. This species is the phylogenetically heterogeneous, diverging into four groups. The three authentic strains of *Flexibacter aggregans*, NBRC 15973, NBRC 15976^T, and NBRC 15990, constitute a tight cluster with *Flexithrix dorotheae*. This result strongly supports Reichenbach’s report (1989a) of a close resemblance between the two species. Based on these results, *Flexibacter aggregans* was included in *Flexithrix dorotheae* (Hosoya and Yokota, 2007). Two strains of *Flexibacter aggregans* NBRC 15974 and NBRC 15975 remain to be reclassified. *Flexibacter aggregans* NBRC 15974 constitutes an independent lineage near *Roseivirga ehrenbergii*. The strain NBRC 15975 belongs to the family *Flavobacteriaceae*. An invalid subspecies, “*Flexibacter aggregans* subsp. *catalaticus*” was transferred to the new genus *Crocinitomix*, which belongs to the new family *Cryomorpaceae* (Bowman et al., 2003).

Flexibacter canadensis is located outside the cluster comprised of the genera *Sphingobacterium* and *Pedobacter*. Steyn et al. (1998) proposed the family *Sphingobacteriaceae* to encompass the genera *Sphingobacterium*, *Pedobacter*, and *Flexibacter canadensis*. This family is characterized by the presence of sphingolipids, but a long-chain base derived from sphingolipids was not detected in this species (Nakagawa et al., 2002). It is suggested that *Flexibacter canadensis* should be excluded from the family as a distinct genus.

Flexibacter filiformis, *Flexibacter japonensis*, and *Flexibacter sancti* are closely related to the genus *Chitinophaga* and they were subsequently transferred to the genus *Chitinophaga* (Kämpfer et al., 2006). *Flexibacter elegans*, *Flexibacter litoralis*, *Flexibacter polymorphus*, and *Flexibacter ruber* are distinct from other known species of *Flexibacter*. Thus, it is suggested that each should be excluded from the genus *Flexibacter*.

Flexibacter roseolus is a heterogeneous species: it includes two phylogenetically different strains (NBRC 16707^T and NBRC 16030), each of them is distinct from known taxa. *Flexibacter tractuosus* is also called “*Microscilla tractuosa*” because it is a marine bacterium. Eight strains assigned to the species were heterogeneous and diverged into four distinct groups. The type strain of *Flexibacter tractuosus*, NBRC 15989^T, clusters with NBRC 15979, NBRC 15981, and “*Microscilla sericea*” NBRC 15983^T. This group is considered to be the genuine *Flexibacter tractuosus* because it includes the type strain. Two strains of *Flexibacter tractuosus* NBRC 16035 and NBRC 16482 constitute one group and are distantly related to all known species. Two other strains of *Flexibacter tractuosus*, NBRC 16037 and NBRC 16038, may be reclassified in the genus *Perexilibacter* because of their close relationships to the type species of that genus. *Flexibacter tractuosus* NBRC 15980 belongs to the family *Flavobacteriaceae*.

The remaining strains belong to the family *Flavobacteriaceae*. *Flexibacter aurantiacus*, *Flexibacter columnaris*, and *Flexibacter psychrophilus* were reclassified as distinct species in the genus *Flavobacterium*, and *Flexibacter aurantiacus* is treated as the junior subjective synonym of *Flavobacterium johnsoniae* (Bernardet et al., 1996). Two non-validated subspecies exist in *Flexibacter aurantiacus*. Of these, “*Flexibacter aurantiacus* subsp. *excathedrus*” belongs to the genus *Flavobacterium*. The other subspecies, “*Flexibacter aurantiacus* subsp. *copepodarum*”, is a marine organism isolated from an offshore crustacean (Lewin, 1969) and is classified in the genus *Tenacibaculum*. *Flexibacter maritimus* and *Flexibacter ovoliticus* have been transferred to the genus *Tenacibaculum* (Suzuki et al., 2001). These phylogenetic groups and their reclassification are summarized in Table 94.

In this chapter, Reichenbach’s definition of the genus is generally followed; however, only the type species, *Flexibacter flexilis* can be justified on the basis of 16S rRNA sequencing analysis as belonging to the genus *Flexibacter*. Other *Flexibacter* species that should be reclassified in the future are listed as other species.

Differentiation of the species of the genus *Flexibacter*

Table 95 lists characteristics that distinguish the *Flexibacter* species from one another.

List of species of the genus *Flexibacter*

1. *Flexibacter flexilis* Soriano 1945, 92^{AL}

flex’i.lis. L. masc. adj. *flexilis* pliable, flexible.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey’s Manual of Determinative Bacteriology*, 9th edition.

Long flexible thread cells with tapering, occasionally crooked ends, 0.5 μm wide and 10–60 μm long (usually 10–20

μm). Motile by gliding but not particularly active. Color of the cell mass is orange, but pigmentation on many media is pale. Aerobic. The optimum growth temperature is 25°C. The optimum pH is around 7. Oxidase-positive. Catalase-negative. Peptones and Casamino acids serve as sole nitrogen source, but not glutamate, NH₄⁺ or NO₃⁻. Growth occurs well on peptone alone. Sugars such as glucose or sucrose may stimulate growth. Gelatin and starch are hydrolyzed, but not chitin or yeast cells. H₂S is produced. Nitrate is not reduced. Growth

TABLE 94. Phylogenetic groups of *Flexibacter* and *Microscilla* strains and their present classification

Phylogenetic group ^a	Species and strain	Present classification
1	<i>F. aggregans</i> NBRC 15975	Excluded from the genus <i>Flexibacter</i> , belongs to the family <i>Flavobacteriaceae</i>

does not occur on seawater media. The major carotenoid is saxorubrin. The flexirubin reaction is positive.

DNA G+C content (mol%): 40–43 (Bd).

Type strain: CR-63, ATCC 23079, CIP 103988, DSM 6793, LMG 3989, NBRC 15060.

Sequence accession no. (16S rRNA gene): AB078049.

Other species

None of the species listed below should be included in the genus *Flexibacter* because 16S rRNA sequence analysis indicates they are not closely related to the genus.

1. ***Flexibacter canadensis*** Christensen 1980, 431^{AL}
ca.na.den'sis. N.L. masc. adj. *canadensis* Canadian.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of

this *Manual*, *Bergey's Manual of Determinative Bacteriology*, 9th edition, and the original description (Christensen, 1980).

Elongated rods, thin and flexible, with slightly tapering ends, 0.4–0.5 µm wide and 2–12 µm long or longer (up to 60 µm in older cultures). Motile by gliding. On solid substrates with a low nutrient content, large whitish swarms develop. On media with a higher concentration of organic compounds, growth becomes compact, pale pink, or dirty

^bData from Reichenbach (1989a, b) and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

white. Colonies often show a yellow-green-blue iridescence. Facultatively anaerobic. Oxidase- and catalase-positive. Casamino acids, gelatin, aspartate, glutamate, and NH₄⁺ serve as sole nitrogen source but not NO₃[–] or urea. Various sugars, glucose, and glycerol are utilized with acid production. Indole is not produced. H₂S is produced. DNA, gelatin, and starch are hydrolyzed, but not agar, chitin, alginate, cellulose, or carboxymethyl cellulose. Pectin is weakly degraded. Nitrate is reduced. H₂S is produced. Growth does not occur in the presence of 2% NaCl. The temperature range for growth is 10–40°C with optimum 18–30°C. The pH range for growth is 5–10 with an optimum of 6–8.

DNA G+C content (mol%): 37 (Bd and T_m).

Type strain: UASM 9D, ATCC 29591, CIP 104802, DSM 3403, JCM 21819, LMG 8368, NBRC 15130.

Sequence accession no. (16S rRNA gene): AB078046.

2. *Flexibacter elegans* (ex Lewin 1969, non Soriano 1945) Reichenbach 1989b, 2067^{AL}

e.l.e.gans. L. masc. adj. *elegans* refined, fashionable, elegant.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Very long, fine filaments with rounded ends, 0.4–0.5 µm wide and 50 µm long, often much longer, rarely shorter than 10–20 µm. On solid substrates the filaments tend to form loops and coils. Motile by gliding. On some media the colonies are spreading. The cell mass is bright orange. Aerobic. Oxidase-positive. Catalase-negative. Peptones and Casamino

acids serve as sole nitrogen source but not glutamate, NH₄⁺, or NO₃[–]. Requires threonine. Growth on media containing peptone alone is very poor or absent but may be stimulated by the addition of a sugar such as glucose. In litmus milk, there is no acid production, coagulation, or reduction of litmus. Acid is produced from glucose. Gelatin is hydrolyzed, but not chitin, starch, or yeast cells. Indole and H₂S are not produced. Nitrate is not reduced. Growth occurs on seawater media, but NaCl is not required. NaCl (2.4%) is tolerated. Optimum conditions for growth are around pH 7 and 30°C. The highest growth temperature is 40–45°C. The major carotenoid is saproxanthin. The flexirubin reaction is negative.

DNA G+C content (mol%): 48 (Bd).

Type strain: NZ-1, ATCC 23112, CIP 104801, DSM 3317, JCM 21159, LMG 10750, NBRC 15055.

Sequence accession no. (16S rRNA gene): AB078048.

3. *Flexibacter litoralis* Lewin 1969, 199^{AL}

li.tora'lis. L. masc. adj. *litoralis* of or belonging to the seashore.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Threads, 0.5–0.7 µm wide and up to 180 µm long, agile, gliding, and bending, apparently without cross-walls. The cell mass is brick red. Aerobic. Catalase-negative. Peptones serve as sole nitrogen source but not glutamate, or NO₃[–]. Requires many amino acids and thiamine. Sugars and organic acid is not utilized. Gelatin and starch are hydrolyzed, but not

agar, alginate, or carboxymethyl cellulose. H_2S is not produced. Nitrate is not reduced. Growth does not occur below half-strength seawater. The highest growth temperature is 30–35°C. The major carotenoid is flexixanthin.

DNA G+C content (mol%): 31 (Bd).

Type strain: SIO-4, ATCC 23117, CIP 106402, DSM 6794, NBRC 15988.

Sequence accession no. (16S rRNA gene): AB078056.

4. **Flexibacter polymorphus** Lewin 1974, 393^{AL}

po.ly.mor'phus. N.L. masc. adj. *polymorphus* (from Gr. adj. *polymorphos -on*) of many shapes, variable in form.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Long flexible filaments, 1.1 μm wide and up to several hundred μm long, with cross-walls 3.5–7 μm apart. The cross-walls are recognizable under the phase-contrast microscope. In media containing 0.1% NaHCO_3 , finer and shorter filaments 0.6 μm wide and 10–40 μm long appear, in addition to the long ones. At a pH above 8 the cells contain optically refractile granules, presumably some lipid material. Sometimes, inflated and branched filaments also occur. The filaments are very actively gliding with speeds up to 12 $\mu\text{m}/\text{s}$ (23°C). The cell mass is orange. Aerobic. Catalase-negative. Peptones, Casamino acids, and glutamate serve as sole nitrogen source but not NH_4^+ or NO_3^- . Requires cobalamine. Agar, alginate, cellulose, and starch are not hydrolyzed. H_2S is not produced. Growth does not occur below half-strength seawater. The highest growth temperature is 32°C. The pH range for growth is 7–8.5. The major carotenoid is saproxanthin.

DNA G+C content (mol%): 29 (Bd).

Type strain: ATCC 27820, DSM 9678, LMG 13859, NBRC 16703.

Sequence accession no. (16S rRNA gene): AB078059.

5. **Flexibacter roseolus** Lewin 1969, 199^{AL}

ro.se'o.lus. L. adj. *roseus* rose-colored; L. masc. suff. *-olus* diminutive ending; N.L. masc. dim. adj. *roseolus* intended to mean with a rosy tinge.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Very long threads, more than 50 μm long. The cell mass is red. Aerobic. Catalase-negative. Peptones and Casamino

acids serve as sole nitrogen source but not glutamate or NO_3^- . Gelatin is hydrolyzed but not starch. H_2S is not produced. Seawater is tolerated. The highest growth temperature is 40°C. The major carotenoid is flexixanthin, demonstrated in a strain CR-141 (=ATCC 23087, NBRC 16030).

DNA G+C content (mol%): 34–38 (Bd).

Type strain: CR-155, ATCC 23088, CIP 106406, DSM 9546, LMG 13856, NBRC 16707.

Sequence accession no. (16S rRNA gene): AB078063.

6. **Flexibacter ruber** Lewin 1969, 199^{AL}

ru'ber. L. masc. adj. *ruber* red.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Very long threads, more than 50 μm long. The cell mass is red. Aerobic. Catalase-negative. Peptones, Casamino acids, glutamate and NO_3^- serve as sole nitrogen source. Various sugars are metabolized with acid production. Gelatin is hydrolyzed. H_2S is not produced. Nitrate is reduced. Growth does not occur on seawater media. The highest growth temperature is 40–45°C. The major carotenoid is flexixanthin.

DNA G+C content (mol%): 37 (Bd).

Type strain: GEY, ATCC 23103, DSM 9560, LMG 13857, NBRC 16677.

Sequence accession no. (16S rRNA gene): AB078064.

7. **Flexibacter tractuosus** Leadbetter 1974, 106^{AL} (*Microscilla tractuosa* Lewin 1969, 199)

trac.tu.o'sus. L. masc. adj. *tractuosus* that draws to itself, drawn or clumped together.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual* and *Bergey's Manual of Determinative Bacteriology*, 9th edition.

Threads, 0.5 μm wide and 5–50 μm long, or longer. The cell mass is orange. Peptones, Casamino acids, and glutamate serve as sole nitrogen source but not NO_3^- . Sugars and glycerol are usually utilized. Agar, alginate, and carboxymethyl cellulose are not degraded. Nitrate is reduced by a few strains. The highest growth temperature is 30–45°C. The major carotenoid is saproxanthin.

DNA G+C content (mol%): 35–40 (Bd).

Type strain: H-43, ATCC 23168, CIP 106410, DSM 4126, LMG 8378, NBRC 15989, VKM B-1430.

Sequence accession no. (16S rRNA gene): AB078072.

Genus IX. **Hymenobacter** Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1999, 1^{VP} emend. Buczolits, Denner, Kämpfer and Busse 2006, 2076^{VP} (Effective publication: Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1998a, 374.)

SANDRA BUCZOLITS AND HANS-JÜRGEN BUSSE

Hy.me.no.bac'ter. Gr. masc. n. *hymen* pellicle, thin layer; N.L. masc. n. *bacter* the equivalent of Gr. neut. n. *baktron* a rod or staff; N.L. masc. n. *Hymenobacter* a rod growing in thin layers.

Rod-shaped, with polyphosphate granules near the cell poles. Cells aggregating with increasing formation of extracellular polymer and spreading in thin, red to pink layers on agar

surfaces. Nonmotile. Gram-stain-negative. Colonies are flat with a small, raised center. Colony edges may show parallel arrangement of cells in the form of palisades. Aerobic. Heterotrophic,

with a **preference for oligotrophic media**. Temperature range for growth, 4–37°C; optimum, 10–28°C. Some strains can grow at 42°C, but most strains do not. Cells do not grow anaerobically with or without light. Catalase- and oxidase-positive. Non-hemolytic. The carbon utilization spectrum is limited to some sugars, sugar alcohols, organic acids, and a few amino acids. Hydrolysis of gelatin, starch, xylan, Tween 80, and Tween 60 is common. DNA may also be hydrolyzed, but cellulose and pectin are not. Cells are highly sensitive towards the action of numerous antibiotics. **meso-Diaminopimelic acid is present in the cell-wall murein. The principal menaquinone is MK-7. The fatty acid profile consists of predominantly branched fatty acids of the iso- and anteiso-type with C_{15:0} iso, C_{15:0} anteiso, C_{16:1} ω7c/C_{15:0} iso 2-OH (summed feature), and C_{17:1} iso I/C_{17:1} anteiso B (summed feature), usually present in moderate to major amounts** (except for *Hymenobacter roseosalivarius*, which lacks C_{15:0} anteiso). Unbranched fatty acids are usually present in moderate amounts, but their content is low in *Hymenobacter ocellatus*. All members of the genus contain a **polar lipid profile** consisting of **phosphatidylethanolamine, an unknown aminophospholipid (APL3), two unknown polar lipids (L3, L5)**, and a mixture of several other unknown aminophospholipids, aminolipids, phospholipids, glycolipids, and polar lipids. **sym-Homospermidine** is the major polyamine.

DNA G+C content (mol%): 55–65.

Type species: ***Hymenobacter roseosalivarius*** Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1999, 1^{VP} (Effective publication: Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1998a, 382.).

Further descriptive information

The genus *Hymenobacter* was described with the single species *Hymenobacter roseosalivarius* that had been isolated from the Dry Valleys region in Antarctica (Hirsch et al., 1998a). In this study, affiliation of three strains - provisionally named “*Taxeobacter chitinovorans*”, “*Taxeobacter gelupurpurascens*”, and “*Taxeobacter ocellatus*” (Reichenbach, 1992b) — to this lineage was demonstrated by rRNA gene sequence similarity and phylogeny. So far, eight other species with validly published names have been effectively described as species of the genus: *Hymenobacter actinosclerus* isolated from irradiated pork (Collins et al., 2000); *Hymenobacter aerophilus* isolated during the examination of airborne bacteria in samples from the Museo Correr in Venice, Italy (Buczolits et al., 2002); *Hymenobacter norwichensis* isolated during the examination of airborne bacteria in samples from the Sainsbury Centre for Visual Arts in Norwich (UK; Buczolits et al., 2006); *Hymenobacter chitinivorans* (formerly designated “*Taxeobacter chitinovorans*”); *Hymenobacter gelipurpurascens* (formerly designated “*Taxeobacter gelupurpurascens*”); *Hymenobacter ocellatus* (formerly designated “*Taxeobacter ocellatus*”) isolated from dried soil which had been stored for several years (Baik et al., 2006; Reichenbach, 1992b); *Hymenobacter rigui* isolated from wetland freshwater in Woopo, South Korea (Baik et al., 2006); *Hymenobacter xinjiangensis* isolated from soil of the Xinjing desert, China following gamma-irradiation (Zhang et al., 2007). Sources of isolation suggest that at least some *Hymenobacter* species have developed strategies to survive under unfavorable conditions such as desiccation, radiation, and cold.

Strains analyzed for their quinone systems and polyamine patterns contain menaquinone MK-7 and the predominant

compound *sym*-homospermidine, respectively. The contents of certain fatty acids such as C_{15:0} iso, C_{15:0} anteiso, C_{16:1} ω5c, C_{16:1} ω7c/C_{15:0} iso 2-OH (summed feature), and C_{17:1} iso I/C_{17:1} anteiso B (summed feature), which were detected in the range 8–37, 0–26, 2–23, 5–30, and 8–27%, respectively, suggest a high potential for differentiation of *Hymenobacter* species and identification of newly isolated strains. Even polar lipid profiles exhibit a diversity that appears to be suitable for differentiation between *Hymenobacter* species (Baik et al., 2006). Physiological and biochemical traits useful for discrimination between *Hymenobacter* species are listed in Table 96.

Nothing is known about pathogenic potential of *Hymenobacter* species.

Differentiation of the genus *Hymenobacter* from other genera

Hymenobacter species do not exhibit extraordinary phenotypic traits which allow their differentiation from closely related genera such as *Adhaeribacter*, *Pontibacter*, and *Effluviibacter*, but differentiation may be accomplished by 16S rRNA gene sequence similarities below 88.0%.

Certain quantitative differences in the fatty acid profiles might be useful for phenotypic differentiation of *Hymenobacter* species from related genera. The content of C_{15:0} iso 2-OH (16.5%) in the fatty acid profile of *Adhaeribacter aquaticus* (Rickard et al., 2005) is significantly higher than in *Hymenobacter* species (Table 97) and contents of C_{17:1} ω6c and lack of “summed feature” (C_{15:0} iso 2-OH/C_{16:1} ω7c) in the profiles of *Adhaeribacter aquaticus* and *Effluviibacter roseus* (Rickard et al., 2005; Suresh et al., 2006) might be useful for differentiation from *Hymenobacter* species. The high G+C content may distinguish *Hymenobacter* (>55 mol%) species from *Pontibacter* and *Adhaeribacter* species (Nedashkovskaya et al., 2005c; Rickard et al., 2005; Zhou et al., 2007). However, the listed distinguishing traits cannot be considered to be highly reliable because each of the nearest related genera so far is represented by only one or two species, and hence the variability of the characteristics within these genera is unknown.

Taxonomic comments

Sequence similarities in the 16S rRNA genes among established species of the genus *Hymenobacter* are above 90%. This value is rather low compared to many other genera where the threshold value for genus affiliation is approximately 95% similarity. This significantly lower threshold value for delineation of the genus suggests a higher mutation rate in the 16S rRNA coding genes or the need for dissection of the genus possibly on the basis of differences in the polar lipid and fatty acid profiles and other distinguishing traits as yet unidentified. However, if the threshold value of 90% for assignment to the genus *Hymenobacter* is considered to be acceptable, deposited 16S rRNA gene sequences indicate presence in institutional culture collections of several strains that might be described as novel species of the genus, as indicated under *Other organisms*.

Phylogenetic relatedness shown in the maximum-likelihood tree after multiple alignments (Figure 75) are in good agreement with that suggested from 16S rRNA gene sequence similarities, demonstrating that *Hymenobacter ocellatus* represents the deepest branching within the genus. 16S rRNA gene based phylogenetic relatedness support placement of all unnamed strains

^dCollins et al. (2000) reported growth at 42°C.

within the genus *Hymenobacter*, but strain *Taxeobacter* sp. SAFR-033 appears to be a representative of a novel genus.

Maintenance procedures

For long-term storage, *Hymenobacter* cultures may be lyophilized by common procedures that are used for many bacteria; alternatively, cultures can be stored at -80°C in potassium phosphate buffer/25% glycerol (v/v).

Enrichment and isolation procedures

Temperatures between 20 and 28°C and, low nutrient media with neutral pH such as R2A* or PYE agar[†] appear to be most

*R2A agar has the following composition (g/l): yeast extract, 0.5; casein hydrolysate, 0.5; glucose, 0.5; starch, 0.5; K₂HPO₄, 0.3; MgSO₄, 0.024; Na-pyruvate, 0.3; agar, 15.0; pH 7.2 ± 0.2.

[†]PYE agar has the following composition (g/l): yeast extract, 3.0; peptone from casein, 3.0; agar, 15.0; pH 7.2.

appropriate for isolation of hymenobacters. The ability of several *Hymenobacter* species to survive under unfavorable conditions such as exposure to increased desiccation (Buczolits

et al., 2002; Hirsch et al., 1998a; Reichenbach, 1992b) or at high levels of radiation (Collins et al., 2000) may be useful for development of more specific isolation procedures.

List of species of the genus *Hymenobacter*

- Hymenobacter roseosalivarius*** Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1999, 1^{VP} (Effective publication: Hirsch, Ludwig, Hethke, Sittig, Hoffmann and Gallikowski 1998a, 382.)

ro'se.o.sa.li.va'ri.us. L. adj. *roseus* rose colored; L. adj. *salivarius* salivary, slimy; N.L. masc. adj. *roseosalivarius* indicating a rose-colored bacterium surrounded by much polymer.

The characteristics are as described for the genus and as listed in Tables 96 and 97, with the following additional features. Cells produce (often subpolarly) extracellular polymer and aggregate to form tight, thin, and spreading reddish layers on agar surfaces. Growth in liquid cultures is turbid. Does not grow at 37°C. L-Aspartate is used as a carbon

source, but not glutamate. The maximum salt tolerance is 0.5–2.0% NaCl. Pectin and cellulose are not hydrolyzed. The fatty acid profile is given in Table 97.

Source: sandstone and soils of the Dry Valleys region of Antarctica.

DNA G+C content (mol%): 56 (HPLC).

Type strain: AA-718, CIP 106397, DSM 11622.

Sequence accession no. (16S rRNA gene): Y18833.

- Hymenobacter actinosclerus*** Collins, Hutson, Grant and Patterson 2000, 733^{VP}

ac.ti.no.scle'rus. Gr. n. *actis*, *actinos* ray, beam; Gr. adj. *sclerus* hard; N.L. masc. adj. *actinosclerus* hard against rays, pertaining to the organism's radiation resistance.

FIGURE 75. Maximum likelihood dendrogram showing phylogenetic relatedness among *Hymenobacter* species and so far unnamed isolates considered to represent novel species of the genus. Numbers at the nodes indicate bootstrap values (500 replications). The scale bar represents 10% sequence divergence.

The characteristics are as described for the genus and as listed in Tables 96 and 97, with the following additional features. Cell dimensions are $0.5\text{--}0.6 \times 2.0\text{--}3.6 \mu\text{m}$. No variation in cell morphology is observed in old cultures. Colonies on yeast extract peptone agar are circular, entire, opaque, and not easily emulsified. A water-insoluble red pigment is produced. Fluorescent pigments are not produced on King's A or B media. Chemo-organotrophic. Aerobic, having a respiratory type of metabolism, with an ability to grow under microaerobic conditions. Oxidase- and catalase-positive. Acid and gas are not produced from D-glucose. Starch is hydrolyzed, but not esculin. Alkaline phosphatase, acid phosphatase, ester lipase C8, cystine arylamidase, leucine arylamidase, valine arylamidase, N-acetyl- β -glucosaminidase, and phosphoamidase activity are detectable with the API ZYM system. Lipase C14, chymotrypsin, trypsin, α -galactosidase, β -galactosidase, β -glucuronidase, β -glucosidase, α -fucosidase,

α -mannosidase, and urease activity are not detectable. Nitrate reduction, H_2S production, and indole production are negative. Growth occurs at 42°C but not at 5°C . Optimal growth temperature, $25\text{--}30^\circ\text{C}$. Highly radiation-resistant with a D_{10} in sodium phosphate buffer of 3.45 kGy and on minced pork of 5.05 kGy. The fatty acid profile is given in Table 97.

Source: pork chops irradiated with 1.75 kGy.

DNA G+C content (mol%): 62 (T_m).

Type strain: CCUG 39621, CIP 106628.

Sequence accession no. (16S rRNA gene): Y17356.

3. ***Hymenobacter aerophilus*** Buczolits, Denner, Vybiral, Wieser, Kämpfer and Busse 2002, 454^{VP}

aer.o.phil'us. Gr. n. *aer* air; N.L. masc. adj. *philus* (from Gr. masc. adj. *philos*) friend, loving; N.L. masc. adj. *aerophilus* air-loving, indicating its survival when suspended in air.

The characteristics are as described for the genus and as listed in Tables 96 and 97, with the following additional features. Cells are 0.4–0.75 × 1.3–5.0 µm. Cells grow best on nutrient-reduced media such as CasMM* and R2A agar. Colonies on CasMM and R2A agar are translucent, red, circular, entire, low-convex, smooth, and slimy; the diameter is as much as 3.0 mm after 5 d at 28°C, and the colonies spread on CasMM agar. Colonies on standard bacteriological media such as PYES† agar and TSA are opaque, red, circular, entire, convex, and smooth; diameter is up to 2.0 mm after 5 d of incubation at 28°C. No growth occurs on MacConkey or Czapek–Dox agar. The optimum growth temperature is room temperature. The temperature range for growth is 4–28°C; no growth occurs at 37°C. Tolerance maximum for growth in the presence of NaCl is 2.0%. A water-insoluble red pigment is produced; the visible absorption spectrum of the acetone-extracted pigment shows a maximum at 482 nm and two slight inflexions at 453 and 505 nm. Cells assimilate acetate, propionate, D-fructose, D-glucose, D-mannose, and sucrose and display positive reactions in the following tests: catalase, L-alanine aminopeptidase, DNase, alkaline phosphatase, esterase (C4), esterase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, valine arylamidase, hydrolysis of Tween 80, *p*-nitrophenyl (pNP) α-D-glucopyranoside, pNP phenylphosphonate, L-proline *p*-nitroanilide (pNA), L-alanine pNA, L-glutamate γ-3-carboxy-pNA, bis-pNP phosphate, and 2-deoxythymidine-5'-pNP phosphate. Depending on the sensitivity of the method applied, strains show either no catalase reaction or only a weakly positive one. Cells are susceptible to bacitracin, chloramphenicol, colistin sulfate, erythromycin, fusidic acid, gentamicin, kanamycin, nitrofurantoin, penicillin G, polymyxin B, tetracycline, and vancomycin. The fatty acid profile is given in Table 97.

Source: air in the Museo Correr, Venice, Italy.

DNA G+C content (mol%): 60–63 (HPLC).

Type strain: I/26-Cor1, CCUG 49624, DSM 13606, LMG 19657.

Sequence accession no. (16S rRNA gene): AJ276901.

4. **Hymenobacter chitinivorans** Buczolits, Denner, Kämpfer and Busse 2006, 2077^{VP} (*Taxeobacter chitinivorans* Reichenbach 1992b, 182)

chi.ti.ni.vo'rans. N.L. neut. n. *chitinum* chitin; L. part. adj. *vorans* devouring; N.L. part. adj. *chitinivorans* devouring chitin.

The characteristics are as described for the genus and as listed in 96 and 97, with the following additional features. Cells are approximately 0.8 × 4.0 µm. Colonies are brick red. Growth occurs on PYES agar, Czapek–Dox agar, and R2A but not on MacConkey agar. Oxidase- and catalase-positive. Nitrate reduction is weakly positive without production of N₂. Negative for production of indole from tryptophan and for arginine dihydrolase and urease. Chitin is degraded. Positive

for alkaline phosphatase, esterase C4 (weakly), esterase lipase C8 (weakly), leucine arylamidase, and naphthol-AS-BI-phosphohydrolase (weakly) with the API ZYM system. Negative for lipase C14, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Sensitive to bacitracin (10 IU), chloramphenicol (30 µg), colistin sulfate (10 µg), erythromycin (15 µg), fusidic acid (10 µg), gentamicin (10 µg), kanamycin (30 µg), penicillin G (10 IU), vancomycin (30 µg), polymyxin B sulfate (300 IU), and tetracycline (10 µg). The fatty acid profile is given in Table 97.

Source: soil.

DNA G+C content (mol%): ~61 (analytical ultracentrifuge).

Type strain: strain Txc1, DSM 11115, LMG 21951.

Sequence accession no. (16S rRNA gene): Y18837.

5. **Hymenobacter gelipurpurascens** Buczolits, Denner, Kämpfer and Busse 2006, 2077^{VP} (*Taxeobacter gelipurpurascens* Reichenbach 1992b, 182)

ge.lu.pur.pu.ras'cens. L. masc. n. *gelus* -us (or L. neut. n. *gelum* -i) the ice cold; L. part. adj. *purpurascens* turning purple; N.L. part. adj. *gelipurpurascens* becoming purple in the cold.

The characteristics are as described for the genus and as listed in Tables 96 and 97, with the following additional features. Size of cells is approximately 0.5 × 2.0 µm. Colonies are brick red, but at a growth temperature of 2–6°C, and colonies grown on a certain medium are deep blood-red (Reichenbach, 1992b). Growth occurs on PYES agar, Czapek–Dox agar, and R2A, but not on MacConkey agar. Oxidase- and catalase-positive. Nitrate reduction is weakly positive without production of N₂. Negative for production of indole from tryptophan and for arginine dihydrolase and urease. Positive for alkaline phosphatase, esterase C4 (weakly), esterase lipase C8 (weakly), leucine arylamidase, valine arylamidase (weakly), and naphthol-AS-BI-phosphohydrolase (weakly) with the API ZYM system. Negative for lipase C14, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Sensitive to bacitracin (10 IU), chloramphenicol (30 µg), colistin sulfate (10 µg), erythromycin (15 µg), fusidic acid (10 µg), gentamicin (10 µg), kanamycin (30 µg), penicillin G (10 IU), vancomycin (30 µg), polymyxin B sulfate (300 IU), and tetracycline (10 µg). The fatty acid profile is given in Table 97.

Source: soil.

DNA G+C content (mol%): ~57–58 (analytical ultracentrifuge).

Type strain: Txg1, DSM 11116, LMG 21873.

Sequence accession no. (16S rRNA gene): Y18836.

6. **Hymenobacter norwichensis** Buczolits, Denner, Kämpfer and Busse 2006, 2077^{VP}

nor.wi.chen'sis. N.L. masc. adj. *norwichensis* of or belonging to Norwich, a city in England where the type strain was isolated.

The characteristics are as described for the genus and as listed in Tables 96 and 97, with the following additional

*CasMM agar (g/l): K₂HPO₄, 0.6; Na₂HPO₄·2H₂O, 0.05; MgSO₄·7H₂O, 0.05; MgCl₂·7H₂O, 0.1; KNO₃, 0.2; FeCl₃·6H₂O, 0.010; casein, 0.8; yeast extract, 0.4; agar, 15.0; pH 7.0.

†PYES agar (g/l): yeast extract, 3.0; peptone from casein, 3.0; sodium succinate, 2.3; agar, 15.0; pH 7.2.

features. Size of cells is approximately $2\text{--}3 \times 0.8 \mu\text{m}$. Colonies are brick red. Growth occurs on PYES agar, and R2A but not on Czapek–Dox agar or MacConkey agar. Oxidase- and catalase-positive. Nitrate reduction is positive without production of N_2 . Negative for production of indole from tryptophan and for arginine dihydrolase and urease. Positive for alkaline phosphatase, esterase C4 (weakly), esterase lipase C8 (weakly), leucine arylamidase, valine arylamidase (weakly), acid phosphatase (weakly), naphthol-AS-BI-phosphohydrolase and β -glucosidase (weakly) with the API ZYM system. Negative for lipase C14, cystine arylamidase, trypsin, chymotrypsin, α -galactosidase, β -galactosidase, β -glucuronidase, α -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase. Sensitive to bacitracin (10 IU), chloramphenicol (30 μg), colistin sulfate (10 μg), erythromycin (15 μg), fusidic acid (10 μg), gentamicin (10 μg), kanamycin (30 μg), penicillin G (10 IU), vancomycin (30 μg), polymyxin B sulfate (300 IU), and tetracycline (10 μg). The fatty acid profile is given in Table 97.

Source: air in the Sainsbury Centre for Visual Arts in Norwich (UK).

DNA G+C content (mol%): not reported.

Type strain: NS/50, DSM 15439, LMG 21876.

Sequence accession no. (16S rRNA gene): AJ549285.

7. **Hymenobacter ocellatus** Buczolits, Denner, Kämpfer and Busse 2006, 2076^{VP} (*Taxeobacter ocellatus* Reichenbach 1992b, 182)

o.cel.la'tus. L. masc. adj. *ocellatus* showing little eyes, referring to the bright granules at the cell poles.

Cells are approximately $1 \times 3\text{--}6 \mu\text{m}$. Colonies are brick red. Growth occurs on PYES agar, Czapek–Dox agar, and R2A but not on MacConkey agar. Oxidase- and catalase-positive. Nitrate reduction is weakly positive without production of N_2 . Negative for production of indole from tryptophan and for arginine dihydrolase and urease. Positive for alkaline phosphatase, esterase lipase C8 (weakly), leucine arylamidase (weakly) and naphthol-AS-BI-phosphohydrolase (weakly) with the API ZYM system. Negative for esterase C4, lipase C14, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α -galactosidase, β -galactosidase, β -glucuronidase, α -glucosidase, β -glucosidase, *N*-acetyl- β -glucosaminidase, α -mannosidase, and α -fucosidase. Sensitive to bacitracin (10 IU), chloramphenicol (30 μg), colistin sulfate (10 μg), erythromycin (15 μg), fusidic acid (10 μg), gentamicin (10 μg), kanamycin (30 μg), penicillin G (10 IU), vancomycin (30 μg), polymyxin B sulfate (300 IU), and tetracycline (10 μg). The fatty acid profile is given in Table 97.

Source: dung of an antelope.

DNA G+C content (mol%): ~65 (analytical ultracentrifuge).

Type strain: Myx 2105, Txo1, DSM 11117, LMG 21874.

Sequence accession no. (16S rRNA gene): Y18835.

8. **Hymenobacter rigui** Baik, Seong, Moon, Park, Yi and Chun 2006, 2191^{VP}

ri'gui. L. gen. n. *rigui*, of a well-watered place.

Cells produce water-insoluble pinkish-red pigment. Cells grow best on R2A and TSA, and weakly on nutrient agar. Colonies on tryptic soy agar are translucent, low-convex,

circular, smooth, and slimy, with a diameter up to 3.0 mm after 5 d at $25\text{--}30^\circ\text{C}$ (pH 7). Growth occurs in the presence of 0–2% (w/v) NaCl (optimum 0%), at pH 5–11 (optimum pH 6), and at $4\text{--}37^\circ\text{C}$ (optimum 30°C). Oxidase-negative and catalase-positive. Nitrate is not reduced to nitrite. Esculin hydrolysis is weakly positive. Citrate is not utilized. Negative for fermentation of glucose. Gelatinase is produced but not arginine dihydrolase, urease, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, H_2S , indole, or acetoin. Positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, valine arylamidase, and α -glucosidase, but not lipase (C14), trypsin, α -chymotrypsin, β -glucuronidase, α -galactosidase, β -galactosidase, β -glucosidase, α -mannosidase, or α -fucosidase. The following substrates are utilized as sole carbon and energy sources: galactose, esculin, starch, lactose, inulin, melezitose, raffinose, glycogen, and gentiobiose. The following substrates are not utilized: glycerol, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, β -methyl-D-xylopyranoside, sorbose, rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, α -methyl-D-mannopyranoside, α -methyl-D-glucopyranoside, *N*-acetylglucosamine, amygdalin, arbutin, melibiose, xylitol, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, and gluconate. The fatty acid profile is given in Table 97.

Source: freshwater of Woopo wetland, Republic of Korea.

DNA G+C content (mol%): 65 (T_m).

Type strain: WPCB131, IMSNU 14116, KCTC 12533, NBRC 101118.

Sequence accession no. (16S rRNA gene): DQ089669.

9. **Hymenobacter xinjiangensis** Zhang, Liu, Tang, Zhou, Shen, Fang and Yokota 2007, 1754^{VP}

xin.jiang.en'sis. N.L. masc. adj. *xinjiangensis* pertaining to Xinjiang, an autonomous region in North-West China).

Cells ($\sim 0.7 \times 2\text{--}5 \mu\text{m}$) are rod-shaped, Gram-stain-negative, aerobic, nonsporeforming bacteria. Motility is not observed. Cells grow best on nutrient-reduced media such as $0.1 \times$ TSA and PYES agar. Colonies on $0.1 \times$ TSA and PYES agar are translucent, pink, circular, entire, low-convex, and rough; diameter is up to 1.5 cm after 5 d at 28°C . The temperature range for growth is $4\text{--}37^\circ\text{C}$; optimum, 28°C . Oxidase- and catalase-positive. Esculin hydrolysis is positive. Negative for fermentation of glucose, nitrate reduction, H_2S production, citrate utilization, indole production, and urease. Using the API ZYM system, the following enzyme activities are detectable: alkaline phosphatase, esterase C4, esterase lipase C8, leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, *N*-acetyl- β -glucosaminidase, and α -mannosidase. The following are not detectable: lipase C14, trypsin, chymotrypsin, α -galactosidase, β -galactosidase, β -glucuronidase, α -glucosidase, β -glucosidase, and α -fucosidase. The following are positive with the Biolog system: dextrin, D-cellobiose, i-erythritol, L-fucose, lactulose, maltose, D-mannitol, D-psicose, D-sorbitol, sucrose, D-trehalose, acetic acid, D-galacturonic acid, D-gluconic acid, D-glucosaminic, γ -hydroxybutyric acid, propionic acid, succinic acid, glucuronamide, L-alanine, glycyl-L-glutamic acid, L-serine, DL-carnitine, thymidine, and

α -D-glucose-1-phosphate. Negative in the Biolog system are: α -cyclodextrin, Tween 40, Tween 80, *N*-acetyl-D-galactosamine, adonitol, L-arabinose, D-arabitol, gentiobiose, α -D-glucose, α -D-lactose, β -methyl-D-glucoside, pyruvic acid methyl ester, succinic acid methyl ester, *cis*-aconitic acid, citric acid, formic acid, D-galactonic acid lactone, α -hydroxybutyric acid, β -hydroxybutyric acid, *p*-hydroxyphenylacetic acid, itaconic acid, α -ketobutyric acid, α -ketoglutaric acid, α -ketovaleric acid, DL-lactic acid, malonic acid, quinic acid, sebacic acid, bromosuccinic acid, succinamic acid, L-alaninamide, L-alanyl-glycine, L-asparagine, glycyl-L-aspartic acid, L-histidine, hydroxy-L-proline, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglutamic acid, D-serine,

L-threonine, γ -aminobutyric acid, urocanic acid, inosine, uridine, phenethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, and glycerol. Sensitive to chloramphenicol, colistin sulfate, erythromycin, gentamicin, penicillin G, polymyxin B sulfate, tetracycline, and vancomycin. Tolerates high doses of gamma radiation with D_{10} of 4.8 kGy. The quinone system is menaquinone MK-7.

Source: soil of the Xinjiang Desert, China following irradiation by gamma rays.

DNA G+C content (mol%): 54 (T_m).

Type strain: X2-1g, CCTCC AB 206080, IAM 15452, JCM 23206.

Sequence accession no. (16S rRNA gene): DQ888329.

Other organisms

If a threshold value of 16S rRNA similarity is considered to be 90% for assignment to the genus *Hymenobacter*, then deposited 16S rRNA gene sequences indicate the presence of several strains in institutional culture collections that might be described as novel species of the genus. These strains, and their % rRNA gene similarity to established species of the genus *Hymenobacter*, are listed below.

1. **Antarctic bacterium** R-7572 (accession no. AJ440980) isolated from a microbial mat, Fryxell Lake, McMurdo Dry Valleys, Antarctica (Van Trappen et al., 2002), has a 16S rRNA similarity value of 91.1–96.8%.
2. **Taxeobacter** sp. GIC34 (accession no. AY439245) isolated from glacial ice core, Greenland (Miteva et al., 2004), has a 16S rRNA similarity value of 90.3–98.1%.
3. **Hymenobacter** sp. 21/4 (accession no. DQ365992) isolated from soil in Victoria Land, Antarctica (Aislabie et al., 2006) has a 16S rRNA similarity value of 90.0–97.1%.
4. **Hymenobacter** sp. zF-IRlt3 (accession no. DQ223662) isolated from ice cores, East Rongbuk Glacier, Mt. Qomolangma, Himalaya (Zhang et al., 2006), has a 16S rRNA similarity value of 90.2–98.4%.
5. **Taxeobacter** sp. SAFR-023 (accession no. AY167836) isolated from spacecraft assembly facilities, has a 16S rRNA similarity value of 87.4–96.0%.
6. **Hymenobacter** sp. Tibet-IIU11 (accession no. DQ177475) isolated from permafrost Qinghai-Tibet Plateau, China has a 16S rRNA similarity value of 90.5–96.6%.*
7. **Hymenobacter** sp. PB17 (accession no. AB251884) isolated from soil in Daejeon, South Korea has a 16S rRNA similarity value of 90.2–92.4%.†
8. **Cytophagales** str. S23328 (accession no. D84607) isolated from paddy field soil near Sendai, Japan (Mitsui et al., 1997) has a 16S rRNA similarity value of 89.4–92.3%.
9. **Bacteroidetes** bacterium P3 (accession no. DQ351728) isolated from soil of La Gorce Mountains, Antarctica has a 16S rRNA similarity value of 90.3–91.3%.
10. **Taxeobacter** sp. SAFR-033 (accession no. AY167836) isolated from spacecraft assembly facilities, shares 86.7–90.0% 16S rRNA gene sequence similarity with established species of the genus *Hymenobacter* but slightly higher values with *Effluviibacter roseus* (90.7%), *Pontibacter actiniarum* (91.6%), and *Adhaeribacter aquaticus* (91.9%).

Genus X. **Larkinella** Vancanneyt, Nedashkovskaya, Snauwaert, Mortier, Vandemeulebroecke, Hoste, Dawyndt, Frolova, Janssens and Swings 2006, 239^{VP}

THE EDITORIAL BOARD

Lar.ki.nel'la. N.L. dim. fem. n. *Larkinella* named in honor of the American microbiologist John M. Larkin, who described the family *Spirosomaceae* in co-authorship with Renée Borrall.

Ring-like and horseshoe-shaped cells 0.5–0.9 μ m wide and with an outer diameter of 1.5–3.0 μ m. **Coils or helices are not formed. Motile by gliding.** Nonsporeforming. Gram-stain-negative. Strictly aerobic. **Produce non-diffusible pale-pink pigments. Flexirubin-type pigments are absent.** Chemo-organotrophic. Oxidase-, catalase-, and alkaline phosphatase-positive. **Acid is not produced from a large variety of carbohydrates, including cellobiose, fructose, galactose, glucose, and sucrose.** Dominant cellular fatty acids are $C_{15:0}$ iso, $C_{16:1}$ ω 5c, $C_{17:0}$ iso 3-OH, and summed feature 3 (comprising $C_{15:0}$ iso 2-OH, $C_{16:1}$ ω 7c, and/or $C_{16:1}$ ω 7t). The main isoprenoid quinone is MK-7.

DNA G+C content (mol%): 53.

Type species: **Larkinella insperata** Vancanneyt, Nedashkovskaya, Snauwaert, Mortier, Vandemeulebroecke, Hoste, Dawyndt, Frolova, Janssens and Swings 2006, 239^{VP}.

Enrichment and isolation procedures

Larkinella insperata was isolated and purified from cooled water produced by a steam generator in a pharmaceutical company

*Editorial note: Meanwhile, *Hymenobacter* sp. Tibet-IIU11 has been described as *Hymenobacter psychrotolerans* (Zhang et al., 2008; IJSEM 58, 1215–1220).

†Editorial note: Meanwhile, *Hymenobacter* sp. PB17 has been described as *Hymenobacter soli* (Kim et al., 2008; IJSEM 58, 941–945).

in Belgium in 2004. Colonies on tryptic soy agar (BBL) at 28°C under aerobic conditions produce non-diffusible pale-pink pigments under aerobic conditions.

Differentiation of the genus *Larkinella* from other genera

Characteristics differentiating the genus *Larkinella* from related or morphologically similar genera are listed in Table 93 in the chapter on the genus *Flectobacillus*.

List of species of the genus *Larkinella*

1. ***Larkinella insperata*** Vancanneyt, Nedashkovskaya, Snaauwaert, Mortier, Vandemeulebroecke, Hoste, Dawyndt, Frolova, Janssens and Swings 2006, 239^{VP}

in.spe.ra'ta. L. fem. adj. *insperata* unexpected, referring to the unexpected source from which the bacterium was isolated.

The characteristics are as described for the genus, with the following additional features. Colonies are 1–2 mm in diameter, circular, and shiny with entire edges. Growth occurs at 10–40°C and with 0–2% NaCl. β-Galactosidase activity is present. Nitrate is not reduced. H₂S, indole, and acetoin (Voges–Proskauer reaction) are not produced. Gelatin and Tween 40 are hydrolyzed. No hydrolysis occurs of agar, casein, starch, DNA, Tweens 20 and 80, urea, cellulose (CM-cellulose or filter paper), and chitin. No acid is produced from adonitol, L-arabinose, D-cellobiose, dulcitol, D-fructose, L-fucose, D-galactose, N-acetylglucosamine,

Taxonomic comments

Vancanneyt et al. (2006) reported that, by 16S rRNA gene sequence analysis, the nearest neighbor of *Larkinella insperata* was *Spirosoma linguale*, with the type strains of the two species sharing a sequence similarity of 88.8%. Similarity values with the type strains of the type species of the genera *Arcicella*, *Dyadobacter*, *Flectobacillus*, and *Runella* were lower: 83.6–86.3%.

D-glucose, glycerol, inositol, D-lactose, D-maltose, mannitol, D-melibiose, L-raffinose, L-rhamnose, sorbitol, L-sorbose, D-sucrose, D-xylose, or L-xylose. L-Arabinose, D-glucose, D-lactose, D-mannose, and D-sucrose are utilized as sole carbon sources for growth, but not citrate, inositol, malonate, mannitol, and sorbitol. Susceptible to ampicillin, carbenicillin, and doxycycline; resistant to benzylpenicillin, chloramphenicol, erythromycin, gentamicin, kanamycin, lincomycin, neomycin, oleandomycin, polymyxin B, streptomycin, and tetracycline. Major fatty acid components (>1.0%) include C_{14:0}, C_{15:0} iso, C_{15:0} anteiso, C_{15:0} iso 3-OH, C_{16:0}, C_{16:1} ω5c, C_{16:0} 3-OH, C_{16:0} iso 3-OH, C_{17:0} iso 3-OH, and summed feature 3 (comprising C_{15:0} iso 2-OH, C_{16:1} ω7c and/or C_{16:1} ω7d).

Source: water produced by a steam generator in a pharmaceutical company in Belgium.

DNA G+C content (mol%): 53 (HPLC).

Type strain: LMG 22510, NCIMB 14103.

Sequence accession no. (16S rRNA gene): AM000022.

Genus XI. *Leadbetterella* Weon, Kim, Kwon, Park, Cha, Tindall, Stackebrandt, Trüper and Go 2005, 2299^{VP}

THE EDITORIAL BOARD

Lead.bet.te.rel'la. N.L. dim. fem. n. *Leadbetterella* named in honor of Edward R. Leadbetter, who studied bacteria belonging to the CFB group.

Rods 0.6–0.9 × 2–7 μm. Nonmotile. **No gliding motility.** Strictly aerobic. Gram-stain-negative. Oxidase- and catalase-positive. Colonies are orange. **Flexirubin-type pigments are present.** **Growth occurs in the presence of 1% NaCl but not 3%.** Several carbohydrates are used as sole carbon sources. Esculin, gelatin, starch, and tyrosine are degraded. Major fatty acids are C_{16:1} ω7c/C_{15:0} iso 2-OH, C_{15:0} iso, C_{15:0} iso 2-OH/C_{16:1} ω7c, C_{17:0} iso 3-OH, and C_{16:0}. The respiratory quinone is MK-7. Isolated from cotton-waste composts.

DNA G+C content (mol%): 33.

Type species: ***Leadbetterella byssophila*** Weon, Kim, Kwon, Park, Cha, Tindall, Stackebrandt, Trüper and Go 2005, 2299^{VP}.

Enrichment and isolation procedures

Leadbetterella byssophila was isolated from cotton-waste composts by plating onto trypticase soy agar (TSA, pH 7.0; Difco) at 30°C.

Differentiation of the genus *Leadbetterella* from other genera

In the family *Cytophagaceae*, *Leadbetterella byssophila* is the only species that has been isolated from cotton-waste composts. Its

failure to grow in the presence of 3% NaCl differentiates it from most marine genera. *Leadbetterella byssophila* differs from *Belliella*, *Cytophaga*, *Cyclobacterium*, *Hongiella*, and *Persicobacter* by its production of flexirubin-type pigments. Its lack of gliding motility distinguishes it from the members of the genus *Cytophaga* and *Reichenbachiella*. The cells of *Leadbetterella* are straight rods, unlike the curved or horseshoe-shaped cells of *Cyclobacterium*. The hydrolysis of gelatin and starch differentiates *Leadbetterella byssophila* from *Dyadobacter*, as well as the much lower mol% G+C of its DNA (33 vs 44–49). *Leadbetterella byssophila* does not hydrolyze agar, unlike *Reichenbachiella* and some species of *Cytophaga*; moreover, it exhibits a lower mol% G+C value than *Reichenbachiella* and *Cytophaga* (33 vs 44.5 and 39–46, respectively).

Taxonomic comments

On the basis on 16S rRNA analyses, Weon et al. (2005) reported that the type strain of *Leadbetterella byssophila* could be positioned in the family “*Flexibacteraceae*”. Moreover, according to a CLUSTAL w alignment of the members of the phylum *Bacteroidetes*, of the named species the type strain showed highest sequence similarity (85.4%) to the type strain of *Belliella baltica*.

List of species of the genus *Leadbetterella*1. *Leadbetterella byssophila* Weon, Kim, Kwon, Park, Cha, Tindall, Stackebrandt, Trüper and Go 2005, 2299^{VP}.

bys.so'phi.la. Gr. n. *byssos* cotton; N.L. fem. adj. *phila* (from Gr. fem. adj. *philē*) friend, loving; N.L. fem. adj. *byssophila* liking cotton.

The characteristics are as described for the genus, with the following additional features. Colonies on TSA are initially light orange and convex with entire margins; with prolonged incubation, they become dark orange. Growth occurs at temperatures of 15–45°C and at pH 6.0–8.0. Growth occurs on 0.5% yeast extract medium. Positive for O/F test (glucose). Positive for indole production and β-galactosidase (API 20NE). Negative for nitrate reduction and arginine dihydrolase (API 20NE). Negative for hydrolysis of casein, cellulose, chitin, DNA, Tweens 40 and 80, and urea. Growth on carbohydrates (API 20NE) occurs with *N*-acetylglucosamine, arabinose, glucose, maltose, and mannose. The following enzyme activities are present (API ZYM system): alkaline phosphatase, leucine arylamidase, valine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase (API ZYM); weak activity is detected for α-galactosidase and β-galactosidase. The following

substrates are oxidized or weakly oxidized (API 50CH system): *N*-acetylglucosamine, amygdalin, D-arabinose, arbutin, D-cellobiose, esculin, D-galactose, gentiobiose, D-glucose, D-lactose, D-maltose, D-mannose, D-melibiose, methyl-α-D-glucopyranoside, methyl-α-D-mannopyranoside, L-rhamnose, salicin, starch, sucrose, and D-trehalose. The following compounds are assimilated or weakly assimilated (Biolog GN 20 system): acetic acid, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, L-alaninamide, L-alanine, L-alanyl-glycine, L-arabinose, D-arabitol, L-asparagine, L-aspartic acid, D-cellobiose, α-cyclodextrin, dextrin, i-erythritol, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose, glucose-1-phosphate, D-glucose 6-phosphate, L-glutamic acid, glycerol, α-DL-glycerol phosphate, glycogen, glycyl-L-aspartic acid, glycyl-L-glutamic acid, L-fucose, α-ketovaleic acid, DL-lactic acid, α-D-lactose, lactulose, maltose, D-mannose, D-melibiose, methyl-β-D-glucoside, methyl pyruvate, monomethylsuccinate, L-ornithine, D-raffinose, L-serine, sucrose, L-threonine, thymidine, D-trehalose, turanose, and uridine.

Source: cotton-waste composts in the Republic of Korea.

DNA G+C content (mol%): 33 (HPLC).

Type strain: 4M15, DSM 17132, KACC 11308.

Sequence accession no. (16S rRNA gene): AY854022.

Genus XII. *Meniscus* Irgens 1977, 42^{AL}

ROAR L. IRGENS

Me.nis'cus. N.L. masc. n. *meniscus* (from Gr. masc. n. *mêniskos*) crescent moon.

Curved or straight rods, 0.7–1.0 μm in diameter and 2.0–3.0 μm in length. Cultures may contain single cells, pairs, tightly coiled spirals, S shapes (two cells, one inverted), and doughnut-shaped cells, where the ends are overlapping before division by binary fission. “Rings” have outer diameters of about 3.0 μm. Single polar flagellum. Stains **Gram-negative. Nonmotile. Resting stages not known. Encapsulated. Gas vacuoles** arranged at random within cells. **Colonies chalky white**. Chemo-organotrophic; strictly **fermentative** metabolism with no gas production. **Catalase and oxidase-negative. Aerotolerantly anaerobic**; capable of growth under an air atmosphere when at least 1% CO₂ is present. Vitamin B₁₂, thiamin and CO₂ are required for growth. Optimum temperature, 30°C. No growth at 10 or 40°C. Isolated from anaerobic digester sludge.

DNA G+C content (mol%): 44.9 (Bd).

Type species: *Meniscus glaucopis* Irgens 1977, 42^{AL}.

Further descriptive information

Cells of *Meniscus* appear as curved or straight rods. The curved rods often form ringlike shapes when the ends of a cell overlap prior to cell separation. Helical, filamentous forms may also be seen. Gas vacuoles (Figures 76 and 77) may be observed by phase-contrast microscopy, and the individual gas vesicles are resolved by observing whole cells or thin sections in the transmission electron microscope.

Colonies are circular, convex in elevation, with an entire margin and smooth, glistening surface. The colonies may appear

translucent or opaque, chalky white. The larger the number of gas vacuoles within the cells of the colony, the whiter the colony. The consistency of the colonies is buttery when grown anaerobically and rubbery when grown aerobically.

When grown to stationary phase in test tubes, the cells often rise to the surface where they form a white band.

The cells apparently do not respire as aerobic and anaerobic cultures have the same cell yields. Fermentation end products when grown on maltose are acetic, propionic, and succinic acids (Irgens, 1977).

Optimum growth occurs around 30°C at pH 7.0. Growth occurs at 15 and 35°C, but not at 10 or 40°C. Cobalamin (vitamin B₁₂), thiamin, and CO₂ are required for growth. Good growth in defined medium occurs with ammonium as the nitrogen source.

The following characteristics are negative: deaminase (Casamino acids), urease, acetyl methyl carbinol, indole, H₂S production and nitrate reduction.

Cells ferment agar (weakly), dextrin, melezitose, raffinose, cellobiose, sucrose, lactose, maltose, melibiose, trehalose, fructose, galactose, glucose, rhamnose (weakly), CH₃-α-D-glucoside, esculin, salicin, D-ribose, D-xylose, and arabinose. They do not ferment mannose, sorbose, glycerol, lactate, mannitol, sorbitol, adonitol, dulcitol, inositol, or amino acids. They do not hydrolyze starch, cellulose, DNA, gelatin, casein, pectin, inulin, gum arabic, tributyrin, chitin, xylan, or glycogen.

Isolated from anaerobic digester sludge but probably also present in anaerobic hypolimnion of lakes.

FIGURE 76. *Meniscus glaucopsis* ATCC 29398. Phase-contrast. Note gas vacuoles. Bar, 2.0 μm .

FIGURE 77. *Meniscus glaucopsis* strain R. Phase-contrast. Note gas vacuoles. Bar, 2.0 μm .

Enrichment and isolation procedures

Members of this genus may be isolated on a complex medium (BGM) having the following composition (per liter): yeast extract, 1.0 g; KH_2PO_4 , 0.5 g; NaCl, 0.4 g; NH_4Cl , 0.4 g; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.01 g; sodium thioglycolate, 0.3 g; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.2 g; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 0.001 g; at least 1% CO_2 ; trace elements solution (TES), 1.0 ml. The TES, modified from Pfennig's formula (personal communication), contains (per liter): $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 0.10 g; $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$, 0.03 g; H_3BO_3 , 0.3 g; $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, 0.2 g; $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, 0.01 g; $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, 0.02 g; $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.03 g; pH 3.0–4.0. The pH of the medium is adjusted to 7.3 with 10% Na_2CO_3 before autoclaving, or the medium may be autoclaved with the pH unadjusted and then adjusted to about pH 7.0 after autoclaving by the addition of 2.0 ml of 5.0% NaHCO_3 ,

sterilized by filtration, per 100 ml of medium. All solid media contain 1.0% CaCO_3 and 1.5% agar. Stock media contain 0.3% agar. Maltose, at a concentration of 0.2–0.5%, is used as the carbon source for growth studies and stock cultures. Pour plates are prepared using anaerobic digester sludge as the inoculum. The plates are incubated in a GasPak anaerobic jar (BBL) at 25–30°C. After 10 d chalky white colonies indicative of the presence of gas vacuoles may be observed.

Maintenance procedures

Stock cultures are maintained in test tubes rendered anaerobic by the pyrogallic acid technique, or they may be maintained on slants in cotton-stoppered test tubes in anaerobic jars. Lyophilized cultures may be stored indefinitely.

Procedures for testing special characters

The presence of gas vacuoles may be demonstrated by the disappearance of the vacuoles upon the application of a sharp blow with a hammer to a wet mount of the cells. The cover slip is protected with a 3–4-mm-thick rubber pad. Phase-contrast microscopic examination of wet mounts made with dilute India ink is used to demonstrate capsules. The hydrolysis of glycogen, inulin, pectin, gum arabic, and dextrin is tested in BGM broth without maltose. Hydrolysis is considered positive if growth occurs and the pH drops.

Differentiation of the genus *Meniscus* from other genera

Two genera of gas-vacuolated curved rods that may be confused with *Meniscus* are “*Brachyarcus*” and *Ancyclobacter* (formerly *Microcycclus*). “*Brachyarcus*” has never been isolated and differs from *Meniscus* in having cells arranged in groups (coenobia) consisting of two, four or more rings (Skuja, 1964). *Ancyclobacter* is differentiated from *Meniscus* as being a catalase-positive, obligate aerobe rather than an aerotolerant anaerobe and by having a mol% G+C of 66–69 (Van Ert and Staley, 1971).

Taxonomic comments

The assignment of *Meniscus* to the family *Cytophagaceae* is uncertain. Garrity et al. (2005) originally classified the genus within the “*Flexibacteraceae*” based upon phenotypic similarities to other members of this group. In preparation of this volume, the type genus of this family was replaced with *Cytophaga* because it has priority over *Flexibacter* (Ludwig et al., 2009), but most members of the group remained the same. In the absence of a sequence for its 16S rRNA gene, the phenotypic evidence was not sufficient to exclude *Meniscus* from the new family. However, the phenotypic evidence does not provide strong support for its assignment to this family. Most of the *Cytophagaceae* are catalase- and oxidase-positive aerobes, while *Meniscus* is catalase- and oxidase-negative and an aerotolerant anaerobe. However, within the *Cytophagaceae*, the genus *Spirosoma* contains a facultative anaerobic species, and a few other genera are either oxidase- or catalase-negative. Likewise, *Arcicella*, *Larkinella* and *Runella* form similar ring-like arrangements of cells, although all possess other morphological differences with *Meniscus*. In addition, gas vacuoles, which are abundant in *Meniscus*, have not been reported in other members of this family. Gas vesicles are also present in many morphologically and physiologically unrelated taxa and are not reliable taxonomic characteristics. At this time, it is also not possible to exclude a relationship

of *Meniscus* to nonvacuolated vibrios within the *Proteobacteria*, such as *Aquaspirillum* and *Vibrio*, and possibly to other Gram-stain-negative, aerotolerant anaerobes such as *Zymomonas* and *Eikenella*. While *Meniscus* was excluded from these genera on phenotypic grounds (Irgens, 1977), a familial relationship may

still exist. *Meniscus glaucopsis* includes both a vibrioid strain and a straight rod strain. This is justified by the fact that all metabolic and physiological characteristics tested are identical for the two strains. These strains are merely morphovars of the same species.

List of species of the genus *Meniscus*

1. *Meniscus glaucopsis* Irgens 1977, 42^{AL}

glau.co'pis. N.L. masc. adj. *glaucopsis* (from Gr. adj. *glaukôpis*) gleaming-eyed (an epithet of the warlike goddess *Athena*), perhaps a reference to the presence of refractile gas vacuoles.

The description of the species is the same as the genus. Isolated from anaerobic digester sludge.

DNA G+C content (mol%): 44.9 (Bd).

Type strain: ATCC 29398.

Sequence accession no. (16S rRNA gene): not available.

Genus XIII. *Microscilla* Pringsheim 1951, 140 emend. Lewin 1969, 194^{AL}

YASUYOSHI NAKAGAWA

Mic.ro.scil'la. Gr. adj. *micros* small; L. n. *oscillum* swing; N.L. fem. n. *Microscilla* intended to mean small swinging organisms.

Long thin flexible threadlike rods usually 10–100 µm long or longer. **Motile by gliding.** Cell mass more or less intensely orange. **Strictly aerobic and chemo-organotrophic.** All grow on peptones as sole source of nitrogen. Chitin and cellulose are not attacked, but other polysaccharides including carboxymethyl cellulose may be decomposed. **Marine** organisms. No growth occurs in half-strength seawater.

DNA G+C content (mol%): 37–44.

Type species: *Microscilla marina* Pringsheim 1951, 140, emend. Lewin 1969, 201^{AL}.

Further descriptive information

The major quinone of *Microscilla marina*, "*Microscilla furvescens*", and "*Microscilla sericea*" is MK-7 (Nakagawa, unpublished). The major polyamines of *Microscilla marina* are cadaverine, spermidine, and putrescine; that of "*Microscilla furvescens*" is homospermidine. "*Microscilla sericea*" contains mainly homospermidine in addition to agmatine (Hamana and Nakagawa, 2001).

Enrichment and isolation procedures

No enrichment media have been designed for isolation of *Microscilla* strains. Standard procedures to isolate marine bacteria can be applied. Colonies of *Microscilla* are usually orange to yellow. *Microscilla* strains have been isolated from marine environments at widely separated sites (Lewin, 1969; Lewin and Lounsbury, 1969). The type strains of *Microscilla marina* and "*Microscilla sericea*" came from the marine aquarium in La Jolla, California. The type strain of "*Microscilla furvescens*" was isolated from marine sand in Samoa.

Maintenance procedures

Cultures of *Microscilla* strains can be preserved by freezing at temperatures lower than –80°C. For freezing, cells are suspended in Marine broth 2216 (Difco) containing 10% glycerol or 7% DMSO. *Microscilla* strains are rather sensitive to drying; however, they can be preserved in a protective medium SM2 or SM3 (see the chapter on *Flammeovirga* for formulations) by the liquid drying method, or by freeze drying.

Differentiation of the genus *Microscilla* from other genera

Phylogenetic analysis based on 16S rRNA sequences shows that *Microscilla marina*, the type species of the genus *Microscilla*, is phylogenetically independent in the phylum *Bacteroidetes* (see Figure 74 of the chapter *Flexibacter*). However, because few taxonomic characteristics have been investigated since the original descriptions, it is impossible to discriminate the genus *Microscilla* from other related genera only by phenotypic characteristics. It is hoped that additional strains will be isolated and useful differential chemotaxonomic, physiologic, and biochemical characteristics of the genus *Microscilla* will be investigated. All species possess MK-7 as the major quinone, which is useful for differentiating the genus from the family *Flavobacteriaceae*, which is characterized by MK-6 (Bernardet et al., 2002; Nakagawa and Yamasato, 1993).

Taxonomic comments

The genus *Microscilla* was first described by Pringsheim (1951) for actively gliding organisms including the marine type species, *Microscilla marina*, and two freshwater species. From the beginning, it was realized that the genus *Microscilla* resembles the genus *Flexibacter* established by Soriano (1945). In addition, the original Pringsheim's strains have been lost. Lewin (1969) reisolated morphologically similar organisms and redefined both genera by classifying marine organisms with longer filaments (20–100 µm) in the genus *Microscilla*. This definition was not followed in the *Bergey's Manual of Determinative Bacteriology*, 8th edition (Leadbetter, 1974), and the genus *Microscilla* was included in the genus *Flexibacter*. Later, Reichenbach (1989a, b) tried to restrict the genus *Microscilla* to marine organisms with G+C content of the DNA of above 37 mol%. However, he also stated that too little was known about these bacteria, that these genera were still heterogeneous, and that future research including modern molecular taxonomy was a prerequisite. Those histories are described in detail in the 1st edition of this *Manual*.

Only the type species, *Microscilla marina*, has been validly published to date. In addition, four non-validated species - "*Microscilla aggregans*" (synonym, *Flexibacter aggregans*), "*Microscilla*

furvescens”, “*Microscilla sericea*”, and “*Microscilla tractuosa*” (synonym, *Flexibacter tractuosus*) — were included in the genus, and three other species — “*Microscilla arenaria*”, *Flexibacter litoralis*, and *Flexibacter polymorphus* — were listed as *Species Incertae Sedis* in the 1st edition of the *Manual*.

16S rRNA sequencing analyses of the genera *Microscilla* and *Flexibacter* have shown a high degree of biological diversity of the genus (Nakagawa et al., 2002). The five strains in the four species *Microscilla marina*, “*Microscilla furvescens*”, “*Microscilla sericea*”, and “*Microscilla arenaria*” diverged into five distinct lineages, as shown in Figure 71 of the chapter on *Flexibacter* and Table 98 (see also Table 94 of the chapter on *Flexibacter*). *Microscilla marina*, the type species of the genus *Microscilla*, was a species secluded from the others, which means that other invalid *Microscilla* species should not be included in the genus. “*Microscilla arenaria*” NBRC 15982^T, which was closely related with the genus *Flammeovirga*, was reclassified as *Flammeovirga arenaria* (Takahashi et al., 2006). “*Microscilla furvescens*” is an independent lineage located next to the cluster composed of *Flexibacter tractuosus* and “*Microscilla sericea*”. Two strains of “*Microscilla sericea*” were

phylogenetically different. The type strain of “*Microscilla sericea*”, NBRC 15983^T, clustered with *Flexibacter tractuosus* and may be classified in the same new taxon. Another strain of “*Microscilla sericea*”, NBRC 16561, occupied an independent position that seemed to require a new taxon. The marine *Flexibacter* species *Flexibacter litoralis* and *Flexibacter polymorphus*, in addition to *Flexibacter aggregans* (“*Microscilla aggregans*”) and *Flexibacter tractuosus* (“*Microscilla tractuosa*”), were not closely related to either the type species of the genus *Microscilla* or that of the genus *Flexibacter*. These marine *Flexibacter* species are discussed in the chapter on *Flexibacter*.

In this chapter, Reichenbach’s definition of the genus is principally followed; however, based on 16S rRNA sequencing analysis, only the type species, *Microscilla marina*, can be justified as a member of the genus *Microscilla*. Other non-validated *Microscilla* species that should be reclassified in the future are listed under *Other species*.

Differentiation of species of the genus *Microscilla*

Table 99 lists characteristics that distinguish the *Microscilla* species from one another.

List of species of the genus *Microscilla*

1. ***Microscilla marina*** Pringsheim 1951, 140, emend. Lewin 1969, 201^{AL}
ma.ri’na. L. fem. adj. *marina* of, or belonging to, the sea, marine.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual*.

Threads may become very long, more than 150 μm. The cell mass is orange. Growth occurs on media containing single- or double-strength seawater. Growth does not occur

at temperatures greater than 35°C. Peptones serve as sole nitrogen source, but not glutamate or NO₃⁻. Glucose is not utilized. Gelatin is degraded, but not agar, alginate, carboxymethyl cellulose, or starch. Nitrate is not reduced. The major carotenoid is saproxanthin. Only one strain — the type strain — is available.

DNA G+C content (mol %): 42 (Bd).

Type strain: S10-8, ATCC 23134, DSM 4236, LMG 18923, NBRC 16560.

Sequence accession no. (16S rRNA gene): AB078080.

Other species

The species listed below should not be included in the genus *Microscilla*, because they are not closely related to the type species of the genus, based on 16S rRNA sequence analysis.

1. “***Microscilla furvescens***” Lewin 1969, 201

fur.ves’cens. L. adj. *furvescens* becoming black.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual*.

Long threads of 10–50 μm. The cell mass is orange. Peptones, Casamino acids, glutamate, and NO₃⁻ serve as sole

nitrogen sources. Various sugars, including glucose are utilized, but acetate is not. Agar, alginate, carboxymethyl cellulose, gelatin, and starch are degraded. Nitrate is not reduced. The major carotenoid is saproxanthin. Only one strain — the type strain — is available.

DNA G+C content (mol %): 44 (Bd).

Type strain: TV-2, ATCC 23129, LMG 13023, NBRC 15994, NCIMB 1419.

Sequence accession no. (16S rRNA gene): AB078079.

2. “***Microscilla sericea***” Lewin 1969, 201

se.ri’cea. L. fem. adj. *sericea* silk-like, silky.

TABLE 98. Phylogenetic groups of *Microscilla* strains and their present classification

^aSymbols: +, >85% positive; –, 0–15% positive; nd, not determined.

^bData from Reichenbach (1989a).

^cExpressed as strength of seawater (S); 0 = freshwater.

The characteristics are as described for the genus with the following additional features taken from the 1st edition of this *Manual*.

Long threads of 30–100 μm. The cell mass is orange. Peptones serve as the sole nitrogen source, but not Casamino acids, glutamate, or NO₃⁻. Various sugars, including glucose and glycerol are utilized. Alginate, gelatin, and starch are degraded, but agar and carboxymethyl cellulose are not. Nitrate is not reduced. The major carotenoid is saproloxanthin.

DNA G+C content (mol%): 38–39 (Bd).

Type strain: SIO-7, ATCC 23182, LMG 13021, NBRC 15983, NCIMB 1403.

Sequence accession no. (16S rRNA gene): AB078081.

Genus XIV. *Pontibacter* Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2585^{VP}

OLGA I. NEDASHKOVSKAYA AND SEUNG BUM KIM

Pontibacter L. masc. n. *pontus* the sea; N.L. masc. n. *bacter* from Gr. n. *baktron* rod, N.L. masc. n. *Pontibacter* a marine bacterium.

Rods usually measuring 0.3–0.7 × 1.2–1.9 μm. **Can move by gliding.** Produce non-diffusible pink pigments. No flexirubin-type pigments are formed. **Chemo-organotrophic. Strictly aerobic.** Oxidase, catalase, alkaline phosphatase and β-galactosidase-positive. **Esculin, gelatin, and DNA are hydrolyzed.** Casein, Tween 80, chitin, and cellulose (CM-cellulose and filter paper) are not degraded, but agar, starch, and Tweens 20 and 40 may be decomposed. Carbohydrates are utilized. Can grow without seawater or sodium ions. Nitrate is not reduced to nitrite. Indole and H₂S are not produced. **The major respiratory quinone is MK-7.**

DNA G+C content (mol%): 48–52.

Type species: *Pontibacter actiniarum* Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2585^{VP}.

Further descriptive information

Phylogenetic analysis of almost-complete 16S rRNA gene sequences of the genus *Pontibacter* revealed that its closest relative is a single species of the genus *Adhaeribacter*, *Adhaeribacter aquaticus*, with similarity of 89.2%. The level of 16S rRNA gene sequence similarity between strains *Pontibacter actiniarum* KMM 6156^T and *Adhaeribacter aquaticus* MBRG 1.5^T was 95%.

The main cellular fatty acids are straight-chain unsaturated and branched-chain unsaturated fatty acids C_{15:1} iso, C_{17:0} iso 3-OH, summed feature 3 comprising C_{15:0} iso 2-OH and C_{16:1} ω7c or both, and summed feature 4 comprising C_{17:1} iso I and C_{17:1} anteiso B or both (Table 100).

On rich nutrient media strains of the genus *Pontibacter* form regular, round, shiny, with entire edges, smooth, pink colonies with diameter of 1–3 mm after cultivation of 24 h.

All strains grow at 6–36°C, at pH 7.0–10.0 and with 0–4% NaCl. According to Biolog GN2 tests, dextrin, glycogen, L-alanine, methyl β-D-glycoside, methyl pyruvate, α-ketobutyric acid, α-ketovaleric acid, DL-lactic acid, succinamic acid, alaninamide,

L-alanyl-glycine, L-asparagine, L-aspartic acid, L-glutamic acid, L-proline, and threonine are utilized, but Tween 80, adonitol, i-erythritol, uridine, urocanic acid, α-D-lactose, D-mannose, citric acid, formic acid, ρ-hydroxyphenylacetic acid, malonic acid, sebacic acid, glucuronamide, D-alanine, D-serine, phenylethylamine, 2-aminoethanol, DL-α-glycerol phosphate, and glucose-1-phosphate are not utilized.

The strains of the genus *Pontibacter* are susceptible to ampicillin, benzylpenicillin, chloramphenicol, erythromycin, carbenicillin, lincomycin, and tetracycline, and resistant to polymyxin B and streptomycin.

The *pontibacters* were isolated from sea animals and from a desert soil sample collected in the temperate latitudes.

Enrichment and isolation procedures

The strains of the genus *Pontibacter* were isolated from an unidentified actinian (sea anemone) and a desert soil sample using the dilution plating techniques on Marine agar (Difco) and on LB agar, respectively. All isolates have been grown on media containing 0.5% of a peptone and 0.1–0.2% yeast extract (Difco). The marine representative of the genus *Pontibacter* remains viable on Marine agar (Difco) or other rich media containing natural or artificial seawater for several weeks. They have survived storage in Marine broth or artificial seawater supplemented with 20% glycerol (v/v) at –80°C for at least 5 years. A soil isolate, cultivated on LB agar, can grow well under very dry environmental conditions.

Differentiation of the genus *Pontibacter* from other genera

Strains of the genus *Pontibacter* differ from its closest phylogenetic neighbor, the freshwater bacterium *Adhaeribacter aquaticus*, by a higher DNA G+C content (48–52 mol% for *Pontibacter* strains compared with 40.0 mol% for *Adhaeribacter aquaticus*), and by the differences in fatty acid compositions (Nedashkovskaya et al., 2005c; Rickard et al., 2005) (Table 100).

TABLE 100. Cellular fatty acid content of *Pontibacter actiniarum* and its closest relative *Adhaeribacter aquaticus*^a

Fatty acid	<i>P. actiniarum</i> KMM 6156 ^T	<i>A. aquaticus</i> MBRG 1.5 ^T
C _{10:0} iso	–	1.2
C _{15:0} iso	28.8	22.5

Differentiation of the species of the genus *Pontibacter*

Despite very different sources of isolation, the strains belonging to the two validly published species of the genus *Pontibacter* have

many common phenotypic features. However, they can clearly be differentiated from each other by the several phenotypic traits shown in Table 101.

List of species of the genus *Pontibacter*

- Pontibacter actiniarum*** Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2586^{VP}

ac.ti.ni.a'rum. N.L. gen. pl. n. *actiniarum* of sea anemones or related animals.

Cells are 0.3–0.4 μm in width and 1.2–1.9 μm in length. On Marine agar, colonies are circular and 2–3 mm in diameter.

Growth occurs at 6–43°C (optimal temperature, 25–28°C) and with 0–10% NaCl. Agar is hydrolyzed (weakly). Acid is formed from arbutin (API 50 CH gallery, bioMérieux). No acid is formed from L-arabinose, D-cellobiose, D-galactose, D-lactose, D-melibiose, L-rhamnose, L-sorbose, DL-xylose, N-acetylglucosamine, glycerol, adonitol, dulcitol, inositol, and mannitol. Biolog GN2 tests show that the type strain does not

utilize *N*-acetyl-D-glucosamine, D-fructose, L-fucose, *myo*-inositol, α -lactose, maltose, sucrose, D-gluconic acid, D-glucuronic acid, succinic acid, and glycerol. Acetoin (Voges–Proskauer reaction) production is negative. According to the API ZYM gallery (bioMérieux), the following enzymes are produced: acid phosphatase, esterase lipase (C8), leucine- and valine-arylamidases, trypsin, naphthol-AS-BI-phosphohydrolase, α -glucosidase, and *N*-acetyl- β -glucosaminidase. The following enzymes are not produced: esterase (C4), lipase (C14), cystine arylamidase, α -chymotrypsin, β -glucosidase, β -glucuronidase, α -mannosidase, and α -fucosidase.

Source: a single strain, KMM 6156, was isolated from unidentified actinians collected in the Rudnaya Bay, Sea of Japan, Pacific Ocean.

DNA G+C content (mol%): 48.7 (T_m).

Type strain: KMM 6156, KCTC 12367, LMG 23027.

Sequence accession no. (16S rRNA gene): AY989908.

2. ***Pontibacter akesuensis*** Zhou, Wang, Liu, Zhang, Zhang, Lai and Li 2007, 324^{VP}

a.ke.su.en'sis. N.L. masc. adj. *akesuensis* pertaining to Akesu, a city of XinJiang Province in the north-west of China from where the type strain was isolated.

According to Zhou et al. (2007), cells are 0.7 μm \times 1.5–1.6 μm . On nutrient agar, colonies are round, 1–2 mm in diameter. Growth occurs at 4–36°C (optimum, 28–30°C), and with 0–4% NaCl. No acid is formed from D-cellobiose, D-galactose, D-lactose, D-melibiose, L-rhamnose, L-sorbose, and DL-xylose.

Source: a single strain, AKS 1, was isolated from the surface layer of a desert soil from Akesu, XinJiang Province, China.

DNA G+C content (mol%): 51.4 (T_m).

Type strain: AKS 1, CCTCC AB 206086, KCTC 12758.

Sequence accession no. (16S rRNA gene): DQ672723.

Genus XV. *Runella* Larkin and Williams 1978, 35^{AL}

THE EDITORIAL BOARD

Ru.nel'la. M.E. n. *rune* an ancient alphabet; L. fem. dim. ending *-ella*; N.L. fem. n. *Runella* that which resembles figures of the runic alphabet.

Rigid straight to curved rods, the degree of curvature varying among cells within a culture. In one species (*Runella slithyformis*), the cells range from nearly straight to **crenate-shaped**, but the ends of a cell may overlap, producing a **ring-like structure** with an outside diameter of 2.0–3.0 μm ; in addition, filaments up to 14 μm long may also be produced, and on rare occasions, a coil of two to three turns may be produced. In other species, the cells are either **long and filamentous** or **straight to slightly bent rods** instead of crenate-shaped or ring-like as found with *Runella slithyformis*. Gram-stain-negative. **Nonmotile**. Resting stages are not known. **Aerobic**. *Runella slithyformis* has a **strictly respiratory metabolism with oxygen as the terminal electron acceptor and produces acid oxidatively from a few carbohydrates, whereas *Runella zaeae* can ferment sugars**. Optimum temperature, 20–35°C. **Colonies contain a pale pink or salmon-colored water-insoluble pigment**. Catalase is either positive or weakly positive. The oxidase reaction differs among species. Chemo-organotrophic. In those species so far tested, the major quinone is MK-7. Isolated from **freshwater** (*Runella slithyformis*), activated sludge (*Runella limosa* and *Runella defluvii*), and the **stems of *Zea mays*** (*Runella zaeae*).

DNA G+C content (mol%): 40–49.

Type species: ***Runella slithyformis*** Larkin and Williams 1978, 35^{AL}.

Further descriptive information

Cells of *Runella slithyformis* typically appear as rods whose degree of curvature varies from nearly straight to crescent shaped (Figure 3.2 in Larkin and Borrall, 1984b). An individual cell may be bent in more than one plane. Cells of *Runella zaeae* are straight to slightly bent rods that form chains of irregular shapes.

Colonies of *Runella slithyformis* on MS agar (see the chapter on *Spirosoma* for the recipe for this medium) produce a pale pink, water insoluble, nonfluorescent pigment. The colonies are circular and convex with an entire margin. Abundant growth occurs on MS agar and on nutrient agar. Scant growth occurs on chocolate agar, peptonized milk agar, and

yeast extract-acetate-tryptone agar. No growth occurs on blood agar, eosin-methylene blue agar, nutrient agar containing 5% sucrose, phenol red mannitol salt agar, phenylethyl alcohol agar, trypticase soy agar (with or without 5% sucrose or 3% glucose), MacConkey agar, bismuth sulfite agar, or Salmonella-Shigella agar (Larkin and Williams, 1978). Colonies of *Runella zaeae* are round, smooth, and salmon in color when grown on R2A medium* at 28°C.

Runella is chemo-organotrophic. By the technique of Hugh and Leifson (1953), acid is produced aerobically only from glucose, maltose, sucrose, and inulin. Strains differ in their ability to produce an acid reaction from rhamnose, galactose, mannose, and raffinose. Sugar alcohols are not acidified. Starch and tributyrin are hydrolyzed; esculin, cellulose, agar, chitin, and casein are not hydrolyzed. None of 11 compounds tested in the medium of Gordon and Mihm (see the chapter on *Spirosoma* for the recipe for this medium) are utilized as sole carbon sources.

Runella species are not known to be pathogenic.

Only two strains of *Runella slithyformis* have been isolated and characterized. Both were isolated from eutrophic fresh waters. Similar organisms were seen in gelatinous deposits on wet plants from a mine (Kraepelin and Passern, 1980), in marine waters (Overbeck, 1974; Sieburth, 1978) and in fresh waters (Larkin, unpublished observations).

Runella zaeae was isolated from the stems of *Zea mays* (Chelius et al., 2002; Chelius and Triplett, 2000) and is not known to occur in other habitats. Only one strain has been isolated and characterized.

Runella limosa was isolated from activated sludge performing enhanced biological phosphorus removal in a sequencing batch reactor. Only one strain has been isolated and characterized.

*R2A medium of Reasoner and Geldreich (1985) contains (g/l): Yeast extract, 0.5; Proteose peptone no. 3 (Difco); Casamino acids, 0.5; glucose, 0.5; soluble starch, 0.5; K_2HPO_4 , 0.3; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.05; sodium pyruvate, 0.3; and agar, 15.0. The pH is adjusted to 7.2 with crystalline K_2HPO_4 or KH_2PO_4 . The medium is sterilized by autoclaving.

Runella defluvi was isolated from the activated sludge of a domestic wastewater treatment plant. Only one strain has been isolated and characterized.

Isolation procedures

Runella slithyformis can be isolated by repeated streaking of water samples onto MS agar with incubation at room temperature for up to 2 weeks. The pale pink pigmentation of the colonies aids detection.

Runella limosa was isolated by serial dilution of a sludge sample in 1% (w/v) saline solution, with subsequent spreading onto R2A agar (Difco) and incubation at 20°C for 5 d. Subcultivation was on R2A agar at 25°C for 3 d.

For isolation of *Runella defluvi*, a sludge sample was serially diluted with 1% (w/v) saline solution, spread onto R2A agar (Difco) and incubated at 20°C for 5 d. Subcultivation was done on R2A agar at 30°C for 3 d.

Runella zea was isolated by the procedure used by Chelius and Triplett (2000) for *Dyadobacter fermentans*. Briefly, maize seeds are surface-sterilized with sodium hypochlorite, planted in a sterilized synthetic soil, and watered with a nitrogen-free nutrient solution. After 6 weeks, the plants are harvested and stems are surface-sterilized with sodium hypochlorite, washed with sterile water, and crushed. The fluid portion is plated onto R2A agar and incubated at 28°C.

Maintenance procedures

Strains of *Runella slithyformis* are grown on MS agar or nutrient agar at room temperature for several days to allow abundant growth. They will then survive refrigeration (4°C) for at least 3 weeks. They may also be preserved indefinitely by lyophilization.

Procedures for testing special characters

Utilization of carbohydrates. For *Runella slithyformis*, the production of acid from carbohydrates by aerobic or anaerobic means is determined by the method of Hugh and Leifson (1953), in which MS agar is used but with the glucose replaced by 1% of the substrate to be tested and the agar concentration lowered to 0.3%. Incubation is continued for 8 weeks for cultures giving negative results.

Utilization of single carbon sources. For *Runella slithyformis*, the basal medium used is that of Gordon and Mihm, to which is added 0.2% of the substrate or the sodium salt of the substrate. If growth occurs through four successive subcultures, the results are considered positive even in the absence of a color change in the bromthymol blue indicator.

Differentiation of the genus *Runella* from other genera

Table 102 in the chapter on the genus *Flectobacillus* provides the primary characteristics that can be used to differentiate

TABLE 102. Characteristics differentiating the species of the genus *Runella*^a

Runella slithyformis and *Runella zaeae* from the morphologically similar genera.

Taxonomic comments

Analyses of the 16S rRNA gene sequences of these organisms support the classification of *Runella* as a distinct genus (Chelius and Triplett, 2000; Nikitin et al., 2004; Woese et al., 1990). Although *Runella slithyformis* and *Runella zaeae* differ in morphology, fermentative ability, and other phenotypic characteristics, a 16S rRNA gene sequence similarity of 94% between the two strains suggests that they are sufficiently related to be included within a single genus (Chelius et al., 2002). The level of DNA–DNA hybridization value between *Runella zaeae* and

Runella slithyformis is 19%, indicating separate species (Chelius et al., 2002).

The addition of *Runella limosa* to the genus is supported by a 16S rRNA gene similarity of 94.8% to the type strain of *Runella slithyformis* (Ryu et al., 2006). Similarly, *Runella defluvi* exhibits a similarity value of 93.6% to *Runella slithyformis*, and a value of 97.1% to *Runella limosa*. The status of *Runella defluvi* as a species separate from *Runella limosa* is supported by a DNA–DNA hybridization value of 25% between the two species.

Differentiation of the species of the genus *Runella*

Table 102 lists characteristics that differentiate the four species of *Runella*.

List of species of the genus *Runella*

1. *Runella slithyformis* Larkin and Williams 1978, 35^{AL}

slith.y.form'is. slithy a nonsense word from Lewis Carroll's *Jabberwocky* for a fictional organism that is “slithy” (presumably a combination of slinky and lithe); L. adj. suff. *-formis -is -e, -like*, in the shape of; N.L. fem. adj. *slithyformis* slithy in form.

The characteristics are as described for the genus and as listed in Table 102. The following additional features are taken from Larkin and Williams (1978) and Larkin and Borrall (1984b).

Good growth occurs on MS agar. Moderate growth occurs on nutrient agar. Scant growth occurs on chocolate agar, peptonized milk agar, and yeast extract-acetate-tryptone agar. No growth occurs on blood agar, eosin-methylene blue agar, nutrient agar plus 5% sucrose, phenol red-mannitol-salt agar, phenylethyl alcohol agar, trypticase soy agar, trypticase soy agar plus 3% glucose, MacConkey agar, bismuth sulfite agar, and Salmonella-Shigella agar.

A positive reaction is obtained in the following tests: β -galactosidase (ortho-nitrophenyl- β -galactoside [ONPG]); phosphatase; acid production from glucose, inulin, maltose, and sucrose; hydrolysis of tributyrin and of starch (weak).

A negative reaction is obtained in the following tests: hydrolysis of gelatin, esculin, lecithin, urea, agar, cellulose, and chitin; lysine decarboxylase; ornithine decarboxylase; phenylalanine deaminase; hemolysin production; indole production; methyl red test, Voges–Proskauer test, nitrate reduction, H₂S production from peptone; acid production from arabinose, α -methyl-D-glucoside, cellobiose, dextrin, dulcitol, erythritol, fructose, glycerol, lactose, mannitol, melibiose, ribose, salicin, sorbitol, sorbose, trehalose, and xylose; utilization of acetate, benzoate, citrate, formate, glycerol phosphate, malonate, methanol, methylamine, propionate, succinate, and tartrate as sole carbon sources. No change occurs in litmus milk.

Acid production from galactose, mannose, raffinose, and rhamnose differs between strains.

Source: freshwater.

DNA G+C content (mol%): 49–50 (T_m : absorbance ratio).

Type strain: ATCC 29530, LMG 11500.

Sequence accession no. (16S rRNA gene): M62786.

2. *Runella defluvi* Lu, Lee, Ryu, Chung, Choe and Jeon 2007, 2602^{VP}

de.flu'vi.i. L. gen. n. *defluvi* of sewage.

The characteristics are as described for the genus and as listed in Table 102. The following additional features are taken from Lu et al. (2007). Rods 0.5–0.9 \times 2.2–6.0 μ m at 30°C on R2A agar. Colonies are slightly raised, circular and salmon pink on R2A agar. Temperature range 15–40°C, optimum, 30–35°C. pH range 6.0–9.5, optimum 7.5–8.0. Nitrate is not reduced to nitrite. Catalase-positive. Oxidase-negative. No anaerobic growth after 7 d at 30°C on R2A agar. Tyrosine, Tween 80, and esculin are hydrolyzed, but not casein, Tween 20, starch, gelatin, and urea. Acid is produced from raffinose, *myo*-inositol, lactose, L-arabinose, D-galactose, D-mannose, D-mannitol, and melibiose, but not from D-glucose, D-fructose, arbutin, or salicin. Indole, H₂S and acetoin are not produced. Citrate is not utilized (API 20E system). Enzyme activities include alkaline phosphatase, trypsin, α -chymotrypsin, N-acetyl- β -glucosaminidase, and naphthol-AS-BI-phosphohydrolase, but not tryptophan deaminase, esterase (C4), lipase (C14) and β -glucuronidase. Weak activities occur for esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, α -galactosidase, β -galactosidase, α -glucosidase, β -glucosidase, α -mannosidase, and α -fucosidase (API ZYM system). Glycerol, methyl β -xyloside, methyl α -D-mannoside, and esculin are used as sole carbon sources but not erythritol, D- or L-arabinose, D-xylose, adonitol, galactose, D-glucose, D-fructose, mannose, dulcitol, inositol, mannitol, sorbitol, N-acetylglucosamine, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, D-raffinose, D-turanose, D- or L-arabitol, gluconate, or 2-ketogluconate. Ribose, L-xylose, sorbose, rhamnose, methyl α -D-glucoside, amygdalin, arbutin, starch, glycogen, xylitol, β -gentiobiose, D-lyxose, D-tagatose, D- and L-fucose, and 5-ketogluconate are weakly utilized (API 50CH system). Cells contain a large amount of phosphatidylethanolamine and small amounts of phosphatidylcholine and an unknown phospholipid as polar lipids. The major quinone is menaquinone-7. The cellular fatty acids are C_{15:0} (29.0%), summed feature 3 (C_{16:1} ω 7c and/or C_{15:0} 2-OH; 20.2%), C_{16:1} ω 5c (10.8%), C_{17:0} 3-OH (9.2%),

C_{15:0} 3-OH (7.4%), C_{15:0} (6.5%), C_{15:1} G (3.4%), C_{16:0} 3-OH (3.3%), C_{13:0} (2.2%), C_{15:1} ω6c (1.8%), C_{16:0} (1.4%), C_{17:1} ω6c (0.9%), C_{14:0} (0.8%), C_{15:0} (0.6%), and unknown ECL 14.959 (2.7%).

Source: activated sludge of a domestic wastewater treatment plant.

DNA G+C content (mol%): 40.1 mol% (HPLC).

Type strain: EMB13, DSM 17976, KCTC 12614.

Sequence accession no. (16S rRNA gene): DQ372980.

3. *Runella limosa* Ryu, Nguyen, Park, Kim and Jeon 2006, 2759^{VP}

li.mo'sa. L. fem. adj. *limosa* muddy, pertaining to sludge, the natural habitat of the species.

The characteristics are as described for the genus and as listed in Table 102. The following additional features are taken from Ryu et al. (2006). Rods, 0.7–0.9 × 4.0–10.0 μm when grown at 25°C on R2A agar. Colonies are slightly raised, circular and salmon-pink on R2A agar. Optimum temperature, 25–30°C. Optimum pH, 7.5–8.0. Nitrate is not reduced to nitrite. Catalase-positive and oxidase-negative. Tyrosine, Tween 80 and esculin are hydrolyzed but not casein, Tween 20, starch, gelatin, or urea. Acid is produced from D-glucose, D-raffinose, *myo*-inositol, D-lactose, D-mannitol, and melibiose, but not from sorbitol, sucrose, rhamnose, amygdalin, D-fructose, D-galactose, D-mannose, L-arabinose, arbutin, or salicin. Alkaline phosphatase, α-chymotrypsin, *N*-acetyl-β-glucosaminidase, and naphthol-AS-BI-phosphohydrolase activities are present, but not esterase (C4), esterase lipase (C8), lipase (C14), or cystine arylamidase. Weak activity occurs for leucine arylamidase, valine arylamidase, trypsin, β-galactosidase, α-glucosidase, β-glucosidase, acid phosphatase, α-galactosidase, β-glucuronidase, α-mannosidase, and α-fucosidase. A large amount of phosphatidylglycerol is present and small amounts of two unknown phospholipids (PL1, PL2). The major quinone is MK-7. The major fatty acids are C_{15:0}, C_{16:1} ω5c, C_{17:0} 3-OH, C_{15:0} 3-OH, C_{16:0} 3-OH, C_{16:0}, and summed feature 3 (C_{16:1} ω7c and/or C_{15:0} 2-OH).

Source: sludge performing enhanced biological phosphorus removal.

DNA G+C content (mol%): 42.7 (HPLC).

Type strain: EMB111, KCTC 12615, DSM 17973.

Sequence accession no. (16S rRNA gene): DQ372985.

4. *Runella zeae* Chelius, Henn and Triplett 2002, 2062^{VP}

ze'ae. L. n. *zea* a kind of grain, spelt, and also a botanical genus name (*Zea*); L. gen. n. *zeae* of *Zea*, named because the organism was isolated from maize, (*Zea mays*).

The characteristics are as described for the genus and as listed in Table 102. The following additional features are taken from Chelius and Triplett (2000) and Chelius et al. (2002).

Straight to slightly bent rods that form chains of irregular shapes. Colonies are round, smooth, and salmon-colored when grown on R2A medium at 28°C. Temperature range for growth, 15–37°C.

The following reactions are positive: growth on peptone water; growth on Ayer's agar (weak); acid production from (and fermentation of) glucose and sucrose; growth on acetate, *N*-acetylglucosamine, amygdalin, D- and L-arabinose, arbutin, cellobiose, dulcitol (weak), erythritol, esculin, D-fructose, D- and L-fucose, fumarate, galactose, β-gentiobiose, D-glucose, glycogen, inositol (weak), inulin, 5-ketogluconate (weak), lactose, D-lyxose, malate, malonate, maltose, mannose, melezitose, melibiose, methyl-α-D-glucoside, methyl-α-D-mannoside, β-methylxyloside, D-raffinose, rhamnose, salicin, sorbitol (weak), sorbose (weak), sucrose, D-tagatose, tartrate, trehalose, D-turanose, and xylitol as sole carbon sources.

The following reactions are negative: nitrogenase; reduction of nitrate to nitrite; hydrolysis of agar, cellulose, and starch; growth in litmus milk; acid production from ribose; growth in the presence of 1.5% NaCl; growth on D- and L-arabitol, formate, glycerol, mannitol, and methanol as sole carbon sources.

Source: the stems of *Zea mays*.

DNA G+C content (mol%): 49 (renaturation rate).

Type strain: NS12, ATCC BAA-293, LMG 21438.

Sequence accession no. (16S rRNA gene): AF137381.

Genus XVI. *Spirosoma* Migula 1894, 237^{AL}

THE EDITORIAL BOARD

Spi.ro.so'ma. Gr. n. *spira* coil; Gr. neut. n. *soma* body; N.L. neut. n. *Spirosoma* coiled body.

Rigid **straight to curved rods**, the degree of curvature varying among individual cells within a culture. The cells measure 0.5–1.0 μm × 1.5–10.8 μm. **Rings 1.5–3.0 μm in outer diameter are formed by overlapping of the ends of a cell** in some species. **Coils and helices may be present**. Long sinuous filaments up to 50 μm long may be present. Gram-stain-negative. **No swimming motility occurs. Gliding motility is present** (Vancanneyt et al., 2006). Resting stages are not known. **Obligate or facultative aerobes**. Acids are produced aerobically from a variety of carbohydrates. Optimum temperature, 20–30°C. **Colonies contain a pale to light yellow, water-insoluble carotenoid pigment. Catalase-positive** and oxidase-negative or positive depending upon the species. Chemo-organotrophic. Isolated from soil and freshwater sources.

DNA G+C content (mol%): 51–53 (*T_m*).

Type species: Spirosoma linguale (Eisenberg 1891) Migula 1894, 235^{AL}.

Further descriptive information

This chapter is taken largely from the previous treatment by Larkin and Borrall (1984d) in the 1st edition of *Bergey's Manual of Systematic Bacteriology*. It has been updated where more recent information was available.

Spirosoma linguale produces rings, coils, and helices and the morphology is illustrated in Figure 3.1 of Larkin and Borrall (1984d). Although a culture typically shows a ringlike morphology, it exhibits variations of shape and size under certain cultural conditions. Occasionally, cultures are composed mainly of relatively straight cells, especially after prolonged subculturing on MS agar. The curly form may be re-obtained by

examining colonies from agar streaked for isolation (Larkin, unpublished observation). Maloy et al. (1978) showed that there is a relationship between morphology and the phosphate content of the medium. The rings, coils, and helices are produced when the phosphate level is below 20 mM at pH 7.2. At 20–60 mM phosphate, long nonseptate filaments develop and the ratio of diphosphatidyl glycerol to phosphatidyl glycerol is twofold higher in the filaments. Normal cells contain twice the amount of muramic acid in the peptidoglycan layer as do the filaments; furthermore, this layer in normal cells contains equal amounts of *N*-acetylglucosamine and *O*-acetylglucosamine, whereas that of filamentous cells has nearly twice as much *N*-acetylglucosamine as *O*-acetylglucosamine (Miller and Raj, 1978). The filamentous forms appear to be multinucleate (Redell et al., 1981). In contrast, the species *Spirosoma rigui* forms filaments but not rings, coils or helices (Baik et al., 2007b).

Vancanneyt et al. (2006) reported that the type strain of *Spirosoma linguale* exhibits gliding motility. *Spirosoma rigui* also exhibits gliding motility.

Colonies on MS agar* produce a yellow water-insoluble, nonfluorescent pigment, and flexirubin-type pigments are absent (Baik et al., 2007b; Vancanneyt et al., 2006). For *Spirosoma rigui*, the pigment extract had an absorption maximum of 451 nm and shoulder at 478 nm. *Spirosoma linguale* grows poorly or not at all on rich media such as chocolate agar or blood agar, or on enteric-selective media such as eosin methylene blue agar, MacConkey agar, or Salmonella-Shigella agar. Only one of the four available strains grows on Trypticase soy agar. *Spirosoma rigui* was isolated on PYGV medium (Staley, 1968) and R2A (Oxoid) agar. Best growth is obtained with R2A, MS, or PCA media. It also grows in tryptone-soy agar or TSA medium (Oxoid).

Spirosoma is chemo-organotrophic. *Spirosoma linguale* is active in the acidification of carbohydrate media. Acidification occurs with all but one (sorbitol) of the 20 carbohydrates tested using the medium of Hugh and Leifson (1953) and aerobic incubation, although up to 3 weeks is sometimes required. Acidification does not occur with any sugar alcohols. Cellulose and chitin are not hydrolyzed, but some strains hydrolyze esculin and (weakly) casein. All strains hydrolyze tributyrin, and (weakly) starch. Three of the available strains of *Spirosoma linguale* produce a soft curd in litmus milk, accompanied by the reduction and then reoxidation of the litmus. A fourth strain produces only an increased alkalinity in litmus milk. Although *Spirosoma rigui* uses glucose and esculin as sole carbon sources, it does not assimilate many other carbohydrates.

Spirosoma linguale strains may be grown in the defined medium of Gordon and Mihm[†] (1957) with various sole carbon sources. Of 11 substrates that have been tested, only glycerol phosphate, succinate, tartrate, and malonate are utilized as sole carbon sources.

Radiorespirometric studies by Kottel and Raj (1973) revealed that *Spirosoma linguale* ATCC 23276 catabolizes glucose almost entirely (96%) by the Embden–Meyerhof pathway

with a small amount (4%) being catabolized by the pentose phosphate pathway. The Entner–Doudoroff pathway is inducible, with 75% of radio-labeled gluconate being metabolized by that pathway. Gluconate recovery patterns of this strain showed evidence for the possibility of a 2–5-diketogluconate pathway or some other unorthodox pathway (Raj and Ordal, 1977). Radiorespirometric and enzymic data indicate that a functional tricarboxylic acid cycle occurs in this strain (Kottel and Raj, 1973).

Spirosoma has the MK-7 menaquinone system (Baik et al., 2007b; Urakami and Komagata, 1986). The cellular fatty acids of *Spirosoma* include large amounts of straight-chain saturated C_{16:0}, unsaturated C_{16:1}, iso C_{15:0}, and iso C_{17:0} (Urakami and Komagata (1986). Vancanneyt et al. (2006) reported the following fatty acid profile for the type strain of *Spirosoma linguale* (% in parentheses): C_{13:0} iso (3.8), C_{15:0} iso (7.6), C_{15:0} anteiso (trace), C_{15:0} iso 3-OH (4.9), C_{16:0} (7.2), C_{16:1} ω5c (17.5), C_{16:0} 3-OH (4.7), C_{17:0} iso 3-OH (6.5), and summed feature 3 (47.9). Summed feature 3 consisted of one or more fatty acids that could not be separated by the Microbial Identification System): C_{15:0} iso 2-OH, C_{16:1} ω7c and/or C_{16:1} ω7t. The composition of *Spirosoma rigui* was very similar: C_{15:0} iso (9.5), C_{15:0} anteiso (1.3), C_{15:0} iso 3-OH (2.6), C_{16:0} (8.8), C_{16:1} ω5c (18.5), C_{16:0} 3-OH (2.8), C_{17:0} iso 3-OH (3.5), and summed feature 3 (45.6). (Baik et al., 2007b).

Analysis of polyamine profiles of *Spirosoma* indicate that spermidine is the major polyamine (Hamana and Nakagawa, 2001).

Spirosoma is not known to be pathogenic.

Four strains of *Spirosoma linguale* have been isolated and characterized: one from garden soil and three from freshwater. *Spirosoma linguale* has also been found in an activated sludge reactor established for the degradation of cutting fluids (Baker et al., 1983). *Spirosoma rigui* was isolated from fresh water at the Woopo wetland, Republic of Korea. *Spirosoma*-like organisms have been seen in gelatinous deposits on wet planks from a mine (Kraepelin and Passern, 1980). Although *Spirosoma* is considered noncellulolytic, cellulolytic “*Spirosoma*-like” bacteria have been isolated from the gut of the termite *Zootermopsis angusticollis* (Wenzel et al., 2002).

Isolation procedures

Spirosoma may be isolated by repeated streaking of water or diluted soil samples onto MS agar or tryptone glucose extract agar (Difco) fortified with 0.1 % yeast extract (TGEY medium; Raj, 1970) with incubation at room temperature for up to 2 weeks. The yellow pigmentation of the colonies aids detection of *Spirosoma*.

Maintenance procedures

Spirosoma linguale is grown on MS agar, TGEY or nutrient agar at room temperature until abundant growth occurs (usually 1–4 d). Cultures may then be stored at 4°C for at least 4 weeks. Preservation by lyophilization is effective for several years.

Differentiation of the genus *Spirosoma* from other genera

Table 93 in the chapter on *Flectobacillus* provides the primary characteristics that can be used to differentiate this genus from several morphologically similar genera.

*MS agar (g/l): peptone, 1.0; yeast extract, 1.0; glucose, 1.0; agar, 15.0.

[†]Gordon and Mihm’s medium (g/l): MgSO₄, 0.2; (NH₄)₂HPO₄, 1.0; KH₂PO₄, 0.5; NaCl, 1.0; carbon source, 2.0; agar, 15.0; and bromthymol blue, 0.08.

Taxonomic comments

In the 8th edition of the *Manual* the genus *Microcyclo* consisted of three species which were placed together primarily because of their ability to form rings during growth. The DNA G+C values were quite different, being 39.5 mol% for “*Microcyclo major*”, 51 mol% for “*Microcyclo flavus*”, and 67 mol% for *Microcyclo aquaticus* (the type species). Claus (1967) and Claus et al. (1968) suggested that “*Microcyclo flavus*” and two additional isolates corresponded to the description of the forgotten genus *Spirosoma*. Moreover, Staley (1974) suggested that the grouping of the three species was unsatisfactory, as did Konopka et al. (1976), who found only a 0–14% binding of the DNA from three *Spirosoma* strains to that of *Microcyclo aquaticus*. Larkin et al. (1977) proposed the reintroduction of the genus *Spirosoma* and emended its description to include “*Microcyclo flavus*” and three other isolates.

The formation of rings or coils is not a sufficiently restrictive character to delineate a single taxonomic group. Ring formation is a characteristic that occurs in several other aerobic, chemoorganotrophic bacteria, e.g., *Flectobacillus*, *Runella*, *Cyclobacterium*, *Ancylobacter*, *Polaribacter*, and *Arcicella*. However, analyses of the 16S rRNA gene sequences of these organisms support the classification of *Spirosoma* as a distinct

genus (Nikitin et al., 2004; Woese et al., 1990). Moreover, as the description of *Spirosoma rigui* proves, rings and coils are not properties of all members of this genus. This observation serves to further illustrate the unreliability of this characteristic in taxonomic assignments.

Vancanneyt et al. (2006) reported that, by 16S rRNA analyses, *Spirosoma linguale* was the nearest neighbor of *Larkinella insperata*, sharing a similarity of 88.8%.

The literature concerning the utilization of sole carbon sources by *Spirosoma linguale* is conflicting. Raj (1970) reported an inability of the species to use malonate, succinate, or tartrate, in contrast to results obtained by Larkin et al. (1977). The discrepancy may be attributable to a difference in the media employed or to the method of detecting growth. Raj (1970) used Simmons citrate agar with various organic substrates substituted for citrate and with 0.2% yeast extract added; growth responses were indicated by a color change. Larkin et al. (1977) used the agar medium of Gordon and Mihm (1957) and estimated visible growth after four successive transfers even in the absence of a color change.

The literature concerning gelatin hydrolysis also is conflicting. Larkin and Borrall (1984d) indicated that all strains hydrolyze gelatin, but Vancanneyt et al. (2006) reported that the type strain did not hydrolyze gelatin.

List of species of the genus *Spirosoma*

1. ***Spirosoma linguale*** (Eisenberg 1891) Migula 1894, 235^{AL} (*Vibrio lingualis* Eisenberg 1891, 212; *Microcyclo flavus* Raj 1970, 62

lin.gua'le. L. n. *lingua* the tongue; L. neut. suff. *-ale* suffix denoting pertaining to; N.L. neut. adj. *linguale* of the tongue.

The characteristics are as described for the genus, with the following additional features. Morphological features are depicted in Figure 3.1 of Larkin and Borrall (1984d). Other features are as described for the genus, with the following additional characteristics. Colonies are circular and convex with an entire margin. Aerobic. Temperature range for growth of the type strain, 5–39°C (Vancanneyt et al., 2006). NaCl range for growth of the type strain, 0–1.25% (Vancanneyt et al., 2006). Starch is weakly hydrolyzed. Tweens 20, 40, and 80 are hydrolyzed by the type strain (Vancanneyt et al., 2006). Some strains hydrolyze esculin and (weakly) casein. The type strain produces β -galactosidase and alkaline phosphatase (Vancanneyt et al., 2006). The following tests are positive: acid production from arabinose, α -methyl-D-glucoside, cellobiose, dextrin, fructose, galactose, glucose, inulin, lactose, maltose, mannose, melibiose, raffinose, rhamnose, ribose, salicin, sucrose, trehalose, and xylose; utilization of glycerol phosphate, malonate, succinate, and tartrate as sole carbon sources. The type strain is reported to utilize mannose and sucrose (Vancanneyt et al., 2006). The following tests are negative: urease; lysine decarboxylase; phenylalanine deaminase; hemolysin production; indole formation;

methyl red test; Voges–Proskauer test; nitrate reduction; H₂S production from peptone; acid production from sorbose, dulcitol, erythritol, glycerol, mannitol, and sorbitol; utilization of acetate, benzoate, citrate, formate, methanol, methylamine, and propionate. L-arabinose, D-glucose, and D-lactose are not utilized by the type strain (Vancanneyt et al., 2006). Found in soil and fresh water.

DNA G+C content (mol%): 51–53 (T_m).

Type strain: DSM 74, ATCC 33905, LMG 10896.

Sequence accession no. (16S rRNA gene): AM000023.

2. ***Spirosoma rigui*** Baik, Kim, Park, Lee, Lee, Ka, Choi and Seong 2007b, 2872^{VP}

ri'gu.i. L. gen. n. *rigui* of a well-watered place, referring to the site of isolation, the Woopo wetland, Korea

The characteristics are as described for the genus, with the following additional features. Cells are rod shaped and do not form rings or coils. Colonies are circular, opaque, convex, smooth, wet and slimy. Facultatively anaerobic. Temperature range for growth, 4–37°C. NaCl range for growth, 0–1%. Uses aesculin and glucose as sole carbon and energy sources. Produces β -galactosidase but not alkaline phosphatase. Does not use the sugars cellobiose, fructose, galactose, lactose, maltose, mannose, melibiose, raffinose, rhamnose, starch, sucrose, and xylose. Does not produce H₂S or acetoin. Isolated from fresh water.

DNA G+C content (mol%): 53.3 (T_m).

Type strain: WPCB118, KCTC 12531, NBRC 101117.

Sequence accession no. (16S rRNA gene): EF507900.

Genus XVII. *Sporocytophaga* Stanier 1940, 629^{AL}

EDWARD R. LEADBETTER

Spo.ro.cy.toph'a.ga. Gr. n. *spora* a seed, and in biology a spore; N.L. fem. n. *Cytophaga* genus name of a bacterium; N.L. fem. n. *Sporocytophaga* sporing *Cytophaga*.

Flexible rods with rounded ends, 0.3–0.5 × 5–8 μm, occurring singly. Sphaeroplasts and distorted cells occur in older cultures. A resting stage, the microcyst, is formed. Motile by gliding. Stains Gram-negative. Chemo-organotrophs. **Strict aerobic**. Metabolism is respiratory, with molecular oxygen used as terminal electron acceptor. **Cellobiose, cellulose, glucose** and, for some strains, **mannose are the only known sources of carbon and energy**. Agar and chitin are not known to be metabolized. Either ammonium or nitrate ions, or peptone, urea or yeast extract, can serve as sole nitrogen source. Amino acids, peptones, yeast extract or nutrient agar (Difco) cannot serve as sole carbon and energy sources. No organic growth factor requirements are known. **Catalase-positive**. Temperature optimum: ~30°C.

DNA G+C content (mol%): 36 (Bd).

Type species: *Sporocytophaga myxococcoides* (Krzemieniowska 1933) Stanier 1940, 629^{AL}.

Further descriptive information

Only one species of the genus has been extensively examined. *Sporocytophaga myxococcoides* was shown by Stanier (1942) to grow on glucose sterilized by filtration and by Kaars Sijpesteijn and Fåhræus (1949) to grow on glucose autoclaved separately from other components of the medium, thus refuting the assertion that growth of the organism is obligately linked to cellulose utilization. Further studies indicate that the organism, when isolated from nature, is unable either to oxidize or to utilize glucose but putative mutants able to use glucose arise in the

population (Leadbetter, unpublished observations). These “mutants” are able to metabolize immediately either cellulose or glucose, irrespective of the substrate in which they are grown. These observations thus confirm and extend those of Kaars Sijpesteijn and Fåhræus (1949).

Recent studies of *Sporocytophaga myxococcoides* have demonstrated that the organism is able to form microcysts when either glucose or cellulose is the carbon and energy source (Gallin and Leadbetter, 1966; Leadbetter, 1963).

During growth on glucose, the Embden–Meyerhof–Parnas pathway is used (Hanstveit and Goksøyr, 1974). Cells also produce a variety of cellulases, some of which have been partially purified (Osmundsvåg and Goksøyr, 1975; Vance et al., 1980).

Major cellular lipids are sulfonolipids (Godchaux and Leadbetter, 1983) which contain a variety of fatty acyl moieties (Godchaux and Leadbetter, 1984). The sulfonolipids predominate in the outer membrane, while phospholipids are present in the inner cell membrane. Phosphatidylethanolamine and lysophosphatidylethanolamine are the major phospholipids (Holt et al., 1979). Homospermidine is the most abundant polyamine, but small amounts of putrescine and spermidine are also present (Hamana and Nakagawa, 2001). The cell-wall peptidoglycan contains diaminopimelic acid (Verma and Martin, 1967). Moreover, cells produce a slime comprised of glucose, mannose, arabinose, xylose, galactose and glucuronic acid (Martin et al., 1968).

The *Bacteroides* transposon Tn4351 can be introduced by conjugation from *Escherichia coli* into *Sporocytophaga* and could serve as the basis for a genetic system (McBride and Baker, 1996).

List of species of the genus *Sporocytophaga*1. *Sporocytophaga myxococcoides* (Krzemieniowska 1933) Stanier 1940, 630^{AL} (*Cytophaga myxococcoides* Krzemieniowska 1933, 400)

myx.o.coc.coi'des. N.L. masc. n. *Myxococcus* genus name of a bacterium; L. suff. *-oides* (from Gr. suff. *eidos* from Gr. n. *eidos* that which is seen, form, shape, figure), resembling, similar; N.L. fem. adj. *myxococcoides* resembling *Myxococcus*.

Single, often flexible rods with rounded ends, 0.3–0.5 × 5–8 μm. Sphaeroplasts and abnormally long forms may occur in old cultures. The resting stage, the microcyst, is spherical and about 1.5 μm in diameter. Both the growing (vegetative) rod and the microcyst have noticeably smaller dimensions when cultures are grown on cellulose rather than on glucose. Microcysts are notably more resistant to ultrasonic disruption than are vegetative cells.

Electron microscopic studies indicate that the vegetative cell has a fine structure typical of Gram-stain-negative bacteria, while the microcyst has a thick, fibrillar capsule exterior to a highly convoluted cell wall (Holt and Leadbetter, 1967).

Growth on cellulose (filter paper)–salts agar (or silica gel) or glucose–salts agar is gummy, and liquid cultures become viscous as a result of extracellular slime production. Cell masses are yellow, reflecting the presence of carotenoid and flexirubin-type pigments. Filter paper on the agar or silica gel surface is eventually dissolved around colonies so that translucent areas result. Colonies on glucose–salts agar medium are raised.

Other characteristics are the same as those of the genus.

Other species

Other species of *Sporocytophaga* have been described, but they are incompletely characterized:

- (a) “*Sporocytophaga cauliformis*” Knorr and Gräf in Gräf 1962, 124.
 (b) “*Sporocytophaga congregata*” subsp. *maroonicum* Akashi 1960, 899.
 (c) “*Sporocytophaga ellipsospora*” (Imshenetski and Solntseva, 1936) Stanier 1942, 190.
 (d) “*Sporocytophaga ochracea*” Ueda, Ishikawa, Itami and Asai 1952, 545.

Family II. *Cyclobacteriaceae* fam. nov.

OLGA I. NEDASHKOVSKAYA AND WOLFGANG LUDWIG

Cyc.lo.bac.te.ri.a'ce.ae. N.L. neut. n. *Cyclobacterium* type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. *Cyclobacteriaceae* the *Cyclobacterium* family.

Regular and curved, ring-like or horseshoe-shaped rods that are $0.3\text{--}0.7 \times 0.3\text{--}10 \mu\text{m}$. Gram-stain-negative. Nonsporeforming. Nonflagellated and nonmotile in liquid media, but some of them can move by gliding on solid substrates.

Aerobic, with respiratory type of metabolism. Optimal temperature is $16\text{--}37^\circ\text{C}$. Chemo-organotrophs. Carbohydrates are oxidized. One species ferments glucose. Colonies are pink, red, or orange in color. For most strains, an addition of seawater or NaCl to nutrient media sufficiently increases growth rates. Oxidase-, catalase-, and alkaline phosphatase-positive. Flexirubin-type pigments are absent. Produce no indole. One taxon

produces hydrogen sulfide. Nitrate may be reduced to nitrite. Most species cannot hydrolyze agar, casein, urea, or chitin.

Menaquinone 7 is a major or single respiratory quinone. Predominant fatty acids are $\text{C}_{15:0}$ iso, $\text{C}_{17:1}$ iso $\omega 9c$ and $\text{C}_{15:0}$ iso 2-OH and/or $\text{C}_{16:1}$ $\omega 7c$. Most species occur in seawater, marine sediments, seaweeds, or marine animals. Some taxa inhabit algal mates of saline lakes, marine solar salterns, soil, or nonsaline groundwater.

DNA G+C content (mol%): 35–49.

Type genus: *Cyclobacterium* Raj and Maloy 1990, 345^{VP} emend. Ying, Wang, Yang and Liu 2006, 2929.

Genus I. *Cyclobacterium* Raj and Maloy 1990, 345^{VP} emend. Ying, Wang, Yang and Liu 2006, 2929

THE EDITORIAL BOARD

Cy.clo.bac.ter'i.um. Gr. n. *cyclos* a circle L. neut. n. *bacterium* a small rod; N.L. neut. n. *Cyclobacterium* a circle-shaped bacterium.

Cells are curved, ring-like or horseshoe-shaped. Nonmotile. Colonies on Marine agar (MA) are pink and shiny. Aerobic, having a strictly respiratory type of metabolism with O₂ as the terminal electron acceptor. Neutrophilic and mesophilic. Chemo-organotrophic. Optimal growth temperature range is $25\text{--}30^\circ\text{C}$. Catalase- and oxidase-positive. The major cellular fatty acids are $\text{C}_{15:0}$ iso, summed feature 3 ($\text{C}_{15:0}$ iso 2-OH and/or $\text{C}_{16:1}$ $\omega 7c$), $\text{C}_{17:1}$ iso $\omega 9c$, $\text{C}_{17:0}$ iso 3-OH, and $\text{C}_{15:0}$ anteiso.

Habitat: marine environments.

DNA G+C content (mol%): 41–45.

Type species: *Cyclobacterium marinum* corrig. (Raj 1976) Raj and Maloy 1990, 346^{VP} [*Flectobacillus marinus* (Raj 1976) Borrall and Larkin 1978, 301^{AL}; *Microcycylus marinus* Raj 1976, 540].

Further descriptive information

The predominant cellular fatty acids of the type strains of *Cyclobacterium amurskyense* and *Cyclobacterium marinum* are straight-chain unsaturated, branched-chain unsaturated and saturated, namely $\text{C}_{15:0}$ iso (22.2 and 23%, respectively), $\text{C}_{15:0}$

anteiso (9.2 and 6.4%), $\text{C}_{15:1}$ iso (8.4 and 9.7%), $\text{C}_{17:1}$ iso $\omega 9c$ (4.3 and 6.3%), $\text{C}_{17:0}$ iso 3-OH (10.7 and 12.7%), and summed feature 3 (24.3 and 23.4%), comprising $\text{C}_{16:1}$ $\omega 7c$ and/or $\text{C}_{15:0}$ iso 2-OH (Nedashkovskaya et al., 2005).

The major cellular fatty acids of *Cyclobacterium lianum* are $\text{C}_{15:0}$ iso (28.3%), summed feature 3 ($\text{C}_{15:0}$ iso 2-OH and/or $\text{C}_{16:1}$ $\omega 7c$; 16.6%), $\text{C}_{17:1}$ iso $\omega 9c$ (10.3%), $\text{C}_{17:0}$ iso 3-OH (8.0%), and $\text{C}_{15:0}$ anteiso (6.4%), similar to the profiles reported for *Cyclobacterium marinum* and *Cyclobacterium amurskyense* (Ying et al., 2006).

The cellular polyamines of *Cyclobacterium marinum* contain homospermidine, whereas those of other ring-forming genera (*Runella*, *Spirosoma*, and *Flectobacillus*) contain spermidine (Hamana and Nakagawa, 2001).

The oxidation of glucose in *Cyclobacterium marinum* occurs mainly via glycolysis, whereas gluconate is catabolized mainly via the Entner–Doudoroff pathway. These pathways act in conjunction with the tricarboxylic acid cycle and with some participation of the pentose phosphate pathway (Raj and Pavoglio, 1983).

Enrichment and isolation procedures

Cyclobacterium marinum can be isolated on MS agar* or on mZ medium.† Incubation is at room temperature (25°C) for several days to allow abundant growth. The cultures will then survive refrigeration at 4°C for at least 3 weeks. They may also be preserved indefinitely by lyophilization.

Cyclobacterium amurskyense was isolated from a seawater sample collected in Amursky Bay, Gulf of Peter the Great. It can be cultured on Marine agar 2216 (Difco).

Cyclobacterium lianum was isolated from sediment of the Xijiang oilfield in the South China Sea, near Fujian Province, China. For isolation, serially diluted sediment samples were spread onto low-organic marine agar 2216 plates (differs from regular Marine agar 2216 [Difco] only by decreasing the peptone concentration from 5 to 0.5 g/l and the yeast extract from 1 to 0.1 g/l). A colony was selected after incubation at 30°C for 10 d and subcultured onto Marine agar 2216.

Differentiation of the genus *Cyclobacterium* from other genera

The genera *Runella*, *Flectobacillus*, and *Spirosoma* have a ring-like or horseshoe-like morphology that resembles that of *Cyclobacterium*. However, *Cyclobacterium* has a marine habitat and can tolerate seawater (although not necessarily requiring NaCl), whereas the other three genera have a freshwater habitat and cannot grow in the presence of seawater or 3% NaCl. Moreover, the cellular polyamines of *Cyclobacterium marinum* contain homospermidine, whereas those of *Runella*, *Spirosoma*, and *Flectobacillus* contain spermidine (Hamana and Nakagawa, 2001).

Taxonomic comments

Cyclobacterium marinum was initially classified in the *Microcycclus* by Raj (1976) as *Microcycclus marinus*. In many features, it resembled *Flectobacillus major*, the type species of the genus *Flectobacillus* Larkin, Williams and Taylor (1977), and it was assigned to that genus as *Flectobacillus marinus* by Borrall and Larkin (1978). H. D. Raj (1979) reported that *Flectobacillus*

major and *Flectobacillus marinus* were sufficiently distinct as to warrant separation of *Flectobacillus marinus* into a new genus; the name *Cyclobacterium* was suggested (H. D. Raj, cited by Larkin and Borrall, 1984a). However, Larkin and Borrall (1984a, b) believed that it would be best to retain the organism in the genus *Flectobacillus* because of the similarity in the mol% G+C content of the DNA and because the DNA–DNA hybridization value between the type strains of *Flectobacillus marinus* and *Flectobacillus major* was 71%, using the renaturation rate method of DeLey et al. (1970); consequently, Larkin and Borrall recommended that *Flectobacillus marinus* should not be used to create the new genus *Cyclobacterium* and that the latter name should be discarded. However, Raj and Maloy (1990) noted that analysis of the oligonucleotide sequence catalogues of the 16S rRNA of these organisms (Woese et al., 1990) indicated a relatively large evolutionary distance (ca. 20%) between *Flectobacillus major* and *Flectobacillus marinus* (Woese, 1987), supporting the idea that *Flectobacillus marinus* should be separated from *Flectobacillus major* at the genus level. Consequently, Raj and Maloy (1990) reclassified *Flectobacillus marinus* as *Cyclobacterium marinus* (later corrected to *marinum* by Euzéby) (1998).

Nedashkovskaya et al. (2005) reported that the level of 16S rRNA gene sequence similarity between the type strain of *Cyclobacterium amurskyense* and that of *Cyclobacterium marinum* was 96.6% (47 nucleotide differences).

Ying et al. (2006) reported that the nearest neighbors of *Cyclobacterium lianum*, based on 16S rRNA gene sequence analysis, were *Cyclobacterium marinum* (93.8% sequence similarity) and *Cyclobacterium amurskyense* (92.8% similarity). Other related genera were *Aquiflexum* (89.7%), *Belliella* (89.7%), *Hongiella* (87.8–90.3%), *Chimaericella* (88.4%), and *Algoriphagus* (88.3–89.5%). *Hongiella* and *Chimaericella* have since been reclassified into *Algoriphagus* by Nedashkovskaya et al. (2007b).

Differentiation of the species of the genus *Cyclobacterium*

Table 103 lists reactions differentiating the three species of *Cyclobacterium*.

List of species of the genus *Cyclobacterium*

1. ***Cyclobacterium marinum*** corrig. (Raj 1976) Raj and Maloy 1990, 346^{VP} [*Flectobacillus marinus* (Raj 1976) Borrall and Larkin 1978, 341^{AL}; *Microcycclus marinus* Raj 1976, 540]

ma.ri'num. L. neut. adj. *marinum* of the sea, marine. The original spelling *marinus* was corrected by Euzéby (1998).

The characteristics are as described for the genus, with the following additional information. In contrast to the original description, NaCl is not required for growth, and growth can occur at 42°C (Nedashkovskaya et al., 2005).

The following reactions are positive (these results also apply to *Cyclobacterium amurskyense* below; Nedashkovskaya et al., 2005): β-galactosidase, alkaline and acid phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, naphthol-AS-BI-phos-

phohydrolase, α- and β-galactosidase, α- and β-glucosidase, N-acetyl-β-glucosaminidase, and α-mannosidase activities; growth at 0–10% NaCl and at 4–40°C; hydrolysis of esculin; acid formation from D-cellobiose, L-fucose, D-galactose, D-lactose, L-raffinose, D-melibiose, L-rhamnose, D-trehalose, D-maltose, and D-sucrose; susceptibility to ampicillin, carbenicillin, lincomycin and oleandomycin; and utilization of glucose, D-mannose, N-acetyl-D-glucosamine, D-fructose, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, arbutin, salicin, inulin, melezitose, gentiobiose, D-turanose, lyxose, tagatose, D-fucose, L-fucose, ribose, sorbose, D-xylose, and methyl β-D-xyloside.

The following reactions are negative (these results also apply to *Cyclobacterium amurskyense* below; Nedashkovskaya et al., 2005): α-chymotrypsin, β-glucuronidase, α-fucosidase, arginine dihydrolase, lysine and ornithine decarboxylase activities; gliding motility; Na⁺ requirement for growth; requirement for organic growth factors; nitrate reduction; flexirubin pigments; H₂S, indole, and acetoin production; degradation of agar, casein, gelatin, DNA, starch, cellulose

*MS agar for marine organisms contains (g/l): peptone, 1.0; yeast extract, 1.0; glucose, 1.0; NaCl, 30.0; agar, 15.0.

†Modified Zobell 2216 (mZ) medium contains (g/l of seawater): peptone, 5.0; yeast extract, 1.0; ferrous sulfate, 0.2; agar, 20.0 (Raj, 1976).

TABLE 103. Characteristics differentiating the species of the genus *Cyclobacterium*^{a,b}

(CM-cellulose, filter paper), chitin, urea, and Tweens 20 and 80; acid production from D-glucose, L-sorbose, adonitol, dulcitol, glycerol, *myo*-inositol, mannitol, malate, fumarate, and citrate; utilization of glycerol, iso-erythritol, adonitol, dulcitol, *myo*-inositol, D-sorbitol, glycogen, xylitol, D-arabitol, L-arabitol, gentiobiose, 2-ketogluconate, 5-ketogluconate, caprate, adipate, malate, citrate, and phenylacetate; and susceptibility to gentamicin, neomycin, and polymyxin B.

DNA G+C content (mol%): 41.9 (T_m) (Nedashkovskaya et al., 2005).

Type strain: Raj, ATCC 25205, DSM 745, LMG 13164.

Sequence accession no. (16S rRNA gene): AJ575266, AY533665.

2. **Cyclobacterium amurskyense** Nedashkovskaya, Kim, Lee, Park, Lee, Lysenko, Oh, Mikhailov and Bae 2005, 2392^{VP}
a.mur.sky.en'se. N.L. neut. adj. *amurskyense* pertaining to Amursky Bay, from which the type strain was isolated.

Cells have a width of 0.3–0.4 µm and an outer diameter of 0.9–1.2 µm. Colonies are pink, circular, low-convex, shiny with entire edges, and 1–3 mm in diameter on Marine agar 2216. Flexirubin pigments are absent. Grows in 0–10% NaCl. Growth occurs at 4–40°C. Esculin is hydrolyzed but not agar, casein, gelatin, starch, cellulose (CM-cellulose and filter paper), chitin, DNA, urea, or Tweens 20, 40, and 80. Nitrate is not reduced. H₂S, indole and acetoin (Voges–Proskauer reaction) are not produced. Positive for β-galactosidase and alkaline phosphatase. Acid is produced from the following compounds: N-acetylglucosamine, L-arabinose, D-cellobiose, L-fucose, D-galactose, D-lactose, D-maltose, D-melibiose, L-raffinose, L-rhamnose, D-sucrose, starch, D-trehalose, and DL-xylose. No acid is formed from adonitol, citrate, dulcitol, fumarate, D-glucose, D-galacturonic acid, glycerol, inositol, mannitol, malate, and L-sorbose. The following compounds are utilized (Biolog GN2 Microplate system): N-acetyl-D-glucosamine, cellobiose, dextrin, D-fructose, D-galactose,

D-galacturonic acid, gentiobiose, α-D-glucose, glucose 1-phosphate, α-DL-glycerol phosphate, α-D-lactose, lactulose, maltose, D-mannose, D-melibiose, methyl β-D-glucoside, methylpyruvate, psicose, D-raffinose, L-rhamnose, sucrose, D-trehalose, and turanose.

The following compounds are oxidized: acetic acid, N-acetyl-D-galactosamine, L-arabinose, glucuronamide, L-glutamic acid, glycogen, L-fucose, glycerol, α-ketobutyric acid, α-ketoglutaric acid, DL-lactic acid, D-mannitol, monomethyl succinate, L-serine, and L-threonine. No oxidation occurs of *cis*-aconitic acid, adonitol, alaninamide, D-alanine, L-alanine, L-alanyl glycine, γ-aminobutyric acid, 2-aminoethanol, D-arabitol, L-asparagine, L-aspartic acid, bromosuccinic acid, 2,3-butanediol, DL-carnitine, citric acid, α-cyclodextrin, iso-erythritol, formic acid, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, glucose 6-phosphate, glycy-L-aspartic acid, glycy-L-glutamic acid, L-histidine, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, hydroxy-L-proline, *p*-hydroxyphenylacetic acid, inosine, *myo*-inositol, itaconic acid, α-ketovaleric acid, L-leucine, malonic acid, L-ornithine, L-phenylalanine, phenylethylamine, propionic acid, L-proline, putrescine, L-pyroglytamic acid, quinic acid, D-saccharic acid, sebacic acid, D-serine, D-sorbitol, succinamic acid, succinic acid, thymidine, Tweens 40 and 80, uridine, uronic acid, and xylitol.

Susceptible to ampicillin, benzylpenicillin, carbenicillin, kanamycin, oleandomycin, and lincomycin. Resistant to neomycin, streptomycin, gentamicin, polymyxin B, and tetracycline.

Source: seawater, collected in Amursky Bay, Gulf of Peter the Great, East Sea (also known as the Sea of Japan).

DNA G+C content (mol%): 41.3 (T_m).

Type strain: KMM 6143, KCTC 12363, LMG 23026.

Sequence accession no. (16S rRNA gene): AY960985.

3. **Cyclobacterium lianum** Ying, Wang, Yang and Liu 2006, 2929^{VP}

li.a'num. N.L. neut. adj. *lianum* pertaining to Li, named in honor of Ji-Lun Li, who devoted himself to microbiological research and education in China.

The characteristics are as described for the genus, with the following additional features. Cells are 0.4–0.5 µm wide and the outer diameter of the rings is 1.5–1.8 µm. Colonies grown for 3 d on Marine agar are circular, 2–3 mm in diameter, light rose in color, and shiny. Growth occurs at 15–42°C; optimum, 33°C. The pH range is 6.5–9.0; optimum, 7.5–8.0. Growth occurs in 0.1–12% NaCl; optimum, 1–4%. Arginine dihydrolase, urease, and lecithinase negative. Indole and H₂S are not produced. Nitrate is not reduced. Esculin and Tween 20 are hydrolyzed, but Tweens 40 and 80 are only weakly hydrolyzed. No hydrolysis occurs of agar, casein, gelatin, starch, DNA, and carboxymethyl-cellulose. The following compounds are used as sole carbon sources: L-arabinose, cellobiose, galactose, gluconate, glucose, inulin, lactose, maltose, melezitose, D-melibiose, methyl α-D-glucoside, D-raffinose, L-rhamnose, ribose, sucrose, and trehalose. Weak utilization occurs of D-fructose, L-glutamic acid, glycerol, lactate, malate, mannitol, D-mannose, pyruvate, succinate, and D-xylose. The following are not used: adonitol, L-alanine, butyric acid, caprate, citrate, dulcitol,

formate, L-fucose, *myo*-inositol, L-lysine, malonate, and L-sorbose. Acid is formed from L-arabinose, cellobiose, galactose, glucose, glycerol (weakly), inulin, lactose, maltose, melezitose, D-melibiose, methyl α -D-glucoside, D-raffinose, L-rhamnose, ribose (weakly), sucrose, trehalose, and D-xylose. The following show strong activity (API ZYM system): alkaline and acid phosphatases, leucine and valine arylamidases, naphthol-AS-BI-phosphohydrolase, β -galactosidase, α - and β -glucosidases and *N*-acetyl- β -glucosaminidase. Weak activity is exhibited for esterases C4 and C8, cystine arylamidase, α -galactosidase, and α -mannosidase. No activity is exhibited for trypsin, α -chymotrypsin, β -glucuronidase, α -fucosidase, or lipase (C14). The following compounds are oxidized (GN2 MicroPlate system): *N*-acetyl-D-glucosamine, L-alaninamide, L-alanine, L-arabinose, 2,3-butanediol, glycerol, DL-carnitine, D-cellobiose, dextrin, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, α -D-glucose, glucose 1-phosphate, glucuronamide, DL- α -glycerol phosphate, DL-lactic acid, α -D-lactose, lactulose, maltose, D-mannose, D-melibiose, methyl β -D-glucoside, D-raffinose,

sucrose, D-trehalose, and turanose. Weak or variable oxidation occurs with glycogen, *N*-acetyl-D-galactosamine, L-alanyl glycine, γ -aminobutyric acid, 2-aminoethanol, L-asparagine, L-aspartic acid, iso-erythritol, D-gluconic acid, glucose 6-phosphate, glutamic acid, α -ketovaleric acid, D-mannitol, monomethyl succinate, L-ornithine, L-proline, D-psi-cose, L-pyroglytamic acid, L-rhamnose, DL-serine, D-sorbitol, succinic acid, L-threonine, and uridine. Sensitivity is exhibited toward the following antibiotics (μ g per disk): ampicillin (10), carbenicillin (100), vancomycin (30), ciprofloxacin (5), rifampicin (5), norfloxacin (10), chloramphenicol (30), benzyl penicillin (10), kanamycin (30), and erythromycin (15). Resistance is exhibited toward the following antibiotics (μ g per disk): gentamicin (10), neomycin (30), polymyxin B (300), streptomycin (10), and tetracycline (30).

Rods usually measuring 0.3–0.7 \times 0.3–10.0 μ m. **Gliding motility is not observed.** Produce non-diffusible carotenoid pigments. No flexirubin type of pigments are formed. **Chemo-organotrophs. Aerobic.** Oxidase, catalase, alkaline phosphatase, and β -galactosidase-positive. Arginine dihydro-lase and tryptophan deaminase are not produced. **Esculin is hydrolyzed.** Cellulose (CM-cellulose and filter paper) and urea are not degraded, but agar, casein, gelatin, starch, DNA, Tweens, and chitin may be decomposed. Carbohydrates are utilized. Can grow without seawater or sodium ions. Hydrogen sulfide and indole are not produced. **The major respiratory quinone is MK-7.**

DNA G+C content (mol%): 35.0–49.0.

Type species: **Algoriphagus ratkowskyi** Bowman, Nichols and Gibson 2003, 1351^{VP}.

Further descriptive information

The main cellular fatty acids are unsaturated and branched-chain unsaturated fatty acids C_{15:0} iso, C_{17:0} iso 3-OH, and summed feature 3 comprising C_{15:0} iso 2-OH, and C_{16:1} ω 7c or both (Table 104).

On Marine agar (Difco) strains of the genus *Algoriphagus* form regular, circular, convex, shiny, smooth, with entire edges, and pink or orange colonies with diameter of 0.5–3 mm after cultivation for 48 h.

All strains grow at 6–41 °C, grow with 0–12% NaCl, and do not form acid from inositol or mannitol. Strains were isolated from sea animals and from seawater samples collected in temperate and tropic latitudes.

Enrichment and isolation procedures

Three strains of the type species *Algoriphagus ratkowskyi* were isolated from the sea-ice algal assemblages on Marine agar 2216, and one strain was recovered from cyanobacterial mat collected in a meromictic lake in Antarctica (Bowman et al., 2003) using a seawater nutrient medium (SWN), containing of 0.05 g of yeast extract, 0.05 g of tryptone, 0.05 g of bacteriological peptone, 0.05g of soluble starch, and 0.02 g of sodium pyruvate dissolved in 1000 ml of natural seawater or artificial seawater (ASW), and supplemented with 0.1 ml of a sterile vitamin solution (Bowman et al., 2003). Six strains of another species, *Algoriphagus antarcticus*, were isolated from microbial mats and cultivated on Marine agar 2216 (Van Trappen et al., 2002, 2004). Strains of *Algoriphagus chordae* and *Algoriphagus winogradskyi* were isolated from the brown alga *Chorda filum* and the green alga *Acrosiphonia sonderi*, respectively, by the standard dilution-plating technique on Marine agar 2216 (Nedashkovskaya et al., 2004). Members of the two species, *Algoriphagus mannitolivorans* and *Algoriphagus ornithinivorans*, were isolated from tidal flat sediments samples using Marine agar 2216, and one strain of *Algoriphagus halophilus* was obtained on medium R2A (Difco) supplemented with artificial sea salts (Sigma) (Yi and Chun, 2004). The representatives of *Algoriphagus aquimarinus*, *Algoriphagus localis*, *Algoriphagus marincola*, and *Algoriphagus yeomjeoni* were isolated from samples of seawater and cultivated on Marine agar 2216 (Nedashkovskaya et al., 2004, 2005a, b; Yoon et al., 2004). Strain *Algoriphagus vanfongensis* KMM 6241^T was isolated from 0.1 ml of tissue homogenates of the coral *Palythoa* sp. by direct plating on a medium containing [in g/l of a mixture of 30% (v/v)

^aData are taken from Ahmed et al. (2007), Nedashkovskaya et al. (2004, 2007b), Schmidt et al. (2006), Tiago et al. (2006a), Yoon et al. (2005a, b, 2006).

^bAmount of the predominant fatty acids is shown in bold font. Values of less than 1% for all strains are not shown.

^cSummed feature 3 consisted of one or more of the following fatty acids which could not be separated by the Microbial Identification System: C_{15:0} iso 2-OH, C_{16:1} ω7c, and C_{16:1} ω7t.

^dSummed feature 4 consisted of one of the following fatty acids: C_{17:1} iso I and C_{17:1} anteiso B.

natural seawater and 70% (v/v) distilled water]: Bacto peptone (Difco), 5.0; sucrose, 5.0; glucose, 1.0; yeast extract (Difco), 2.5; KH₂PO₄, 0.1; MgSO₄, 0.1 g; and Bacto agar (Difco), 15.0 (Nedashkovskaya et al., 2007a). Several members of the genus *Algoriphagus* have a terrestrial origin. Thus, strain *Algoriphagus alkaliphilus* AC-74^T was recovered from sample of the alkaline artesian water and cultivated on a modified R2A medium without NaCl (Tiago et al., 2004, 2006a). *Algoriphagus terrigena* was isolated from soil sample using the dilution-plating on 10× diluted nutrient agar (Difco) with distilled water (Yoon et al., 2006). For isolation of a single strain of *Algoriphagus boritolerans*, soil samples (5 g) were incubated in 50 ml of phosphate-buffered saline (PBS) solution at 30°C supplemented with 10 mM boron per day for several days. The supernatant was streaked on Luria-Bertani (LB) agar plates containing different levels of boron up to 200 mM (Ahmed et al., 2007). Strain T-22^T was isolated on LB agar medium containing high boron concentration and cultivated on modified R2A medium (designated R3A-V) (Tiago et al., 2004) or on marine agar 2216 at 30°C.

Maintenance procedures

Almost all of the *Algoriphagus* strains remain viable on Marine agar (Difco) or other rich medium based on natural or artificial seawater for several weeks. They have survived storage at -80°C in Marine broth or artificial seawater supplemented with 20% glycerol (v/v) for at least 5 years. Strain *Algoriphagus alkaliphilus* AC-74^T is cultivated on R3A-V medium at 30°C and maintained at -70°C in the same medium supplemented with 15% glycerol. *Algoriphagus boritolerans* is grown on R3A-V medium or on Marine agar 2216 at 30°C and maintained at -80°C in the same medium supplemented with 35% glycerol.

Differentiation of the genus *Algoriphagus* from other genera

Bacteria belonging to the genus *Algoriphagus* have many similar phenotypic features with the representatives of their closest phylogenetic relatives, the genera *Aquiflexum*, *Belliella*, *Cyclobacterium*, *Echinicola*, and *Rhodonellum* (Table 105). All of them are

TABLE 105. Phenotypic characteristics that differentiate the genus *Algoriphagus* from its close relatives in the family *Cyclobacteriaceae*^{a,b}

^aSymbols: +, >85% positive; -, 0–15% positive; D, different reactions occur in different taxa (species of a genus).

^bData are taken from Ahmed et al. (2007); Bowman et al. (2003); Brettar et al. (2004a, b); Nedashkovskaya et al. (2004, 2005, 2006, 2007a, b); Schmidt et al. (2006); Tiago et al. (2006a), Van Trappen et al. (2004), Yi and Chun (2004), Ying et al. (2006), Yoon et al. (2004, 2005a, b, 2006).

aerobic bacteria that form the pink-pigmented colonies on suitable solid nutrient media and grow without NaCl or seawater. However, *Algoriphagus* species may be easily differentiated from the genus *Cyclobacterium* by their inability to form ring-like or horseshoe-shaped cells on solid media (Raj and Maloy, 1990; Ying et al., 2006). Gliding motility and the absence of oxidase activity clearly distinguish representatives of the genus *Algoriphagus* from the genera *Echinicola* and *Rhodonellum*, respectively (Nedashkovskaya et al., 2006, 2007a; Schmidt et al., 2006). Notably, species of *Algoriphagus* are characterized by very diverse phenotypic features. These characteristics are suitable for the species differentiation (Table 104), but separation of members of the genus *Algoriphagus* from their close relatives, especially from members of the genera *Aquiflexum* and *Belliella*, is more difficult because their phenotypic properties are very variable. Therefore, to order discriminate *Algoriphagus* from its nearest neighbors, a polyphasic approach, including fatty acid methyl-ester (FAME) (Table 106) and 16S rRNA-based phylogenetic analysis, should be used.

Taxonomic comments

The genus *Algoriphagus*, consisting of a single species *Algoriphagus ratkowskyi*, was established for accommodation of marine, saccharolytic, and cold-adapted *Cytophaga*-like bacteria by Bowman and co-workers in 2003. Shortly thereafter, a new genus of marine bacteria, *Hongiella*, closely related to the genus *Algoriphagus*, was described by Yi and Chun (2004). One of them, *Hongiella halophila*, was moved to the genus *Algoriphagus* because of phylogenetic relatedness (96.8–97.5%) and phenotypic similarity with the *Algoriphagus* species (Nedashkovskaya et al., 2004), while *Hongiella mannitolivorans* and *Hongiella ornithinivorans* were more distantly related (93.7–94.0 and 94.3–94.6%, respectively). The descriptions of the genera *Algoriphagus* and *Hongiella* were also emended in that study (Nedashkovskaya et al., 2004). Later, the description of the genus *Chimaereicella*, comprising a single species *Chimaereicella alkaliphila*, isolated from alkaline artesian water, was reported by Tiago and colleagues (2006a). Despite a close phylogenetic relationship

between *Chimaereicella alkaliphila* and the *Algoriphagus* species (sequence similarity was 94.3–95.5%) and a resemblance in their fatty acid composition, the new bacterium was placed in a new genus based on a distinct isolation source. Later, another *Chimaereicella* species, *Chimaereicella boritolterans*, recovered from soil, was described (Ahmed et al., 2007). A level of 16S rRNA gene sequence similarity between *Chimaereicella boritolterans* and its closest relative, *Chimaereicella alkaliphila*, was 97.6%. The similarity values between *Chimaereicella boritolterans* and representative members of the genera *Algoriphagus* and *Hongiella* were 94.7–96.0 and 95.1–96.7%, respectively. DNA–DNA relatedness between a soil isolate and *Chimaereicella alkaliphila* AC-74^T was 28.3%. This fact supported the affiliation of the new isolate with the genus *Chimaereicella* as a separate species, *Chimaereicella boritolterans*. In course of studying a novel marine bacterium, designated strain KMM 6241^T, Nedashkovskaya et al. (2007b) carried out phylogenetic analysis based on sequencing of 16S rRNA gene. This analysis revealed an equidistant position of strains *Chimaereicella alkaliphila* AC-74^T relative to members of the genera *Algoriphagus* and *Hongiella*, with sequence similarity of 94.7–97.0%. Similar phenotypic features, including the presence of oxidase activity and esculin hydrolysis and the absence of gliding motility and aerobic metabolism, may argue for moving the genus *Chimaereicella* to the genus *Algoriphagus*. In addition, the species of the genus *Hongiella* possess a close relatedness with validly published *Algoriphagus* species with sequence similarities ranging from 93.7 to 96.5%. These results taken together with similarity in fatty acid compositions and phenotypic properties could be considered strong confirmation of the proposal to transfer these species of the genus *Hongiella* to the genus *Algoriphagus*. Consequently, the phylogenetic evidence and the resemblance of phenotypic characteristics (Table 105) and fatty acid composition (Table 106) support the joining of the genera *Algoriphagus*, *Chimaereicella*, and *Hongiella* into the single genus *Algoriphagus*, thereby requiring an emended description of the genus *Algoriphagus* (Nedashkovskaya et al., 2007b). Phylogenetic analysis of the almost-complete 16S rRNA gene sequences reveal that species

of the genus *Algoriphagus* have a 16S rRNA gene sequence similarity of 93.5–99.6% and that the genus *Algoriphagus* forms a cluster with the genera *Belliella*, *Rhodonellum*, *Aquiflexum*, *Echinicola*, and *Cyclobacterium* with sequence similarities of 91.5–93.4, 91.1–93.0, 90.8–93.2, 88.8–92.4, and 88.7–91.7%, respectively.

Differentiation of species of the genus *Algoriphagus*

The species of the genus *Algoriphagus* have many common phenotypic features. However, they can be differentiated from each other by several phenotypic traits as shown in Table 107.

List of species of the genus *Algoriphagus*

- 1. *Algoriphagus alkaliphilus*** (Tiago, Mendes, Pires, Morais and Veríssimo 2006a) Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1993^{VP} (*Chimaereicella alkaliphila* Tiago, Mendes, Pires, Morais and Veríssimo 2006b, 925^{VL}; effective publication: Tiago, Mendes, Pires, Morais and Veríssimo 2006a, 107.)

al.ka.li.phi'la. N.L. n. *alkali* (from Arabic article *al* the; Arabic n. *qaliy* ashes of saltwort, soda), alkali; Gr. adj. *philos* loving; N.L. masc. adj. *alkaliphilus* loving alkaline environments.

Cells are 0.5 × 2.1–3.3 μm. Colonies are small and red. Optimal growth occurs at about 30°C, at pH 8.0 and without NaCl. Hippurate is hydrolyzed, but elastin is not. Xylanase is not produced. D-Arabitol, L-arabitol, ribitol, α-methylmannoside, and 2-ketogluconate are utilized but erythritol, galactitol, β-methyl-xyloside, amygdalin, ribose, L-sorbose, glycogen, and inulin are not. Acid is formed from α-methylglucoside, arbutin, salicin, β-gentiobiose, D-turanose, and 5-ketogluconate. Susceptible to ceftazidim and cephalothin.

Source: artesian water collected at Cabeço de Vide, Southern Portugal.

DNA G+C content (mol%): 43.5 (HPLC).

Type strain: AC-74, CIP 108470, LMG 22694.

Sequence accession no. (16S rRNA gene): AJ717393.

2. **Algoriphagus antarcticus** Van Trappen, Vandecandelaere, Mergaert and Swings 2004, 1972^{VP}

ant.arc'ti.cus. L. masc. adj. *antarcticus* southern, of the Antarctic, the environment from where the strains were isolated.

Cells are up to 0.5 µm in width and 2–3 µm in length. On Marine agar, colonies are 0.5–3 mm in diameter, opaque, and orange-red after 6 d incubation. Optimal growth occurs at 20°C and with 2% NaCl. Pectin and tyrosine are not hydrolyzed. No acid is produced from carbohydrates. Gluconate, caprate, adipate, and phenylacetate are not utilized.

Source: microbial mats from lakes Reid, Fryxell, and Ace, Antarctica.

DNA G+C content (mol%): 39.9–41.0 (HPLC).

Type strain: R-10710, LMG 21980, DSM 15986.

Sequence accession no. (16S rRNA gene): AJ577141.

3. **Algoriphagus aquimarinus** Nedashkovskaya, Vancanneyt, Van Trappen, Vandemeulebroecke, Lysenko, Rohde, Falsen, Frolova, Mikhailov and Swings 2004, 1762^{VP}

a.qui.ma.ri'nus. L. fem. n. *aqua* water, L. masc. adj. *marinus* marine, of the sea; N.L. masc. adj. *aquimarinus*, of seawater.

Cells range from 0.5–0.7 µm in width and 1–10 µm in length. On Marine agar, colonies are 2–3 mm in diameter and pale-pink. Optimal temperature for growth is 23–25°C. No acid is produced from L-sorbose, adonitol, or glycerol.

Source: seawater from Amursky Bay, Gulf of Peter the Great, Sea of Japan.

DNA G+C content (mol%): 41.0 (T_m).

Type strain: KMM 3958, LMG 21971, CCUG 47101.

Sequence accession no. (16S rRNA gene): AJ575264.

4. **Algoriphagus boritolerans** (Ahmed, Yokota and Fujiwara 2007) Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1993^{VP} (*Chimaericella boritolerans* Ahmed, Yokota and Fujiwara 2007, 991^{VP})

bo'ri.to.le.rans. N.L. n. *borum* boron; L. part. adj. *tolerans* tolerating; N.L. part. adj. *boritolerans* boron-tolerating).

Cells are 0.3–0.4 × 1.2–3.4 µm, occurring singly and occasionally in pairs. Colonies are red and small in diameter after several days of incubation at 30°C. Growth is observed at pH 6.5–10.0. Optimal growth occurs at 28–30°C and pH 8.0–9.0. Tolerant up to 300 mM boron but grows optimally without boron supply. Acid is produced from D-turanose, gentiobiose, inulin, potassium 5-ketogluconate, methyl α-D-mannopyranoside, glycogen, and D-lyxose but not from salicin, glycerol, erythritol, D-ribose, L-sorbose, D-tagatose, D- and L-fucose, D- and L-arabitol, potassium gluconate, potassium 2-ketogluconate, methyl β-D-xylopyranoside, D-adonitol, dulcitol, D-sorbitol, amygdalin, D-melezitose, or xylitol. Amygdalin, arbutin, and melezitose are utilized, but erythritol, D-ribose, L-xylose, methyl β-D-xylopyranoside, L-sorbose, D-melibiose, D-trehalose, D-raffinose, potassium

gluconate, L-fucose or D-tagatose are not. α-Chymotrypsin, leucine arylamidase, valine arylamidase, naphthol-AS-BI-phosphohydrolase, esterase (C4), esterase lipase (C8), trypsin, acid phosphatase, and α-glucosidase are produced. Weakly susceptible to rifampin and cefoperazone but resistant to oxacillin, sulfamethizol, and metronidazole. Susceptible to amoxycycline and ofloxacin; resistant to cephalothin and chloramphenicol.

Source: naturally boron-contaminated soil of the Hisarcik area in the Kutahya province of Turkey.

DNA G+C content (mol%): 42.5 (HPLC).

Type strain: T-22, ATCC BAA-1189, DSM 17298, NBRC 101277.

Sequence accession no. (16S rRNA gene): AB197852.

5. **Algoriphagus chordae** Nedashkovskaya, Vancanneyt, Van Trappen, Vandemeulebroecke, Lysenko, Rohde, Falsen, Frolova, Mikhailov and Swings 2004, 1763^{VP}

chor'dae. N.L. gen. n. *chordae* of *Chorda*, the generic name of the brown alga *Chorda filum*, from which the type strain was isolated.

Cells are 0.5–0.7 µm in width and 1–10 µm in length. On Marine agar, colonies are 2–3 mm in diameter, bright pink, and sunken into the agar. Optimal temperature for growth is 23–25°C. No acid is produced from L-sorbose, adonitol, or glycerol.

Source: brown alga *Chorda filum*, Troitsa Bay, Gulf of Peter the Great, Sea of Japan.

DNA G+C content (mol%): 37–40 (T_m).

Type strain: KMM 3957, LMG 21970, CCUG 47095.

Sequence accession no. (16S rRNA gene): AJ575265.

6. **Algoriphagus halophilus** (Yi and Chun 2004) Nedashkovskaya, Vancanneyt, Van Trappen, Vandemeulebroecke, Lysenko, Rohde, Falsen, Frolova, Mikhailov and Swings 2004, 1763^{VP} (*Hongiella halophila* Yi and Chun 2004, 160^{VP})

ha.lo.phi'lus. Gr. n. *hals halos* salt; Gr. adj. *philos* loving; N.L. masc. adj. *halophilus*, salt-loving.

Cells are 0.3–0.5 µm in width and 1.0–1.8 µm in length. On Marine agar, colonies are flat, translucent, and pink-orange. Optimal growth occurs at 35°C, pH 7.0, and with 1–2% NaCl or 1–2% artificial sea salts. Alginic acids and egg yolk are not decomposed. No acid is produced from L-sorbose, adonitol or glycerol. D-Cellobiose, D-fructose, and D-salicin are utilized but acetamide, acetate, benzoate, citrate, D-ribose, ethanol, glycine, inulin, 2-propanol, L-arginine, L-ascorbate, L-asparagine, L-lysine, L-ornithine, polyethylene glycol, salicylate, succinate, tartrate, or thiamin is not. Leucine arylamidase, acid phosphatase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, β-glucuronidase and α- and β-glucosidases activities are present, but esterase (C4), esterase lipase (C8), lipase (C14), cystine arylamidase, valine arylamidase, trypsin, α-mannosidase, and α-fucosidase activities are absent. Maximum absorption of pigment occurs at 475 nm.

Source: sediment sample of getbol, the Korean tidal flat, Sea of Japan.

DNA G+C content (mol%): 37 (HPLC).

Type strain: JC 2051, KCTC 12051, DSM 15292, IMSNU 14013.

Sequence accession no. (16S rRNA gene): AY264839.

7. **Algoriphagus locisalis** Yoon, Kang and Oh 2005b, 1638^{VP}

lo.ci.sa'lis. L. n. *locus* place, locality; L. gen. n. *salis*, of salt; N.L. gen. n. *locisalis*, of a place of salt.

Cells are rods 0.4–0.7 µm in width and 1.5–3.0 µm in length. On Marine agar, colonies are 1–2 mm in diameter and orange after 3 d incubation at 30°C. Optimal growth occurs at 30°C, pH 7.0–8.0, and with 2% (w/v) NaCl. Hypoxanthine, xanthine, and tyrosine are not decomposed. No acid is produced from D-melezitose or D-sorbitol. Salicin is utilized but succinate, formate, and L-glutamate are not. Utilization of D-trehalose is strain-dependent (positive for the type strain). Susceptible to chloramphenicol.

Source: seawater from a marine solar saltern of the Yellow Sea in Korea.

DNA G+C content (mol%): 42 (HPLC).

Type strain: MSS-170, KCTC 12310, JCM 12597.

Sequence accession no. (16S rRNA gene): AY835922.

8. **Algoriphagus mannitivorans** (Yi and Chun 2004) Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1993^{VP} (*Hongiella mannitivorans* Yi and Chun 2004, 160^{VP})

man.ni.to.li.vo'rans. N.L. n. *mannitolium* mannitol; L. v. *vorare* to devour; N.L. part. adj. *mannitolivorans* mannitol-devouring, utilizing mannitol.

Cells are 0.4–0.5 × 1.1–1.7 µm. Colonies are pink-orange on Marine agar. Optimal growth is observed at 35–40°C, pH 7.0 and with 1% NaCl or 0.5–1.5% artificial sea salts. Alginic acids and egg yolk are not decomposed. Acid is not formed from D-adonitol, glycerol or D-sorbitol. D-Fructose, acetamide, acetate, benzoate, citrate, D-ribose, D-sorbitol, ethanol, glycine, inulin, 2-propanol, L-arginine, L-ascorbate, L-asparagine, L-lysine, L-ornithine, polyethylene glycol, salicylate, tartrate, and thiamine are not utilized. Leucine arylamidase, valine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-galactosidase are produced, but esterase lipase (C8), lipase (C14), cystine arylamidase, β-glucuronidase, α- and β-glucosidases, α-mannosidase, and α-fucosidase are not. Susceptible to chloramphenicol, doxycycline, and erythromycin. Maximum absorption of pigment occurs at 480 nm.

Source: sediment of getbol, of the Korean tidal flat.

DNA G+C content (mol%): 42 (HPLC).

Type strain: JC 2050, DSM 15301, IMNSNU 14012, KCTC 12050.

Sequence accession no. (16S rRNA gene): AY264838.

9. **Algoriphagus marincola** (Yoon, Yeo and Oh 2004) Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1993^{VP} (*Hongiella marincola* Yoon, Yeo and Oh 2004, 1848^{VP})

ma.rin'co.la. L. n. *mare* -is the sea; L. n. *incola* inhabitant; N.L. n. *marincola* inhabitant of the sea.

Cells are 0.4–0.6 × 2.0–3.0 µm. Colonies are low convex, reddish-orange, and 1–2 mm in diameter after 72 h incubation at 37°C on Marine agar. Optimal growth occurs at 37°C, pH 6.5–7.5, and with 2–3% NaCl. Tyrosine is hydrolyzed weakly. Hypoxanthine, xanthine and birchwood xylan are not degraded. Acid is produced from D-melezitose but not from D-ribose, glycerol or adonitol. D-Trehalose is utilized but D-fructose, acetate, benzoate, citrate, formate, and

succinate are not. Leucine arylamidase, valine arylamidase, cystine arylamidase, esterase (C4), esterase lipase (C8), acid phosphatase, trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and β-glucosidase are produced, but lipase (C14), α-galactosidase, α-mannosidase, α-fucosidase, or β-glucuronidase is not. Susceptible to chloramphenicol, doxycycline, and erythromycin.

Source: seawater from the East Sea of Korea.

DNA G+C content (mol%): 43 (HPLC).

Type strain: SW-2, DSM 16067, JCM 12319, KCTC 12180.

Sequence accession no. (16S rRNA gene): AY533663.

Reference strain: SW-26.

Sequence accession no. (16S rRNA gene): AY533664.

10. **Algoriphagus ornithivorans** (Yi and Chun 2004) Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1993^{VP} (*Hongiella ornithivorans* Yi and Chun 2004, 160^{VP})

or'ni.thi.ni.vo'rans. N.L. n. *ornithinum* ornithine; L. v. *vorare* to devour; N.L. part. adj. *ornithivorans* ornithine-devouring, utilizing ornithine.

Cells are 0.3–0.4 × 0.8–2.6 µm. Colonies are pink-orange on Marine agar. Optimal growth is observed at 35–40°C, pH 7.0, and with 1% NaCl or 1.0–2.5% artificial sea salts. Maximum absorption of pigment occurs at 480 nm. Hydrolysis of alginic acids and egg yolk is not detected. Leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-BY-phosphohydrolase, trypsin, α-chymotrypsin, α-galactosidase, α-glucosidase, and β-glucosidase are produced, but esterase (C4), esterase lipase (C8), lipase (C14), cystine arylamidase, β-glucuronidase, α-mannosidase, or α-fucosidase are not. Acid is not produced from D-adonitol, glycerol or D-sorbitol. D-Fructose, D-trehalose, D-salicin, and L-ornithine are utilized, but acetamide, acetate, benzoate, citrate, D-ribose, D-sorbitol, ethanol, glycine, inulin, 2-propanol, L-arginine, L-ascorbate, L-asparagine, L-lysine, polyethylene glycol, salicylate, succinate, tartrate, and thiamine are not. Susceptible to chloramphenicol, doxycycline, and erythromycin.

Source: sediment of getbol, of the Korean tidal flat.

DNA G+C content (mol%): 38 (HPLC).

Type strain: JC 2052, DSM 15282, IMSNU 14014, KCTC 12052.

Sequence accession no. (16S rRNA gene): AY264840.

11. **Algoriphagus ratkowskyi** Bowman, Mancuso, Nichols and Gibson 2003, 1352^{VP}

rat.kow'sky.i. N.L. gen. masc. n. *ratkowskyi* of Ratkowsky, named in honor of David A. Ratkowsky, who made significant contributions to growth modelling of bacteria, including psychrophilic bacteria.

Cells are 0.3–0.4 × 0.3–0.9 µm. On Marine agar, colonies are 1–3 mm in diameter and salmon-pink. Optimal growth occurs at 16–19°C and with 0–6% NaCl. Tributyrin is not hydrolyzed. α-Fucosidase and glutamyl glycine arylamidase activities are present; some strains produce β-glucuronidase. Acid is not formed from sugar alcohols. Salicin, β-glycerol phosphate, D-gluconate, propionate, isobutyrate, succinate, pimelate, azelate, L-proline, 2-aminobutyrate, and L-serine are utilized. Utilization of L-ornithine, glycogen, n-butyrate, glutarate, aconitate, and hydroxyl-L-proline

is strain-dependent. The following substrates are not utilized as sole carbon sources: L-fucose, 2-ketogluconate, adonitol, D-arabitol, dulcitol, iso-erythritol, methanol, itaconate, *n*-valerate, suberate, 3-DL-hydroxybutyrate, oxaloacetate, DL-lactate, DL-tartrate, methylamine, isovalerate, heptanoate, caproate, nonanoate, adipate, 2-oxoglutarate, L-alanine, L-aspartate, L-asparagine, L-phenylalanine, L-glutamate, L-histidine, L-threonine, L-tyrosine, L-leucine, putrescine, and urate.

Source: cold marine and marine-derived habitats, including sea ice and algal mats of saline lakes.

DNA G+C content (mol%): 35–36 (T_m).

Type strain: IC025, ACAM 646, LMG 21435, CIP 107452.

Sequence accession no. (16S rRNA gene): U85891.

12. **Algoriphagus terrigena** Yoon, Lee, Kang and Oh 2006, 779^{VP}

ter.ri.ge'na. L. masc. or fem. n. *terrigena* child of the earth, referring to the isolation of the type strain from soil.

Cells are 0.4–0.6 × 0.8–2.5 µm. On Marine agar, colonies are 1–2 mm in diameter and light orange after incubation for 7 d at 25°C. Optimal growth occurs at 25°C, pH 6.5–7.5, and with 2% (w/v) NaCl. Hypoxanthine, xanthine, and tyrosine are not decomposed. α-Mannosidase is present but β-glucuronidase and α-fucosidase are absent. Acid is formed from D-melezitose and D-ribose but not from D-sorbitol. Salicin is utilized as a sole carbon and energy source but not succinate or L-glutamate. Susceptible to chloramphenicol and novobiocin but resistant to cephalothin.

Source: soil of island Dokdo, Korea.

DNA G+C content (mol%): 49.0 (HPLC).

Type strain: DS-44, KCTC 12545, CIP 108837.

Sequence accession no. (16S rRNA gene): DQ178979.

13. **Algoriphagus vanfongensis** Nedashkovskaya, Kim, Kwon, Shin, Luo, Kim and Mikhailov 2007b, 1990^{VP}

van.fong.en'sis. N.L. masc. adj. *vanfongensis* pertaining to the Vanfong Bay, from which the type strain was isolated.

Cells are 0.4–0.5 × 1.0–2.5 µm. Colonies are light-pink on Marine agar. Optimal growth is observed with 1–4% NaCl. Acid is not produced from L-sorbose, glycerol, adonitol or dulcitol. Gluconate, caprate, adipate, malate,

citrate, or phenylacetate is not utilized. Susceptible to chloramphenicol, doxycycline, and erythromycin.

Source: coral *Palithoa* sp. collected in Vanfong Bay, South China Sea, Vietnam.

DNA G+C content (mol%): 43.8 (T_m).

Type strain: KMM 6241, DSM 17529, KCTC 12716.

Sequence accession no. (16S rRNA gene): EF392675.

14. **Algoriphagus winogradskyi** Nedashkovskaya, Vancanneyt, Van Trappen, Vandemeulebroecke, Lysenko, Rohde, Falsen, Frolova, Mikhailov and Swings 2004, 1763^{VP}

wi.no.grad'sky.i. N.L. gen. masc. n. *winogradskyi*, of Winogradsky, named to honor Sergey N. Winogradsky, for his contributions to the study of *Cytophaga*-like bacteria.

Cells are 0.5–0.7 × 1–10 µm. On Marine agar, colonies are 2–4 mm in diameter, bright pink, and sunken into the agar. Optimal temperature for growth is 25–28°C. No acid is produced from L-sorbose, adonitol, or glycerol.

Source: green alga *Acrosiphonia sonderi*, Troitsa Bay, Gulf of Peter The Great, Sea of Japan.

DNA G+C content (mol%): 39–42 (T_m).

Type strain: KMM 3956, LMG 21969, JCM 13505, CCUG 47094.

Sequence accession no. (16S rRNA gene): AJ575263.

15. **Algoriphagus yeomjeoni** Yoon, Kang, Jung, Lee and Oh 2005a, 869^{VP}

yeom.jeo'ni. N.L. gen. n. *yeomjeoni*, of a yeomjeon, the Korean name for a marine solar saltern.

Cells are 0.4–0.7 × 1.5–2.5 µm. On Marine agar, colonies are 0.8–1.0 mm in diameter and vivid orange after 3 d incubation at 30°C. Optimal growth occurs at 25–30°C, pH 7.0–8.0, and with 2% (w/v) NaCl. Hypoxanthine, xanthine, and tyrosine are not decomposed. No acid is produced from D-melezitose, D-ribose, or D-sorbitol. Salicin is utilized but succinate and L-glutamate are not. Susceptible to chloramphenicol.

Source: seawater in a marine solar saltern of the Yellow Sea in Korea.

DNA G+C content (mol%): 41 (HPLC).

Type strain: strain MSS-160, KCTC 12309, JCM 12598.

Sequence accession no. (16S rRNA gene): AY699794.

Reference strain: MSS-161.

Genus III. **Aquiflexum** Brettar, Christen and Höfle 2004b, 2339^{VP}

INGRID BRETTAR, RICHARD CHRISTEN AND MANFRED G. HÖFLE

A.qui.fle'xum. L. fem. n. *aqua* water; L. part. adj. *flexus* -a -um bent, winding; N.L. neut. n. *Aquiflexum* to indicate the bacterium's aquatic origin and its long flexible rods.

Rods, occurring singly or in chains of up to five cells. Nonmotile (no flagella, no gliding activity), **Gram-stain-negative. Aerobic. Heterotrophic.** Oxidase- and catalase-positive. Cells contain a **high percentage of branched-chain fatty acids (>80%)**, and of **C_{15:0} anteiso**. Cells contain **carotenoids** but no flexirubin. **NaCl is not needed for growth**, but growth is **improved** by its presence. **Nitrate** is reduced to nitrite. **Gelatin is hydrolyzed.**

DNA G+C content (mol%): 38.4 (HPLC).

Type species: ***Aquiflexum balticum*** Brettar, Christen and Höfle 2004b, 2339^{VP}.

Further descriptive information

The genus *Aquiflexum* is so far represented by a single strain and a single species, *Aquiflexum balticum* BA160^T.

Enrichment and isolation procedures

Strain BA160^T was isolated during a cruise onboard the research vessel (RV) *Aranda* in September 1998 from surface water (5 m, 15°C, 6‰ salinity, pH 8.2) from a site in the Central Baltic Sea at the entrance of the Gulf of Finland (station LL12, 59.2900° N, 22.5398° E). The strain was isolated by spreading 0.1 ml

of seawater on 1/5 diluted Marine agar (Difco 2216, Marine broth or agar diluted by a factor of 5; final concentration of agar, 1.8%) and subsequently purified and cultured on this medium.

Maintenance procedures

The strain can be kept alive for months at 4°C on agar plates (dilute or regular Marine agar), mixed with glycerol and stored at -70°C, or freeze-dried. For growing the strain from old or preserved biomass, incubation at 30–35°C is recommended. At room temperature, cultivation is often not successful or shows long lag-periods.

Differentiation of the genus *Aquiflexum* from other genera

According to 16S rRNA gene sequence analysis, *Aquiflexum* is most closely related to the genera *Belliella*, *Algoriphagus*, *Hongiella*, and *Cyclobacterium* (see phylogenetic tree in the genus description of *Belliella*). The nearest relative is *Belliella baltica* (Brettar et al., 2004a), having a 16S rRNA gene sequence similarity of 92.4%. By phenotypic traits, *Aquiflexum* can be distinguished from *Belliella* by its temperature range and optimum, hydrolysis of gelatin, acid production from 13 substrates, assimilation of three substrates, and utilization of eight substrates. Compared to *Belliella baltica*, BA160^T showed a higher versatility in using organic substrates,

except for amino acids. Compared to *Belliella baltica*, *Aquiflexum* has a higher fraction of branched-chain fatty acids (BA160^T: 87%, *Belliella baltica*: 70%), lower number of detectable fatty acid compounds, and considerably different composition. The major difference is the higher abundance of anteiso branched fatty acids (*Aquiflexum balticum*, 22%; *Belliella baltica*, 8%). The most abundant was C_{15:0} anteiso (*Aquiflexum balticum*, 19%; *Belliella baltica*, 4.5%). Additionally, C_{17:1} anteiso ω9c was detectable for *Aquiflexum balticum*, but not for *Belliella baltica*.

A table of comparison is given in the chapter on *Belliella*.

Taxonomic comments

The genus *Aquiflexum* belongs to the family *Cyclobacteriaceae* of the class *Cytophagia*. The phylogenetic tree in the chapter on *Belliella* reflects the phylogenetic relationships within the family *Cyclobacteriaceae*.

Acknowledgements

We are grateful to H. Kuosa and the crew of the Finnish RV *Aranda* for their assistance with sampling and seawater analysis of the Baltic Sea, to J. Bötel for excellent technical assistance, and to the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ) staff for analysis of fatty acids and physiological tests.

List of species of the genus *Aquiflexum*

1. *Aquiflexum balticum* Brettar, Christen and Höfle 2004b, 2339^{VP}

bal'ti.cum. N. L. neut. adj. *balticum* of or belonging to the Baltic sea, referring to the source of the type strain.

The characteristics are as given for the genus with the following additional characteristics. Cells are 0.3–0.6 μm × 1.1–4.8 μm. The dominant fatty acids are of C_{15:0} iso, C_{15:0} anteiso, C_{15:1} iso G, and C_{16:1} iso H. Colonies are circular, smooth, convex, and entire; they are red and transparent when young but become opaque with ongoing incubation (>1 week, 30°C, on ½× Marine agar). The temperature range is 4–40°C; optimum, around 30°C. Growth occurs in 0–6% NaCl; optimum, around 1.5%. The pH range is 7–9; optimum, at neutral pH. Esculin, starch, and gelatin are hydrolyzed. No degradation of cellulose or tyrosine occurs. Indole is not produced. Growth does not occur on media with 0.5% yeast, casein, DNA, chitin, or pectin. Acid is produced (using the API 50CHE system) from galactose, D-glucose, D-fructose, D-mannose, rhamnose, α-methyl-D-mannoside, α-methyl-D-glucoside, N-acetylglucosamine, amygdalin, arbutin, esculin salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol,

β-gentiobiose, D-turanose, L-fucose, and 5-ketogluconate. Enzymic activities (i.e., positive results using the API 20NE and API ZYM systems) include α- and β-glucosidase; β-galactosidase; acid and alkaline phosphatase; leucine-, valine-, and cystine-arylamidase; trypsin; chymotrypsin; naphthol-phosphohydrolase; and N-acetyl-β-glucosaminase. The following substrates are assimilated (using the API 20NE system): glucose, arabinose, mannose, N-acetylglucosamine, maltose, and gluconate. The following substrates are utilized (using the Biolog GN2 system): L-arabinose, cellobiose, L-fructose, D-galactose, gentiobiose, α-D-glucose, α-D-lactose, lactulose, maltose, D-mannose, β-methyl-D-glucoside, D-psicose, D-sorbitol, sucrose, D-trehalose, turanose, mono-methyl-succinate, acetic acid, α-ketoglutaric acid, lactic acid, and propionic acid. All unmentioned tests using the API 20CHE, API ZYM, API 20NE, and Biolog GN2 test systems were negative. No utilization of amino acids was detected, but aminopeptidase was produced.

Source: marine or estuarine.

DNA G+C content (mol%): 38.4 (HPLC).

Type strain: BA160, CIP 108445, DSM 16537, LMG 22565.

Sequence accession no. (16S rRNA gene): AJ744861.

Genus IV. *Belliella* Brettar, Christen and Höfle 2004a, 69^{VP}

INGRID BRETTAR, RICHARD CHRISTEN AND MANFRED G. HÖFLE

Bel.li.el'la. N.L. fem. dim. n. *Belliella* named in honor the aquatic microbiologist Russell Bell of the University of Uppsala.

Rods occurring as single cells or chains of up to five cells. **Non-motile** (no flagella, no gliding activity). Gram-stain-negative. **Aerobic**. Oxidase- and catalase-positive. Chemoheterotrophic. The dominant fatty acids are C_{15:0} iso, C_{15:1} iso G, C_{17:1} iso ω9c,

and C_{17:1} ω6c. Cells contain **carotenoids** but no flexirubin. **NaCl is not required** for growth and does not influence growth up to 3%. **Nitrate** is reduced to nitrite. **Gelatin is not hydrolyzed**.

DNA G+C content (mol%): 35.3–35.5.

Type species: Belliella baltica Brettar, Christen and Höfle 2004a, 69^{VP}.

Further descriptive information

The genus *Belliella* is so far represented by a single species comprising two strains, *Belliella baltica* BA1 and BA134^T, both isolated from the central Baltic Sea.

Enrichment and isolation procedures

The strains of *Belliella baltica* were isolated during a cruise onboard the research vessel (RV) *Aranda* in September 1998 from surface water (5 m, 15°C, 7‰ salinity, pH 8.4) of two stations in the Central Baltic Sea (Gotland Deep BY-15 [57.1920°N, 20.0302°E] and TEILI1 [59.2607°N, 21.3002°E]). Strains were isolated by spreading 0.1 ml of seawater on 1/5 diluted Marine agar (Difco 2216; Marine broth or agar diluted by a factor of 5; final concentration of agar, 1.8%), and subsequently purified and cultured on this medium.

Maintenance procedures

The strain can be kept alive for months at 4°C on agar plates (dilute or regular Marine agar), mixed with glycerol and stored at -70°C, or freeze-dried. Recovery from old biomass or from preserved biomass is recommended on Marine agar (half-strength) at 20–25°C.

Differentiation of the genus *Belliella* from other genera

According to 16S rRNA gene sequence analysis, *Belliella* is most closely related to the genera *Aquiflexum*, *Algoriphagus*, *Hongiella*, and *Cyclobacterium* (see Figure 78). The nearest relative is *Aquiflexum balticum* (Brettar et al., 2004b), having a 16S rRNA gene sequence similarity of 92.4%. *Belliella* can be distinguished from *Aquiflexum* on the basis of its temperature range and optimum, hydrolysis of gelatin, acid production from 13 substrates, assimilation of three substrates, and utilization of eight substrates (Table 108). Compared to *Aquiflexum balticum*, *Belliella* is less able to use organic substrates. The cellular fatty acids show significant differences between *Aquiflexum* and *Belliella*. The major

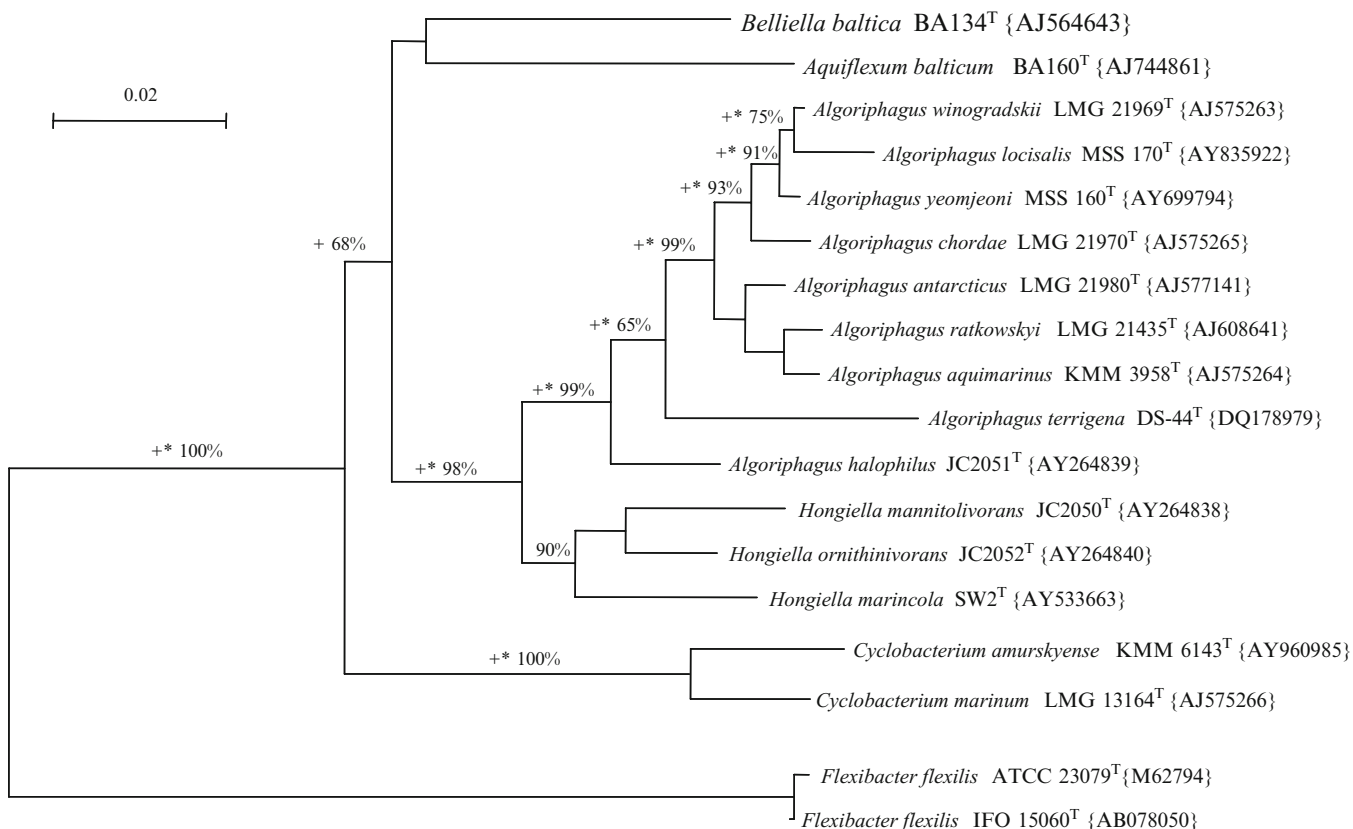

FIGURE 78. Phylogenetic position of *Belliella baltica* and *Aquiflexum balticum* within the family *Cyclobacteriaceae*. According to the phylogenetic analysis of almost complete 16S rRNA gene sequences, *Aquiflexum balticum* BA160^T and *Belliella baltica* BA134^T belong to a well defined clade (all three phylogenetic methods – see below) that also includes genera such as *Algoriphagus*, *Hongiella*, and *Cyclobacterium*. *Aquiflexum balticum* and *Belliella baltica* fail to cluster robustly with any of these genera or with each other, strongly supporting their position as independent genera. A domain (positions 85–1416 of the *Aquiflexum balticum* sequence, corresponding to a domain sequenced for every species) was chosen for phylogenetic analysis. Parsimony and maximum-likelihood (G option) were performed using programs from the PHYLIP package. For neighbor-joining, distances were calculated with DNADIST (from PHYLIP) and the Kimura 2 parameters correction. A tree was generated using the BioNJ algorithm (Gascuel, 1997). Bootstrap analysis (1000 replications) was performed using the NJ algorithm as described previously. The topology of the tree is based on NJ analysis, with the results of the other analyses reported on the figure: *, for a branch also found by maximum-likelihood; +, for a branch also found by parsimony; %, indicates % of bootstrap.

TABLE 108. Differential features of *Belliella baltica* and *Aquiflexum balticum*^{a,b}

Characteristic	<i>Belliella baltica</i>	<i>Aquiflexum balticum</i>

differences are the higher abundance of C_{15:0} anteiso for *Aquiflexum balticum*, and the occurrence or absence of four fatty acids (Table 108).

Taxonomic comments

The genus *Belliella* belongs to the family *Cyclobacteriaceae* of the class *Cytophagia*. The phylogenetic affiliation within the family is reflected by the phylogenetic tree (Figure 78).

List of species of the genus *Belliella*

1. ***Belliella baltica*** Brettar, Christen and Höfle 2004a, 69^{VP}
bal'ti.ca. N. L. fem. adj. *baltica* of or belonging to the Baltic Sea (the source of the type strain).

Acknowledgements

We are grateful to H. Kuosa and the crew of the Finnish RV *Aranda* for their assistance with sampling and seawater analysis of the Baltic Sea.

The characteristics are as given for the genus with the following additional information. The cells are 0.3–0.5 × 0.9–3.0 μm. Colonies are circular, smooth, convex, and entire; they are pink and transparent when young but become orange

and opaque with ongoing incubation (>2 weeks, 20°C, on 1/2× Marine agar). The temperature range is 4–37°C; optimum, around 25°C. NaCl is not needed for growth; growth occurs at salinities up to 6% NaCl; optimum, 0–3%. The pH range is 7–10; optimum, around pH 7. Growth occurs on 0.5% yeast extract. Esculin, starch, and DNA are hydrolyzed. Indole is not produced. Tyrosine, cellulose, and chitin are not degraded. Growth does not occur on media with casein and pectin. Acid is produced (using the API 50CHE system) from L-arabinose, D-xylose, galactose, D-glucose, D-fructose, esculin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, D-raffinose, and starch. The following enzymic activities occur (using the API 20NE and API ZYM systems): α - and β -glucosidase; β -galactosidase; acid and alkaline

phosphatase; lipase (C8); leucine-, valine-, and cystine-arylamidase; trypsin, chymotrypsin, and naphthol-phosphohydrolase. The following substrates are assimilated (using the API 20NE system): glucose, arabinose, and maltose. The following substrates are utilized (using the Biolog GN2 system): D-galactose, gentobiose, α -D-glucose, α -D-lactose, lactulose, maltose, D-trehalose, acetic acid, α -ketobutyric/glutaric/valeric-acid, and L-glutamic acid. All other tests using the API 20CHE, API ZYM, API 20NE, and Biolog GN2 test systems were negative.

Source: marine or estuarine.

Genus V. *Echinicola* Nedashkovskaya, Kim, Vancanneyt, Lysenko, Shin, Park, Lee, Jung, Kalinovskaya, Mikhailov, Bae and Swings 2006, 955^{VP}

OLGA I. NEDASHKOVSKAYA AND SEUNG BUM KIM

E.chi.ni.co'la. L. masc. n. *echinus* -i a sea urchin; L. suff. -cola derived from L. masc. or fem. n. *incola* a dweller; N.L. fem. n. *Echinicola* a sea-urchin dweller.

Rods usually measuring 0.3–0.5 × 1.1–2.3 μ m. **Motile by gliding.** Produce non-diffusible carotenoid pigments. No flexirubin-type pigments are formed. **Chemo-organotrophs. Aerobic.** Can ferment D-glucose. Oxidase-, catalase-, alkaline phosphatase-, and β -galactosidase-positive. **Starch is hydrolyzed.** Casein, urea, chitin, and cellulose (CM-cellulose and filter paper) are not decomposed, but agar, gelatin, and Tweens may be decomposed. Carbohydrates are utilized. Can grow without seawater or sodium ions. Nitrate is not reduced to nitrite. Indole is not produced. **The major respiratory quinone is MK-7.**

DNA G+C content (mol%): 44–s.

Type species: *Echinicola pacifica* Nedashkovskaya, Kim, Vancanneyt, Lysenko, Shin, Park, Lee, Jung, Kalinovskaya, Mikhailov, Bae and Swings 2006, 955^{VP}.

Further descriptive information

The main cellular fatty acids are straight-chain unsaturated and branched-chain unsaturated fatty acids C_{15:0} iso, C_{16:1} ω 5c, C_{15:0} iso 3-OH, C_{17:1} iso ω 9c, C_{17:1} ω 6c, C_{17:0} iso 3-OH, summed feature 3 comprising C_{15:0} iso 2-OH and C_{16:1} ω 7c or both (Table 109).

On Marine agar (Difco), strains of the genus *Echinicola* form regular, circular, convex, shiny, smooth, and pink colonies with entire edges and a diameter of 2–3 mm after cultivation for 48 h.

All strains grow at 6–41°C and with 0–12% NaCl. The *Echinicola* strains do not form acid from melibiose, raffinose, sorbose, glycerol, adonitol, dulcitol, inositol, or mannitol. They utilize arabinose, glucose, lactose, mannose, and sucrose, but not myo-inositol, mannitol, or sorbitol. The strains are susceptible to lincomycin and resistant to ampicillin, benzylpenicillin, gentamicin, kanamycin, neomycin, polymyxin B, streptomycin, and tetracycline.

Strains of the genus *Echinicola* were isolated from sea animals and from seawater samples collected in the temperate and tropic latitudes.

Enrichment and isolation procedures

Strains of *Echinicola pacifica* were isolated from a sea urchin, *Strongylocentrotus intermedius*, using the dilution plating technique on Marine agar 2216 (Nedashkovskaya et al., 2006). A single strain *Echinicola vietnamensis*, KMM 6221^T, was isolated from seawater by direct plating on a medium containing (in g/l of a 1:1 mixture of natural seawater and distilled water): Bacto peptone (Difco), 5.0; casein hydrolysate (Merck), 2.0; Bacto yeast extract (Difco), 2.0; glucose, 1.0; KH₂PO₄, 0.2; MgSO₄, 0.05; Bacto agar (Difco), 15.0. All isolates have been grown on media containing 0.5% of a peptone and 0.1–0.2% yeast extract (Difco) (Nedashkovskaya et al., 2007a).

Maintenance procedures

Echinicola strains remain viable for several weeks on Marine agar or other rich media based on natural or artificial seawater. They have survived storage –80°C for at least 5 years in Marine broth or artificial seawater supplemented with 20% glycerol (v/v).

Differentiation of the genus *Echinicola* from other genera

The genus *Echinicola* differ from its closest phylogenetic relatives, the genera *Algoriphagus*, *Belliella*, and *Cyclobacterium* by its gliding motility and by its ability to grow in the presence of 15% NaCl (Table 110). The absence of nitrate reductase and a higher mol% G+C content of its DNA (44–46 vs 35.4) separate members of the genus *Echinicola* from their nearest neighbor, *Belliella baltica*. Differences in fatty acid composition may also be helpful for discrimination of the *Echinicola* strains from their closest relatives (Table 109).

Taxonomic comments

Phylogenetic analysis of almost-complete 16S rRNA gene sequences of the genus *Echinicola* indicates that its closest

^bData are from Nedashkovskaya et al. (2006, 2007a).

relatives are the genera *Belliella*, *Algoriphagus*, and *Cyclobacterium*, with sequence similarity values of 91.7–92.1, 88.8–92.4, and 89.5–91.5%, respectively. A level of 16S rRNA gene sequence similarity between the two species of the genus, *Echinicola pacifica* and *Echinicola vietnamensis*, is 94.7–95.0%. The 16S rRNA gene sequence similarity between the type strain *Echinicola pacifica* KMM 6172^T and reference strains KMM 6166 and KMM

6173 ranges from 99.4 to 99.9%. The DNA–DNA hybridization values between these strains vary from 93 to 98%.

Differentiation of the species of the genus *Echinicola*

The strains of the two species of the genus *Echinicola* have many similar phenotypic features. However, they can be differentiated from each other by the several phenotypic traits shown in Table 111.

List of species of the genus *Echinicola*

1. ***Echinicola pacifica*** Nedashkovskaya, Kim, Vancanneyt, Lysenko, Shin, Park, Lee, Jung, Kalinovskaya, Mikhailov, Bae and Swings 2006, 955^{VP}

pa.ci'fi.ca. L. fem. adj. *pacifica* pacific, and by extension referring to the Pacific Ocean, from which the type strain was isolated.

Cells are 0.3–0.4 µm in width and 1.2–1.9 µm in length. On Marine agar, colonies are sunken into the agar. Growth occurs at 6–41°C and with 0–12% NaCl. The optimal temperature for growth 25–28°C. Decomposes gelatin (weakly) and esculin. Hydrolysis of Tweens 20 and 80 is strain-dependent. DNA is not hydrolyzed. Produces acid from N-acetylglucosamine. Can oxidize D-galactose and D-sucrose. Does not form acid from L-fucose. According to the API 20E gallery (bioMérieux), strain KMM 6172^T utilizes citrate, forms acid from amygdalin, and is negative for arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase. Results of Biolog GN2 (Biolog) testing show that strain KMM 6172^T utilizes α-cyclodextrin, dextrin, glycogen, α-D-glucose, D-fructose, L-fucose, D-galactose, gentiobiose, α-lactose, α-D-lactose, lactulose, D-melibiose, methyl β-D-glucoside, psicose, D-raffinose, D-trehalose, turanose, D-galacturonic acid, D-glucuronic acid, α-ketobutyric acid, alaninamide, L-alanine, L-alanyl-glycine, L-asparagine, L-aspartic acid, L-glutamic acid, hydroxy-L-proline and L-threonine. The following compounds are not utilized: Tween 80, N-acetyl-D-galactosamine, adonitol, L-arabitol, i-erythritol, *myo*-inositol, D-mannitol, D-sorbitol, xylitol, methyl pyruvate, monomethyl succinate, acetic acid, *cis*-aconitic acid, citric acid, formic acid, D-galactonic acid, D-gluconic acid, D-glucosaminic acid,

α-, β-, and γ-hydroxybutyric acids, *p*-hydroxyphenylacetic acid, itaconic acid, α-ketoglutaric acid, α-ketovaleric acid, DL-lactic acid, malonic acid, propionic acid, quinic acid, D-saccharic acid, sebacic acid, succinic acid, bromosuccinic acid, succinamic acid, glucuronamide, D-alanine, glycyl-L-aspartic acid, glycyl-L-glutamic acid, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglytamic acid, D-serine, L-serine, DL-carnitine, γ-aminobutyric acid, urocanic acid, inosine, uridine, thymidine, phenylethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, glycerol, DL-α-glycerol phosphate, glucose 1-phosphate, and glucose-6-phosphate. H₂S is produced. Indole and acetoin (Voges–Proskauer reaction) are not produced. According to API ZYM gallery (bioMérieux), the following enzyme activities are present: α-galactosidase, acid phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α- and β-glucosidases, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Lipase (C14) and β-glucuronidase are not present. The predominant fatty acids are C_{15:0} iso (17.3–18.0%), C_{16:1} ω5c (6.7–7.8%), C_{17:1} iso ω9c (6.3–6.9%), C_{17:1} ω6c (4.3–4.8%), C_{15:0} iso 3-OH (3.4–5.0%), C_{17:0} iso 3-OH (9.4–10.0%) and summed feature 3 (30.7–30.8%), comprising C_{16:1} ω7c and/or C_{15:0} iso 2-OH (Table 109).

Source: sea urchin *Strongylocentrotus intermedius* collected in Troitsa Bay, Gulf of Peter the Great, the East Sea (also known as the Japan Sea).

DNA G+C content (mol%): 44–45 (*T_m*).

Type strain: KMM 6172, KCTC 12368, LMG 23350.

Sequence accession no. (16S rRNA gene): DQ185611.

2. **Echinicola vietnamensis** Nedashkovskaya, Kim, Hoste, Shin, Beleneva, Vancanney and Mikhailov 2007a, 763^{VP}

vi.et.nam.en'sis. N. L. fem. adj. *vietnamensis* of or belonging to Vietnam, the country of origin of the type strain.

Cells are 0.4–0.5 × 1.1–2.3 µm. Colonies are light pink on Marine agar. Growth occurs at 6–44°C and with 0–15% NaCl. The optimal temperature for growth is 30–32°C. Tweens 20 and 80 are not hydrolyzed. Acid is not produced from D-fructose, D-galactose, D-sucrose, or N-acetylglucosamine. The fatty acids accounting for more than 1% of the total

are C_{15:0} anteiso (1.4%), C_{15:0} iso (20.0%), C_{15:1} ω6c (1.2%), C_{15:0} (1.5%), C_{16:1} ω5c (4.9%), C_{17:1} iso ω9c (4.4%), C_{17:0} iso (1.0%), C_{17:1} ω6c (4.5%), C_{15:0} iso 3-OH (3.7%), C_{16:0} 3-OH (2.3%), C_{17:0} iso 3-OH (10.0%), summed feature 3 (34.5%), comprising C_{16:1} ω7c and/or C_{15:0} iso 2-OH and summed feature 4 (5%), comprising C_{17:1} iso I and/or C_{17:1} anteiso B.

Source: seawater collected in a mussel farm located in a lagoon of Nha Trang Bay, South China Sea, Vietnam.

DNA G+C content (mol%): 45.9 (T_m).

Type strain: KMM 6221, DSM 17526, LMG 23754.

Sequence accession no. (16S rRNA gene): AM406795.

Genus XV. *Rhodonellum* Schmidt, Priemé and Stougaard 2006, 2891^{VP}

THE EDITORIAL BOARD

Rho.do.nell.um. Gr. neut. n. *rhodon* a rose; L. neut. dim. ending *-ellum*; N.L. dim. neut. n. *Rhodonellum* a small rose, referring to the red color of the colonies.

Rods 0.7–1.0 × 0.8–3.0 µm. Gram-stain-negative. Oxidase-negative. Catalase-positive. Aerobic. Chemoheterotrophic. **Colonies are pink to red due to carotenoids. Temperature range, 0–22°C; optimum, ca. 5°C. pH range, 7.5–10.7** when grown at 5–10°C. **NaCl range for growth, 0–3%**; optimum, 0.6%. Predominant fatty acids are C_{17:1} iso ω9c, C_{17:0} iso 3-OH (12.5–18.5%), and summed feature 3. Cells contain red pigment in the form of carotenoids. Optimal growth occurs above pH 9. NaCl is not required for growth, but growth is enhanced by the presence of up to 0.6% NaCl.

DNA G+C content (mol%): 44.2.

Type species: ***Rhodonellum psychrophilum*** Schmidt, Priemé and Stougaard 2006, 2891^{VP}.

Further descriptive information

Predominant fatty acids of *Rhodonellum psychrophilum* are C_{15:1} iso G (6.3%), C_{15:0} iso (7.6%), C_{16:1} iso H (7.3%), C_{17:1} iso ω9c (17.5%), C_{17:1} ω6c (6.8%), C_{17:0} iso 3-OH (17.5%), and summed feature 3, comprising C_{16:1} ω7c and/or C_{15:0} iso 2-OH (12.6%), and summed feature 4, comprising C_{14:0} 2-OH and/or C_{15:0} iso 2-OH (6.5%), which could not be distinguished by the method used (Schmidt et al., 2006).

Enrichment and isolation procedures

Rhodonellum psychrophilum was isolated from submarine ikaite tufa columns collected from the Ikka Fjord, southwest Greenland (Schmidt et al., 2006). The columns were conserved in 15% glycerol and kept at –20°C. Isolation was achieved on agar plates containing 0.1 × R2A medium (Difco).

Differentiation of the genus *Rhodonellum* from other genera

Rhodonellum psychrophilum can be differentiated from *Belliella baltica* by its pH range for growth (7.5–10.7 vs 6–10), negative oxidase reaction, temperature range of 0–22°C vs 4–37°C, an optimum temperature of 5°C vs 25–30°C, and a higher mol% G+C of the DNA (43.1 vs 35).

Taxonomic comments

Schmidt et al. (2006) reported that, based on 16S rRNA gene sequence analysis, the type strain of *Rhodonellum psychrophilum*, together with five related isolates from ikaite columns, formed a separate cluster with 86–93% gene sequence similarity to their closest relative, *Belliella baltica*.

List of species of the genus *Rhodonellum*

1. ***Rhodonellum psychrophilum*** Schmidt, Priemé and Stougaard 2006, 2891^{VP}

psy.chro'phi.lum. Gr. adj. *psychros* cold; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*), friend, loving; N.L. neut. adj. *psychrophilum* cold-loving.

The characteristics are as described for the genus, with the following additional features. Colonies are smooth, circular, and red due to the presence of carotenoids when grown under low light intensity. Colonies are white to light red when grown at a light intensity of 20–40 µE/m²/s. Growth occurs from pH 7.5 to above pH 10.7, with an optimum at pH 9.2–10.0. At optimal growth temperature, the range of

tolerated pH is largest, whereas at, below, and above the optimal growth temperature, a narrower pH range is tolerated. NaCl is not required for growth, but up to 3% (w/v) NaCl is tolerated. Optimal growth occurs around 0.6% (w/v) NaCl. Strains can use a wide spectrum of carbon sources such as galactose, glycerol, lactose, maltose, mannose, sorbitol, and starch.

Source: the permanently alkaline and cold ikaite columns in the Ikka Fjord in southwest Greenland.

DNA G+C content (mol%): 44.2 (HPLC).

Type strain: GCM71, DSM 17998, LMG 23454.

Sequence accession no. (16S rRNA gene): DQ112660.

Family III. **Flammeovirgaceae** fam. nov.

OLGA I. NEDASHKOVSKAYA AND WOLFGANG LUDWIG

Flam.me.o.vir.ga'ce.a.e. N.L. fem. n. *Flammeovirga* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Flammeovirgaceae* the *Flammeovirga* family.

Cells are **straight, flexible or curved rods**, that are 0.2–1.0×1.5–100 µm or longer. **Gram-stain-negative. Chemo-organotrophs.** Nonsporeforming. Nonflagellated and nonmotile in liquid media, but most of them move by gliding on solid substrates. Cells of one species can form sheathed filaments. **Colonies are pink, red, orange or apricot in color.** Colonies of the majority of strains are characterized by a spreading growth and some of them produce gelase fields and form deep craters in agar plates.

Strains of the majority species are strictly aerobic, but strains of one genus are characterized as facultatively anaerobic organisms. **Optimal grown temperature is 20–33°C. Carbohydrates are oxidized.** Two species ferment glucose. **Most strains require seawater or NaCl for growth. All strains are alkaline phosphatase-positive and arginine dihydrolase-, lysine decarboxylase-, and ornithine decarboxylase-negative.** The most strains produce oxidase and catalase. Only one species produces flexirubin type pigments. The majority of the strains cannot produce acetoin, hydrogen sulfide or indole. Nitrate may be reduced to nitrite. **Most species hydrolyze esculin, gelatin, and DNA.** Agar, casein, starch, carboxymethylcellulose and Tweens may be decomposed, but crystalline cellulose is not.

Menaquinone 7 is a major or single respiratory quinone. **Predominant fatty acids are C_{15:0} iso, C_{15:1} iso, C_{17:0} iso 3-OH and C_{15:0} iso 2-OH and/or C_{16:1} ω 7c.** The main polyamines for the majority species are **spermidine or homospermidine.** The most strains produced carotenoid pigment sproxanthin. All species occur in different marine environments including sea water, marine sediments, seaweeds, or marine animals, one of them was isolated from marine aquarium outflow.

DNA G+C content (mol%): 31–45.

Type genus: **Flammeovirga** Nakagawa, Hamana, Sakane and Yamasato 1997, 221^{VP} emend. Takahashi, Suzuki and Nakagawa 2006, 2097^{VP}.

Taxonomic comments

Family *Flammeovirgaceae* comprises the recognized genera *Flammeovirga*, *Fabibacter*, *Flexithrix*, *Marinoscillum*, *Perexilibacter*, *Persicobacter*, *Rapidithrix*, *Reichenbachiella*, and *Roseivirga*, and generically misclassified species [*Flexibacter*] *litoralis*, [*Flexibacter*] *polymorphus*, [*Flexibacter*] *roseolus*, "*Microscilla sericea*", and "*Microscilla tractuosa*", which are phylogenetically distant from the type species of their genera. In the last two decades the

strains currently affiliated with the family *Flammeovirgaceae* have been subjected to intensive taxonomic investigation by using a polyphasic approach and, especially, a phylogenetic analysis based on comparison of 16S rRNA gene sequences (Nakagawa et al., 2002). The species described as [*Cytophaga*] *aprica* and [*Cytophaga*] *diffluens* by Reichenbach (1989a) in the previous edition of *Bergey's Manual of Systematic Bacteriology*, were placed in the novel genera *Flammeovirga* and *Persicobacter*, respectively (Nakagawa et al., 1997). Later, Takahashi et al. (2006) emended the description of the genus *Flammeovirga* to include misclassified species "*Microscilla arenaria*" and the novel species *Flammeovirga yaeyamensis*; *Flammeovirga kamogawensis* was subsequently described by Hosoya and Yokota (2007a). A species with an uncertain taxonomic position, "[*Flexibacter*] *aggregans*" (Lewin, 1969) Leadbetter 1974, was reclassified as a later heterotypic synonym of *Flexithrix dorotheae* Lewin 1970 because of the very close phylogenetic relationship between them (Hosoya and Yokota, 2007b). In order to accommodate the single and type strain of species "*Microscilla furvescens*" and a representative of a novel species, the genus *Marinoscillum* was created (Seo et al., 2009). Recently a precise taxonomic position of the misclassified species "*Microscilla sericea*" and "*Microscilla tractuosa*" was determined, and it was proposed to reclassify them in the novel genus "*Marivirga*" as two distinct species (Nedashkovskaya et al., 2009).

In addition, the single and type strain of *Fabibacter halotolerans* forms a coherent phylogenetic cluster with species of the other member of the family, the genus *Roseivirga*. They share many phenotypic features in common and, perhaps, will be joined to the single genus.

From a view of the heterogeneity of the family *Flammeovirgaceae*, it should be noted that the representatives of all recognized and newly proposed genera such as *Flexithrix*, *Perexilibacter*, *Persicobacter*, *Rapidithrix*, *Roseivirga*, and generically misclassified species [*Flexibacter*] *litoralis*, [*Flexibacter*] *polymorphus* and [*Flexibacter*] *roseolus* can be considered as members of novel families in future.

Differential characteristics of the genera of *Flammeovirgaceae* are given in Table 112. Please note that *Marinoscillum* (Seo et al., 2009), "*Marivirga*" (Nedashkovskaya et al., 2009), *Perexilibacter* (Yoon et al., 2007), and *Rapidithrix* (Srisukchayakul et al., 2007) were proposed after the valid publication deadline for this volume and are not described in greater detail than given here.

Genus I. **Flammeovirga** Nakagawa, Hamana, Sakane and Yamasato 1997, 221^{VP} emend. Takahashi, Suzuki and Nakagawa 2006, 2097^{VP}

YASUYOSHI NAKAGAWA

Flam.me.o.vir'ga. L. adj. *flammeus* fire-colored; L. fem. n. *virga* rod; N.L. fem. n. *Flammeovirga* fire-colored rod.

Rods 0.4–0.9 µm wide and 1.7–96 µm long or longer. **Motile by gliding.** Nonsporeforming. Gram-stain-negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the

terminal electron acceptor. Chemo-organotrophic. **Colonies spread and produce large gelase fields and deep craters in agar plates. Cell mass is orange to reddish orange.** Sproxanthin is

present as the major carotenoid pigment. **Flexirubin-type pigments are absent.** Oxidase and catalase activities differ among species. **Marine organisms. Seawater is required for growth; NaCl alone can substitute.** The optimum pH for growth is 7. Nitrate is reduced. Agar, alginic acid, esculin, and starch are degraded. The major respiratory quinone is MK-7. Predominant cellular fatty acids are C_{15:0} iso, C_{20:4} ω6,9,12,15c, and C_{16:0} 3-OH.

DNA G+C content (mol%): 31–36.

Type species: Flammeovirga aprica (Reichenbach 1989b) Nakagawa, Hamana, Sakane and Yamasato 1997, 221^{VP} emend. Takahashi, Suzuki and Nakagawa 2006, 2099^{VP} [*Cytophaga aprica* (ex Lewin 1969) Reichenbach 1989c, 495^{VP}; *Cytophaga diffluens* var. *aprica* Lewin 1969, 197].

Further descriptive information

All species are negative for acid production from API 50CH system substrates including adonitol, D-arabinose, L-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, gluconate, glycerol, inositol, inulin, 2-ketogluconate, D-lyxose, methyl β-D-xyloside, D-tagatose, D-turanose, and L-xylose. All species are negative for the utilization of Biolog GN2 Microplate system substrates including N-acetyl-D-galactosamine, cis-aconitic acid, adonitol, D-alanine, γ-aminobutyric acid, 2-aminoethanol, L-arabinose, D-arabitol, bromosuccinic acid, 2,3-butanediol, DL-carnitine, citric acid, i-erythritol, formic acid, D-fructose, D-galactonic acid lactone, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, glucuronamide, D-glucuronic acid, L-glutamic acid, glycerol, DL-α-glycerol phosphate, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, hydroxy-L-proline, p-hydroxyphenylacetic acid, inosine, myo-inositol, itaconic acid, α-ketoglutaric acid, α-ketovaleric acid, L-leucine, malonic acid, D-mannitol, methyl-β-D-glucoside, methyl pyruvate, L-phenylalanine, phenylethylamine, D-psicose, putrescine, L-pyroglutamic acid, quinic acid, D-raffinose, D-saccharic acid, sebacic acid, D-serine, D-sorbitol, succinamic acid, succinic acid, sucrose, Tween 40, Tween 80, turanose, and xylitol.

Enrichment and isolation procedures

No enrichment media have been designed for isolation of *Flammeovirga* strains. Standard procedures to isolate marine bacteria can be applied. Colonies of *Flammeovirga* are usually orange to reddish orange and spread rapidly.

Flammeovirga strains have been isolated from marine environments at widely separated sites (Lewin, 1969; Nakagawa, 2004; Takahashi et al., 2006). The type strain of *Flammeovirga aprica* came from Kailua, Hawaii. The type strain of *Flammeovirga arenaria* was isolated from marine sand in Mexico. Strains of *Flammeovirga yaeyamensis* have been isolated from seaweeds, coastal sands, and dead leaves along the seashores of Iriomote and Ishigaki Islands (24° 20' N 123° 45' E and 24° 20' N 124° 9' E, respectively).

Maintenance procedures

Cultures of *Flammeovirga* strains can be preserved by freezing at lower than –80°C. For freezing, cells are suspended in Marine broth 2216 (Difco) containing 10% glycerol or 7% DMSO. *Flammeovirga* strains are rather sensitive to drying; however, they can be preserved by the liquid drying method using a protective medium such as SM2* or SM3[†] (Sakane et al., 1996), or by freeze drying.

Differentiation of the genus *Flammeovirga* from other genera

Characteristics differentiating the genus *Flammeovirga* from other mesophilic genera in the family *Flammeovirgaceae* are listed in Table 113. Presence of C_{15:0} iso, C_{16:0} 3-OH, and C_{20:4} ω6,9,12,15c as major fatty acids and sproxanthin (the major carotenoid) are useful characters to discriminate the genus *Flammeovirga* from other genera.

Taxonomic comments

The genus *Flammeovirga* was created by Nakagawa et al. (1997) to accommodate the misclassified species *Cytophaga aprica*. Until 2006, the genus contained a single species, *Flammeovirga aprica*. However, Nakagawa et al. (2002) reported that “*Microscilla arenaria*” Lewin 1969 was related to the genus *Flammeovirga*, and then Takahashi et al. (2006) reclassified it as *Flammeovirga arenaria*, with the proposal of a third species, *Flammeovirga yaeyamensis* isolated from the Yaeyama Islands, Japan. These three species are clearly differentiated from each other by DNA–DNA hybridizations and phenotypic characteristics (Table 114).

Differentiation of the species of the genus *Flammeovirga*

Table 114 lists characteristics that distinguish the *Flammeovirga* species from one another.

List of species of the genus *Flammeovirga*[‡]

1. ***Flammeovirga aprica*** (Reichenbach 1989b) Nakagawa, Hamana, Sakane and Yamasato 1997, 221^{VP} emend. Takahashi, Suzuki and Nakagawa 2006, 2099^{VP} [*Cytophaga aprica* (ex Lewin 1969) Reichenbach 1989c, 495^{VP}; *Cytophaga diffluens* var. *aprica* Lewin 1969, 197]

a'pri.ca. L. fem. adj. *aprica* sunlit, sun-loving.

The characteristics are as described for the genus and as listed in Table 113, with the following additional features. Cells are 0.5–0.9 μm wide and 1.7–96 μm long or longer. The cell mass is orange to reddish orange. Growth occurs at 15–30°C; optimum, 25°C. The pH range for growth is 6–8; optimum, 7. Growth occurs in the presence of 1–5% NaCl; optimum, 3%. Oxidase- and catalase-positive. Urease-negative. Agar, alginic acid, carboxymethylcellulose, DNA, esculin and

starch are degraded, but not cellulose, chitin, gelatin, inulin, Tween 80, or tyrosine. Casein is weakly degraded. H₂S is produced. Indole-negative. The oxidation/fermentation test for catabolism of glucose is fermentative. Utilization (with the Biolog GN2 microplate system) is positive for cellobiose, α-cyclodextrin, dextrin, L-fucose, D-galactose, gentiobiose,

*SM2 consists of: monosodium glutamate monohydrate, 50 g; adonitol, 15 g; D(-)-sorbitol, 10 g; artificial seawater, 750 ml; and distilled water, 250 ml; pH 7.0.

†SM3 consists of: monosodium glutamate monohydrate, 50 g; adonitol, 15 g; D(-)-sorbitol, 10 g; L(-)-proline, 2 g; 2% methyl cellulose [4000 centipoise (cps)] solution, 100 ml; artificial seawater, 900 ml; pH 7.0.

‡*Flammeovirga kakegawaensis* was published after completion of the manuscript. Refer to Hosoya S. and A. Yokota. 2007. *Flammeovirga kamogawaensis* sp. nov., isolated from coastal seawater in Japan. Int. J. Syst. Evol. Microbiol. 57: 1327–1330.

^bData from Takahashi et al. (2006).

α -D-glucose, glucose 1-phosphate, glucose 6-phosphate, glycogen, glycyl-L-glutamic acid, DL-lactic acid, α -D-lactose, lactulose, maltose, D-mannose, monomethyl succinate, and D-trehalose, but negative for N-acetyl-D-glucosamine, L-alanyl glycine, D-melibiose, L-ornithine, L-rhamnose, L-threonine, and urocanic acid. Acid production (API 50CH system) is positive for N-acetylglucosamine, amygdalin, cellobiose, esculin, galactose, gentiobiose, glycogen, lactose, maltose, salicin, starch, and D-xylose, and weakly positive for glucose, L-fucose, mannose, and ribose, but negative for arbutin, mannitol, melibiose, melezitose, methyl α -D-glucoside, raffinose, rhamnose, sorbitol, and xylitol. The major cellular fatty acids are C_{15:0} iso, C_{20:4} ω 6, 9, 12, 15c, C_{16:0} 3-OH, and C_{14:0}.

DNA G+C content (mol%): 34.2 (HPLC).

Type strain: JL-4, ATCC 23126, CIP 104807, IFO (now NBRC) 15941, JCM 21138, NCIMB 13348, NRRL B-14729.

Sequence accession no. (16S rRNA gene): AB247553.

2. **Flammeovirga arenaria** (ex Lewin 1969) Takahashi, Suzuki and Nakagawa 2006, 2099^{VP} (*Microscilla arenaria* Lewin 1969, 197)

a.re.na'ria. L. fem. adj. *arenaria* of or pertaining to sand, (referring to the source of the organism).

The characteristics are as described for the genus and as listed in Table 113, with the following additional features. Cells are 0.5–0.9 μ m wide and 2.0–40 μ m long or longer. The cell mass is orange. Temperature range for growth, 10–30°C; optimum, 25°C. The pH range for growth, 6–8; optimum, 7. Growth occurs at 1–5% NaCl; optimum, 3%. Oxidase, catalase, and urease activities are negative. Agar, alginic acid, esculin, and starch are hydrolyzed, but not carboxymethylcellulose, cellulose, chitin, DNA, inulin, gelatin, Tween 80, or tyrosine. Casein is weakly degraded. H₂S is produced. Indole-negative. The O-F test of glucose catabolism is oxidative.

Utilization (with the Biolog GN2 microplate system) is positive for N-acetyl-D-glucosamine, cellobiose, α -cyclodextrin, dextrin, L-fucose, D-galactose, gentiobiose, α -D-glucose, glucose-1-phosphate, glucose 6-phosphate, L-glutamic acid, glycogen, glycyl-L-aspartic acid, glycyl-L-glutamic acid, α -D-lactose, lactulose, maltose, D-mannose, and D-melibiose, and weakly positive for alaninamide, L-alanine, L-alanyl glycine, L-aspartic acid, DL-lactic acid, L-ornithine, and L-threonine, but negative for monomethyl succinate, L-rhamnose, and urocanic acid. Acid production (API 50CH system) is positive for N-acetylglucosamine, amygdalin, arbutin, cellobiose, esculin, L-fucose, galactose, gentiobiose, glucose, glycogen,

lactose, maltose, mannose, melibiose, starch, and trehalose, and weakly positive for fructose, 5-ketogluconate, mannitol, methyl α -D-glucoside, methyl- α -D-mannoside, melezitose, raffinose, ribose, salicin, sorbitol, sucrose, and xylitol, but negative for rhamnose and D-xylose. The major cellular fatty acids are C_{15:0} iso, C_{14:0}, C_{16:0} 3-OH, C_{20:4} ω 6, 9, 12, 15c, C_{16:1} ω 5c, and C_{15:0} iso 3-OH.

DNA G+C content (mol%): 31.8 (HPLC).

Type strain: HJ-1, CIP 109101, JCM 21777, LMG 18922, NBRC 15982, NCIMB 1413.

Sequence accession no. (16S rRNA gene): AB078078.

3. **Flammeovirga yaeyamensis** Takahashi, Suzuki and Nakagawa 2006, 2099^{VP}

ya.e.ya.men'sis. N.L. fem. adj. *yaeyamensis* of or belonging to the Yaeyama Islands, from where the organisms were isolated.

The characteristics are as described for the genus and as listed in Table 113, with the following additional features. Cells are 0.4–0.9 μ m wide and 1.7–90 μ m long or longer. The cell mass is orange. Temperature range for growth, 15–35°C; optimum, 30°C. The pH range for growth is 6–10; optimum, 7. Growth occurs at 1–5% NaCl; optimum, 3%. Oxidase activity is positive. Catalase activity differs among strains. Urease-negative. Agar, alginic acid, carboxymethylcellulose, DNA, esculin, inulin, gelatin, starch and Tween 80 are degraded, but not casein, cellulose, chitin, or tyrosine. H₂S is produced. Indole-negative. The O-F test of glucose catabolism is fermentative. Utilization (with the Biolog GN2 microplate system) is positive for N-acetyl-D-glucosamine, cellobiose, D-galactose, gentiobiose, glycyl-L-glutamic acid, D-melibiose, L-rhamnose, and urocanic acid, and weakly positive for L-alanyl glycine, α -D-glucose, maltose, L-ornithine, and L-threonine, but negative for glucose 1-phosphate, glucose 6-phosphate, and monomethyl succinate. Acid production (API 50CH system) is positive for N-acetylglucosamine, amygdalin, arbutin, cellobiose, esculin, galactose, gentiobiose, glucose, glycogen, lactose, maltose, mannose, melibiose, rhamnose, salicin, starch, and D-xylose, and positive or weakly positive for L-fucose, methyl α -D-glucoside, raffinose, and xylitol, but negative for mannitol, melezitose, ribose, and sorbitol. The major cellular fatty acids are C_{15:0} iso, C_{20:4} ω 6, 9, 12, 15c, C_{16:0} 3-OH, C_{15:0} iso 3-OH, C_{16:0}, and C_{14:0}.

DNA G+C content (mol%): 33.4–35.7 (HPLC).

Type strain: IR25-3, CIP 109099, NBRC 100898.

Sequence accession no. (16S rRNA gene): AB247554.

Genus II. **Fabibacter** Lau, Tsoi, Li, Plakhotnikova, Dobretsov, Wu, Wong, Pawlik and Qian 2006, 1062^{VP}

THE EDITORIAL BOARD

Fa.bi.bac'ter. L. fem. n. *faba* bean; N.L. masc. n. *bacter* rod; N.L. masc. n. *Fabibacter* bean(-like) rod.

Curved rods 0.5 \times 1.5 μ m. Gram-stain-negative. Strictly aerobic. **Gliding motility is present.** Chemo-organotrophic. Colonies on marine agar are pink. The major respiratory quinone is MK-7. **Flexirubin-type pigments are not produced. Acid is produced from carbohydrates.** Oxidase- and catalase-positive. **Tween 80**

is hydrolyzed but not gelatin. NaCl is not required for growth. Isolated from the marine sponge *Tedania ignis*.

DNA G+C content (mol%): 42.5.

Type species: **Fabibacter halotolerans** Lau, Tsoi, Li, Plakhotnikova, Dobretsov, Wu, Wong, Pawlik and Qian 2006, 1062^{VP}.

Enrichment and isolation procedures

Fabibacter halotolerans was isolated on marine agar* from the marine sponge *Tedania ignis* in the Bahamas. The strains appeared as pink-pigmented after 48 h of cultivation at 30°C on marine agar.

Differentiation of the genus *Fabibacter* from other genera

Unlike *Roseivirga echinomitans* and *Roseivirga ehrenbergii*, *Fabibacter halotolerans* exhibits a different cell shape (curved rod vs straight rod), gliding motility, no requirement for NaCl for growth, a higher range of tolerance to NaCl (0–12% vs 1–8%), an ability to hydrolyze Tween 80 but not gelatin, the production of acid from carbohydrates, a narrower temperature range for growth (12–36°C vs 4.0–39°C), and a slightly higher mol% G+C value for its DNA (42.5 vs 40.2–41.3). Moreover, the fatty acid profile of *Fabibacter halotolerans* differs from those described for the members of *Roseivirga* mainly by having larger quantities of C_{15:0} iso 3-OH, C_{16:0} iso 3-OH, and summed feature 3 (SF3) and by the additional presence of C_{14:0} iso 3-OH, C_{15:0} 2-OH, and C_{15:0} 3-OH (Lau et al., 2006).

List of species of the genus *Fabibacter*

1. *Fabibacter halotolerans* Lau, Tsoi, Li, Plakhotnikova, Dobretsov, Wu, Wong, Pawlik and Qian 2006, 1062^{VP}

ha.lo.to'le.rans. Gr. masc. n. *hals*, *halos* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating.

The description is as given for the genus, with the following additional features. All the characteristics described below are based on cultures grown on marine agar at 30°C for 48 h. Colonies are pink, circular, 2.0–4.0 mm in diameter, convex with a smooth surface and an entire margin. No diffusible pigment is formed. Growth occurs between 12 and 36°C (optimum, 28–30°C) and between pH 5.0 and 10.0. Sodium ions are not required for growth. The organisms tolerate up to 12% NaCl. Predominant fatty acids (>5%) are C_{15:0} iso, C_{15:1}, C_{15:0} iso 3-OH, C_{16:0} iso 3-OH, C_{17:0} iso 3-OH, and SF 3 (comprising C_{15:0} iso 2-OH and/or 16:1 ω7c). These fatty acids represent 80.7% of the total. Produces acetoin, but not indole or H₂S. Nitrate is not reduced. DNA and Tweens 20, 40, and 80 are hydrolyzed, but not agar, casein, carboxymethylcellulose, chitin, or gelatin. Starch is weakly hydrolyzed. The following enzyme activities are present: N-Acetyl-β-glucosaminidase, acid phosphatase, alkaline phosphatase, arginine dihydrolase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, α-chymotrypsin, cystine arylamidase, leucine arylamidase, valine arylamidase, esterase (C4), esterase lipase (C8), lipase (C14), α-mannosidase, trypsin, and naphthol-AS-BI-phosphohydrolase. No

Lau et al. (2006) indicated that *Fabibacter* was also closely related to the *Marinicola seohaensis*; however, *Marinicola seohaensis* has been formally reclassified to the genus *Roseivirga* as *Roseivirga seohaensis* (Lau et al., 2006). *Fabibacter halotolerans* differs from *Roseivirga seohaensis* by having a different cell shape (curved rod vs straight rod), orange colonies, lack of flexirubin pigments, a slightly higher mol% G+C value for its DNA (42.5 vs 40.3), no requirement for NaCl for growth, a higher range of tolerance to NaCl (0–12% vs 2–8%), the production of acid from carbohydrates, and by exhibiting activities for arginine dihydrolase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, and α-mannosidase.

Taxonomic comments

Lau et al. (2006) found that the type strain of *Fabibacter* was most closely related to the members of the genera *Marinicola* (see above) and *Roseivirga*, with 93.1–93.3% 16S rRNA gene sequence similarity.

activities are exhibited for α-fucosidase, β-glucuronidase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, or urease. Growth occurs on the following sole carbon sources (API 20E, 20NE and 50CH systems): D-cellobiose, D-lactose, D-maltose, and starch. Acid is produced from the following sole carbon sources in the API 20E and 50CH systems: amygdalin, arbutin, D-cellobiose, esculin ferric citrate, D-galactose, D-glucose, gentiobiose, maltose, methyl α-D-glucopyranoside, D-raffinose, salicin, sucrose, starch, and D-trehalose. The following carbon sources are utilized (MicroLog 3 system): L-alaninamide, L-alanine, L-alanyl-glycine, L-aspartic acid, D-cellobiose, dextrin, D-galacturonic acid, gentiobiose, α-D-glucose, D-glucose 6-phosphate, L-glutamic acid, glycogen, glycyl-L-aspartic acid, glycyl-L-glutamic acid, α-ketobutyric acid, α-ketoglutaric acid, α-ketovaleric acid, DL-lactic acid, α-D-lactose, lactulose, maltose, D-melibiose, methyl-β-D-glucoside, L-ornithine, L-proline, L-pyroglytamic acid, D-raffinose, succinamic acid, sucrose, D-trehalose, turanose, and L-threonine. In disc-diffusion tests, susceptibility is shown toward to ampicillin (1 μg), chloramphenicol (1 μg), penicillin (1 μg), streptomycin (0.1 μg), and tetracycline (5 μg), but not to kanamycin (tested up to 100 μg).

Source: marine sponge *Tedania ignis* in the Bahamas.

DNA G+C content (mol%): 42.5±0.3 (HPLC).

Type strain: UST030701-097, JCM 13334, NRRL B-41220.

Sequence accession no. (16S rRNA gene): DQ080995.

Genus III. *Flexithrix* Lewin 1970, 513^{VP} emend. Hosoya and Yokota 2007b, 1087^{VP} emend.

YASUYOSHI NAKAGAWA

Flex'i.thrix. L. part. adj. *flexus* flexible; Gr. fem. n. *thrix* hair; N.L. fem. n. *Flexithrix* flexible hair (flexible rod).

Rods 0.4–0.9 μm wide and 1.5–70 μm long or longer. **Motile by gliding**. Nonsporeforming. Sheath is present or not. Gram-stain-negative. **Aerobic**. Chemo-organotrophic. **The cell mass**

is golden yellow to yellow. Zeaxanthin is present as the major carotenoid pigment. **Flexirubin-type pigments are absent**. Oxidase- and catalase-positive. Urease activity is negative or weakly positive. **Marine organisms. Seawater is required for growth; NaCl alone can substitute**. The optimum pH for growth is 7. Nitrate is not reduced. H₂S and indole are not produced. Esculin, gelatin, starch, and Tween 80 are degraded. The major

*Marine agar medium (Lau et al., 2006) composed of (g/l of filter-sterilized seawater): peptone (Oxoid), 5.0; and yeast extract (Oxoid), 3.0.

respiratory quinone is MK-7. Predominant cellular fatty acids are C_{15:0} iso and C_{16:1} ω5c.

DNA G+C content (mol%): 35–37.

Type species: *Flexithrix dorotheae* Lewin 1970, 511^{AL} emend. Hosoya and Yokota 2007b, 1087^{VP} emend.

Further descriptive information

All strains are negative for utilization of Biolog GN2 Microplate system substrates including *cis*-aconitic acid, adonitol, γ -amino butyric acid, 2-amino ethanol, D-arabitol, bromosuccinic acid, 2,3-butanediol, DL-carnitine, citric acid, i-erythritol, formic acid, D-galactonic acid lactone, D-glucosaminic acid, glucose-6-phosphate, glycerol, DL- α -glycerol phosphate, L-histidine, α -hydroxybutyric acid, β -hydroxybutyric acid, γ -hydroxybutyric acid, *p*-hydroxy phenylacetic acid, hydroxy L-proline, inosine, *m*-inositol, itaconic acid, α -ketobutyric acid, α -ketoglutaric acid, α -ketovaleric acid, L-leucine, malonic acid, methylpyruvate, L-phenylalanine, phenyl ethylamine, propionic acid, putrescine, L-pyroglytamic acid, quinic acid, D-saccharic acid, sebacinic acid, D-serine, D-sorbitol, succinamic acid, thymidine, Tween 40, Tween 80, uridine, urocanic acid, and xylitol.

All strains are negative for acid production from API 50CH system substrates including adonitol, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, gluconate, glycerol, glycogen, inositol, 2-keto-gluconate, 5-keto-gluconate, mannitol, β -methyl-D-xyloside, sorbitol, sorbose, D-tagatose, xylitol, and L-xylose. All strains are negative for API ZYM system substrates including β -glucosidase and β -glucuronidase. All strains are sensitive to ampicillin, benzylpenicillin, chloramphenicol, erythromycin, nalidixic acid, nitrofurantoin, novobiocin, and oleandomycin, but resistant to bacitracin, carbenicillin, colistin sulfate, gentamicin, kanamycin, neomycin, polymyxin B, streptomycin, and tetracycline.

Enrichment and isolation procedures

No special enrichment media have been designed for isolation of *Flexithrix* strains. Standard procedures to isolate marine bacteria can be applied. Colonies of *Flexithrix* are usually yellow and spread on agar media. *Flexithrix* strains have been isolated from marine environments at widely separated sites (Lewin, 1969, 1970; Lewin and Lounsbury, 1969). The type strain of *Flexithrix dorotheae* came from Ernakulum, India.

Maintenance procedures

Cultures of *Flexithrix* strains can be preserved by freezing at lower than -80°C . For freezing, cells are suspended in Marine

broth 2216 (Difco) containing 10% glycerol or 7% DMSO. *Flexithrix* strains are rather sensitive to drying; however, they can be preserved by the liquid drying method using a protective medium such as SM2 or SM3 (see the chapter on *Flammeovirga* for the formulations), or by freeze drying.

Differentiation of the genus *Flexithrix* from other genera

Characteristics differentiating the genus *Flexithrix* from other mesophilic genera in the family *Flammeovirgaceae* are listed in Table 113 in the chapter on *Flammeovirga*. The presence of C_{15:0} iso and C_{16:1} ω5c as major fatty acids and zeaxanthin as a major carotenoid are useful characters to discriminate the genus *Flammeovirga* from other genera.

Taxonomic comments

The genus *Flexithrix* was created by Lewin (1970) to accommodate a sheathed gliding bacteria strain QQ-3 (NBRC 15987^T) isolated from brown silt from the coast of Kerala, India. Until the 1st edition of *Bergey's Manual of Systematic Bacteriology*, the genus contained a single strain belonging to a single species *Flexithrix dorotheae*; however, Reichenbach (1989d) mentioned that the genus *Flexithrix* closely resembles *Flexibacter aggregans* ("*Microscilla aggregans*") when it lacks sheathed filaments. Nakagawa et al. (2002) reported that three strains belonging to *Flexibacter aggregans* (NBRC 15973, NBRC 15976^T, and NBRC 15990) were closely related to the genus *Flexithrix* by 16S rRNA gene sequence analysis. Hosoya and Yokota (2007b) proposed reclassification of *Flexibacter aggregans* as *Flexithrix dorotheae* and emended the description of the genus *Flexithrix* and the species *Flexithrix dorotheae*. However, the emended descriptions did not cover characteristics of all *Flexithrix* strains, because they were based only on type strains (NBRC 15976^T and NBRC 15987^T). We have investigated all four strains belonging to the genus *Flexithrix*, phenotypically, chemotaxonomically, and genotypically (unpublished). The type strain of *Flexithrix dorotheae* exhibits more than 70% DNA–DNA relatedness with the three strains of *Flexibacter aggregans*, and they also share many not previously known phenotypic and chemotaxonomic characteristics. Those characteristics are described in this chapter. In addition, we found that presence of zeaxanthin (the major carotenoid) can be used to differentiate the genus *Flexithrix* from other mesophilic genera of *Flammeovirgaceae*. Therefore, we propose the emendation of the genus *Flexithrix* and the species *Flexithrix dorotheae* as indicated in this chapter.

List of species of the genus *Flexithrix*

1. *Flexithrix dorotheae* Lewin 1970, 511^{AL} emend. Hosoya and Yokota 2007b, 1087^{VP} emend. (*Microscilla aggregans* Lewin 1969, 197; *Flexibacter aggregans* (Lewin 1969) Leadbetter 1974, 106^{AL})

do.ro.the'ae. N.L. gen. fem. n. *dorotheae* of Dorothy; named after a deceased technical assistant, Dorothy White.

The characteristics are as described for the genus, with the following additional features. Cells are 0.4–0.9 μm wide and 1.5–70 μm long or longer. The cell mass is golden yellow to yellow. Growth occurs at 10–40 $^{\circ}\text{C}$; optimum, 25–30 $^{\circ}\text{C}$. The pH range for growth is 6–11; optimum, 7. Growth occurs in the presence of 1–5% NaCl; optimum, 3%. Some strains can grow

in the presence of 7% NaCl. Oxidase- and catalase-positive. Esculin, gelatin, starch, and Tween 80 are degraded, but not agar, cellulose, chitin, inulin, and yeast cells. Alginate is strongly or weakly degraded. Sole nitrogen sources include ammonium sulfate, Casamino acids, peptone, sodium glutamate, and sodium nitrate. Utilization (with the Biolog GN2 microplate system) is positive for *N*-acetyl-D-galactosamine, alaninamide, L-alanyl-glycine, dextrin, D-fructose, L-fucose, D-galactose, DL-lactic acid, D-melibiose, β -methyl D-glucoside, D-raffinose, L-rhamnose, D-trehalose, and turanose, and positive or weakly positive for acetic acid, *N*-acetyl-D-glucosamine, L-alanine, L-arabinose, L-asparagine, L-aspartic acid, gentiobiose,

α -D-glucose, glucuronamide, D-glucuronic acid, L-glutamic acid, glycyl-L-aspartic acid, glycyl-L-glutamic acid, α -D-lactose, lactulose, maltose, L-ornithine, D-psicose, L-serine, sucrose, and L-threonine. Acid production (API 50CH system) is positive for cellobiose, esculin, fructose, galactose, lactose, maltose, melibiose, salicin, sucrose, trehalose, and D-turanose, and positive or weakly positive for *N*-acetylglucosamine, amygdalin, L-arabinose, arbutin, glucose, inulin, D-xylose, mannose, melezitose, α -methyl-D-glucoside, α -methyl-D-mannoside,

raffinose, and D-xylose. Enzyme production (API ZYM system) is positive for *N*-acetyl- β -glucosaminidase, acid phosphatase, alkaline phosphatase, β -galactosidase, leucine allyl amidase, and valine allyl amidase. The major cellular fatty acids are C_{15:0} iso, C_{16:1} ω 5c, and C_{16:0}.

DNA G+C content (mol %): 35.9–36.1 (HPLC).

Type strain: QQ-3, ATCC 23163, DSM 6795, NBRC 15987, NBRC 102100, NCIMB 1390.

Sequence accession no. (16S rRNA gene): AB078077.

Genus IV. *Persicobacter* Nakagawa, Hamana, Sakane and Yamasato 1997, 221^{VP}

YASUYOSHI NAKAGAWA

Per.si.co.bac'ter. Gr. neut. n. *persikon* peach; N.L. masc. n. *bacter* rod; N.L. masc. n. *Persicobacter* peach rod, because the organism is a peach-colored rod.

Slender rods 0.4–0.6 μ m wide and 0.9–30 μ m long or longer. **Motile by gliding.** Nonsporeforming. Gram-stain-negative. **Facultatively anaerobic.** Chemo-organotrophic. **Colonies spread and produce large gelase fields and deep craters in agar plates.** The cell mass is pink to orange. Saproxanthin is present as the major carotenoid pigment. **Flexirubin-type pigments are absent.** Oxidase- and urease-negative. Strongly or weakly catalase-positive. **Marine organisms. Seawater is required for growth; NaCl alone can substitute.** The optimum pH for growth is 7. Nitrate is reduced. H₂S and indole are not produced. Agar, alginic acid, esculin, and gelatin are degraded. Starch is weakly degraded. The major respiratory quinone is MK-7. Predominant cellular fatty acids are C_{15:0} iso and C_{17:0} iso 3-OH.

DNA G+C content (mol %): 42–44.

Type species: *Persicobacter diffluens* (Reichenbach 1989b) Nakagawa, Hamana, Sakane, Yamasato 1997, 222^{VP} [*Cytophaga diffluens* (ex Stanier 1940) Reichenbach 1989c, 495^{VP}; *Cytophaga diffluens* Stanier 1940, 623 emend. mut. char. Lewin 1969, 197].

Further descriptive information

All species are negative for acid production from API 50CH system substrates including adonitol, L-arabinose, D-arabitol, L-arabitol, dulcitol, erythritol, D-fucose, L-fucose, gluconate, glycerol, inositol, inulin, 2-ketogluconate, 5-ketoglucomate, mannitol, melezitose, β -methyl-D-xyloside, raffinose, ribose, sorbitol, D-tagatose, D-turanose, and L-xylose. All species are negative for the utilization of Biolog GN2 Microplate system substrates including *N*-acetyl-D-galactosamine, *cis*-aconitic acid, adonitol, D-alanine, γ -amino butyric acid, 2-amino ethanol, L-arabinose, D-arabitol, bromosuccinic acid, 2,3-butanediol, DL-carnitine, citric acid, i-erythritol, formic acid, D-galactonic acid lactone, D-gluconic acid, glucuronamide, glycerol, DL- α -glycerol phosphate, L-histidine, α -hydroxybutyric acid, β -hydroxybutyric acid, γ -hydroxybutyric acid, *p*-hydroxy phenylacetic acid, hydroxy-L-proline, inosine, *m*-inositol, itaconic acid, α -ketoglutaric acid, malonic acid, D-mannitol, mono-methyl succinate, L-phenylalanine, phenyl ethylamine, propionic acid, D-psicose, putrescine, L-pyroglutamic acid, quinic acid, D-saccharic acid, sebacic acid, D-serine, D-sorbitol, succinamic acid, succinic acid, Tween 80, uridine, and xylitol. All species are sensitive to chloramphenicol, lincomycin, nitrofurantoin, novobiocin, oleandomycin,

and tetracycline, but resistant to colistin sulfate, gentamicin, kanamycin, polymyxin B, and streptomycin.

Enrichment and isolation procedures

No enrichment media have been designed for isolation of *Persicobacter* strains. Standard procedures to isolate marine bacteria can be applied. Colonies of *Persicobacter* are usually orange to pink, degrade agar, and spread rapidly.

Persicobacter strains have been isolated from marine environments at widely separated sites (Lewin, 1969; Lewin and Lounsbury, 1969; Nakagawa, 2004). The type strain of *Persicobacter diffluens* came from Bombay, India. The type strain of "*Persicobacter psychrovividus*" was isolated from a clam, *Ruditapes philippinarum*, collected off a seacoast in Chiba, Japan.

Maintenance procedures

Cultures of *Persicobacter* strains can be preserved by freezing at lower than -80°C . For freezing, cells are suspended in Marine broth 2216 (Difco) containing 10% glycerol or 7% DMSO. *Persicobacter* strains are rather sensitive to drying; however, they can be preserved by a liquid drying method using a protective medium SM2 or SM3 (see the chapter on *Flammeovirga* for formulations), or by freeze drying.

Differentiation of the genus *Persicobacter* from other genera

Characteristics differentiating the genus *Persicobacter* from other mesophilic genera in the family *Flammeovirgaceae* are listed in Table 115 in the chapter on *Flammeovirga*. The presence of C_{15:0} iso and C_{17:0} iso 3-OH as major fatty acids and saproxanthin as the major carotenoid are useful characters to discriminate the genus *Persicobacter* from other genera.

Taxonomic comments

The genus *Persicobacter* was created by Nakagawa et al. (1997) to accommodate the misclassified species *Cytophaga diffluens*. Until now, the genus contained a single species, *Persicobacter diffluens*. However, we isolated a new *Persicobacter* strain Asr22-19 from the gut of the clam (*Ruditapes philippinarum*) (Muramatsu et al., in press). This strain could grow both aerobically and anaerobically. Strain Asr22-19 with two other strains, NBRC 101035

TABLE 115. Characteristics differentiating the species of the genus *Persicobacter*^{a,b}

Characteristic	<i>P. diffluens</i>	<i>"P. psychrovividus"</i>
Growth at 5–10°C	–	+

^bData from Takahashi et al. (unpublished).

and NBRC 101041, constituted a single independent species in the genus *Persicobacter* by DNA–DNA hybridization. In addition, those three strains could be phenotypically differentiated from *Persicobacter diffluens* (Table 115). The genus *Persicobacter* was originally described as oxidase-positive, catalase-negative, and aerobic. However, we found that both species produce catalase but not oxidase. Thus, we conclude that the three strains [Asr22-19 (NBRC 101262), NBRC 101035, and NBRC 101041] should be assigned to a new species of the genus *Persicobacter* for which the name *Persicobacter psychrovividus* sp. nov. is proposed.

Differentiation of the species of the genus *Persicobacter*

Table 115 lists characteristics that distinguish the *Persicobacter* species from one another.

List of species of the genus *Persicobacter*

- Persicobacter diffluens*** (Reichenbach 1989b) Nakagawa, Hamana, Sakane and Yamasato 1997, 222^{VP} [*Cytophaga diffluens* (ex Stanier 1940) Reichenbach 1989c, 495^{VP}; *Cytophaga diffluens* Stanier 1940, 623 emend. mut. char. Lewin 1969, 197] difflu.ens. L. part. adj. *diffluens* flowing away.

The characteristics are as described for the genus and as listed in Table 115, with the following additional features. Cells are 0.4–0.5 µm wide and 0.9–3.0 µm long or longer. The cell mass is pink to orange. Growth occurs at 15–40°C; optimum, 30–35°C. The pH range for growth is 6–11; optimum, 7. Growth occurs in the presence of 1–5% NaCl; optimum, 3%. Some strains can grow at 45°C, pH 3, or 7% NaCl. Oxidase-negative. Catalase-positive. Agar, alginate, carboxymethyl cellulose, DNA, esculin, gelatin, and yeast cells are degraded, but not cellulose and tyrosine. Starch and chitin are weakly degraded. Utilization (with the Biolog GN2

microplate system) is positive for L-alanine, L-asparagine, cellobiose, α-cyclodextrin, dextrin, D-galactose, α-D-glucose, glycogen, glycyL-L-aspartic acid, glycyL-L-glutamic acid, DL-lactic acid, α-D-lactose, maltose, D-mannose, L-threonine, and D-trehalose, positive or weakly positive for alaninamide, D-fructose, L-fucose, gentiobiose, glucose 1-phosphate, lactulose, and L-rhamnose, but negative for N-acetyl-D-glucosamine, L-aspartic acid, and L-glutamic acid. Acid production (API 50CH system) is positive for N-acetyl glucosamine, amygdalin, arbutin, cellobiose, esculin, galactose, gentiobiose, glucose, glycogen, lactose, maltose, mannose, salicin, starch, and trehalose. The major cellular fatty acids are C_{15:0} iso, C_{17:0} iso 3-OH, C_{15:0} anteiso, and C_{16:0}.

DNA G+C content (mol%): 42.6–43.8 (HPLC).

Type strain: strain B-1 Lewin, ATCC 49458, DSM 3658, JCM 8513, LMG 13036, NBRC 15940, NCIMB 1402.

Sequence accession no. (16S rRNA gene): AB260929.

Other organisms

- "Persicobacter psychrovividus"*** Muramatsu, Takahashi, Kaneyasu, Iino, Suzuki and Nakagawa (in press) psychro'viv'idus. Gr. adj. *psychros* cold; L. adj. *vividus* full of life, vigorous, active; N.L. masc. adj. *psychrovividus* active at low temperatures.

Cells are 0.4–0.6 µm wide and 0.9–6 µm long or longer. The cell mass is orange. Growth occurs at 5–45°C; optimum, 25°C. Some strains can grow at 45°C. The pH range for growth is 3–11; optimum 7. Growth occurs in the presence of 1–7% NaCl; optimum 5%. Oxidase-negative. Catalase-positive or weakly catalase-positive. Agar, alginate, esculin, gelatin, chitin, and Tween 80 are degraded, but not cellulose, carboxymethyl cellulose, yeast cells, or tyrosine. Starch is degraded weakly. Utilization (with the Biolog GN2 microplate system) is positive for N-acetyl-D-glucosamine, L-asparagine, α-cyclodextrin,

dextrin, D-galactose, gentiobiose, α-D-glucose, L-glutamic acid, glycogen, glycyL-L-aspartic acid, glycyL-L-glutamic acid, DL-lactic acid, α-D-lactose, maltose, D-mannose, L-threonine, and D-trehalose, and positive or weakly positive for L-alanine, L-alanyl-glycine, L-aspartic acid, cellobiose, α-ketobutyric acid, and lactulose, but negative for L-fucose and glucose 1-phosphate. Acid production (API 50CH system) is positive for N-acetyl glucosamine, amygdalin, arbutin, cellobiose, esculin, galactose, gentiobiose, glucose, glycogen, lactose, maltose, mannose, rhamnose, salicin, starch, trehalose, and D-xylose. The major cellular fatty acids are C_{15:0} iso, C_{17:0} iso 3-OH, C_{15:0} iso 3-OH, C_{16:0} 3-OH, and C_{16:0}.

DNA G+C content (mol%): 42.0–42.7 (HPLC).

Type strain: Asr 22-19, CIP 109100, NBRC 101262.

Sequence accession no. (16S rRNA gene): AB260934.

Genus V. **Reichenbachiella** Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2587^{VP} (*Reichenbachia* Nedashkovskaya, Suzuki, Vysotskii and Mikhailov 2003, 82)

OLGA I. NEDASHKOVSKAYA AND MAKOTO SUZUKI

Rei.chen.bach.i.el'la. N.L. fem. dim. n. *Reichenbachiella* named after Hans Reichenbach, a German microbiologist who has made a great contribution to the taxonomy of bacteria belonging to the phylum *Bacteroidetes*.

Thin rods 0.5–0.7 × 5–15 µm. **Motile by gliding.** Produce non-diffusible, orange, flexirubin pigments. **Chemo-organotrophs. Strictly aerobic.** Oxidase-, catalase-, and alkaline phosphatase-positive. Agar, alginate, gelatin, casein, starch, urea, DNA, and Tween 20 are hydrolyzed, but casein, chitin, cellulose (CM-cellulose and filter paper), and Tweens 40, 60, and 80 are not hydrolyzed. **The major respiratory quinone is MK-7.** **Marine,** isolated from coastal habitats in temperate latitudes. Growth does not occur without seawater or sodium ions.

DNA G+C content (mol%): 44–45.

Type species: Reichenbachiella agariperforans (Nedashkovskaya, Suzuki, Vysotskii and Mikhailov 2003) Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2587^{VP} (*Reichenbachia agariperforans* Nedashkovskaya, Suzuki, Vysotskii and Mikhailov 2003, 83).

Further descriptive information

Affiliation of the genus *Reichenbachiella* with known families of the phylum *Bacteroidetes* is not yet clear. It has no near neighbors among members of the phylum, and its closest relatives are the type strains of [*Flexibacter*] *tractuosus* and *Pescobacter diffluens*, with similarities of 16S rRNA genes of 88.1 and 86.5%, respectively. DNA–DNA hybridization values between *Reichenbachiella* and other representatives of the phylum *Bacteroidetes* are less than 86.2%.

The main cellular fatty acids are straight-chain unsaturated and branched-chain saturated fatty C_{15:0} iso, C_{16:1} ω5c and summed feature 3 comprising C_{15:0} iso 2-OH and/or C_{16:1} ω7c.

On Marine agar 2216 (Difco), *Reichenbachiella agariperforans* forms regular, round, smooth, bright orange colonies that are sunken into the agar. They have entire edges and a diameter of 3–5 mm after 48 h at 28°C. *Reichenbachiella agariperforans* grows on media containing 0.5% of a peptone and 0.1–0.2% yeast extract (Difco), prepared with natural or artificial seawater or supplemented with 2–3% NaCl. Good growth is observed on Marine agar 2216. Growth occurs at 4–35°C (optimum, 25–28°C). Growth occurs with 1–6% NaCl. The pH range for growth is 5.5–10.0 (optimum, 7.5–8.5).

The single available strain of *Reichenbachiella agariperforans* is susceptible to carbenicillin, oleandomycin, lincomycin, and tetracycline and resistant to ampicillin, benzylpenicillin, streptomycin, gentamicin, neomycin, and polymyxin B.

Enrichment and isolation procedures

The organisms were isolated from seawater by direct plating on Marine agar. Natural or artificial seawater is suitable for their cultivation. Strain KMM 3525^T has been grown on media containing 0.5% of a peptone and 0.1–0.2% yeast extract (Difco). The organisms may remain viable on Marine agar or other rich medium based on natural or artificial seawater for 1 week. They have survived storage at –80°C for at least 5 years.

Differentiation of the genus *Reichenbachiella* from other genera

Reichenbachiella differs from its closest relative [*Flexibacter*] *tractuosus* ATCC 23168^T by its production of flexirubin type pigments and agarase, NaCl requirement for growth, and the lower G+C content of its DNA. The production of catalase and flexirubin type pigments clearly distinguishes *Reichenbachiella* from its nearest neighbor, *Pescobacter diffluens*.

Taxonomic comments

Previously, the genus *Reichenbachia* and the species *Reichenbachia agariperforans* were described to accommodate strain KMM 3525^T (Nedashkovskaya et al., 2003). However, the name *Reichenbachia* is illegitimate according to the International Code of Bacteriological Nomenclature because it is a later homonym of a plant genus, and also a later homonym of an insect genus. Therefore, replacement of the names *Reichenbachia* and *Reichenbachia agariperforans* with *Reichenbachiella* and *Reichenbachiella agariperforans*, respectively, was proposed by Nedashkovskaya et al. (2005c).

Nedashkovskaya et al. (2003) reported that strain KMM 3525^T did not utilize carbohydrates but could produce acid from several of them (Nedashkovskaya et al., 2005c).

List of species of the genus *Reichenbachiella*

1. ***Reichenbachiella agariperforans*** (Nedashkovskaya et al., 2003) Nedashkovskaya, Kim, Suzuki, Shevchenko, Lee, Lee, Park, Frolova, Oh, Bae, Park and Mikhailov 2005c, 2587^{VP} (*Reichenbachia agariperforans* Nedashkovskaya, Suzuki, Vysotskii and Mikhailov 2003, 83).

a.ga.ri.per.fo'rans. N.L. n. *agarum*, agar (algal polysaccharide); L. part. adj. *perforans* perforating (making holes); N.L. part. adj. *agariperforans*, making holes in agar, i.e., bacterium making deep hollows in agar.

Cells are 0.5–0.7 × 5–15 µm. Colonies are 3–5 mm in diameter, circular, sunken into agar, shiny, with entire edges and

orange-pigmented on solid media containing high nutrient levels. Growth occurs at 4–35°C, with an optimum of 25–28°C and with 1–6% NaCl. Agar, starch, alginate, gelatin, DNA, urea, and Tween 20 are hydrolyzed, but cellulose (CM-cellulose and filter paper), chitin, casein, and Tweens 40, 60, and 80 are not. Acid is formed from L-arabinose, D-cellobiose, L-fucose, D-glucose, arbutin, esculin, and N-acetylglucosamine, but not from D-galactose, D-lactose, D-maltose, D-melibiose, L-rhamnose, D-sucrose, DL-xylose, adonitol, dulcitol, inositol, or mannitol. Lactose, mannose, and mannitol are utilized, but citrate, fumarate, and malate are not. Leucine- and

valine-arylamidases, trypsin, naphthol-AS-BI-phosphohydrolase, α - and β -galactosidases, α - and β -glucosidases, *N*-acetyl- β -glucosaminidase, and alkaline and acid phosphatases are present, but not esterase (C4), esterase lipase (C8), lipase (C14), cystine arylamidase, α -chymotrypsin, β -glucuronidase, α -mannosidase, and α -fucosidase. Flexirubin pigments are produced. Nitrate is not reduced. H₂S and indole production are negative. The predominant fatty acids are C_{15:0} iso (28.6%),

C_{16:1} ω 5c (21.9%), and summed feature 3 (20.7%; comprising C_{15:0} iso 2-OH and/or C_{16:1} ω 7). The single available strain was isolated from seawater sample collected in the Amursky Bay, the Gulf of Peter the Great, the Sea of Japan.

Source: coastal marine environments.

DNA G+C content (mol%): 44.5 (*T_m*).

Type strain: JCM 11238, KMM 3525, NBRC 16625.

Sequence accession no. (16S rRNA gene): AB058919.

Genus VI. **Roseivirga** Nedashkovskaya, Kim, Lee, Lysenko, Shevchenko, Frolova, Mikhailov, Lee and Bae 2005a, 232^{VP}, emend. Nedashkovskaya, Kim, Lysenko, Park, Mikhailov, Bae and Park 2005b, 1800^{VP}

OLGA I. NEDASHKOVSKAYA AND SEUNG BUM KIM

Ro.se.i.vir'ga. L. adj. *roseus* pink-colored; L. fem. n. *virga* rod; N.L. fem. n. *Roseivirga* a pink-colored and rod-shaped marine bacterium.

Thin rods usually measuring 0.2–0.5 \times 2.0–4.0 μ m. **Gliding motility can be observed.** Produce nondiffusible pink-orange pigments. Flexirubin type of pigments can be formed. **Chemo-organotrophs. Strictly aerobic.** Can require seawater or sodium ions for growth. Oxidase-, catalase-, and alkaline phosphatase-positive. Arginine dihydrolase, lysine, and ornithine decarboxylases, and tryptophan deaminase are absent. Agar, casein, starch, urea, cellulose (CM-cellulose and filter paper), and chitin are not attacked, but gelatin, DNA, and Tweens may be decomposed. H₂S and indole are not produced. **The major respiratory quinone is MK-7. Marine**, from coastal habitats.

DNA G+C content (mol%): 40–45.

Type species: ***Roseivirga ehrenbergii*** Nedashkovskaya, Kim, Lee, Lysenko, Shevchenko, Frolova, Mikhailov, Lee and Bae 2005a, 233^{VP}.

Further descriptive information

Phylogenetic analysis based on 16S rRNA gene sequencing indicates that the genus *Roseivirga* forms a distinct lineage within the phylum *Bacteroidetes* and the class *Cytophagia* (Figure 6). The genus *Fabibacter* is the closest relative of the *Roseivirga* species, showing sequence similarities of 93.9–95%. The range of 16S rRNA gene sequence similarities between the *Roseivirga* species is 96–99.8%.

Dominant cellular fatty acids are straight-chain unsaturated and branched-chain unsaturated fatty acids C_{15:1} iso, C_{15:0} anteiso, C_{15:0} iso, C_{15:0} iso 3-OH, and C_{17:0} iso 3-OH.

On Marine agar 2216 (Difco), colonies are circular, glistening, convex, smooth, with entire edges, pink or pink-orange-pigmented, and 1–3 mm in diameter after 72 h at 25–30°C.

All isolated strains have been grown on media containing 0.5% of a peptone and 0.1–0.2% yeast extract (Difco), prepared with natural or artificial seawater or supplemented by 2–3% NaCl. Growth occurs at 4–40°C, with 1–8% NaCl and at pH 5.5–10.0. Optimal growth is observed at 21–30°C, with 2–3% NaCl and at pH 7.0–8.0. According to API ZYM testing, all studied strains of the genus *Roseivirga* produce esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, α -chymotrypsin, acid phosphatase, and naphthol-AS-BI-phosphohydrolase, but not β -glucuronidase, and α -fucosidase.

Strains of the genus *Roseivirga* are susceptible to carbenicillin, lincomycin, and oleandomycin, and resistant to benzylpenicillin,

gentamicin, kanamycin, neomycin, polymyxin B, streptomycin, and tetracycline. Sensitivity to ampicillin is variable.

The strains of the genus *Roseivirga* inhabit coastal marine environments. They were isolated from seaweeds, seawater, sponges, and echinoderms in the temperate latitudes.

Enrichment and isolation procedures

The roseivirgas were isolated by direct or standard dilution plating technique on marine agar (Difco). Natural or artificial seawater is suitable for cultivation of the representatives of some species. They can grow on Casamino acids, peptone, and tryptone as the sole carbon and nitrogen sources (Yoon et al., 2005). All isolated strains have been grown on media containing 0.5% peptone and 0.1–0.2% yeast extract (Difco). Strains remain viable on Marine agar (Difco) or other rich medium based on natural or artificial seawater for one or several weeks. They survive storage at –80°C for at least 5 years.

Differentiation of the genus *Roseivirga* from other genera

The genus *Roseivirga* and its closest relative, *Fabibacter halotolerans*, have many common traits (Lau et al., 2006; Nedashkovskaya et al., 2005a). However, *Roseivirga* strains can be differentiated from *Fabibacter halotolerans* by their inability to hydrolyze starch and by their distinctive fatty acid composition (Table 116).

Taxonomic comments

Since a description of the genus *Roseivirga* was published (Nedashkovskaya et al., 2005a), Yoon et al. (2005) have described a novel genus, *Marinicola*. We have found high levels of 16S rRNA gene similarity between *Marinicola seohaensis* SW-152^T and *Roseivirga ehrenbergii* KMM 6017^T and *Roseivirga echinicomitans* (99.8 and 99.1%, respectively) (Nedashkovskaya et al., 2005b). Consequently, we proposed placement of the genus *Marinicola* in the genus *Roseivirga*. This conclusion was supported by the results of genomic, chemotaxonomic, and phenotypic analyses, which revealed many common features between members of the genera *Marinicola* and *Roseivirga*. These data have been incorporated in the emended description of the genus *Roseivirga* (Nedashkovskaya et al., 2005b), and *Marinicola seohaensis* has been formally reclassified to the genus *Roseivirga* as *Roseivirga seohaensis* (Lau et al., 2006). Notably, DNA–DNA hybridization experiments were not conducted for genomic comparison

of the type strains of *Roseivirga seohaensis* SW-152^T and its nearest phylogenetic neighbors, *Roseivirga ehrenbergii* KMM 6017^T and *Roseivirga echinomitans* KMM 6058^T. Therefore, an additional study on the determination of a level of DNA–DNA reassociation between the above-mentioned *Roseivirga* strains is needed to clarify the species status of strain SW-152^T.

Differentiation of the species of the genus *Roseivirga*

Although species of the genus *Roseivirga* are very close phylogenetically to each other and have similar fatty acid compositions (Table 116) and phenotypic characteristics, they can be differentiated by a set of phenotypic traits (Table 117).

List of species of the genus *Roseivirga*

1. ***Roseivirga echinomitans*** Nedashkovskaya, Kim, Lysenko, Park, Mikhailov, Bae and Park 2005b, 1799^{VP}

e.chi.ni.co'mi.tans. L. n. *echinus* -i sea urchin; L. pres. part. *comitans* (from L. v. *comito*) accompanying; N.L. part. adj. *echinomitans* accompanying a sea urchin.

Cells are 0.3–0.5 μm wide and 2.1–3.2 μm long. On Marine agar, colonies are 2–3 mm in diameter, circular, shiny with entire edges, and pink-pigmented. The optimal temperature for growth is 21–23°C. Acid is not formed from L-arabinose, D-cellobiose, L-fucose, D-galactose, D-glucose, D-lactose, D-maltose, D-melibiose, L-raffinose, L-rhamnose, L-sorbose, D-sucrose, DL-xylose, N-acetylglucosamine, citrate, adonitol, dulcitol, glycerol, inositol, or mannitol. L-Arabinose, D-lactose, D-mannose, mannitol, inositol, malonate, gluconate, caprate, malate, and phenylacetate are not utilized.

Produces (API ZYM kit) cystine arylamidase and trypsin. Utilizes (Microlog GN2 [Biolog] system) i-erythritol, D-galactose, D-sorbitol, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyrroglutamic acid, and 2,3-butanediol but not α-cyclodextrin, dextrin, glycogen, Tween 80, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, adonitol, D-arabitol, cellobiose, D-fructose, L-fucose, gentiobiose, α-D-glucose, m-inositol, α-lactose, α-D-lactose lactulose, D-mannitol, D-melibiose, methyl β-D-glucoside, psicose, D-raffinose, L-rhamnose, sucrose, D-trehalose, turanose, xylitol, methylpyruvate, monomethyl succinate, acetic acid, *cis*-aconitic acid, citric acid, formic acid, D-galactonic acid, D-gluconic acid, D-glucosaminic acid, D-glucuronic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, itaconic acid, α-ketobutyric acid, α-ketoglutaric acid, DL-lactic acid, malonic acid, propionic acid, quinic

acid, D-saccharic acid, sebacic acid, succinic acid, bromosuccinic acid, succinamic acid, glucuronamide, alaninamide, D-alanine, L-alanyl glycine, L-asparagine, L-aspartic acid, glycyL L-aspartic acid, glycyL L-glutamic acid, L-histidine, hydroxy-L-proline, D-serine, L-serine, L-threonine, DL-carnitine, γ -aminobutyric acid, urocanic acid, uridine, phenylethylamine, putrescine, 2-aminoethanol, glucose 1-phosphate, and glucose 6-phosphate. Only one strain has been isolated.

Source: the sea urchin *Strongylocentrotus intermedius* in the Troitsa Bay, Sea of Japan.

DNA G+C content (mol%): 41.3 (T_m).

Type strain: KCTC 12370, KMM 6058, LMG 22587.

Sequence accession no. (16S rRNA gene): AY753206.

2. ***Roseivirga ehrenbergii*** Nedashkovskaya, Kim, Lee, Lysenko, Shevchenko, Frolova, Mikhailov, Lee and Bae 2005a, 233^{VP} eh.ren.ber'gi.i. N.L. gen. masc. n. *ehrenbergii* of Ehrenberg, named after the German biologist Christian Gottfried Ehrenberg (1795–1876) for his contribution to the development of microbiology.

Cells are 0.3–0.5 μ m wide and 2.1–3.2 μ m long. On Marine agar, colonies are 2–4 mm in diameter, circular, shiny with entire edges and pink-pigmented. Optimal growth occurs at 23–25°C. No acid is formed from L-arabinose, D-cellobiose, L-fucose, D-galactose, D-glucose, D-lactose, D-maltose, D-melibiose, L-raffinose, D-sucrose, L-rhamnose, DL-xylose,

adonitol, dulcitol, glycerol, inositol, mannitol, or sorbitol. The following substrates are not utilized: D-lactose, D-mannose, D-sucrose, mannitol, inositol, sorbitol, malonate, gluconate, caprate, malate, or phenylacetate. Utilizes (Microlog GN2 [Biolog] system) glycogen, L-arabinose, methyl pyruvate, α -ketoglutaric acid, glucuronamide, alaninamide, L-alanyl-glycine, L-asparagine, L-aspartic acid, glycyl-L-aspartic acid, L-histidine, L-ornithine, L-proline, L-serine, L-threonine, and putrescine. API ZYM galleries indicate the presence of cystine arylamidase and trypsin.

Source: the green alga *Ulva fenestrata* collected in the Pallada Bay of the Gulf Peter the Great of the Sea of Japan.

DNA G+C content (mol%): 40.2 (T_m).

Type strain: JCM 13514, KCTC 12282, KMM 6017, LMG 22567.

Sequence accession no. (16S rRNA gene): AY608410.

3. **Roseivirga seohaensis** Lau, Tsoi, Li, Plakhotnikova, Dobretsov, Wu, Wong, Pawlik and Qian 2006, 1064^{VP} (*Marinicola seohaensis* Yoon, Kang, Lee and Oh 2005, 862^{VP})

seoha.en'sis. N.L. fem. adj. *seohaensis* of Seohae, the Korean name for the Yellow Sea in Korea, from where the organism was isolated.

Cells are 0.2–0.3 μm wide and 2.0–4.0 μm long and move by gliding. On marine agar, colonies are 1–2 mm in diameter, circular, shiny with entire edges, and pink-orange in color. Optimal growth is observed at 30°C and with 2–3% NaCl. Tween 60 is hydrolyzed but not hypoxanthine, xanthine, or L-tyrosine. No acid is formed from L-arabinose, D-cellobiose, D-fructose, L-fucose, D-galactose, D-glucose, D-lactose, D-maltose, D-mannose, D-melibiose, D-melezitose, D-raffinose, L-rhamnose, D-ribose, D-sucrose, D-trehalose, D-xylose, N-acetylglucosamine, adonitol, D-sorbitol, *myo*-inositol, or D-mannitol. The following substrates are not utilized: L-arabinose, D-lactose, D-mannose, D-sucrose, D-ribose, inositol,

mannitol, sorbitol, DL-aspartate, L-leucine, or L-proline. Cystine arylamidase and trypsin are not produced. Susceptible to chloramphenicol, doxycycline, and erythromycin. Polar lipids are phosphatidylethanolamine, diphosphatidylglycerol, an unidentified glycolipid, an unidentified phospholipid, and a ninhydrin-positive lipid.

Source: seawater of the Yellow Sea, Korea.

DNA G+C content (mol%): 40.3 (HPLC).

Type strain: SW-152, KCTC 12312, JCM 12600.

Sequence accession no. (16S rRNA gene): AY739663.

4. **Roseivirga spongicola** Lau, Tsoi, Li, Plakhotnikova, Dobretsov, Wu, Wong, Pawlik and Qian 2006, 1063^{VP}

spon.gi'co.la. L. n. *spongos-i* sponge; L. masc./fem. suff. *-cola* (from L. n. *incola*) inhabitant; N.L. n. (nominative in apposition) *spongicola* inhabitant of sponges.

Cells are 0.5 μm in width and 2.0 μm in length and move by gliding. On Marine agar, colonies are pink, 2–4 mm in diameter, and circular with entire edges. Growth occurs at pH 5.0–10.0. Optimal growth is observed at 20–30°C. Tween 60 is hydrolyzed but not hypoxanthine, xanthine, or L-tyrosine. No acid is formed from L-arabinose, D-cellobiose, D-fructose, L-fucose, D-galactose, D-glucose, D-lactose, D-maltose, D-mannose, D-melibiose, D-melezitose, D-raffinose, L-rhamnose, D-ribose, D-sucrose, D-trehalose, D-xylose, N-acetylglucosamine, adonitol, D-sorbitol, *myo*-inositol, or D-mannitol. The following substrates are not utilized: L-arabinose, D-lactose, D-mannose, D-sucrose, D-ribose, inositol, mannitol, sorbitol, DL-aspartate, L-leucine, or L-proline. Cystine arylamidase and trypsin are not produced. Susceptible to chloramphenicol, doxycycline, and erythromycin.

Source: the marine sponge *Tedania ignis* in the Bahamas.

DNA G+C content (mol%): 43.7 (HPLC).

Type strain: UST030701-084, JCM 13337, NRRL B-41219.

Sequence accession no. (16S rRNA gene): DQ080996.

Order II. Incertae sedis

The genera *Rhodothermus* and *Salinibacter* were previously assigned to the "Crenotrichaceae" by Garrity et al. (2005), but subsequent analyses transferred *Crenothrix* to the *Proteobacteria*. Phylogenetic analyses of the 16S rRNA suggests that these genera represent a very deep group and are only distantly related to any of the previously described orders within the *Bacteroidetes*. In view of their ambiguous status, they have been assigned to their own order *incertae sedis*.

Family I. Rhodothermaceae fam. nov.

WOLFGANG LUDWIG, JEAN EUZÉBY AND WILLIAM B. WHITMAN

Rho.do.ther.ma.ce'a.e. N.L. masc. n. *Rhodothermus* type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. *Rhodothermaceae* the *Rhodothermus* family.

Straight or curved rods that stain Gram-negative. Nonmotile or motile with flagella. **Chemoheterotrophic aerobes** that preferentially utilize sugars or amino acids. Catalase-positive. **Most strains form red or orange colonies**, due to a carotenoid pigment. **Moderately** (0.6 to >6% NaCl) or **extremely halophilic** (>15% NaCl). May be thermophilic, **growing at**

54–77°C, or mesophilic. Common habitats include hot springs and salterns.

DNA G+C content (mol%): 64–68.

Type genus: **Rhodothermus** Alfredsson, Kristjansson, Hjörleifsdottir and Stetter 1995, 418^{VP} (Effective publication: Alfredsson, Kristjansson, Hjörleifsdottir and Stetter 1988, 304.).

Genus I. **Rhodothermus** Alfredsson, Kristjansson, Hjörleifsdóttir and Stetter 1995, 418^{VP} (Effective publication: Alfredsson, Kristjansson, Hjörleifsdóttir and Stetter 1988, 304.)

THE EDITORIAL BOARD

Rho.do.ther'mus. Gr. n. *rhodon* rose; Gr. masc. adj. *thermos* hot; N.L. masc. n. *Rhodothermus* the red thermophile.

Straight rods about 0.5×2.0 – $2.5 \mu\text{m}$, with curved ends. **Occur singly, never in chains or filaments. Nonmotile.** Gram-stain-negative. A slime capsule is formed on carbohydrate-rich medium. **Most strains form red colonies**, due to a carotenoid pigment. Colonies are low convex, 3–4 mm in diameter with an entire edge. **Aerobic. Thermophilic, growing at 54–77°C.** Neutrophilic. Heterotrophic. **Growth is strictly salt-dependent, occurring in the range of 0.6 to >6% NaCl.** Catalase-positive. The oxidase reaction varies among strains. No dissimilatory nitrate reduction occurs. **Growth occurs on most common sugars.** The major cellular fatty acids are C₁₅ iso, C₁₅ anteiso, C₁₇ iso and C₁₇ anteiso. The major quinone is menaquinone 7. The habitat is submarine freshwater alkaline hot springs, marine hot springs, geothermal sites, and borehole effluents.

DNA G+C content (mol%): 64–66 (T_m).

Type species: **Rhodothermus marinus** Alfredsson, Kristjansson, Hjörleifsdóttir and Stetter 1995, 418^{VP} (Effective publication: Alfredsson, Kristjansson, Hjörleifsdóttir and Stetter 1988, 304; *Rhodothermus obamensis* Sako, Takai, Ishida, Uchida and Katayama 1996, 1103.).

Further descriptive information

Although *Rhodothermus marinus* is considered to be nonmotile, the presence of a polar flagellum has been reported (Nunes et al., 1992a).

Red colonies are formed by most strains of *Rhodothermus marinus*, but two distinct subgroups of colorless isolates that were correlated with their geographic origin were found by Petursdóttir et al. (2000).

Rhodothermus marinus accumulates osmolytes in response to increasing salinity of its growth medium. Mannosylglycerate, which occurs in some hyperthermophilic organisms and protects enzymes against inactivation by temperature and freeze-drying (Ramos et al., 1997), accumulates in *Rhodothermus marinus* in response to growth at supraoptimal temperature and salinity. The amide form, mannosylglyceramide, which has been found only in *Rhodothermus marinus* (Santos and da Costa, 2002), accumulates exclusively in response to salt stress (Nunes et al., 1995; Silva et al., 1999). Martins et al. (1999) elucidated the biosynthetic pathways of mannosylglycerate in *Rhodothermus marinus* and characterized the enzyme mannosylglycerate synthase, which catalyzes the final step in the synthesis of mannosylglycerate. *Rhodothermus marinus* is the only organism known to have two distinct pathways for the synthesis of mannosylglycerate: a two-step pathway and a single-step pathway. The level of mannosylglycerate synthase involved in the single-step pathway was selectively enhanced by heat stress, whereas mannosylglyceramide was overproduced in response to osmotic stress. The two alternative pathways for the synthesis of mannosylglycerate are regulated differently at the level of expression to play specific roles in the adaptation of *Rhodothermus marinus* to two different types of stress (Borges et al., 2004).

Rhodothermus marinus is noted for its production of thermostable enzymes; a detailed review has been provided by Björnsdóttir et al. (2006). Some examples of the most heat-tolerant enzymes and their optimum temperature for activity include cellulase (100°C; Halldorsdóttir et al., 1998); β -glucanase (85°C; Spilliaert et al., 1994); laminarinase (85°C; Krah et al., 1998); mannanase (85°C; Politz et al., 2000), mannosylglycerate synthase (85–90°C; Martins et al., 1999), and xylanase (80°C; Nordberg Karlsson et al. (1997, 1998).

The original isolation of *Rhodothermus marinus* was from submarine alkaline freshwater hot springs in Iceland by Alfredsson et al. (1988). Additional strains have since been isolated from various marine hot springs, geothermal sites, and borehole effluents. Nunes et al. (1992a) isolated ten strains from hot springs on a beach on the island of Sao Miguel, Azores. Moreira et al. (1996) isolated *Rhodothermus marinus* from hot springs in Naples, Italy. Petursdóttir et al. (2000) isolated 81 strains from four different geothermal sites in Iceland. These locations were coastal springs at Reykjanes in Isafjardur in northwest Iceland, an effluent from the geothermal power plant at the Blue Lagoon in southwest Iceland, the effluent from the salt factory at Reykjanes in southwest Iceland, and coastal springs and effluent from a borehole in Oxarfjörður in northeast Iceland.

Petursdóttir et al. (2000) found that even though *Rhodothermus marinus* strains were isolated at different geographic locations, they exhibited a close genetic relatedness, based on high DNA–DNA reassociation values (>68%) and almost identical 16S rRNA gene sequences. However, other measures of genetic diversity, viz., ribotyping and pulsed-field gel electrophoresis (Moreira et al., 1996) and electrophoretic analysis of allelic variation in 13 genes encoding enzymes (Pétursdóttir et al., 2000) have indicated a relatively high degree of genetic variance. Petursdóttir et al. (2000) concluded that this variance is most likely the result of genetic changes occurring independently in the different geographic locations studied.

Tindall (Tindall, 1991) reported that the major cellular fatty acids of *Rhodothermus marinus* were iso-even, i.e., C₁₄ iso, C₁₆ iso, and C₁₈ iso, in the type strain and another strain. Contrasting results were reported by Nunes et al. (1992b), who found the predominant acids to be iso-odd, i.e., C₁₅ iso and C₁₇ iso) and anteiso-odd (C₁₅ and C₁₇) in the type strain and in the type strain and four other strains. Chung et al. (1993) found that the culture medium affected the fatty acid composition of five strains of *Rhodothermus marinus*. They cultured the organisms on four different media: basal salts medium 162 (Degryse et al., 1978) supplemented with yeast extract plus tryptone (medium A); yeast extract plus sodium glutamate (medium B); yeast extract alone (medium C) and glutamate alone (medium D). In media A and C, branched-chain C₁₅ iso and C₁₇ iso fatty acids were the major fatty acids, and C₁₆ iso and normal-chain fatty acids were minor components. In medium B, the relative proportion of C₁₆ iso increased to high levels. Glutamate had a profound effect on

the fatty acid composition: in medium D, with glutamate as sole source of carbon and energy, normal-chain C₁₆ constituted the major component, and normal-chain fatty acids reached about 50% of the total fatty acids. Moreira et al. (1996) reported that the fatty acid composition of 21 strains of *Rhodothermus marinus* isolated from three different locations, including a nonpigmented variant, were all highly similar. The medium used was agar-solidified basal salts medium 162 supplemented with NaCl, tryptone, and yeast extract. The major fatty acids were iso- and anteiso-branched fatty acids. Under the conditions used, C_{17:0} iso was the major fatty acid, but C_{15:0} anteiso was also relatively high.

Pereira et al. (2004) summarized the types of respiratory complexes from thermophilic aerobic prokaryotes. The components so far identified in the respiratory chain of *Rhodothermus* include NADH:quinone oxidoreductase type 1 (NDH-1); succinate:quinone oxidoreductase (type B); quinol:cytochrome *c* oxidoreductase *bc*; a *caa3* oxygen reductase (type A2) and a *cbb3* oxygen reductase (type C); menaquinone 7; and HiPIP (the electron carrier between the *bc* complex and the *caa3* oxygen reductase).

The genome size of *Rhodothermus marinus* is approximately 3.3–3.6 Mbp (Moreira et al., 1996). A gene transfer system for *Rhodothermus marinus* has been established by Bjornsdottir et al. (2005).

A thorough review of the physiology and molecular biology of *Rhodothermus* has been given by Bjornsdottir et al. (2006).

Enrichment and isolation procedures

Alfredsson et al. (1988) isolated *Rhodothermus marinus* from samples collected directly from the openings of alkaline submarine hot springs in Iceland at a depth of 2–3 m. It was not possible to exclude seawater completely when sampling. The samples, which consisted of fine gravel and water, were kept refrigerated until processed further. Water samples were filtered directly, but sand and gravel samples were washed with sterile seawater, which was then filtered through membrane filters having a pore size of 0.45 µm. The filters were put on plates containing nutrient agar medium 162 of Degryse et al. (1978) containing 3% (w/v) NaCl and incubated at 72°C for 4 d. Red-pigmented colonies were selected and purified by streaking

onto the same medium. The bacteria were routinely cultured on nutrient agar medium 162 containing 1% NaCl.

Sako et al. (1996) obtained strains previously classified as *Rhodothermus obamensis* from samples of effluent water and sediment from hydrothermal vents and sedimentary materials adjacent to vents. The samples were inoculated into a series of media, including Jx medium.* All of the Jx medium tubes containing sediment were turbid after 1 d of incubation at 80°C. Cultures were then streaked onto Jx medium plates and incubated at 70°C. Well-defined colonies were streaked onto another plate, and this plate was incubated at 70°C. This procedure was repeated at least five times and red colonies were selected.

Differentiation of the genus *Rhodothermus* from other genera

The combination of a high optimum temperature and a salt requirement distinguish *Rhodothermus* from other genera in the *Bacteroidetes*. The other aerobic thermophilic genus in this phylum is *Thermonema*, some strains of which require a low concentration of Na⁺. *Rhodothermus* can also be differentiated from *Thermonema* by its lack of filament formation and its ability to use most common sugars and starch.

Taxonomic comments

Sako et al. (1996) isolated a thermophilic bacterium from a shallow marine hydrothermal vent environment in Tachibana Bay, Japan, that belonged to the genus *Rhodothermus* on the basis of rRNA gene sequencing. This organism was named *Rhodothermus obamensis*. However, Silva et al. (2000) reported that the type strain of *Rhodothermus obamensis*, JCM 9785, has a DNA–DNA reassociation value of 78% with the type strain of *Rhodothermus marinus*, DSM 4252. On the basis of the DNA–DNA reassociation value, 16S rRNA gene sequence comparison, and fatty acid profiles, Silva et al. concluded that *Rhodothermus obamensis* and *Rhodothermus marinus* represent the same species and that the name *Rhodothermus obamensis* should be regarded as a later synonym of *Rhodothermus marinus*.

Antón et al. (2002) reported that the *Rhodothermus marinus* was the closest cultivated relative of *Salinibacter ruber*, with a 16S rRNA gene sequence similarity of about 89%.

List of species of the genus *Rhodothermus*

1. ***Rhodothermus marinus*** Alfredsson, Kristjánsson, Hjörleifsdóttir and Stetter 1995, 418^{VP} (Effective publication: Alfredsson, Kristjánsson, Hjörleifsdóttir and Stetter 1988, 304; *Rhodothermus obamensis* Sako, Takai, Ishida, Uchida and Katayama 1996, 1103^{VP}.)

ma.ri'nus, L. masc. adj. *marinus* of the sea, marine.

The characteristics are as given for the genus, with the following additional features. Optimum temperature is 65–80°C. Optimum pH is 7; optimum NaCl concentration is 2–3%. Growth occurs in the presence of 5–6% NaCl. The major cellular fatty acid components are anteiso- and C₁₇ and anteiso- and C₁₅ acids, and the major quinone is menaquinone 7, with

smaller amounts of menaquinones 6 and 5 (Sako et al., 1996). The natural habitat is submarine alkaline hot springs.

Source: the type strain was isolated from a marine hot spring at Reykjanes, NW Iceland.

DNA G+C content (mol %): 65–67 (*T_m*).

Type strain: ATCC 43812, DSM 4252.

Sequence accession no. (16S rRNA gene): AF17493.

*Jx medium contains (per liter): Jamarin S synthetic seawater powder (Jamarin Laboratory, Osaka, Japan), 35 g; Jamarin S synthetic seawater solution, 5 ml; yeast extract (Difco), 1 g; and Trypticase peptone (BBL), 1 g; pH adjusted to 6.8–7.2 with H₂SO₄.

Genus II. *Salinibacter* Antón, Oren, Benlloch, Rodríguez-Valera, Amann and Rosselló-Mora 2002, 490^{VP}

JOSEFA ANTÓN, RUDOLF AMANN AND RAMON ROSSELLÓ-MORA

Sa.li.ni.bac'ter. L. fem. pl. n. *salinae* salterns, salt-works; N.L. masc. n. *bacter* masc. equivalent of the Gr. neut. n. *baktron* a rod; N.L. masc. n. *Salinibacter* a rod from salt-works.

Rod-shaped, often slightly curved. Gram-stain-negative. **Motile** by means of flagella. Obligately **aerobic**. Catalase- and oxidase-positive. Nitrate is not reduced. **Extremely halophilic**, requiring at least 15% NaCl (w/v) to grow; optimum, 20–30%. Chemoheterotrophic. Grows best at low substrate concentrations; high levels of organic compounds may be inhibitory. Amino acids are the preferred substrates for growth. *Salinibacter* strains form a deep branch of the phylum *Bacteroidetes* of the domain *Bacteria*. Colonies are **bright red/orange**-pigmented. Among the most salt-tolerant and salt-requiring strains within the bacterial domain.

DNA G+C content (mol%): 66.3–67.7 (HPLC).

Type species: Salinibacter ruber Antón, Oren, Benlloch, Rodríguez-Valera, Amann and Rosselló-Mora 2002, 490^{VP}.

Further descriptive information

The typical cells are slightly curved rods, but larger, round structures at the ends of the cells can also be found in some cultures (Figure 79). Maintenance of cell shape does not depend on the presence of high salt concentrations.

Salt concentrations of at least 15% (w/v) are required and all strains grow at NaCl concentrations up to saturation. *Salinibacter* apparently uses KCl to provide osmotic balance and lacks high concentrations of organic solutes (Oren et al., 2002). In this aspect, its physiology resembles that of the halophilic *Archaea* more than other aerobic bacteria. The potassium content relative to cell protein in *Salinibacter* is in the same order as for haloarchaea (in $\mu\text{mol}/\text{mg}$: 11.4–15.2 in *Salinibacter*, 13.2

in *Haloarcula marismortui*, and 12.0 in *Halobacterium salinarum*). The only other *Bacteria* known to use KCl rather than organic solutes to provide osmotic balance are the anaerobic fermentative members of the order *Halanaerobiales*. The optimal pH range for growth is 6.5–8.0 with an optimum temperature of 35–45°C. Under optimal growth conditions, the generation time is 14–18 h.

Although the original description of *Salinibacter ruber* stated that simple sugars and organic acids (acetate, succinate) did not support growth as sole carbon and energy sources, Oren and Mana (2003) showed that the addition of glucose, maltose, and starch to a medium with yeast extract had a pronounced stimulatory effect on growth. However, sugars are not the preferred growth substrates and their consumption starts after the exhaustion of other substrates (Oren and Mana, 2003). Glycerol is probably a readily available carbon and energy source in hypersaline water bodies, for it is produced in high quantities as an osmotic solute by unicellular green algae of the genus *Dunaliella* (Oren, 2005). However, the use of radioactive substrates did not indicate an ability of *Salinibacter* to metabolize glycerol during a period of 24–48 h (Rosselló-Mora et al., 2003). On the other hand, Sher et al. (2004) showed that growth in pure culture is stimulated by glycerol, although glycerol alone was not sufficient to support growth. After 190 h of incubation, 25% of the radioactive label was incorporated into the cells, with part of the glycerol transformed into CO_2 . As with haloarchaea, *Salinibacter* proteins showed a high content of acidic amino acids, a low amount of basic amino acids, a low content of hydrophobic amino acids, and a high content of serine (Oren and Mana, 2002). In addition, biochemical studies of enzymes such as NAD-dependent isocitrate dehydrogenase, NADP-dependent isocitrate dehydrogenase, NAD-dependent malate dehydrogenase, NAD-dependent glutamate dehydrogenase, and two distinct glutamate dehydrogenases showed that *Salinibacter* enzymes are adapted to function in the presence of high salt concentrations (Bonete et al., 2003; Oren and Mana, 2002). On the other hand, Madern and Zaccari (2004) found that malate dehydrogenase behaves like a non-halophilic protein, since it is completely stable in the absence of salts, its amino acid composition does not display the strong acidic character specific of halophilic proteins, and its activity is reduced by high salt concentration. As pointed out by Oren (2005), the general trend of salt dependence of *Salinibacter* proteins is clear, although there are significant differences for individual enzymes.

Salinibacter is sensitive to penicillin G, ampicillin, chloramphenicol, streptomycin, novobiocin, rifampin and ciprofloxacin. No growth inhibition was found with kanamycin, bacitracin, tetracycline and colistin. The cells are resistant to anisomycin and aphidicolin, two potent growth inhibitors of halophilic *Archaea* of the order *Halobacteriales*.

Salinibacter harbors pigment concentrations in the same order of magnitude as halophilic *Archaea* (Oren and Rodríguez-Valera, 2001). The principal pigment of *Salinibacter* is salinixanthin, a C40-carotenoid acyl glycoside [(all-*E*, 2'-*S*)-2'-hydroxy-1'-[6-

FIGURE 79. Micrograph of a *Salinibacter ruber* culture grown in 23% MGM (modified growth media with 23% total salts), showing the round structures that occasionally appear at the end of the cells. Picture courtesy of Dr. Mike Dyall-Smith, Max Planck Institute for Biochemistry, Department of Membrane Biochemistry, Am Klopferspitz 18a, Martinsried D82152, Germany. Scale bar: 5 μm .

O-(13-methyltetradecanoyl)- β -D-glycopyranosyloxy]-3',4'-didehydro-1',2'-dihydro- β , ψ -caroten-4-one], that accounts for more than 96% of the total pigments (Lutnæs et al., 2002). The remarkable structural conformity between salinixanthin and the major carotenoid acyl glucoside from *Rhodothermus marinus* is consistent with the 16S rRNA phylogeny (Lutnæs et al., 2004). Bright-red pigmentation is common in microorganisms inhabiting salt lakes and saltern ponds; for instance, the *Halobacteriaceae* possess bacterioruberins, and *Dunaliella*, synthesizes β -carotene. Thus, colony color alone is not a reliable trait to allow classification of extremely halophilic prokaryotes as members of the domains *Archaea* or *Bacteria*.

Salinibacter has a membrane lipid composition with glycerophospholipids containing ester-linked fatty acyl chains that are typical of *Bacteria*. According to Peña et al. (2005) the major lipids in *Salinibacter ruber* strains are diphosphatidylglycerol and the unknown polar lipid L7. Phosphatidylethanolamine, as well as three unknown glycolipids, several polar lipids, and one phospholipid were usually found in moderate to minor amounts. Contrary to previous observations (Oren et al., 2004), no phosphatidylglycerol was detected nor could phosphatidylcholine (PC) be unambiguously identified in any of the 17 *Salinibacter ruber* strains analyzed. In addition, a spot staining with Dragendoff reagent (specific for quaternary nitrogen found in PC but rarely in other lipids) with similar but not identical chromatographic behavior was found also by Peña et al. (2005). *Salinibacter ruber* M31 contains a novel sulfonolipid with the structure 2-carboxy-2-amino-3-*O*-(13'-methyltetradecanoyl)-4-hydroxy-18-methylnonadec-5-ene-1-sulfonic acid. This lipid accounts for 10% of total cellular lipids and appears to be a structural variant of sulfonolipids found in the cell walls of gliding *Cytophaga* and diatoms (Corcelli et al., 2004). A peak at *m/z* 660, corresponding to this sulfonolipid, has been proposed as the lipid signature of *Salinibacter*.

The genome of the type strain of the type species, *Salinibacter ruber* M31, has been completely sequenced by Mongodin et al. (2005). It harbors one 3,551,823 bp chromosome (62.29 mol% G+C, slightly lower, but in good agreement with earlier HPLC measurements) and one plasmid of 35,505 bp (57.9 mol% G+C) containing 2934 and 33 ORFs, respectively. The calculated isoelectric point (5.2) for the proteome of *Salinibacter* is nearer to those of haloarchaea than its closest sequenced relatives, *Bacteroides fragilis* and *Chlorobium tepidum*. M31, as do all other 16 strains characterized so far (Peña et al., 2005), has a single rRNA operon. The 16S rRNA gene sequence is almost identical for all the analyzed *Salinibacter ruber* strains, while the similarity for their 16S–23S gene spacer regions is above 97% (Peña et al., 2005).

Emden-Meyerhoff glycolytic pathway genes have been found in the chromosome, contrary to previous growth studies that suggested that *Salinibacter* uses the classic Entner-Doudoroff pathway for catabolism of glucose (Oren and Mana, 2003). Genes related to the transport and metabolism of glycerol and glycine betaine, as well as some genes related to adaptations to microoxic environments have been annotated. One so-called “hypersalinity island” encoding proteins of crucial importance to a hyperhalophilic lifestyle (such as K⁺ uptake/efflux systems and cationic amino acid transporters) was also found. The M31 genome harbors genes encoding four retinal proteins: halorhodopsin (Antón et al., 2005), two sensory rhodopsins and xanthorhodopsin (Balashov

et al., 2005). Genome analysis suggested that the convergence on an aerobic hyperhalophilic lifestyle between haloarchaea and *Salinibacter* has arisen through convergence at the physiological level (different genes producing similar overall phenotype) and the molecular level (independent mutations yielding similar sequences or structures). Mongodin et al. (2005) hypothesize that several genes and gene clusters might have suffered lateral transfer from (or may have been laterally transferred to) haloarchaea, although the total number of apparent lateral gene transfers between *Salinibacter* and haloarchaea appears to be modest. Without a doubt, one of the most striking features of *Salinibacter* is the presence of xanthorhodopsin (XR), a proton pump with a light-harvesting carotenoid antenna XR contains two chromophores, retinal and salinixanthin, in a molar ratio of about 1:1. Light energy absorbed by the carotenoid is transferred to the retinal, extending the wavelength range of the collection of light for uphill transmembrane proton transport. Thus XR shares characteristics with the archaeal (e.g., bacteriorhodopsin and archaeorhodopsin), bacterial (proteorhodopsin), and eukaryal (letospheria rhodopsin) retinal-based light-driven proton pumps, as well as with the chlorophyll-based light-harvesting complexes and reaction centers. As pointed out by Balashov et al. (2005), “the XR complex represents the simplest electrogenic pump with an accessory antenna pigment, and it might be an early evolutionary development in using energy transfer for energy capture.” Strictly speaking, heterotrophy is not the only source of energy for *Salinibacter ruber* M31.

In 2000, the high abundance and growth of a group of uncultured *Bacteria* was reported for samples from crystallizer ponds (salinity 30–37%) in a saltern in Alicante, Spain. This group, that was then named as “*Candidatus Salinibacter*” gen. nov. accounted for 5–25% in crystallizers from different locations and was affiliated with the phylum *Bacteroidetes* (Antón et al., 2000). This study followed the first evidence that *Bacteria* could be present in high numbers in crystallizer ponds that was reported in 1999 with the use of fluorescence *in situ* hybridization (FISH) with *Archaea*- and *Bacteria*-specific probes (Antón et al., 1999). This kind of approach allows for direct quantification of prokaryotes in the environment and lacks the pitfalls associated with a PCR based approach. FISH with *Bacteria*-specific probes showed that this group accounted for 11–18% in crystallizer samples from a Spanish solar saltern. The finding of abundant *Bacteria* with high cellular rRNA content in such a hypersaline environment was unexpected in light of previous reports that suggested that almost all the active biomass was of archaeal origin. In a pioneering study of the molecular microbial ecology of the salterns using a PCR-based approach, Martínez-Murcia et al. (1995) reported that the bacterial population present in crystallizers was very different (based on similarities of 16S rDNA-RFLP) from the populations inhabiting lower salinity ponds. Although these authors stated that crystallizers probably represented an extremely specialized niche for *Bacteria*, they also pointed out that only a very small proportion of the crystallizer biomass could correspond to *Bacteria*, and that the bacterial DNA detected by PCR could come from allochthonous microbiota carried over from lower salinity ponds. In 1995, Benlloch et al. analyzed 16S rRNA gene clone libraries from a crystallizer pond and obtained five bacterial clones that were partially sequenced (around 200 bp); all were related (82.6–83.6% similarities) to the α -proteobacterium *Rhodopseudomonas*

marina. These sequences (accession nos: X84322, X84323 and X84324) could indeed correspond to *Salinibacter* since they have from 89 to 96% similarity with *Salinibacter ruber* in the analyzed 16S rRNA gene sequence fragment. However, the authors pointed out that “considering the salt concentration in the pond (30.8%) no known *Bacteria* could be physiologically active”. Indeed, the idea that only *Archaea* could thrive in hypersaline environments was very strong. We must point out, however, that direct proof of activity of *Salinibacter* species in the highest salinity (37%) ponds has not been obtained so far. In fact, Gasol et al. (2004) found that above 32% salinity, all the prokaryotic activity was carried out by haloarchaea in the very same saltern ponds where *Salinibacter ruber* represented up to 18% of the DAPI (4',6-diamidino-2-phenylindole) counts (total counts). This observation is based on the assumption that *Salinibacter* species are not inhibited by taurocholate, which is a potent haloarchaeal inhibitor.

The occurrence of *Salinibacter* in the environment has been studied by several methods: FISH (Antón et al., 2000; Rosselló-Mora et al., 2003), pigment analysis (Oren and Rodríguez-Valera, 2001), total DNA melting profiles and reassociation techniques (Øvrås et al., 2003), Denaturing gradient gel electrophoresis (DGGE) (Benlloch et al., 2002), and 16S rRNA gene clone library analysis, among others. These techniques show that there is a considerable degree of microdiversity among the environmental sequences related to *Salinibacter ruber*. Using the above-mentioned culture-independent approaches, *Salinibacter* has been found in crystallizer pond salterns from locations in Santa Pola (mainland Spain), Balearic (Mallorca and Ibiza) and Canary Islands, which accounted for 5–27% of the total prokaryotic community. In Santa Pola salterns, *Salinibacter* was not detected in ponds having up to 22.4% salinity, whereas it was found in increasingly high numbers (3.5–12%) in three ponds of 25, 31.6 and 37% salinity. The *Salinibacter* lipid signature peak at *m/z* 660 was evident in the ESI-MS profile in the lipid extract from a crystallizer pond in the Margherita di Savoia salterns (Italy) (Corcelli et al., 2004), indicating the presence of *Salinibacter* in this environment. In some instances, e.g., Andean and Eilat (Israel) salterns, *Salinibacter* was not detected by culture-independent analyses, although it could be readily isolated (Elevi-Bardavid et al., 2007; Maturrano et al., 2006). Although crystallizers are the most frequently reported habitat for *Salinibacter*, sequences with a similarity of 92–97% to those of *Salinibacter* were very abundant in 16S rRNA gene libraries constructed with DNA extracted from the different layers of an endoevaporite (crystallized gypsum-halite matrix in near-saturated salt water) from salt-works in Guerrero Negro, Mexico (Spear et al., 2003). Partial 16S rRNA gene sequences with similarities of less than 92% to *Salinibacter* have been retrieved from biofilms colonizing ancient limestone Mayan monuments in Uxmal (Mexico) (Ortega-Morales et al., 2004). *Salinibacter* 16S rRNA gene sequences were also found in clone libraries obtained from a hypersaline endoevaporite microbial mat from Eilat salterns (Sørensen et al., 2005). These sequences were most abundant in the green layer of the mat. Finally, 16S rRNA gene sequences that fall within the radiation of the genus *Salinibacter*, but represent distinct novel lineages have been recovered from evaporite crusts in brine pools at the Badwater site in Death Valley National Park, California (Elevi-Bardavid et al., 2007). Isolates having 93–94% 16S rRNA gene similarity with *Salinibacter ruber* have been obtained from these samples

(Hollen et al., 2003). These authors claimed that they have isolated a new species of *Salinibacter*.

Enrichment and isolation procedures

The strains used for the genus description and for intraspecific comparative analyzes, were all isolated by plating dilutions of crystallizer samples on agar plates. They were recognized as members of the genus by 16S rRNA gene analysis or by polar lipids thin layer chromatography (TLC). The fact that *Salinibacter* is insensitive to the haloarchaeal inhibitors anisomycin and bacitracin has been used to design selective enrichment and isolation protocols (Elevi-Bardavid et al., 2007).

Strains of *Salinibacter* can be preserved by lyophilization.

Differentiation of the genus *Salinibacter* from closely related genera

No extreme halophiles are known so far among taxa closely related to *Salinibacter*, thus the differentiation from these taxa can be made on the basis of salt needed for optimum growth. However, *Salinibacter* shares its habitats with haloarchaea (i.e., the family *Halobacteriaceae*). Interestingly, there is a surprising similarity between these two groups: both are aerobic heterotrophs, maintain high intracellular K⁺ concentrations, require high salt concentrations for growth with optima in the range of 12–25% total salts, are red pigmented, and have a similar mol% G+C content of their DNA. For these reasons, *Salinibacter* can be easily mistaken as haloarchaea based only on phenotypic characteristics. Therefore, we recommend phylogenetic identification as the easiest way to identify *Salinibacter* strains. Lipid and pigment analyzes (Elevi-Bardavid et al., 2007) can also be used for strain identification.

Taxonomic comments

The closest 16S rRNA sequence similarity (86.4%) relative to *Salinibacter* is *Rhodothermus*, a genus of slightly halophilic (optimum 0.5–2% NaCl), thermophilic (optimum 65–70°C) bacteria isolated from marine hot springs (Alfredsson et al., 1988). The phylogenetic branch comprising the two genera *Salinibacter* and *Rhodothermus* bifurcates close to the divergence node between the two main phyla *Bacteroidetes* and *Chlorobi*. This observation made upon 16S rRNA gene sequence analysis has been corroborated by the use of independent phylogenetic approaches based on concatenating two sets of 22 and 74, respectively, protein sequences (Soria-Carrasco et al., 2007). From the single protein phylogenies it can be observed that in nearly 30% of the cases the affiliation was with *Chlorobi*. This may be an indication of an early divergence from *Bacteroidetes*, and a future classification as a single phylum cannot be discarded (Figure 80).

Note added in proof. A novel halophilic member of the *Bacteroidetes*, *Salisaeta longa* gen. nov., sp. nov., was published after acceptance of the present chapter. It is able to grow at concentrations of 5–20% NaCl, with an optimum at 10% plus 5% MgCl₂·6H₂O and has been described as halophilic (not extremely halophilic, as *Salinibacter ruber*). The 16S rRNA genes of *Salinibacter ruber* and *Salisaeta longa* have 88.3% similarity and thus, according to this parameter, this new species is now the closest relative of *Salinibacter ruber*; instead of *Rhodothermus marinus*. They can be differentiated based on their morphology, 16S rRNA gene sequences and salt optimum needed for growth, among other characteristics. However, a 16S rRNA primer originally designed as specific for *Salinibacter ruber* (Antón et al., 2002) is no longer specific.

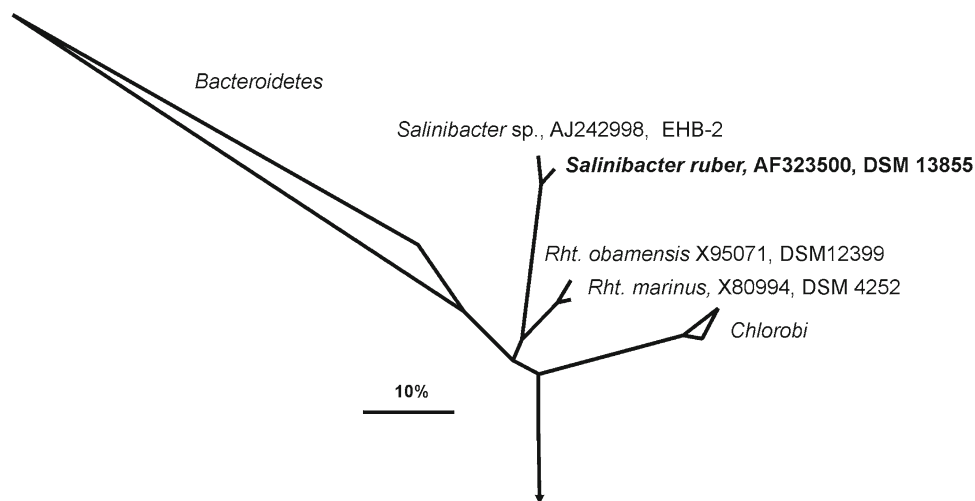

FIGURE 80. Tree reconstruction based on 16S rRNA gene sequences showing the affiliation of *Salinibacter ruber* strain M31 with its closest relative genus *Rhodothermus*, and to the hitherto uncultured *Salinibacter* species EHB-2 (Antón et al., 2000). The tree also shows the branch position relative to the rest of the members of the phyla *Bacteroidetes* and *Chlorobi*. The reconstruction was based on a dataset of more than 50,000 primary aligned 16S rRNA gene structures as implemented in the ARB software package, and corresponding to the released database available at <http://www.arb-home.de> (Ludwig et al., 2004). The phylogenetic analyzes were performed by using the sequences corresponding to all type strains of both phyla, and by using the neighbor-joining, maximum-parsimony, and maximum-likelihood algorithms. All treeing approaches rendered an identical topology. The bar indicates 10% of estimated sequence divergence.

Order III. Incertae sedis

Thermonema was previously assigned to the “*Flammeovirgaceae*” by Garrity *et al.* (2005), but subsequent analyses of the 16S rRNA suggests that it represents a very deep group and is only dis-

tantly related to any of the previously described orders within the *Bacteroidetes*. In view of its ambiguous status, it has been assigned to its own order *incertae sedis*.

Genus I. **Thermonema** Hudson, Schofield, Morgan and Daniel 1989, 487^{VP}

THE EDITORIAL BOARD

Ther.mo.ne'ma. Gr. adj. *thermos* hot; Gr. neut. n. *nema* a thread; N.L. neut. n. *Thermonema* a thermophilic thread.

Apparently unicellular filaments ~0.7 μ m in diameter and ~ 60 to several hundred μ m long. Motile by gliding. Gram-stain-negative. **Aerobic. Optimum temperature, ~60°C; poor or no growth occurs at 70°C.** Colonies are orange (Schofield *et al.*, 1987) or yellow (Tenreiro *et al.*, 1997), depending on the medium. Cells possess acetone-extractable pigments with an absorbance peak at 450 nm. Flexirubin-type pigments are not produced. Oxidase- and catalase-positive. Aminopeptidase-positive. Casein, gelatin, and hippurate are hydrolyzed but not starch, xylan, or cellulose. **Growth occurs on vitamin-free Casamino acids and on a mixture of the 20 natural amino acids, but not on single amino acids. Growth does not occur on pentoses, hexoses, N-acetylglucosamine, disaccharides, polyols, or organic acids.** Na⁺ may not be required; but if required, only low concentrations are needed. Menaquinone 7 is the major respiratory quinone. Sphingolipids are present.

Type species: Thermonema lapsum Hudson, Schofield, Morgan and Daniel 1989, 487^{VP}.

Further descriptive information

The initial isolate of *Thermonema lapsum* was obtained by Schofield *et al.* (1987) from hot-spring water samples collected from Kuirau Park, Rotorua, New Zealand. Marteinson *et al.* (2001) isolated seven marine strains belonging to the genus *Thermonema* from the concentrated fluid issuing from giant geothermal cones on the seafloor at a depth of 65 m in Eyjafjörður, Northern Iceland. The isolates were obtained only from the outer zone of the chimney, where cold seawater mixes into the vent fluid with increasing salinity and decreasing temperature. Mountain *et al.* (2003) obtained *Thermonema* isolates from sinters in New Zealand hot springs. Tenreiro *et al.* (1997) isolated *Thermonema rossianum* strains from saline hot springs along the Bay of Naples, Italy.

Schofield et al. (1987) indicated that colonies are orange on Castenholz medium D (CMD; Ramaley and Hixson, 1970). Tenreiro et al. (1997) reported colonies as bright yellow on medium 162 (Degryse et al., 1978) agar containing 1.0% NaCl.

Patel et al. (1994) determined that the major normal fatty acid components of the phospholipids and lipopolysaccharide of *Thermonema lapsum* were (in decreasing order of abundance) C_{15:0} iso, C_{15:0} anteiso, and C_{15:0}. No monounsaturated fatty acids occurred. Tenreiro et al. (1997) reported that the fatty acid composition of *Thermonema rossianum* strains was dominated by C_{15:0} iso and C_{17:0} iso 3-OH. C_{15:0} anteiso, C_{15:0} iso 2-OH, and C_{15:0} iso 3-OH also occurred in moderate relative concentrations, but the concentrations of other fatty acids were minor or negligible. The total relative proportion of hydroxy fatty acids was very high, about 40% of the total fatty acids.

Homospermidine and homospermine have been detected in *Thermonema lapsum* as the major polyamines (Hamana et al., 1992).

Enrichment and isolation procedures

Schofield et al. (1987) spread hot-spring water onto Castenholz medium D solidified with 3% agar and incubated the cultures for 24 h at 70°C. Single colonies were selected, and subsequent transfers grew well at 60°C but poorly at 70°C. Spreading occurred on media containing 1.5% agar but not 3% agar. In static broth cultures, the organisms grew as a pellicle that later formed clumps. Gliding motility was observed in hanging drop preparations at room temperature.

Mountain et al. (2003) inoculated media with samples (0.1–1.0 ml) of water collected from sinters in New Zealand hot springs, and incubated the cultures at temperatures in the range 30–60°C. Microbial growth, as indicated by turbidity in

liquid media (composition not specified), or by colonies on agar plates, was subcultured on solid media. Pure cultures were stored in glycerol at –80°C.

Tenreiro et al. (1997) isolated *Thermonema rossianum* strains from saline hot springs along the Bay of Naples, Italy. Water samples were filtered through membrane filters (0.45 µm pore diameter) and the filters were placed on the surfaces of medium 162 agar containing 1.0% NaCl. The plates were wrapped in plastic bags and incubated at 60°C for up to 7 d. Cultures were purified by subculturing and were maintained at –80°C in medium 162 containing 1.0% NaCl and 15.0% glycerol.

Differentiation of the genus *Thermonema* from other genera

The other aerobic thermophilic genus in the phylum *Bacteroidetes* is *Rhodothermus marinus*, which is slightly halophilic, requiring about 0.25% NaCl for growth. It can be differentiated from *Thermonema* by its lack of filament formation and its ability to use most common sugars and starch.

Taxonomic comments

Based on 1490 nucleotides constituting 97% of the 16S rRNA gene of *Thermonema lapsum*, Patel et al. (1994) concluded that *Thermonema lapsum* was the deepest member of what is now the phylum *Bacteroidetes*.

Tenreiro et al. (1997) found *Thermonema rossianum* strains to be related to other members of the phylum *Bacteroidetes* by 79–97.5% similarity in 16S rRNA gene sequences. The highest relatedness was exhibited toward *Thermonema lapsum* (97.2–97.5% sequence similarity). DNA–DNA reassociation values among *Thermonema rossianum* strains were high (>91%), but they were lower (37–41%) between these strains and *Thermonema lapsum*.

List of species of the genus *Thermonema*

1. *Thermonema lapsum* Hudson, Schofield, Morgan and Daniel 1989, 487^{VP}

lap'sum. L. neut. part. adj. *lapsum* gliding, from L. v. *labor* to glide.

The characteristics are as given for the genus, with the following additional features. Optimum growth in medium 162 occurs without added NaCl (thus differentiating this species from *Thermonema rossianum*); addition of NaCl causes a decrease in growth, and no growth occurs at 4% NaCl (Tenreiro et al., 1997). Negative for α- and β-galactosidase-negative. Positive for DNase. Proteolytic. Casein, gelatin, and hippurate are hydrolyzed but not cellulose, starch, and xylan. The following basal medium supplements do not support growth: acetate, L-alanine, casein, L-cystine, galactose, gelatin, gluconate, glucose, inositol, lactose, L-malate, L-proline, propan-1-ol, pyruvate, rhamnose, ribose, skim milk, sorbitol, succinate, sucrose, and yeast extract (all at concentrations of 1 g/l) plus the glutamate amino acid family (glutamate, proline, and arginine) (all at concentrations of 3.3 g/l). The following basal medium supplements do support growth: Casamino acids, amino acid mixture 1 (aspartic acid, threonine, serine, glutamic acid, proline, glycine, alanine, valine, methionine, isoleucine, leucine, tyrosine, phenylalanine, lysine, histidine, and arginine), and amino acid mixture 2

(the same as amino acid mixture 1 but lacking methionine, phenylalanine, tyrosine, and leucine).

Source: New Zealand hot springs.

DNA G+C content (mol%): 47 (T_m).

Type strain: 23/9, ATCC 43542, DSM 5718.

Sequence accession no. (16S rRNA gene): L11703.

2. *Thermonema rossianum* Tenreiro, Nobre, Rainey, Miguel and da Costa 1997, 125^{VP}

ros.si.a'num. N.L. neut. adj. *rossianum* pertaining to Rossi, in honor of Mosé Rossi, the noted Neapolitan biochemist.

The characteristics are as described for the genus, with the following additional features. Colonies on medium 162 are yellow and 2 mm in diameter after 48 h. Optimum temperature, approximately 60°C; no growth occurs at 30 and 70°C in medium 162. Optimum pH, 7.0–7.5; no growth occurs at pH 5.0 or 10.0. The optimum NaCl concentration for growth is 1.0–3.0%; no growth occurs in medium 162 without added NaCl (thus differentiating this species from *Thermonema lapsum*) or with >6.0% NaCl. The major fatty acids are C_{15:0} iso and C_{17:0} iso 3-OH. Nitrate is not reduced to nitrite. Casein, elastin, and gelatin are degraded; starch, xylan, and cellulose are not degraded. Casamino acids and complex amino acid mixtures are utilized for growth. Growth

does not occur on single amino acids, sugars, organic acids, and polyols.

Source: thermal water tap at the Stufe di Nerone.

DNA G+C content (mol%): 50.9 (HPLC).

Type strain: NR-27, DSM 10300.

Sequence accession no. (16S rRNA gene): Y08956.

Order IV. Incertae sedis

Toxothrix was previously assigned to the “*Crenotrichaceae*” by Garrity et al. (2005), but subsequent analyses transferred *Crenotrichix* to the *Proteobacteria*. Phylogenetic analyses of the 16S rRNA suggests that *Toxothrix* represents a very deep group and is only

distantly related to any of the previously described orders within the *Bacteroidetes*. In view of its ambiguous status, it has been assigned to its own order *incertae sedis*.

Genus I. *Toxothrix* Molisch 1925, 144^{AL*}

PETER HIRSCH

To.xo'thrix. Gr. n. *toxón* a bow; Gr. fem. n. *thrix* a thread; N.L. fem. n. *Toxothrix* bent thread.

Cells cylindrical, colorless, 0.5–0.75×3–6 µm, in **filaments** (trichomes) **up to 400 µm long**. A dense body (**polyphosphate?**) is often located at either end of the cell (Figure 81). Gram reaction not recorded. **Filaments often U-shaped** (Figure 81a and b) and **rotating while slowly moving forward with the rounded part in the lead**; a **mucoïd substance**, excreted from several sites on the trailing ends, **is deposited as a double track** (“railroad track”) **of twisted strings** each 0.2 µm wide (Figure 81). **Fan-shaped structures may be deposited laterally** along the tracks, as the arms of the U move from side to side, and between the tracks, as a result of the middle section being lifted and then touched down again (Figure 81; Krul et al., 1970). **Oxidized iron may be deposited on the mucoïd threads**, rendering them yellowish brown and brittle and giving them a diameter of 2.5 µm. Pure cultures have not been obtained, but chemoorganotrophic and psychrophilic cultures have been maintained for long periods at 5 and 10°C. **Filaments are extremely fragile during laboratory examination, and explosive disintegration of filaments has been observed**

after short periods under the microscope. Grow attached to surfaces and develop best at reduced oxygen tensions (Hässelbarth and Lüdemann, 1967) and slightly below neutrality (pH 5.1–7.7). Originally found in water reservoir near the Biological Station at the Dnjepr River in the U.S.S.R. Widely distributed in cold iron springs, brooks, forest ponds, and lakes containing ferrous iron and with reduced oxygen tension (Hirsch, 1981).

DNA G+C content (mol%): not known.

Type species: ***Toxothrix trichogenes*** (Cholodny 1924) Beger in Beger and Bringmann 1953, 332^{AL}.

Further descriptive information

The normal trichome does not appear to have cross-walls when viewed with the phase microscope (Figure 81). Cholodny (1924) thought the organisms had a thin, tubular sheath that split repeatedly longitudinally, thus giving rise to the “twisted thread rope.” However, Krul et al. (1970) followed the formation of the double tracks and fan-shaped structures on living, undisturbed and actually growing specimens.

Toxothrix trichogenes has been reported to be cultivated by Teichmann (1935). Hirsch (1981) kept natural samples

*Editorial note: this chapter is reproduced from Vol. 1 of the 1st edition of *Bergey's Manual of Systematic Bacteriology*.

FIGURE 81. *Toxothrix trichogenes* observed in a small iron spring catch basin. (a and b) Laboratory wet mounts of living trichomes during the first minute. Phase-contrast micrographs. (c and d) Excreted polymer coated with iron oxides, through the peculiar type of motion, form fan-shaped structures (c) or double tracks (d). (Reproduced with permission from J.M. Krul et al., 1970. *Antonie van Leeuwenhoek Journal of Microbiology* 36: 409–420.)

containing *Toxothrix* in the laboratory for several months; *Toxothrix* cells survived if the samples contained sediment and organic detritus and were kept cold (5°C) and dark.

The appearance of *Toxothrix* throughout the year (except for May and June) has been reported (Hirsch, 1981). Usually, it is found where *Gallionella ferruginea* grows and in waters with Fe²⁺ (1–2.7 mg/l). But *Toxothrix* cells, contrary to *Gallionella* cells, prefer habitats with a slightly higher concentration of organic compounds. An iron spring catch basin with cold, Fe-containing water and decaying leaves appears to be the optimal *Toxothrix* habitat.

Differentiation of the genus *Toxothrix* from other genera

In the absence of Fe deposition, the *Toxothrix* filaments closely resemble *Herpetosiphon*, *Haliscomenobacter*, or “*Achroonema*” filaments. But *Herpetosiphon* filaments are extremely long

(300–1200 μm) and vary in their cell diameter. Also, transparent sections at the filament tips of *Herpetosiphon* (called necridia) are not present in *Toxothrix*. Strains of *Haliscomenobacter* are not known to glide or to show true branches, and their optimum pH is 7.0–8.0; also, they do not deposit iron oxides. “*Achroonema*” filaments do not glide in a U-shaped way but remain straight and fairly rigid.

Taxonomic comments

Balashova (1968) has pointed out that in some respects *Toxothrix* resembles *Gallionella*. The great differences in cell shape do not seem to support this view. Beger and Bringmann (1954) described “*Toxothrix gelatinosa*” on the basis of smaller filaments (diameter with slime threads: 1.5–1.7 μm) and the fan-shaped arrangements of individual filaments in a gelatinous matrix. However, the individual cell size (0.5×3 μm) falls within the range given for *Toxothrix trichogenes*.

List of species of the genus *Toxothrix*

1. ***Toxothrix trichogenes*** (Cholodny 1924) Beger *in* Beger and Bringmann 1953, 332^{AL} (*Leptothrix trichogenes* Cholodny 1924, 296; *Toxothrix ferruginea* Molisch 1925, 144; *Chlamydothrix trichogenes* (Cholodny 1924) Naumann 1929, 513; *Sphaerotilus trichogenes* (Cholodny 1924) Pringsheim 1949, 234)

tri.cho'ge. nes. Gr. n. *thrix trichos* hair; N.L. suff. *-genes* (from Gr. v. *gennaō* to produce) producing; N.L. adj. *trichogenes* hair-producing.

Description is the same as for the genus.

DNA G+C content (mol%): unknown.

Type strain: no culture isolated.

Phylum XV. Spirochaetes Garrity and Holt 2001

BRUCE J. PASTER

Spi.ro.chae'tes. N.L. fem. pl. n. *Spirochaetales* type order of the phylum; dropping the ending to denote a phylum; N.L. fem. pl. n. *Spirochaetes* the phylum of *Spirochaetales*.

Spirochetes are Gram-stain-negative, helical or spiral-shaped, motile cells that can flex, rotate and translate through liquid and semisolid environments. Most spirochetes possess a cellular ultrastructure unique to bacteria in that they have internal organelles of motility, namely periplasmic flagella. Consequently, the spirochetes are one of the few bacterial phyla whose phenotypic characteristics, e.g., cell morphology, reflect its phylogenetic relationships as based on 16S rRNA gene sequence comparisons (Garrity and Holt, 2001), forming a distinct line of evolutionary descent among the bacteria (Garrity et al., 2005).

Spirochetes are chemo-organotrophic and, depending upon the species or phylogenetic group, may grow under anaerobic, microaerophilic, facultatively anaerobic or aerobic conditions. Some are free-living and others are host-associated, e.g.,

arthropods, mollusks, and mammals, including humans. Some species are known to be pathogenic.

Type order: Spirochaetales Buchanan 1918, 163^{AL}.

Class I. Spirochaetia class. nov.

BRUCE J. PASTER

Spi.ro.chae'ti.a. N.L. fem. n. *Spirochaeta* type genus of the type order *Spirochaetales*; suff. *-ia* ending proposed by Gibbons and Murray and by Stackebrandt et al. to denote a class; N.L. neut. pl. n. *Spirochaetia* the class of *Spirochaetales*.

Members of the class *Spirochaetia* are as described for the phylum. The class contains spirochetes in one order, *Spirochaetales*, which is presently comprised of four families, namely *Spirochaetaceae*, *Brachyspiraceae*, *Brevinemataceae*, and *Leptospiraceae*.

Type order: Spirochaetales Buchanan 1918, 163^{AL}.

Reference

- Buchanan, R.E. 1918. Studies in the nomenclature and classification of the bacteria: X. Subgroups and genera of the *Myxobacteriales* and *Spirochaetales*. *J. Bacteriol.* 3: 541–545.

Order I. Spirochaetales Buchanan 1917, 163^{AL}

BRUCE J. PASTER

Spi.ro.chae.ta'les. N.L. fem. n. *Spirochaeta* type genus of the order; *-ales* suffix to denote an order; N.L. fem. pl. n. *Spirochaetales* the *Spirochaeta* order.

Based on 16S rRNA gene sequence comparisons, spirochetes form a coherent phylogenetic phylum (Paster et al., 1991). The order *Spirochaetales* contains the families *Spirochaetaceae*, *Brachyspiraceae*, *Brevinemataceae*, and *Leptospiraceae*, as shown in Figure 82.

Helically shaped, motile bacteria, 0.1–3 µm in diameter and 4–250 µm in length. Cells have **internal organelles of motility called periplasmic flagella** (which have been previously called axial fibrils, axial filaments, flagella, endoflagella, and periplasmic fibrils) (Canale-Parola, 1978; Paster and Canale-Parola, 1980). Periplasmic flagella are inserted subterminally at each end of the

protoplasmic cylinder and extend along most of the length of the cell overlapping in the central region, but the other end of the flagella are inserted (Figure 82). This results in a n:2n:n flagellar arrangement where n ranges from 1 to 100s depending upon the species. However, the periplasmic flagella do not overlap in cells of members of the family *Leptospiraceae*. The protoplasmic cylinder and flagella are encased by an “outer sheath” which has some features analogous the outer membrane of traditional Gram-stain-negative bacteria (Figure 82). Under certain growth conditions, periplasmic flagella of some species protrudes outside of the cell (Charon et al., 1992) (Figure 82).

FIGURE 82. Schematic representation of a spirochete. The dotted line indicates the outer sheath encasing the helical protoplasmic cell and the periplasmic flagella which are inserted at each end of the cell.

Chemoheterotrophic. Carbohydrates, amino acids, long-chain fatty acids, or long-chain fatty alcohols serve as carbon and energy sources. **Anaerobic, facultatively anaerobic, microaerophilic, and aerobic.** Stains Gram-negative.

Free-living or in association with animal, insect, and human hosts. Some species are pathogenic.

DNA G+C content (mol%): 25–66.

Type genus: **Spirochaeta** Ehrenberg 1835, 313^{AL}.

Further descriptive information

Spirochetes have three main types of movements in liquids, namely locomotion, rotations about their longitudinal axis, and flexing (Canale-Parola, 1978). Cells can translocate in highly viscous environments, such as methyl cellulose or in media containing 1% agar. Cells also have been reported to creep or crawl on solid surfaces.

Some “free-living pleomorphic spirochetes”, referred to as FLiPS (Ritalahti and Löffler, 2004), have been recently described. One species from the termite hindgut has been named *Spirochaeta coccoides* (Dröge et al., 2006). These species do not have the characteristic ultrastructural and behavioral features of spirochetes; namely helical, motile cells with protoplasmic cylinder and periplasmic flagella enclosed in an outer sheath. However based on 16S rRNA gene sequence analysis, these species fall within the family *Spirochaetaceae* (see chapter on *Spirochaeta*, below).

“*Spirochaeta culicis*” was isolated recently from the mosquito and is the only species of the genus (Cechová et al., 2004). Although it has not yet been formally named, it falls phylogenetically within the family *Spirochaetaceae* (Figure 83) and likely warrants separate genus designation from other genera of the family.

Sequences of species of the genera *Treponema* and *Spirochaeta* in the family *Spirochaetaceae*, *Brevinema* in the family *Brevinemataceae*, and *Leptospira* in the family *Leptospiroaceae* are unusual among bacteria in that they possess a 20–30 base 5′ extension of 16S rRNA molecule (Paster et al., 1991). The function of this 5′ extension is unknown, but the region is highly variable and was proposed to form helices of 2–12 bases. The 5′ extension has not been reported in other spirochetal species.

Key to the families of the order *Spirochaetales*

1. Cell diameter 0.1–3 μm. Ends of cells are usually not hooked. Periplasmic flagella overlap in the central region of the cell.

FIGURE 83. Phylogeny of the order *Spirochaetales*. The order is comprised of four families, namely *Spirochaetaceae*, *Brachyspiroaceae*, *Brevinemataceae*, and *Leptospiroaceae*. Bar = 5% difference in 16S rRNA gene sequences.

The diamino acid in the peptidoglycan is L-ornithine. Anaerobic or facultatively anaerobic. Use carbohydrates and/or amino acids as carbon and energy sources. Free-living and host associated.

→ Family I. *Spirochaetaceae*

2. Cell diameter 0.2–0.4 μm. Cell ends may be blunt or pointed, and are not hooked. Periplasmic flagella overlap in the central region of the cell. The diamino acid in the peptidoglycan is L-ornithine. Obligately anaerobic, aerotolerant. Use monosaccharides, disaccharides, the trisaccharide trehalose, and amino sugars as carbon and energy sources. Does not use polysaccharides. Host-associated.

→ Family II. *Brachyspiroaceae*

3. Cell diameter 0.2–0.3 μm. Cells are short, 4–5 μm in length with only one or two turns. Ends of cells are usually not hooked. Periplasmic flagella overlap in the central region of the cell. The diamino acid in the peptidoglycan is not known. Microaerophilic. Peptones are required for growth. Host-associated.

→ Family III. *Brevinemataceae*

4. Cell diameter 0.1–0.3 μm. Ends of cells are usually hooked. The diamino acid in the peptidoglycan is diaminopimelic acid. Periplasmic flagella do not appear to overlap in the central region of the cell. Obligately aerobic, or microaerophilic. Use long-chain fatty acids or long-chain fatty alcohols as carbon and energy sources. Do not use carbohydrates or amino acids. Free-living and host-associated.

→ Family IV. *Leptospiroaceae*

Family I. Spirochaetaceae Swellengrebel 1907, 581^{AL}

BRUCE J. PASTER

Spi.ro.chae.ta.ce'ae. N.L. fem. n. *Spirochaeta* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Spirochaetaceae* the *Spirochaeta* family.

Helical cells, 0.1–3.0 µm in diameter and 3.5–250 µm in length. Cells do not have hooked ends as do members of the family *Leptospiraceae*. Periplasmic flagella are inserted subterminally at each end of the cell and extend along most of the length of the cell overlapping in the central region (Figure 82). **The diamino acid in the peptidoglycan is L-ornithine.** Motile.

Anaerobic, facultatively anaerobic, or microaerophilic. Chemo-organotrophic. **Utilize carbohydrates and/or amino acids as carbon and energy sources.** Do not use long-chain fatty acids or long-chain fatty alcohols as energy sources.

Free-living or in association with animal, insect and human hosts. Some species are pathogenic. The DNA G+C content is 36–66 mol% (T_m , Bd, and genetic sequence analysis). Species examined by 16S rRNA sequence analysis are distinct from members of the families *Brachyspiraceae*, *Brevinemataceae*, and *Leptospiraceae* (Figure 83).

Type genus: *Spirochaeta* Ehrenberg 1835, 313^{AL}.

Key to the genera of the family Spirochaetaceae

- Cells are 0.2–75 µm in diameter and 5–250 µm in length. Obligately anaerobic and facultatively anaerobic. Carbohydrates serve as energy and carbon sources. Amino acids are not used as growth substrates. Free-living in fresh water and marine environments, including mud, sediments and water of ponds, lakes, streams, and marshes. Many not-yet-cultivated species identified as based on 16S rRNA gene sequence comparisons. Not considered as pathogenic. The DNA G+C content is 45–66 mol% (T_m , Bd, and HPLC).
→ Genus I. *Spirochaeta*
- Cells are 0.2–0.3 µm in diameter and 3–20 µm in length. Microaerophilic. Arthropod-borne pathogens of man, other mammals, and birds. The causative agents of tick-borne Lyme disease and relapsing fever and louse-borne relapsing fever in man. The DNA G+C content of a limited number of species is 27–32 mol% (T_m , HPLC, and genome sequencing).
→ Genus II. *Borrelia*
- Cells are 0.5–3 µm in diameter and 30–180 µm in length. Hundreds of periplasmic flagella present as a bundle forming a ridge called crista. Inhabit the crystalline style of the digestive tract of aquatic mollusks. Not grown in pure culture. The DNA G+C content is not known.
→ Genus III. *Cristispira*
- Cells are 0.1–0.4 µm in diameter and 5–20 µm in length. Obligately anaerobic. Carbohydrates and amino acids serve as energy and carbon sources. Found in the oral cavity, intestinal tract, and genital areas of humans and animals. Some species are pathogenic. Also found in the hindgut of termites. Many not-yet-cultivated species identified as based on 16S rRNA gene sequence comparisons. The DNA G+C content is 36–54 mol% (T_m , HPLC, genome sequence).
→ Genus IV. *Treponema*

Genus I. *Spirochaeta* Ehrenberg 1835, 313^{AL} (*Spirochoeta* Dujardin 1841, 225, and *Spirochaete* Cohn 1872, 180 (orthographic variants of *Spirochaeta*); *Ehrenbergia* Gieszczykiewicz 1939, 24)

SUSAN LESCHINE AND BRUCE J. PASTER

Spi.ro.chae'ta. Gr. n. *speira* (L. transliteration *spira*) a coil; Gr. fem. n. *chaitê* (L. transliteration *chaete*) hair; N.L. fem. n. *Spirochaeta* coiled hair.

Flexible helical cells 0.2–0.75 µm in diameter and 5–250 µm in length. All species have two periplasmic flagella per cell except *Spirochaeta plicatilis*, which has many periplasmic flagella. Under unfavorable conditions, spherical cells or structures 0.5–2.0 µm (occasionally up to 10 µm) in diameter are formed. Cells translocate when suspended in liquids and crawl or creep when in contact with solid surfaces. **Obligately anaerobic or facultatively anaerobic.** Under aerobic growth conditions the **facultatively anaerobic species usually produce carotenoid pigments** that give a yellow, yellow-orange, or red coloration to colonies or cells in liquid media. Thermophilic species are known. Optimum temperature range, 25–68°C. **Chemo-organotrophic,**

using a variety of carbohydrates as carbon and energy sources. The main products of anaerobic carbohydrate metabolism are ethanol, acetate, CO₂, and H₂. Under aerobic conditions, facultatively anaerobic species oxidize carbohydrates yielding primarily CO₂ and acetate. Indigenous to aquatic freshwater and marine environments such as the sediments, mud and water of ponds, marshes, swamps, lakes, rivers, and hot springs. Occur commonly in H₂S-containing environments. **Free-living.** None reported to be pathogenic.

DNA G+C content (mol%): 50–65 (Bd), 45–66 (T_m), 50–58.5 (HPLC).

Type species: *Spirochaeta plicatilis* Ehrenberg 1835, 313^{AL}.

Further descriptive information

Cells of all species are helical in shape and possess the typical ultrastructural features of spirochetes (Canale-Parola, 1984a). The outermost structure of the cells is an "outer membrane", or "outer sheath", which encloses the coiled cell body ("protoplasmic cylinder") consisting of the cytoplasm, the nuclear region, and the peptidoglycan-cytoplasmic membrane complex. Organelles ultrastructurally similar to bacterial flagella are located in the area between the outer membrane and the protoplasmic cylinder. These organelles are essential components of the motility apparatus of spirochetes (Paster and Canale-Parola, 1980) and are usually called "periplasmic flagella". One end of each periplasmic flagellum is inserted near a pole of the protoplasmic cylinder, while the other end is not inserted. Individual periplasmic flagella extend for most of the length of *Spirochaeta* cells so that those inserted near opposite ends overlap in the central region of the organism.

The nature of the spherical structures, called "spherical bodies", that are formed under unfavorable growth conditions has not been determined. Spherical bodies occur either in physical association with helical cells or free.

When suspended in liquids, cells translocate "in straight lines or nearly straight lines, and they appear to spin rapidly about their longitudinal axis (Berg, 1976). The motility of a strain of *Spirochaeta aurantia* in liquid environments has been described (Greenberg et al., 1985, 1977c). Occasionally a cell stops momentarily and flexes, and then resumes spinning and translational motility. However, when translation resumes, the direction of movement is usually altered..." and frequently the previously leading cell end becomes the trailing end (Greenberg and Canale-Parola, 1977c). During runs, *Spirochaeta aurantia* cells have an average linear speed of approximately 16/s (Fosnaugh and Greenberg, 1988). Flexes last from a fraction of a second to several seconds. The average frequency of reversals in cell populations is approximately 0.31 reversals/5 s (Fosnaugh and Greenberg, 1988). Cells in motion usually retain their basic helical configuration, but they assume a variety of shapes as a result of flexing, undulating, and contracting, as well as wave propagation. Broad secondary coils or waves superimposed on the smaller primary coils are formed frequently (Canale-Parola, 1977, 1978). During creeping movements of *Spirochaeta plicatilis* on solid surfaces (Blakemore and Canale-Parola, 1973), "... the rear coils follow the tortuous path of the anterior cell end almost exactly" (Canale-Parola, 1978).

Cells retain translational motility in environments of relatively high viscosity, usually becoming immotile at viscosities of 300–1000 centipoise, depending on the strain (Greenberg and Canale-Parola, 1977a, b).

Strains of *Spirochaeta aurantia* exhibit chemotaxis toward carbohydrates, but not toward amino acids (Breznak and Canale-Parola, 1975; Greenberg and Canale-Parola, 1977c). Effective attractants for *Spirochaeta aurantia* strain M1 are as follows: D-glucose, 2-deoxy-D-glucose, α -methyl-D-glucoside, D-galactose, D-fucose, D-mannose, D-fructose, D-xylose, maltose, cellobiose, and D-glucosamine (Greenberg and Canale-Parola, 1977c). Taxis toward D-galactose and D-fucose is induced by the presence of D-galactose in the growth medium.

The helical shape of the cells is maintained by the peptidoglycan layer (Joseph and Canale-Parola, 1972). L-Ornithine is the only diaminoamino acid in the peptidoglycan of *Spirochaeta*

stenostrepta, *Spirochaeta litoralis*, *Spirochaeta aurantia*, and *Spirochaeta halophila* (Joseph et al., 1973; B.J. Paster and E. Canale-Parola, unpublished data). The peptidoglycans of *Spirochaeta zuelzeriae* and *Spirochaeta plicatilis* have not been tested for the presence of L-ornithine.

The peptidoglycan of *Spirochaeta stenostrepta* is composed of acylglucosamine, acylmuramic acid, L-alanine, D-glutamic acid, L-ornithine, and D-alanine (Joseph et al., 1973; Schleifer and Joseph, 1973). Peptidoglycan of similar composition is present in *Spirochaeta litoralis*. At least 50% of the peptide subunits of the peptidoglycan of *Spirochaeta stenostrepta* contain the tripeptide N-acyl-muramyl-L-alanyl- α -D-glutamyl-L-ornithine. Cross-linkage (30%) between the 6-amino group of L-ornithine and the carboxyl group of D-alanine occurs in the remaining peptide subunits of sequence N-acyl-muramyl-L-alanyl- α -D-glutamyl-L-ornithyl-D-alanine (Schleifer and Joseph, 1973).

A lipoprotein layer, adjacent and external to the peptidoglycan, has been detected in *Spirochaeta stenostrepta* (Joseph et al., 1970). This layer consists of a fine array of tightly packed, longitudinally oriented helices measuring 2.5 nm in diameter (Holt and Canale-Parola, 1968).

Colonies of *Spirochaeta* diffuse or spread through the agar medium in which they are growing. This phenomenon is especially apparent in agar media containing low substrate concentrations and 1% or less agar. Diffusion of colonies is due to migration of the growing cells through the agar medium. Migration of the cells is the result of chemotaxis toward the growth substrate and of the ability of spirochetes to locomote through agar gels (Canale-Parola, 1977, 1978).

The growth of obligately anaerobic species of *Spirochaeta* is abundant in media with 1.0 or 1.5 g of agar/100 ml, whereas the growth of some strains of facultatively anaerobic species of *Spirochaeta* is inhibited in media containing more than 1.0% agar. However, these strains grow abundantly when the agar concentration in the medium is 1% or lower. Under anaerobic conditions, *Spirochaeta stenostrepta*, *Spirochaeta litoralis*, *Spirochaeta aurantia*, and *Spirochaeta halophila* ferment carbohydrates to pyruvate via the Embden–Meyerhof pathway (Canale-Parola, 1977; Greenberg and Canale-Parola, 1976). Pyruvate is metabolized to acetyl-CoA, CO₂, and H₂ by means of a clostridial-type clastic reaction. Acetyl-CoA is converted to acetate in reactions catalyzed by phosphotransacetylase and acetate kinase, and to ethanol through a double reduction involving aldehyde and alcohol dehydrogenase activities (Canale-Parola, 1977). These pathways constitute the major anaerobic energy-yielding mechanisms utilized by the four *Spirochaeta* species mentioned above (Canale-Parola, 1977). The pathways of carbohydrate catabolism utilized by *Spirochaeta zuelzeriae* have not been elucidated. This spirochete does not form ethanol, but produces succinate and larger amounts of lactate than do other species.

In addition to carbohydrates, *Spirochaeta isovalerica* ferments L-leucine, L-isoleucine, and L-valine, forming isovaleric, 2-methylbutyric, and isobutyric acids, respectively, as end products (Harwood and Canale-Parola, 1983). Fermentation of the amino acids in the absence of glucose does not support measurable growth of *Spirochaeta isovalerica*, but serves to generate ATP, which is utilized as a source of maintenance energy by the spirochete when fermentable carbohydrates are not available (Harwood and Canale-Parola, 1981a, 1983). In addition to the branched-chain fatty acids, amino acid catabolism by

Spirochaeta isovalerica yields small quantities of isobutanol and isoamyl alcohol (Harwood and Canale-Parola, 1981b, 1983).

When growing aerobically, *Spirochaeta aurantia* and *Spirochaeta halophila* derive energy by performing an incomplete oxidation of carbohydrates, with CO₂ and acetate being the main dissimilatory products. The tricarboxylic acid cycle either is not present or serves in a minor catabolic capacity in these two species. Determinations of molar growth yields and other studies indicate that, when growing aerobically, *Spirochaeta aurantia* and *Spirochaeta halophila* generate ATP via oxidative phosphorylation as well as by substrate level phosphorylation (Breznak and Canale-Parola, 1972a; Greenberg and Canale-Parola, 1976). Cytochromes *b*₅₅₈ and cytochrome *o* are present in *Spirochaeta aurantia* (Breznak and Canale-Parola, 1972a).

Spirochaeta species are able to synthesize all of their cell lipids *de novo*. The chain length of cellular fatty acids varies from 12 to 18 carbons (Livermore and Johnson, 1974). *Spirochaeta aurantia* and *Spirochaeta zuelzeri* but not *Spirochaeta litoralis* and *Spirochaeta stenostrepta* synthesize unsaturated fatty acids. *Spirochaeta stenostrepta* and *Spirochaeta zuelzeri* but not *Spirochaeta litoralis* and *Spirochaeta aurantia* synthesize anteiso branched-chain fatty acids (Livermore and Johnson, 1974).

Spirochaeta species are resistant to the antibiotic rifampicin (rifampin) at concentrations of 1–50 µg rifampicin/ml. Resistance to rifampicin may be due to low affinity of the spirochetal RNA polymerase for the antibiotic.

Enrichment and isolation procedures

Anaerobic and facultatively anaerobic spirochetes occur commonly in aquatic freshwater and marine environments such as the sediments, mud and water of ponds, marshes, swamps, lakes, rivers, and hot springs, often in association with decomposing plant biomass (Harwood and Canale-Parola, 1984; Leschine, 1995). *Spirochaeta* strains are readily isolated from natural environments by means of selective procedures and usually grow abundantly in ordinary laboratory media. Anaerobic growth yields of the isolates range from 2 to 10⁸ to approximately 10⁹ cells/ml, but commonly are 6–8×10⁸ cells/ml (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976; Harwood and Canale-Parola, 1984; Hespell and Canale-Parola, 1970a, b). Cell population doubling times in anaerobic cultures are 2.2–12 h, depending on the species and the growth conditions. Aerobically grown cultures yield 0.7–1.2×10⁹ spirochetes/ml, with doubling times of 2–4 h (Breznak and Canale-Parola, 1975; Canale-Parola, 1973; Greenberg and Canale-Parola, 1976).

A procedure in which the antibiotic rifampicin (rifamycin) serves as a selective agent is quite effective for the isolation of free-living (genus *Spirochaeta*) and host-associated (genus *Treponema*) spirochetes from natural environments (Harwood et al., 1982; Patel et al., 1985; Stanton and Canale-Parola, 1979; Weber and Greenberg, 1981). This procedure (described below) is based on the observation that spirochetes in general are naturally resistant to rifampicin (Leschine and Canale-Parola, 1986; Stanton and Canale-Parola, 1979). Thus, spirochetes such as *Spirochaeta stenostrepta* and *Spirochaeta aurantia* grow in the presence of as much as 100–200 µg of rifampicin per ml of medium (Leschine and Canale-Parola, 1986), whereas the growth of many other bacteria is inhibited. The resistance of spirochetes to rifampicin is probably due to the low affinity of their RNA

polymerase for the antibiotic (Allan et al., 1986; Leschine and Canale-Parola, 1986).

Enrichment procedures used in the isolation of *Spirochaeta* species are based on one or more of the following selective factors: (1) resistance to rifampicin (mentioned above), (2) the ability of spirochetes to pass through filters that retain most other bacteria, (3) the migratory movement of spirochetes through agar media (Canale-Parola, 1973, 1984b). The latter two procedures will enrich for species of *Spirochaeta* measuring less than 0.5 µm in diameter.

In the enrichment-by-filtration procedure (described below), separation of *Spirochaeta* species from most of the microorganisms present in mud or water is achieved by techniques involving filtration through cellulose ester filter discs (e.g., Millipore filters) having a mean pore diameter of 0.3 or 0.45 µm. Spirochetes pass through these filter discs because their cell diameter is relatively small, and probably also because their motility apparatus enables them to swim freely in liquids as well as to move in contact with solid surfaces.

The enrichment-by-migration procedure uses the ability of spirochetes to move through agar gels or media containing as much as 1–2% (w/v) agar. This movement or migration occurs primarily within the agar gel, i.e., below the surface of the agar medium. In contrast, flagellated bacteria usually cannot carry out translational movement through gels or media containing agar at the above-mentioned concentrations, although several exceptions have been reported (Greenberg and Canale-Parola, 1977a). Apparently, the cell coiling of spirochetes is important for their translational motion through agar gels, inasmuch as this type of movement is impaired in mutant spirochetes lacking the cell-coiling characteristic of the parental strain (Greenberg and Canale-Parola, 1977b).

Migration of spirochetes through agar media results from the unique motility mechanism of these bacteria (Canale-Parola, 1977, 1978), as well as from chemotaxis toward the energy and carbon source (Breznak and Canale-Parola, 1975; Greenberg and Canale-Parola, 1977c; Terracciano and Canale-Parola, 1984). The role of chemotaxis in the migration of saccharolytic spirochetes through agar media has been studied (Breznak and Canale-Parola, 1975). When these spirochetes are inoculated in the center of glucose-containing agar medium plates, they grow using this sugar as their energy source. Utilization of the sugar by the spirochetes gives rise to a glucose concentration gradient that moves away from the center of the plate as more of this carbohydrate is metabolized by the spirochetes. Because the spirochetes exhibit chemotaxis toward glucose and are able to move through the agar gel, they migrate into the areas of higher glucose concentration within the gradient. Thus, the spirochetal population, by following the outward movement of the gradient, migrates toward the periphery of the plate. This behavior results in the formation of a growth "veil" or "ring" of spirochetes for which glucose serves both as the energy source for growth and as the chemoattractant (Breznak and Canale-Parola, 1975; Canale-Parola, 1973). The veil or ring increases continuously in diameter during incubation and may reach the outer edge of the plate. The migration rate of the spirochetal population is greatest in agar media containing low substrate concentrations (e.g., 0.02% glucose). In these media the substrate becomes rapidly depleted in the region where spirochetes are growing, and the spirochetal population moves toward the

outer zone of higher substrate concentrations at a relatively fast rate (Breznak and Canale-Parola, 1975).

In procedures for the isolation of *Spirochaeta* species from natural environments, the chemotactic behavior and the ability of these bacteria to move through agar gels have important selective functions. In a typical isolation procedure, a small, shallow cylindrical hole is made through the surface of an agar medium containing a low concentration of carbohydrate. Rifampicin may be included in the medium as an additional selective agent for spirochetes. The medium may be in a Petri dish or a small bottle. A tiny drop of pond water, or of any other material in which spirochetes have been observed, is placed within the hole. The chemotactic, saccharolytic spirochetes in the inoculum multiply and form a growth veil that extends outwardly through the agar medium. Thus, the spirochetes in the veil move away from contaminants, which remain mainly in the vicinity of the inoculation site. Spirochetal cells from the outermost edge of the veil are used to obtain pure cultures by conventional methods, such as streaking on agar medium plates. Isolation procedures involving chemotaxis and movement through agar gels are described below.

Selective isolation techniques have not been developed for the large *Spirochaeta* species, such as *Spirochaeta plicatilis*.

Maintenance procedures

Species of *Spirochaeta* remain viable for many years when stored in the frozen state at the temperature of liquid nitrogen. Methods for liquid nitrogen storage of *Spirochaeta* species and for the preparation of other types of stock cultures of these bacteria have been described (Canale-Parola, 1973).

Differentiation of the genus *Spirochaeta* from other genera

Members of the genus *Spirochaeta* are readily differentiated from other genera of spirochetes as shown in Table 118.

Taxonomic comments

Based on 16S rRNA gene sequence comparisons (Paster et al., 1984, 1991), members of the genus *Spirochaeta* belong within the family *Spirochaetaceae* and are clearly distinct from the other genera of spirochetes (Figure 84). These data also suggest that *Spirochaeta aurantia* warrants separate genus designation, although it would still fall within the family *Spirochaetaceae* (Figure 84). However, several species of *Spirochaeta*, including *Spirochaeta*

stenostrepta, *Spirochaeta zuelzeriae*, and *Spirochaeta caldaria*, do not belong with other free-living *Spirochaeta* (shown in Figure 84), but are more closely related to members of the genus *Treponema*. The phylogenetic clustering of these species has also been confirmed by single-base signature analysis, i.e., the sequences of these species have more signature bases found in the sequences of the treponemes than in the sequences of *Spirochaeta* species. Consequently, these species should be classified as species of *Treponema*, but since there has been no formal renaming, they remain *Spirochaeta* spp. in this chapter. These “free-living”

FIGURE 84. Phylogenetic tree of the genus *Spirochaeta* and related organisms, based on 16S ribosomal RNA gene (rRNA) sequences. Some of the named *Spirochaeta* species shown in brackets, namely [*Spirochaeta*] *zuelzeriae*, [*Spirochaeta*] *caldaria*, [*Spirochaeta*] *stenostrepta*, [*Spirochaeta*] *xylanolyticus* and [*Spirochaeta*] *taiwanensis*, are phylogenetically more related to members of the genus *Treponema*. The scale bar represents a 5% difference in nucleotide sequence.

^anr, Not reported or not determined.

^bSome species of the free-living *Spirochaeta* are more closely related to species of *Treponema* based on 16S rRNA sequence comparisons.

spirochetes might represent transitional species, i.e., they could be descendants of precursors of host-associated treponemes. Alternatively, these species may have been from a mammalian host and were disseminated via fecal contamination.

Two other purported species of *Spirochaeta* that belong more with the treponemes have been described. Two thermophilic anaerobic, xylan-degrading spirochetal strains were isolated from a hot spring in Taiwan. They have been provisionally named (unpublished) as *Spirochaeta taiwanensis* (AY735103) and *Spirochaeta xylanolyticus* (AY735097), but are likely the same species with nearly identical 16S rRNA sequences. However, these thermophilic spirochetes are also close relatives of *Spirochaeta caldaria* and consequently are likely members of the genus *Treponema*.

16S rRNA sequences of these *Spirochaeta* species possess a 20–30-base extension at the 5' end, which is typical of 16S rRNA sequences of species of *Spirochaeta*, *Treponema*, *Leptospira*, and *Leptonema* (Defosse et al., 1995; Paster et al., 1991).

Differentiation of the species of the genus *Spirochaeta*

Sixteen species of *Spirochaeta* are presently known and listed below. Characteristics that differentiate these species are shown in Table 119. *Spirochaeta plicatilis* has not been grown in pure culture, but its ultrastructure and some of its ecological characteristics have been described (Blakemore and Canale-Parola, 1973). Ten species (*Spirochaeta stenostrepta*, *Spirochaeta litoralis*, *Spirochaeta zuelerae*, *Spirochaeta isovalerica*, *Spirochaeta bajacaliforniensis*, *Spirochaeta thermophila*, *Spirochaeta caldaria*, *Spirochaeta smargdinae*, *Spirochaeta asiatica*, and *Spirochaeta americana*) are obligate anaerobes, and two species (*Spirochaeta alkalica* and *Spirochaeta africana*) are aerotolerant anaerobes. Three other species, *Spirochaeta aurantia*, *Spirochaeta halophila*, and *Spirochaeta cellobiosiphila* are facultative anaerobes. When grown aerobically, *Spirochaeta aurantia* and *Spirochaeta halophila* but not *Spirochaeta*

cellobiosiphila characteristically produce carotenoid pigments (Breznak and Warnecke, 2008; Greenberg and Canale-Parola, 1975). Most species of *Spirochaeta* are mesophilic, growing at optimum temperatures in the range 15–40°C. However, the thermophilic species, *Spirochaeta thermophila* and *Spirochaeta caldaria*, both from thermal springs, have optimum growth temperature of 66–68 and 48–52°C, respectively.

Two subspecies of *Spirochaeta aurantia* are known. One of these (*Spirochaeta aurantia* subsp. *stricta*) is characterized by significantly narrower coils than the other (*Spirochaeta aurantia* subsp. *aurantia*), and its DNA possesses a slightly lower G+C content (Breznak and Canale-Parola, 1975; Canale-Parola, 1984b).

Spirochaeta stenostrepta, *Spirochaeta zuelerae*, *Spirochaeta caldaria*, and *Spirochaeta aurantia* are freshwater species, whereas *Spirochaeta litoralis*, *Spirochaeta isovalerica*, *Spirochaeta bajacaliforniensis*, *Spirochaeta thermophila*, and *Spirochaeta cellobiosiphila* are marine species and require sodium ion (Na⁺) concentrations in the range 200–480 mM for optimal growth (Aksenova et al., 1990, 1992; Breznak and Warnecke, 2008; Fracek and Stolz, 1985; Harwood and Canale-Parola, 1983; Hespell and Canale-Parola, 1970b). *Spirochaeta halophila* was isolated from a high-salinity pond and grows optimally when 750 mM NaCl, 200 mM MgSO₄, and 10 mM CaCl₂ are present in the medium (Greenberg and Canale-Parola, 1976). Other halophilic species include *Spirochaeta americana*, *Spirochaeta asiatica*, *Spirochaeta alkalica*, and *Spirochaeta africana*, which were isolated from the sediments of hypersaline lakes and require Na⁺ concentrations in the range 850–1200 mM for optimal growth (Hoover et al., 2003; Zhilina et al., 1996). The latter three species are also alkaliphilic and growth does not occur below pH 8. *Spirochaeta smargdinae*, isolated from a production water sample collected from an offshore oilfield, requires at least 170 mM NaCl and grows optimally with 850 mM NaCl (Magot et al., 1997).

List of species of the genus *Spirochaeta*

1. *Spirochaeta plicatilis* Ehrenberg 1835, 313^{AL}

pli.ca'ti.lis. L. fem. adj. *plicatilis* flexible.

Helical cells, 0.75 µm in diameter and usually 80–250 µm in length. Cells have regular primary coils, which are stable (persist both in the presence and absence of movement). Cells in motion may exhibit broad secondary coils superimposed on the smaller primary coils and when suspended in liquids, they display rotation about the longitudinal axis and wide waves traveling along the length of the organism. Cells creep in contact with solid surfaces (Blakemore and Canale-Parola, 1973).

Regularly spaced cross-walls or transverse septa are present (Blakemore and Canale-Parola, 1973). Long specimens may consist of chains of multicellular spirochetes. Many periplasmic flagella are present, occurring as a bundle wound around the protoplasmic cylinder. Phase-contrast photomicrographs and electron micrographs of the cells have been published (Blakemore and Canale-Parola, 1973).

Not cultivated in pure culture. Presumed to be either a microaerophile or an anaerobe that can tolerate low O₂ tensions. Present in H₂S-containing freshwater, brackish and marine mud, frequently in association with *Beggiatoa* trichomes.

DNA G+C content (mol%): not determined.

Type strain: not yet grown in pure culture.

Sequence accession no. (16S rRNA gene): none.

2. *Spirochaeta africana* Zhilina 1996, 310^{VP}

a.fri.ca'na. L. fem. adj. *africana* of African continent, found in African alkaline Lake Magadi.

Motile, helical cells, 0.25–0.3 µm in diameter and 15–30 µm in length, with shorter (7.5 µm) and longer (up to 40 µm) cells occurring in culture. Outermost structure is an outer membrane enclosing periplasmic flagella and a protoplasmic cylinder. Cells have regular, stable primary coils. Cell mass is orange.

Anaerobic, aerotolerant, fermentative; utilizes carbohydrates, mainly mono- and disaccharides, as carbon and energy sources. Preferred substrates: fructose > maltose = trehalose = sucrose > cellobiose > glucose > glycogen > starch; poor growth with mannose or xylose; no growth with galactose, N-acetylglucosamine, or ribose (the optical isomers of the sugars were not described). Amino acids do not serve as fermentable substrates. A supplement of vitamins is required; yeast extract can be omitted from culture media. Aerotolerant; develops under a cotton plug in liquid medium.

^aAbbreviations: ObAn, obligate anaerobe; FAn, facultative anaerobe; O₂An, oxygen-tolerant anaerobe; A, acetic acid; E, ethanol; H, hydrogen; C, carbon dioxide; L, lactic acid; F, formate; nd, not determined.

Primary products of glucose fermentation are acetate, ethanol, and H₂. Lactate is a minor product in stationary phase.

Halophilic, growing in sodium carbonate medium, but not requiring it. Depends on sodium; no growth below 3% (w/v) or above 10% (w/v) NaCl. Optimal growth at pH 8.8–9.75. No growth at pH 8.0–10.8. Optimum temperature for growth, 30–37°C; range, 15–47°C; slow growth at 6°C after a long lag phase.

Source: a bacterial bloom in the brine under trona (e.g., a sedimentary deposit that results from the evaporation of seawater) from alkaline equatorial Lake Magadi.

DNA G+C content (mol%): 57.1 (*T_m*).

Type strain: strain Z-7692, ATCC 700263, DSM 8902.

Sequence accession no. (16S rRNA gene): X93928.

3. *Spirochaeta alkalica* Zhilina 1996, 309^{VP}

al.ka.li'ca. N.L. n. *alkali* (from Arabic *al-qalyi* the ashes of saltwort), soda ash; L. fem. suff. *-ica* suffix used with the sense of pertaining to; N.L. fem. adj. *alkalica* intended to mean alkaline, developing in the alkaline medium.

Motile, helical cells, 0.4–0.5 µm in diameter and 9–18 µm in length, with shorter (6 µm) and longer (up to 35 µm) cells occurring in culture. Outermost structure is an outer membrane enclosing periplasmic flagella and a protoplasmic cylinder. Cells have regular, stable primary coils. Cell mass is orange.

Anaerobic, aerotolerant, fermentative; utilizes carbohydrates, mainly mono- and disaccharides, as carbon and energy sources. Preferred substrates: sucrose > trehalose > cellobiose > glucose = maltose > xylose > starch; poor growth with fructose, galactose, ribose, or *N*-acetylglucosamine (the optical isomers of the sugars were not described); no growth with mannose or glycogen. Amyolytic and agarolytic. Amino acids do not serve as fermentable substrates. A supplement of vitamins and yeast extract is required. Aerotolerant; growth develops under a cotton plug in liquid medium.

Primary products of glucose fermentation are acetate, H₂, and CO₂. Minor products in stationary phase are ethanol and lactate.

Alkaliphilic; growth in sodium carbonate medium optimally at pH 8.7–9.6. No growth at pH 8.3 or 10.8. Dependent on sodium; no growth below 3% (w/v) or above 10% (w/v) NaCl. Growth is possible when NaCl is substituted by equimolar Na₂CO₃+NaHCO₃. Requires carbonate anion. Optimum temperature for growth, 33–37°C; range, 15–44°C; slow growth at 6°C after a long lag phase.

Source: a cyanobacterial mat in a warm spring from under the horst in the equatorial alkaline Lake Magadi.

DNA G+C content (mol%): 57.1 (*T_m*).

Type strain: strain Z-7491, ATCC 700262, DSM 8900.

Sequence accession no. (16S rRNA gene): X93927.

4. *Spirochaeta americana* Hoover, Pikuta, Bej, Marsic, Whitman, Tang and Krader 2003, 820^{VP}

a.me.ri.ca'na. N.L. fem. adj. *americana* of American continent, isolated from soda Mono Lake, California, USA.

Cells are motile and helix-shaped. Flagellum present in periplasmic space. Gram-stain-negative. Cells have regular,

unstable primary coils. Sphaeroplasts are formed at the end of the growth phase.

Strictly anaerobic, catalase-negative chemoheterotroph with fermentative type of metabolism. Preferred substrates are D-glucose, fructose, maltose, sucrose, starch, and D-mannitol. Requires vitamins and yeast extract for growth. Primary end products of glucose fermentation is H₂, acetate, ethanol, and formate. Resistant to kanamycin and rifampicin, but sensitive to gentamicin, tetracycline, and chloramphenicol.

Haloalkaliphile that cannot grow at pH 7.0. Growth is dependent upon the presence of carbonate and sodium ions in the medium. No growth occurs below 2% (w/v) NaCl or above 12% (w/v) NaCl. Mesophilic. Cells can be stored frozen in a liquid medium.

Source: mud sediments of the alkaline, hypersaline, meromictic, soda Mono Lake in Northern California, USA.

DNA G+C content (mol%): 58.5 (HPLC).

Type strain: strain ASpG1, ATCC BAA-392, DSM 14872.

Sequence accession no. (16S rRNA gene): AF373921.

5. *Spirochaeta asiatica* Zhilina 1996, 311^{VP}

a.si.a'ti.ca. L. fem. adj. *asiatica* from the Asian continent, in the central part of which the organism was found.

Motile, helical cells, 0.2–0.25 µm in diameter and 15–22.5 µm in length, with shorter (7.5 µm) and longer (up to 40 µm) cells occurring in culture. Outermost structure is an outer membrane enclosing periplasmic flagella and a protoplasmic cylinder. Cells have regular, nonstable primary coils. Round bodies, usually nonviable, are formed at the end of the growth period. Nonpigmented.

Strictly anaerobic, fermentative, and utilizes simple and complex carbohydrates. Preferred substrates: glucose > maltose > glycogen > mannose > trehalose > cellobiose > sucrose > starch > galactose > pectin > xylan; poor growth with xylose or arabinose; no growth with fructose, ribose, lactose, agar, or *N*-acetylglucosamine (the optical isomers of the sugars were not described). Amino acids are not fermented. A supplement of vitamins is required; yeast extract enhances growth.

Fermentation products from glucose include acetate, ethanol, and lactate; H₂ not produced.

Haloalkaliphilic; growth in soda solution at optimal pH 8.4–9.4 with limits pH 7.9–9.7. Growth is Na-dependent. No growth below 2% (w/v) NaCl or above 8% (w/v) NaCl. Optimum NaCl concentration, 3–6% (w/v). Requires carbonate anion. Optimum temperature for growth, 33–37°C; range, 20–43°C; broad thermal adaption with prolonged lag phase.

Source: mud of alkaline Lake Khatyn in Tuva, Central Asia.

DNA G+C content (mol%): 49.2 (*T_m*).

Type strain: strain Z-7591, ATCC 700261, DSM 8901.

Sequence accession no. (16S rRNA gene): X93926.

6. *Spirochaeta aurantia* Canale-Parola 1980, 594^{VP}

au.ran'tia. N.L. fem. adj. *aurantia* orange-colored.

Helical cells, 0.3 µm in diameter and 5–50 µm in length. Most cells in cultures measure 10–20 µm in length during exponential growth. Spherical bodies 0.5–2.0 µm in diameter are present, especially in the stationary phase of growth

or when the cells are incubated at temperatures unfavorable for growth (e.g., 37°C). The spherical bodies are either in association with cells or free. Each cell has two subterminally inserted periplasmic flagella in a 1:2:1 arrangement. Phase-contrast photomicrographs and electron micrographs of the cells have been published (Breznak and Canale-Parola, 1969, 1975; Canale-Parola et al., 1968).

Colonies on aerobic plates (in media containing 1 g of agar/100 ml; see Breznak and Canale-Parola, 1975) are 1–4 mm in diameter, yellow-orange to orange, round with slightly irregular edges, growing primarily within the agar medium just under the surface, sometimes with a slightly raised center. At low carbohydrate concentrations (see Breznak and Canale-Parola, 1975), the colonies are larger, and they diffuse through the agar medium in the shape of almost perfect circles. Under these growth conditions, the colonies have a lower cell density and their pigmentation is not readily apparent. Anaerobically grown colonies are white. Subsurface anaerobic colonies are spherical, fluffy, 1–3 mm in diameter.

Facultatively anaerobic, having both fermentative and respiratory types of metabolism. Carbohydrates, but not amino acids, are utilized as energy sources for growth (Breznak and Canale-Parola, 1969, 1975). Amino acids but usually not inorganic ammonium salts or nitrates serve as sole nitrogen sources. Exogenous thiamine is required by all strains tested, and riboflavin is required by most strains. Exogenous biotin is required for growth of the type strain and is stimulatory to the growth of other strains (Breznak and Canale-Parola, 1975). Nitrate is reduced to nitrite anaerobically. Oxidase-negative. Weakly catalase-positive. Superoxide dismutase (SOD) is present, and levels of SOD are higher in aerobically grown cells than anaerobically grown cells.

Optimum growth occurs between 25 and 30°C. Slow growth occurs at 15°C and usually no growth occurs at 5°C. There is poor or no growth at 37°C. Optimum growth yields result when the initial pH of the medium is 7.0–7.3.

Cells grown anaerobically, ferment glucose primarily to ethanol, acetic acid, CO₂, and H₂ (Breznak and Canale-Parola, 1969, 1972b). Under aerobic conditions, growing cells oxidize glucose mainly to CO₂ and acetic acid (Breznak and Canale-Parola, 1972a).

Cells growing aerobically produce carotenoid pigments responsible for the yellow-orange to orange color of colonies. The major carotenoid pigment is 1',2'-dihydro-1'-hydroxytorulene (Greenberg and Canale-Parola, 1975). Nonpigmented mutants have been isolated.

Chemotactic toward carbohydrates, but not toward amino acids.

Based on 16S rRNA sequence comparisons, *Spirochaeta aurantia* branches deeply within the family *Spirochaetaceae* and may warrant separate genus designation (Figure 84).

Source: Water and mud of freshwater ponds and swamps.

DNA G+C content (mol%): 61–65 (Bd).

Type strain: strain J1, ATCC 25082, DSM 1902.

Sequence accession no. (16S rRNA gene): M57740.

6a. ***Spirochaeta aurantia* subsp. *aurantia*** Canale-Parola 1980, 594^{VP}

The characteristics are as described for the species. Distinguished from the subspecies *stricta* by having a cell

wavelength of 2.0–2.8 μm, a wave amplitude of 0.5 μm (the cells have loose coils), and a mol% G+C of 62–65 (Bd).

Type strain: ATCC 25082.

6b. ***Spirochaeta aurantia* subsp. *stricta*** subsp. nov.

stric'ta. L. v. *stringere* to draw tight, compress; L. fem. part. adj. *stricta* drawn tight.

The characteristics are as described for the species. Distinguished from the subspecies *aurantia* by having a cell wavelength of 1.1–1.5 μm, a wave amplitude of 0.35 μm (cells have tight coils), and a mol% G+C of 61 (Bd).

Type strain: J4T (Breznak and Canale-Parola, 1975).

7. ***Spirochaeta bajacaliforniensis*** Fracek and Stolz 2004, 631^{VP} (Effective publication: Fracek and Stolz 1985, 324.)

baja.ca.li.for.ni.en'sis. N.L. fem. adj. *bajacaliforniensis* of or belonging to Baja California for the geographical location from where it was isolated.

Helical cells, 0.2–0.3 μm by 15–45 μm. Shorter (10 μm) and longer (up to 300 μm) cells may occur. Highly motile. The amplitude is 0.5 μm and the wavelength is 1.0–1.5 μm. Two subterminally inserted periplasmic flagella are present in a 1:2:1 arrangement. The ratio of protoplasmic cylinder diameter to the cell diameter is 2:3. The surface of the protoplasmic cylinder has a characteristic polygonal pattern. Subsurface colonies are fluffy, white, and spherical.

Strictly anaerobic. Arabinose, cellobiose, galactitol, fructose, galactose, gluconate, glucose, inulin, lactose, malate, maltose, mannitol, pyruvate, rhamnose, sorbose, and trehalose are fermented (the optical isomers of the sugars were not described (Fracek and Stolz, 1985). Products of glucose fermentation are acetate, ethanol, CO₂, and H₂. No test for formate was performed. Catalase-negative.

Grow in media containing at least 20% seawater and 0.12 M NaCl. Reducing agent required in liquid medium. Growth on solid medium occurs in an 80% N₂, 17% CO₂, and 3% H₂ atmosphere.

Temperature optimum: 36°C. Do not grow below 25°C or above 44°C. Optimum growth at pH 7.5.

Source: anaerobic sulfide-rich mud underlying the laminated sediment of the microbial mats at North Pond, Laguna Figueroa, Baja California Norte, Mexico.

DNA G+C content (mol%): 50.1 (Bd).

Type strain: strain BA-2, ATCC 35968, DSM 16054.

Sequence accession no. (16S rRNA gene): M71239.

8. ***Spirochaeta caldaria*** Pohlschroeder 1994, 21^{VP}

cal.da'ri.a. L. fem. adj. *caldaria* of warm water, inhabiting warm water.

Motile, helical cells, 0.2–0.3 μm in diameter and mostly 15–45 μm in length, the outermost structure being an outer membrane (outer sheath) enclosing the periplasmic flagella in a 1:2:1 arrangement and the protoplasmic cylinder. Cells have regular, stable primary coils. Broader secondary coils occasionally are present in cells in motion. Subsurface colonies (in media containing 1 g agar per 100 ml) are white, fluffy, cotton ball-like, approximately 2–3 mm in diameter.

Obligately anaerobic, fermentative, utilizes carbohydrates as carbon and energy sources. Amino acids do not serve as fermentable substrates for growth. Fermentable compounds

include L-arabinose, D-galactose, D-glucose, D-mannose, D-fructose, D-xylose, cellobiose, cellotriose, cellotetraose, lactose, maltose, sucrose, and starch. The following substances are not fermented: D-ribose, mannitol, cellulose, xylan, glycerol, peptone, casein hydrolysate, and sodium acetate. Exogenous fatty acids, reported to be needed by *Treponema* species for cellular lipid synthesis and growth (Livermore and Johnson, 1974; Miller et al., 1991), are not required. A supplement of vitamins is required. Specific vitamin requirements have not been determined. Products of D-glucose fermentation are H₂, CO₂, acetate, and lactate.

Grows in the presence of rifampicin (100 µg/ml of medium). Growth is inhibited by penicillin G, neomycin, chloramphenicol, or tetracycline (10 µg/ml of medium each).

Thermophilic. Grows optimally between 48 and 52°C. No growth at 25 or 60°C. No growth in the presence of 0.4% NaCl or higher NaCl concentrations.

Source: freshwater hot springs.

DNA G+C content (mol%): 45 (T_m).

Type strain: strain H1, ATCC 51460, DSM 7334.

Sequence accession no. (16S rRNA gene): M71240, EU580141.

9. **Spirochaeta cellobiosiphila** Breznak and Warnecke 2008, 2762^{VP}

cel.lo.bi.o.si'phi.la. N.L. neut. n. *cellobiosum* cellobiose; N.L. fem. adj. *phila* from Gr. fem. adj. *philê* friendly to, loving; N.L. fem. adj. *cellobiosiphila* loving cellobiose, isolated from a microbial mat, Little Sippewissett salt marsh, Woods Hole, MA, USA.

Cells are pale yellow, 0.3–0.4×10–12 µm in size and helical, with a body pitch of 1.4 µm. Motile by means of two (occasionally four) periplasmic flagella, of which one (or two) is inserted near each end of the cell. Facultatively anaerobic and catalase-negative. Growth occurs at 9–37°C (optimally at or near 37°C), at initial pH 5–8 (optimally at initial pH 7.5) and in media prepared with 20–100% (v/v) seawater (optimally at 60–80%) or containing 0.10–1.00 M NaCl (optimally at 0.30–0.40 M). A variety of monosaccharides and disaccharides and pectin (but not cellulose or arabinoxytan) are used as energy sources; the most rapid growth occurs on cellobiose. Neither organic acids nor amino acids are utilized as energy sources. One or more amino acids in tryptone and one or more components of yeast extract are required for growth. The products of cellobiose fermentation are acetate, ethanol, CO₂, H₂, and small amounts of formate. Aerated cultures oxidize cellobiose incompletely to acetate (and, presumably, CO₂) plus small amounts of ethanol and formate; they exhibit a Y_{cellobiose} value that is 1.2-fold greater than that of cellobiose-fermenting cultures.

Source: interstitial water of a cyanobacteria-containing microbial mat collected from Little Sippewissett salt marsh, Woods Hole, MA, USA.

DNA G+C content (mol%): 41.4 (HPLC).

Type strain: strain SIP1, ATCC BAA-1285, DSM 17781.

Sequence accession no. (16S rRNA gene): EU448140.

10. **Spirochaeta halophila** Greenberg and Canale-Parola 1976, 193^{AL}

ha.lo.phi'la. Gr. n. *hals*, *halos* salt; Gr. adj. *philus* -ê-on loving; N.L. fem. adj. *halophila* salt-loving.

Helical cells, 0.4 µm in diameter and 15–30 µm in length. Some of the cells in cultures are as short as 5 µm and as long as 60 µm. Cells have regular, stable primary coils. Spherical bodies 1–2 µm in diameter occur in cultures, especially in the stationary phase of growth or during growth at unfavorable temperatures (e.g., 45°C). Each cell has two subterminally inserted periplasmic flagella that overlap in the central region of the cell (1:2:1 arrangement). Phase-contrast micrographs and electron micrographs of the cells have been published (Greenberg and Canale-Parola, 1976).

Colonies growing aerobically on ISM plates (0.75 g of agar/100 ml of medium) are red, round, with areas of diffuse growth at their periphery, and usually 2–6 mm in diameter (after 5 d at 35°C). Each colony grows partially above and partially below the surface of the agar medium. Anaerobically grown colonies are white. When cells are streaked onto agar medium plates and incubated anaerobically, the colonies grow below the surface of the medium and are spherical, diffuse and white.

Facultatively anaerobic, having both respiratory and fermentative types of metabolism. Carbohydrates, but not amino acids, are utilized as energy sources for growth (Greenberg and Canale-Parola, 1976). Cells have specific growth requirements for relatively high concentrations of Na⁺, Cl⁻, Ca²⁺, and Mg²⁺ (Greenberg and Canale-Parola, 1976). Optimum cell yields result when 0.75 M NaCl, 0.2 M MgSO₄, and 0.01 M CaCl₂ are included in growth media containing (in g/100 ml) a carbohydrate (0.5), peptone (0.2), and yeast extract (0.4). No growth occurs when any one of the three inorganic salts is omitted from the medium (e.g., ISM medium). Nitrate is reduced to nitrite anaerobically. Catalase-negative. Cells growing anaerobically ferment glucose primarily to ethanol, acetic acid, CO₂, and H₂ (Greenberg and Canale-Parola, 1976). Under aerobic conditions, growing cells oxidize glucose mainly to CO₂ and acetic acid (Greenberg and Canale-Parola, 1976).

Optimum temperature, 35–40°C. Poor growth occurs at 45°C and no growth occurs at 22°C. Cells growing aerobically produce carotenoid pigments responsible for the red color of the colonies. The major carotenoid pigment is 4-keto-1',2'-dihydro-1'-hydroxytorulene (Greenberg and Canale-Parola, 1975). Nonpigmented mutants, occurring spontaneously in cultures, have been isolated.

Source: H₂S-containing mud of a high salinity pond (Solar Lake) located on the Sinai shore of the Gulf of Elat.

DNA G+C content (mol%): 62 (T_m, Bd).

Type strain: strain RS1, ATCC 29478, DSM 10522.

Sequence accession no. (16S rRNA gene): M88722.

11. **Spirochaeta isovalerica** Harwood and Canale-Parola 1983, 578^{VP}

i.so.va.le.ri'ca. N.L. n. *acidum isovalericum* isovaleric acid; N.L. fem. adj. *isovalerica* intended to mean pertaining to isovaleric acid, the major acid formed as a fermentation product from branched-chain amino acids.

Helical cells, 0.4 µm in diameter and 10–15 µm in length. Shorter (6 µm) and longer (up to 50 µm) cells occur in cultures. Motile. Two subterminally inserted periplasmic (axial) fibrils are present in a 1:2:1 arrangement. The protoplasmic cylinder and periplasmic fibrils are enclosed in an outer sheath. Gram-stain-negative.

Chemo-organotrophic. Grows (final yield, $6\text{--}9 \times 10^8$ cells per ml) in medium containing yeast extract, trypticase, peptone, a carbohydrate, and inorganic salts under anaerobic conditions. No growth occurs aerobically. Subsurface colonies in medium containing 0.8% agar (Difco) are spherical and white, resembling cotton balls in appearance. Growth (final yield, $3\text{--}6 \times 10^8$ cells per ml) occurs in a chemically defined medium containing glucose, cysteine or sulfide, asparagine, vitamins, 0.3 M NaCl, 0.05 M MgSO_4 , 0.01 M KCl, 0.01 M CaCl_2 , and trace elements. Exogenously supplied vitamins are not required for growth, but a mixture of vitamins stimulates growth. Fails to grow when NaCl is omitted from the medium. Growth is stimulated by MgSO_4 and CaCl_2 . Inorganic ammonium salts or amino acids serve as nitrogen sources. Carbohydrates, but not amino acids, serve as carbon and energy sources for growth.

The major products of glucose fermentation are CO_2 , H_2 , acetate, and ethanol. Cells have the ability to generate ATP by catabolizing L-leucine, L-isoleucine, and L-valine to form isovalerate, 2-methylbutyrate, and isobutyrate, respectively, as end products. ATP formed in this way is utilized by cells to prolong survival during periods of growth substrate starvation. Smaller amounts of isobutanol and isoamyl alcohol are also formed by cells from valine, isoleucine, and leucine. Catalase-negative. Nitrate not reduced to nitrite.

Optimum temperature range, 15–35°C. Poor growth at 5 and 39°C.

Source: anoxic marine marsh mud.

DNA G+C content (mol%): 63.6–65.6 (T_m).

Type strain: strain MA-2, ATCC 33939, DSM 2461.

Sequence accession no. (16S rRNA gene): M88720.

12. ***Spirochaeta litoralis*** Canale-Parola 1980, 594^{VP}

li.to.ra'lis. L. fem. adj. *litoralis* of the shore.

Helical cells, 0.4–0.5 μm in diameter and 5.5–7.0 μm in length. The cells are regularly and tightly coiled during the exponential phase of growth. Spherical bodies (2.0–3.5 μm in diameter) are present in the stationary growth phase under unfavorable growth conditions (e.g., in the presence of O_2). Two subterminally inserted periplasmic flagella are present in a 1:2:1 arrangement. Phase-contrast photomicrographs and electron micrographs of the cells have been published (Hespell and Canale-Parola, 1970b; Joseph and Canale-Parola, 1972).

Subsurface colonies in agar media are spherical, fluffy, cream colored, 1–5 mm in diameter. Surface colonies (anaerobic) are round, growing partially within the agar medium, cream colored, and 2–5 mm in diameter.

Obligately anaerobic, having a fermentative type of metabolism. Various carbohydrates are fermented (Hespell and Canale-Parola, 1970b). Main products of glucose fermentation are ethanol, acetic acid, CO_2 , H_2 , and trace amounts of lactic, formic, and pyruvic acids (Hespell and Canale-Parola, 1970b, 1973). Nitrite is not accumulated in the medium by cells growing in the presence of nitrate. Catalase-negative.

Cells grow in media prepared with seawater, but do not grow in media prepared with freshwater unless NaCl is added (minimum concentration, 0.05 M; optimum, 0.35 M). Cells have specific requirements for Na^+ and Cl^- .

Exogenous supplements of biotin, niacin, and coenzyme A are required for growth. Coenzyme A may be replaced by pantothenate, but the resulting cell yields are low. Added thiamine is stimulatory for growth. A reducing agent (e.g., sulfide or cysteine) is required for growth in laboratory media. Cells grow in chemically defined media containing glucose, $(\text{NH}_4)_2\text{SO}_4$ or amino acids, sulfide, NaCl, vitamins, coenzyme A, and inorganic salts (Hespell and Canale-Parola, 1970b).

Optimum temperature, near 30°C. Growth occurs slowly at 15°C and not at all at 5°C or 40°C. Optimum growth yields result when the initial pH of the medium is between 7.0 and 7.5.

Source: sulfide-containing marine mud.

DNA G+C content (mol%): 51 (Bd).

Type strain: strain RI, ATCC 27000, DSM 2029.

Sequence accession no. (16S rRNA gene): M88723.

13. ***Spirochaeta smaragdinae*** Magot, Fardeau, Arnaud, Lanau, Ollivier, Thomas and Patel 1997, 190^{VP}

sma.rag.di'nae. L. masc. n. *smaragdus* emerald; N.L. gen. n. *smaragdinae* intended to mean from Emerald, the name of the oilfield in Congo, Central Africa.

Spirochetes with corkscrew-like motility. Spiral cells are 0.3–0.5 μm in diameter and 5–30 μm in length with two periplasmic flagella in a 1:2:1 arrangement. Produce translucent colonies with regular edges and a diameter of 0.5 mm after 2 weeks at 37°C.

Obligately anaerobic chemo-organotroph. Growth occurs in the presence of fructose, galactose, D-xylose, D-glucose, ribose, D-mannose, mannitol, glycerol, yeast extract, biotrypticase, and fumarate, but not with D-arabinose, rhamnose, sorbose, L-xylose, sucrose, maltose, acetate, butyrate, propionate, pyruvate, lactate, or Casamino acids. Yeast extract is required for growth and cannot be replaced by a vitamin mixture. Thiosulfate and elemental sulfur are reduced to sulfide. Glucose is oxidized to lactate, acetate, CO_2 , and H_2S in the presence of thiosulfate, and to lactate, ethanol, CO_2 , and H_2 in its absence. Fumarate is fermented to acetate and succinate.

Obligately halophilic. Optimum NaCl concentration for growth is 5% and the NaCl concentration range for growth is 1.0–10%. Optimum temperature for growth is 37°C with growth occurring between 20 and 40°C. Optimum pH is 7.0 with growth occurring between pH 5.5 and 8.0. Doubling time in the presence of glucose and thiosulfate under optimal conditions is about 25 h.

Source: oil-injection water from Emerald oilfield in Congo, Central Africa.

DNA G+C content (mol%): 50 (HPLC).

Type strain: strain SEBR 4228, DSM 11293, JCM 15392.

Sequence accession no. (16S rRNA gene): U80597.

14. ***Spirochaeta stenostrepta*** Zuelzer 1912, 17^{AL}

ste.no.strep'ta. Gr. adj. *stenos* narrow; Gr. adj. *streptos* -ê -onpliant, easily bent; N.L. fem. adj. *stenostrepta* tightly coiled.

Helical cells, 0.2–0.3 μm in diameter and 15–45 μm in length. Some of the cells in cultures are shorter than 15 μm . In the late exponential and stationary phases the organisms increase in length (up to 300 μm). Long organisms

occasionally pair and become entwined, or a single organism becomes partially wrapped around itself. The cells have regular, stable primary coils. Cells in motion occasionally exhibit broader secondary coils or waves superimposed on the smaller primary coils. Spherical bodies generally 1–3 µm in diameter are occasionally observed in cultures. The spherical bodies occur either free or in association with helical cells. Each cell has two subterminally inserted periplasmic flagella that overlap in the central region of the cell (1:2:1 arrangement). Phase-contrast photomicrographs and electron micrographs of the cells have been published (Canale-Parola et al., 1967, 1968; Holt and Canale-Parola, 1968).

Subsurface colonies (in GYPT medium containing 1.5 g agar/100 ml) are white, spherical, fluffy, and approximately 2–3 mm in diameter when fully developed. Smaller spherical colonies may occasionally lack the characteristic fluffiness.

Obligately anaerobic, having a fermentative type of metabolism. Various carbohydrates are fermented (Hespell and Canale-Parola, 1970a). The main products of glucose fermentation are ethanol, acetic acid, CO₂, H₂, and smaller amounts of lactic acid (Canale-Parola et al., 1967, 1968; Hespell and Canale-Parola, 1970a). Catalase-negative.

Growth reported only on complex media. Minimal growth requirements are unknown. Growth occurs between 15 and 40°C; optimum temperature is 35–37°C. Optimum growth yields result when the initial pH of the medium is between 7.0 and 7.5.

Based on 16S rRNA sequence comparisons, *Spirochaeta stenostrepta* does not belong with other free-living *Spirochaeta*, but is more closely related with members of the genus *Treponema* (Figure 84).

Source: H₂S-containing mud of a freshwater pond (Canale-Parola et al., 1967, 1968).

DNA G+C content (mol%): 60 (Bd).

Type strain: strain ZI, ATCC 25083, DSM 2028.

Sequence accession no. (16S rRNA gene): M88724.

15. ***Spirochaeta thermophila*** Aksenova, Rainey, Janssen, Zavarzin and Morgan 1992, 176^{VP}

ther.mo'phi.la. Gr. n. *thermê* heat; Gr. fem. adj. *philê* loving; N.L. fem. adj. *thermophila* heat-loving.

Helical cells, 0.2–0.25 µm in diameter and 16–50 µm in length. An outer sheath encloses a protoplasmic cylinder; two periplasmic flagella in a 1:2:1 arrangement are subterminally anchored by an insertion disc. No cell lysis in 3% KOH.

Strictly anaerobic chemo-organotroph. Utilizes various mono-, di-, and polysaccharides but not sugar alcohols, organic acids, or amino acids. Glucose is fermented via the Embden–Meyerhof–Parnas pathway, involving a pyrophosphate-dependent phosphofructokinase. Fermentation end products from glucose are acetate, CO₂, H₂, and lactate. Ethanol and succinate not produced. No reduction of fumarate, nitrate, oxygen, sulfate, or sulfur. Indole not formed; urea not hydrolyzed. Sulfide not produced from cysteine; esculin hydrolyzed. Inhibited by penicillin, neomycin, erythromycin, tetracycline, polymyxin B, and novobiocin but resistant to rifampicin and streptomycin.

Temperature range for the type strain, 40–73°C (optimum, 66–68°C). pH range for the type strain, 5.9–7.7

(optimum, 7.5). NaCl concentration range for the type strain, 0.5–4.5% (optimum, 1.5%). Doubling time, 70 min. Temperature, pH, and salinity parameters vary for different strains, reflecting the environmental conditions prevailing at the sites of isolation.

Source: marine hot spring near the beach on Shishkotan Island, Soviet Far East, USSR.

DNA G+C content (mol%): 52 (*T_m*).

Type strain: strain Z-1203, ATCC 700085, DSM 6578.

Sequence accession no. (16S rRNA gene): X62809, L09180.

16. ***Spirochaeta zuelzeræ*** Canale-Parola 1980, 594^{VP} (*Treponema zuelzeræ* Veldkamp 1960, 122)

zu.el.ze'rae. N.L. fem. gen. n. *zuelzeræ* of Zuelzer, named after Margarete Zuelzer, who described the occurrence of morphologically diverse spirochetes in sulfide-containing environments.

Helical cells, 0.2–0.35 µm in diameter and 8–16 µm in length. Shorter cells (as short as 2–3 µm) are occasionally observed in cultures. Long organisms (up to 80 µm) are present in old cultures. Exponentially growing cells have fairly regular, stable primary coils. Secondary coils or waves are present infrequently. Spherical bodies, generally not exceeding 3–4 µm in diameter, are formed usually at the ends of the cells in the stationary phase of growth. Two subterminally inserted periplasmic flagella are present in a 1:2:1 arrangement. Phase-contrast photomicrographs and electron micrographs of the cells have been published (Canale-Parola et al., 1968; Joseph and Canale-Parola, 1972).

The type strain was originally isolated from an enrichment culture for green photosynthetic bacteria that had been inoculated with sulfide-containing mud from a freshwater pond (Veldkamp, 1960). Subsurface colonies in agar media (for composition of medium, see Veldkamp (1960), and also SZ medium in table) are white, fluffy, spherical, with a tendency to diffuse in the agar medium. Disc-shaped colonies are present occasionally.

Obligately anaerobic, having a fermentative type of metabolism. Various carbohydrates are fermented (Veldkamp, 1960). Cells growing in media containing 0.05% NaHCO₃ ferment glucose mainly to acetic, lactic, and succinic acids, CO₂, and H₂ (Veldkamp, 1960). Catalase-negative.

Growth occurs at 20°C but not at 45°C. The optimum temperature range is 37–40°C. Growth is optimum when the initial pH of the medium is between 7 and 8. Inorganic ammonium salts or nitrates are not utilized as sole nitrogen sources. Added CO₂ is an absolute requirement for growth (Veldkamp, 1960). Growth has been reported only on complex media. The minimal growth requirements are unknown.

Cells have a protein antigen that gives a positive complement fixation reaction with syphilitic serum.

Based on 16S rRNA sequence comparisons, *Spirochaeta zuelzeræ* does not belong with other free-living *Spirochaeta*, but is more closely related with members of the genus *Treponema* (Figure 84).

DNA G+C content (mol%): 56 (Bd).

Type strain: ATCC 19044, DSM 1903.

Sequence accession no. (16S rRNA gene): M88725.

Other organisms

1. ***Spirochaeta coccoides*** Dröge, Fröhlich, Radek and König 2006, 1460^{VP} (Effective publication: Dröge, Fröhlich, Radek and König 2006, 396.)

coc.co'i.des. Gr. n. *kokkos* a berry; L. fem. suff. *-oides* [from Gr. suff. *-eides* (from Gr. n. *eidos* that which is seen, form, shape, figure)], resembling, similar. N.L. fem. adj. *coccoides* berry-shaped.

Placement within the genus *Spirochaeta* is questionable owing to the absence of defining morphological, ultrastructural, and behavioral features (i.e., helically shaped motile cells with protoplasmic cylinder and periplasmic fibrils enclosed in an outer sheath). In this regard, this species resembles isolates from freshwater sediments referred to as “free-living pleomorphic spirochetes” or FLiPS (Ritalahti and Löffler, 2004). 16S rRNA sequence analysis indicates that these microbes form a cluster within the *Spirochaeta-Treponema* branch of the *Spirochaetaceae* tree, and should be considered for separate taxonomic status.

Type strain: strain SPN1, DSM 17374, ATCC BAA-1237.

Sequence accession no. (16S rRNA gene): AJ698092.

It has long been known that greater diversity exists among the free-living spirochetes capable of anaerobic growth than is reflected by the species presently recognized in the genus *Spirochaeta*. For example, a free living, strictly anaerobic spirochete (strain Z4), resembling *Spirochaeta zuelzeriae* morphologically, but differing in certain physiological properties, has been isolated from freshwater mud (Canale-Parola et al., 1968). The spirochete ferments glucose to acetic, lactic, succinic, and formic acids, ethanol, CO₂, and H₂. Unlike *Spirochaeta zuelzeriae*, it does not require an exogenous source of CO₂ and the mol% G+C of its DNA is 59.2 (Bd).

Additionally, diverse obligate anaerobic thermophilic strains of *Spirochaeta* have been isolated from thermal springs and other high temperature environments. For example, a strain isolated from a hydrothermal spring on Raoul Island of the Kermadec archipelago of New Zealand exhibited maximum growth at 73°C (Rainey et al., 1991). This isolate fermented a range of mono-, di-, and polysaccharides, including cellulose.

Various strains of facultatively and obligately anaerobic spirochetes have been isolated from marine environments, including intertidal muds and water. An obligately

anaerobic strain was isolated from water collected at a depth of 2550 m near the Galápagos hydrothermal vents in the Pacific Ocean (Harwood et al., 1982). These isolates are indigenous to marine environments inasmuch as they have Na⁺ requirements typical of marine bacteria. The facultatively anaerobic marine isolates form either white or yellow colonies. Thus, they differ both in salt requirements and in pigmentation from the facultatively anaerobic species *Spirochaeta aurantia*, which is a freshwater species and forms orange colonies, and *Spirochaeta halophila*, which requires high concentrations of Ca⁺ and Mg⁺ and forms red colonies. However, 16S rRNA sequences are not available for these strains to determine their phylogenetic relationships with other species of *Spirochaeta*.

Diversity of not-yet-cultivated species. The breadth of diversity of species of *Spirochaeta* is impressive. By cloning and sequencing of 16S rRNA genes amplified from DNA isolated from a wide variety of environments, over 100 phylotypes of not-yet-cultivated species of *Spirochaeta* have been identified. These environments include the following: (1) microbial mats from deltas in France and Spain (Berlanga et al., 2003), Puerto Rico, and California; (2) hypersaline soda lakes in Asia, Africa, Egypt, and California; (3) volcano seep sediments in Greece and Japan; (4) marine sediments in China and Japan; (5) gray whale bone from deep-sea; (6) *Alvinella pompejana* white tube worms and other gutless worms from deep-sea vents; (7) forested wetlands; (8) fresh water ponds or lakes in China, Japan, Greece, and Massachusetts, USA; (9) karyomastigonts (protozoa); and (10) termite hindguts. Phylogenetic analysis of representatives of these taxa and their GenBank accession numbers are shown in Figure 85.

Notably, some of these not-yet-cultivated species of *Spirochaeta* are “host-associated”, i.e., found in termite hindguts (Figure 85). In contrast, most termite spirochetes fall within the genus *Treponema* (see chapter on *Treponema*). Conversely, as discussed above, there are several “free-living” species of *Spirochaeta*, e.g., *Spirochaeta zuelzeriae*, *Spirochaeta stenostrepta*, and *Spirochaeta caldaria*, that are more closely related to “host-associated” members of the genus *Treponema* than to other “free-living” members of the genus *Spirochaeta*. Consequently, these data suggest that “free-living” vs “host-associated” designations may not be valid taxonomic criteria to differentiate species of *Spirochaeta* and *Treponema*.

Genus II. ***Borrelia*** Swellengrebel 1907, 582^{AL}

GUIQING WANG AND IRA SCHWARTZ

Bor.re'li.a. N.L. fem. n. *Borrelia* named after Amedée Borrel (1867–1936).

Helical cells are 0.2–0.5 mm by 3–30 mm, composed of 3–10 loose coils. The cells are surrounded by a surface layer, an outer membrane, periplasmic flagella, and a protoplasmic cylinder (Figure 86). Typically, 15–20 periplasmic flagella (which also have been termed **endoflagella**, axial fibrils, or periplasmic fibrils) originate at each end of the cell and wind about the protoplasmic cylinder to overlap in the middle of the cell. The protoplasmic cylinder consists of a peptidoglycan layer and an inner

membrane which encloses the internal components of the cells. **The cells are actively motile** with frequent reversal of the direction of translational movement. Gram-stain-negative. Stain well with Giemsa stain. Species which have been grown *in vitro* are **microaerophilic**. Nutritional requirements for *in vitro* growth are complex. **Arthropod-borne pathogens** of man, other mammals, and birds. **The causative agents of tick-borne Lyme disease and relapsing fever and louse-borne relapsing fever in man.**

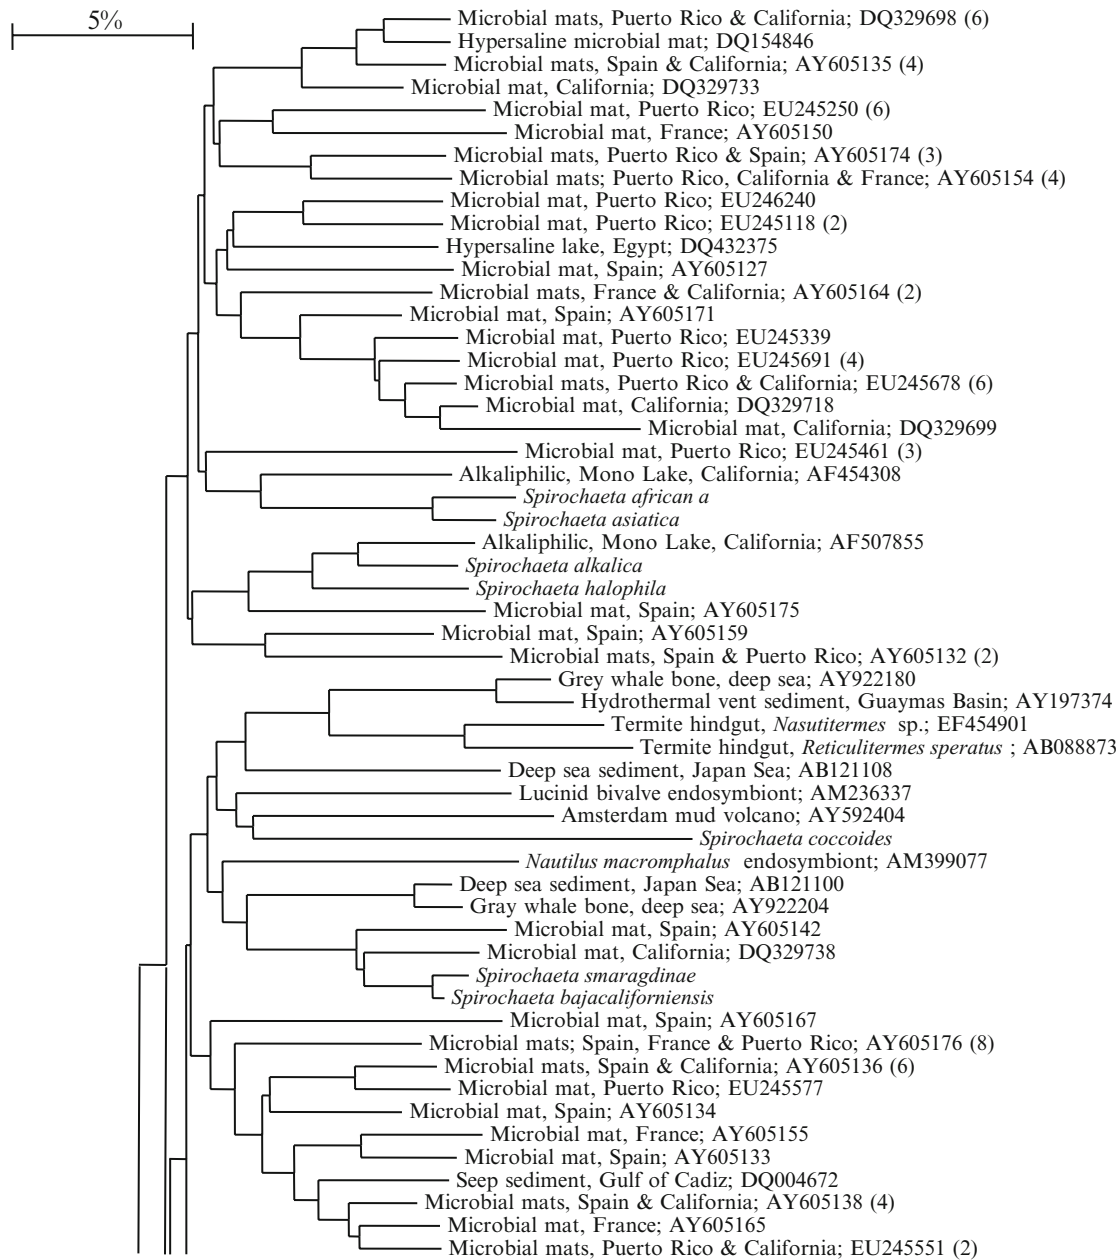

FIGURE 85. Phylogenetic tree illustrating the diversity of cultivable and not-yet-cultivated species of the genus *Spirochaeta* based on 16S rRNA sequence comparisons. Not-yet-cultivated species are noted by their environmental source, location, and GenBank accession numbers. Numbers in parentheses indicate the number of sequences available for a given phylotype. The scale bar represents a 5% difference in nucleotide sequence.

DNA G+C content (mol%): 27–32.

Type species: Borrelia anserina (Sakharoff 1891) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 435^{AL}.

Further descriptive information

DNA sequence analysis of rRNA and other conserved genes (e.g., *fla*, *hbb*) has established that *Borrelia* spp. fall into two major groups (Figure 87). The first major group contains the agents of Lyme borreliosis that were first isolated from *Ixodes scapularis* ticks (Burgdorfer et al., 1982). These include the three human-pathogenic species *Borrelia burgdorferi* (Johnson et al., 1984), *Borrelia afzelii* (Canica et al., 1993), and *Borrelia*

garinii (Baranton et al., 1992) and seven other species that are minimally pathogenic or nonpathogenic: *Borrelia japonica* (Kawabata et al., 1993), *Borrelia lusitaniae* (Le Fleche et al., 1997), *Borrelia tanukii*, *Borrelia turdi* (Fukunaga et al., 1996a), *Borrelia sinica* (Masuzawa et al., 2001), *Borrelia spielmanii* (Richter et al., 2006), and *Borrelia valaisiana* (Wang et al., 1997). Spirochetes in the first major group are all transmitted by hard ticks in the *Ixodes ricinus* complex, and are referred to collectively as “*Borrelia burgdorferi sensu lato*” (Baranton et al., 1992; Wang et al., 1999). The second major group includes more than 20 *Borrelia* species associated with relapsing fever that are mainly transmitted by soft-bodied or argasid ticks, with the exception

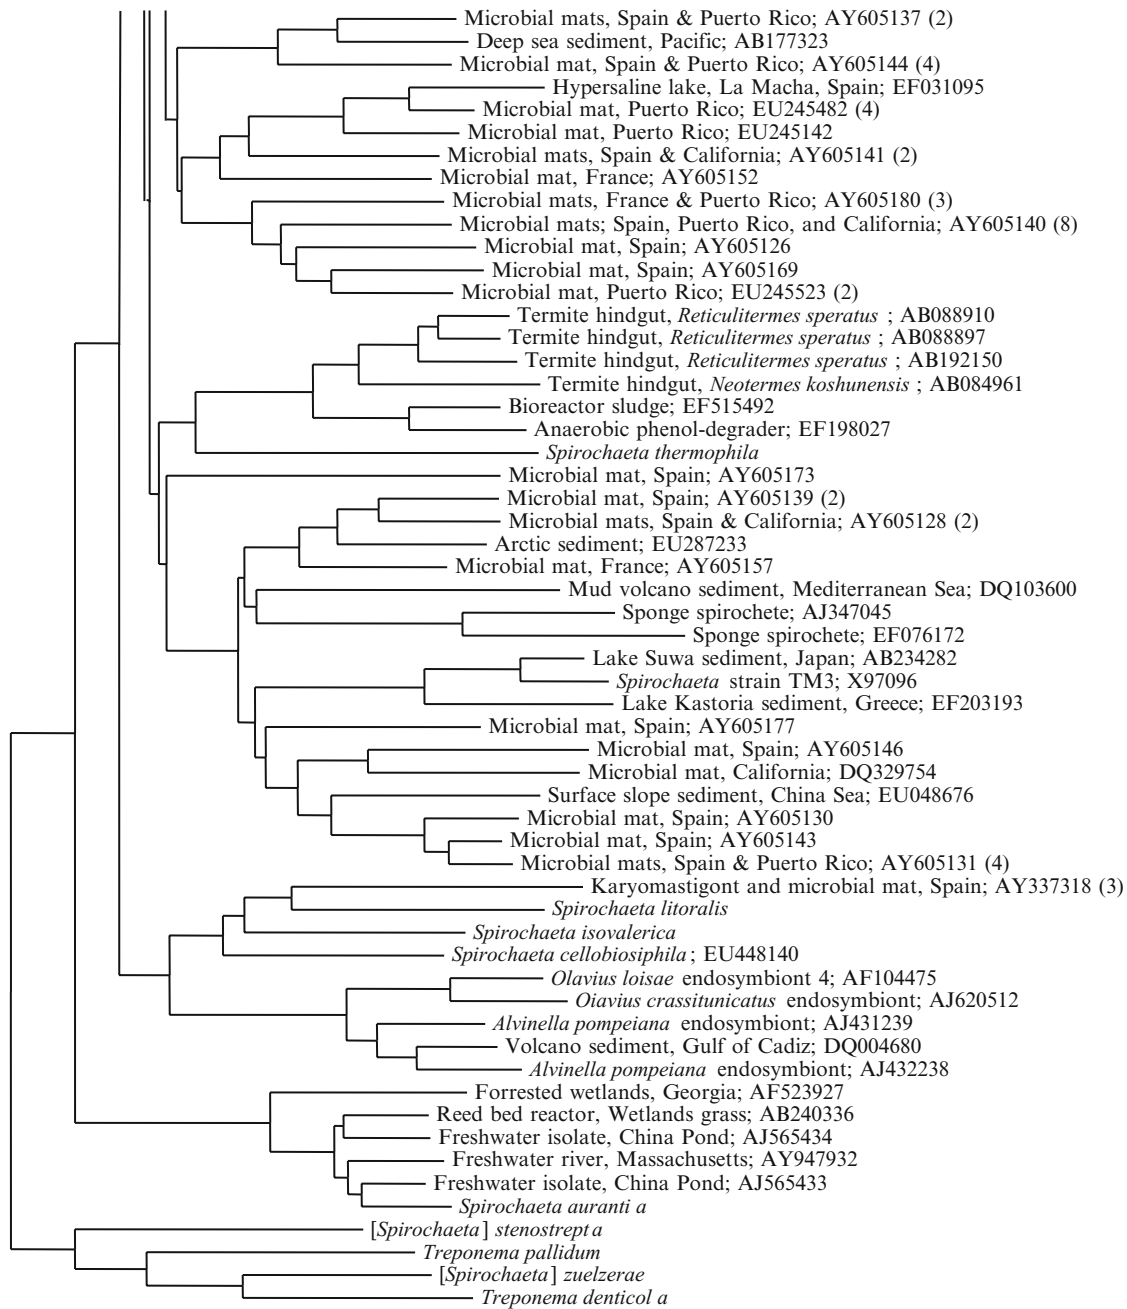

FIGURE 85. (continued)

of louse-borne *Borrelia recurrentis* (Table 121). Additional novel *Borrelia* species or strains closely related to the Lyme disease or relapsing fever borreliae have been described. Their taxonomic status and pathogenicity in humans remain to be determined.

Cells of all species are helically shaped with similar cell morphology and ultrastructure (Barbour and Hayes, 1986; Cutler, 2001; Wang et al., 2001). Among these, the Lyme disease borreliae are the longest (20–30 μm) and narrowest (0.2–0.3 μm).

Borrelia burgdorferi periplasmic flagella have both skeletal and motility functions. Inactivation of the gene encoding the major periplasmic flagellar filament protein FlaB results in nonmotile cells that are also rod-shaped rather than helical (Motaleb et al.,

2000). Further, mutants may show only asymmetrical flagellar rotation in the nonchemotactic mutants (Li et al., 2002).

The lipid compositions of the outer membrane and whole cell are highly similar, suggesting that bulk transfer of lipid occurs between the cytoplasmic and outer membranes. The isolated outer membrane of *Borrelia burgdorferi* has a specific gravity of 1.12–1.19 g/cm^3 , depending on the purification procedure used (Bledsoe et al., 1994; Radolf et al., 1995); this comprises approximately 16.5% of the whole spirochete by dry weight. Chemical analysis of the outer envelope of *Borrelia burgdorferi* revealed a composition of 45.9% protein, 50.8% lipid, and 3.3% carbohydrate (Coleman et al., 1986). The purified periplasmic

FIGURE 86. Micrographs of *Borrelia burgdorferi* by light microscopy (a) and high voltage electron microscopy (b). The cell diameter of *Borrelia burgdorferi* strain 297 shown in electron microscopy is 0.33 μm . The bundle of periplasmic flagella is clearly visible in the cell on the right (the EM micrograph was provided by K. Buttle, S.F. Goldstein and N.W. Charon). (c) Cross-section of *Borrelia burgdorferi* strain B31. The periplasmic flagella are visible in the lower right of the cell (micrograph provided by N.W. Charon, West Virginia University). Reprinted from Wang et al. (2001), with permission.

FIGURE 87. Phylogenetic tree based on 16S rRNA gene sequences of *Borrelia* species. A neighbor-joining phylogenetic tree was constructed based on Kimura’s two-parameter distance estimation method using MEGA 2.1 program. Accession numbers are shown in parentheses. The numbers at the branch nodes indicate the results of the bootstrap analysis. The bar represents 2% sequence divergence. *Treponema pallidum* subsp. *pallidum* strain Nichols was used as an outgroup.

TABLE 120. Barbour–Stoenner–Kelly (BSK) II medium^a

After detergent cleaning, all glassware is rinsed thoroughly with glass-distilled water and then autoclaved.

To 900 ml of glass-distilled water are added 100 ml of 10× concentrate of CMRL 1066 without glutamine.

Add to the 1× CMRL 1066 in the following order:

5 g Neopeptone
 50 g Bovine serum albumin, Fraction V
 2 g Yeastolate
 6 g *N*-2-Hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid
 5 g Glucose
 0.7 g Sodium citrate
 0.8 g Sodium pyruvate
 0.4 g *N*-Acetylglucosamine
 2.2 g Sodium bicarbonate

Adjust the pH of medium at 20–25°C to 7.6 with 1 N NaOH.

Add 200 ml of 7% gelatin which had been dissolved in boiling water.

Sterilize by filtration with air pressure (0.2 µm nitrocellulose). Store medium at 4°C.

Before use, add unheated rabbit serum to a final concentration of 6%.

Dispense to glass or polystyrene tubes or bottles. Fill containers to 50–90% capacity and cap tightly.

Incubate at 34–37°C.

^aReprinted from Barbour (1984) with permission. Modifications of BSK II medium include BSK-H with removal of gelatin and different proportions of certain ingredients compared to BSK II (Pollack et al., 1993), and Kelly's medium Preac-Mursic (MKP) (Preac-Mursic et al., 1986).

membrane possesses a lower specific gravity (1.12 g/cm³) but a higher percentage of proteins (56%) by dry weight of the membrane. Since *Borrelia burgdorferi* lacks the ability to elongate long-chain fatty acids, the fatty acid composition of the cells reflects that present in the growth medium.

Chemical analysis of *Borrelia hermsii* cells that were cultivated *in vitro* has demonstrated the presence of muramic acid and ornithine in the whole cells and in the protoplasmic cylinders, but not in the outer envelope preparations (Klaviter and Johnson, 1979). These data suggest that ornithine is a component of the cell wall. *Borrelia hermsii* contains cholesterol glucoside and its acylated derivatives (Livermore et al., 1978), and the lipid composition and metabolism of this species of *Borrelia* is remarkably similar to that of several species of mycoplasmas.

Spirochetes of the genus *Borrelia* do not have lipopolysaccharides containing lipid A (Takayama et al., 1987), and potent exotoxins are not evident.

Borrelia species are routinely cultured in liquid Barbour–Stoenner–Kelly (BSK) II medium under microaerophilic conditions. *Borrelia burgdorferi* isolates can form colonies when plated onto BSK medium solidified with 1.5% agarose (Kurti et al., 1987). Colonies are typically observed after 2–3 weeks of incubation and may differ in morphology among different strains, e.g., compact, round colonies (mean diameter, 0.43 mm) restricted to the surface of the agarose medium, diffuse colonies (mean diameter, 1.80 mm) penetrating into the solid medium, or colonies with a raised center surrounded by a diffuse ring of spirochetes.

Borrelia burgdorferi lacks genes encoding enzymes required for the synthesis of most amino acids, fatty acids, enzyme cofactors, and nucleotides. Instead, there are 52 open reading frames (ORFs) that encode transport and binding proteins which would contribute to 16 distinct membrane transport systems for amino acids, carbohydrates, anions, and cations (Fraser et al.,

1997). *Borrelia burgdorferi* also shows limited metabolic capacity. Growth of *Borrelia burgdorferi* depends largely on the availability of nutrients provided in the culture medium or from the host (mammal or tick). Analysis of the genome and reconstruction of metabolic pathways suggests that *Borrelia burgdorferi* uses glucose as a primary carbon and energy source, although other carbohydrates such as glycerol, glucosamine, fructose, and maltose may be used in glycolysis. *Borrelia burgdorferi* does not contain genes encoding enzymes of the tricarboxylic acid cycle or components of the electron transport system (Fraser et al., 1997). Thus, it is assumed that lactic acid is the main end product of glycolysis, which is consistent with the microaerophilic nature of this spirochete. Since genes for the respiratory electron transport chain were not identified, ATP production must be accomplished by substrate-level phosphorylation.

Borrelia hermsii and *Borrelia parkeri* ferment glucose, maltose, trehalose, starch, dextrin, and glycogen, but not raffinose. In contrast, *Borrelia turicatae* is able to ferment only glucose, raffinose, and dextrin.

The genome of the borreliae is composed of a small linear chromosome of approximately 1000 kb and a collection of linear and circular plasmids that are variable in number and size among species and strains. The DNA–DNA homology of Lyme disease borreliae is 76–100% among strains within species and 46–74% between different species (Baranton et al., 1992; Hyde and Johnson, 1984). For the relapsing fever spirochetes, there is >70% DNA homology between *Borrelia hermsii* and *Borrelia turicatae* (86%) or *Borrelia parkeri* (77%) that are endemic in North America, whereas 17–63% DNA relatedness was demonstrated between *Borrelia hermsii* and other relapsing fever agents (Barbour and Hayes, 1986). All *Borrelia* species studied to date have DNA G+C contents of approximately 30 mol%.

The complete genome of *Borrelia burgdorferi* has been determined (Casjens et al., 2000; Fraser et al., 1997). The genome size of the type strain *Borrelia burgdorferi sensu stricto* B31^T is 1,521,419 bp. This consists of a linear chromosome of 910,725 bp, with a DNA G+C content of 28.6 mol%, and 21 plasmids (9 circular and 12 linear) with a combined size of 610,694 bp (Casjens et al., 2000; Fraser et al., 1997). The genomes of two other pathogenic Lyme disease borreliae, *Borrelia garinii* strain PBI and *Borrelia afzelii* strain PKo, have colinear chromosomes of comparable size to *Borrelia burgdorferi* B31^T with only minor insertions and deletions. The plasmid fraction may vary significantly between different species. About 40% of *Borrelia burgdorferi* B31^T genomic DNA is of plasmid origin, whereas plasmid DNA constitutes only 29 and 36% of the analyzed genomes of *Borrelia garinii* PBI and *Borrelia afzelii* PKo, respectively (Glockner et al., 2004, 2006).

Genome analysis revealed that the Lyme disease borreliae possess some genetic structures that are unique among prokaryotes (Casjens et al., 2000; Fraser et al., 1997). These include: (1) the presence of a linear chromosome and multiple linear and circular plasmids in a single bacterium; (2) unique organization of the rRNA gene cluster, consisting of a single 16S rRNA gene and tandemly repeated 23S and 5S rRNA genes; (3) significantly higher frequency of lipoprotein-encoding genes (4.9% of the chromosomal genes and 14.5% of the plasmid genes); (4) a substantial fraction of plasmid DNA that appears to be in a state of evolutionary decay; and (5) evidence for numerous, and potentially recent, DNA rearrangements among the plasmid genes.

^a nd, Not determined.

The genomes of relapsing fever *Borrelia* species are largely linear. Each genome consists of a linear chromosome of about 1000 kb and different types of linear and circular plasmids. The size of linear plasmids is 10–200 kb and of circular plasmids is 8–40 kb. The presence of multiple copies of the chromosome and linear plasmids in some relapsing fever strains has been reported (Kitten and Barbour, 1992). The complete genomes of two relapsing fever borreliae, *Borrelia hermsii* and *Borrelia turicatae*, have been sequenced (NCBI Genome Databases, <http://www.ncbi.nlm.nih.gov>).

Borrelia burgdorferi is strictly a clonal organism, in spite of the observed genetic diversity and evidence for lateral gene transfer and recombination of selected plasmid genes among and within *Borrelia* species (Dykhuizen et al., 1993). Genetic manipulation of *Borrelia* species is very difficult, but basic tools are now available and their application has begun to provide information about the identities and roles of key bacterial components in both the tick vector and the mammalian host (Rosa et al., 2005). Phage particles have been observed in *Borrelia burgdorferi* culture supernatants (Eggers and Samuels, 1999).

Antigenic variation has been well documented in *Borrelia* species and extensively studied in the relapsing fever agent *Borrelia hermsii* and the Lyme disease spirochete *Borrelia burgdorferi*. About 30 variable major protein (VMP) serotypes, which are divided about equally between a variable large protein (Vlp) of about 36 kDa and variable small proteins (Vsp) of about 20 kDa, have been described in *Borrelia hermsii*. The Vlp/Vsp antigenic variation system of *Borrelia hermsii* involves an expression site that can acquire either *vlp* or *vsp* surface lipoprotein genes from up to 59 different archival copies arranged in clusters on at least five different plasmids. Gene conversion occurs through recombination events at upstream homology sequences found in each gene copy, and at downstream homology sequences found periodically among the *vlp/vsp* archival genes (Dai et al., 2006). Genes that are homologous to *vlp* and *vsp* of *Borrelia hermsii* are detected in other relapsing fever borreliae, including *Borrelia turicatae*, *Borrelia recurrentis*, *Borrelia crocidurae*, and *Borrelia duttonii* (Cutler, 2001, 1999). This property of relapsing fever borreliae is responsible for the numerous relapses which occur in the infected host. In *Borrelia burgdorferi*, antigenic variation can result by promiscuous recombination of plasmid-encoded *vls* sequence cassettes and may contribute to evasion of the host immune response, allowing persistence of the spirochete (Zhang et al., 1997).

More than 50 protein bands are visible in whole-cell lysates of cultivable *Borrelia* species. Serodiagnosis of Lyme disease is achieved by detection of antibodies specific to Lyme borrelial antigens (Centers for Disease Control and Prevention, 1995; Dressler et al., 1993). Since antibodies against glycerophosphodiester phosphodiesterase (GlpQ) are demonstrated only in sera from hosts infected with relapsing fever borreliae, this antigen could be used for serodiagnosis to distinguish Lyme disease from relapsing fever borrelial infections.

Borrelia species are susceptible to several classes of antimicrobial agents, including penicillins, second- and third-generation cephalosporins, tetracyclines, macrolides, and glycopeptides, but they are relatively resistant to aminoglycosides, trimethoprim, rifampicin, and quinolones (Preac-Mursic et al., 1986; Wormser et al., 2006).

Borreliae are pathogens of man, other mammals, and birds. Infections are acquired from ticks or lice which are parasitized

with borreliae. Two distinct clinical syndromes are associated with *Borrelia* infections in humans: Lyme disease and relapsing fever. *Borrelia burgdorferi*, *Borrelia garinii*, and *Borrelia afzelii* are causative agents of human Lyme borreliosis. *Borrelia burgdorferi* is the sole species responsible for Lyme borreliosis in North America, whereas all three pathogenic Lyme borreliae are documented in Eurasia. Human Lyme borreliosis generally occurs in stages and may manifest as one or more symptoms including erythema migrans, carditis, neuroborreliosis, and arthritis (Steere, 2001). Association between different clinical manifestations and the infecting *Borrelia* species or genotypes has been reported (van Dam et al., 1993; Wang et al., 1999; Wormser et al., 1999).

Infections with the relapsing fever borreliae in man produce a severe septicemic illness of which two varieties are recognized: tick-borne and louse-borne relapsing fever. A single spirochete of *Borrelia duttonii*, *Borrelia hermsii*, or *Borrelia turicatae* may be sufficient to infect experimental animals.

Borrelia species exist in nature in enzootic cycles primarily involving ticks and a wide range of animal hosts. Lyme disease borreliae are transmitted among reservoirs and hosts by ticks of the family *Ixodidae*, mainly ticks within the *Ixodes ricinus* complex. *Ixodes scapularis* and *Ixodes pacificus* in the United States, and *Ixodes ricinus* and *Ixodes persulcatus* in Eurasia are the principal vectors of the spirochetes (Burgdorfer et al., 1991). All *Ixodes* species are three-host ticks; each individual tick feeds on three different host animals during its life. The white-footed mouse (*Peromyscus leucopus*) in the United States, and the wood mouse (*Apodemus sylvaticus*) and bank vole (*Clethrionomys glareolus*) in Europe are among the most important reservoirs for Lyme borreliae (Anderson, 1989; Gern et al., 1998). Migrating birds may be reservoirs of certain species such as *Borrelia garinii* and *Borrelia valaisiana*. Larval ticks acquire *Borrelia burgdorferi* by feeding on infected hosts. The spirochetes survive through the molts and remain present in all subsequent stages of the vectors. Transovarial transmission of *Borrelia burgdorferi* may occur in *Ixodes* ticks but does not represent an important factor in maintaining infected ticks in nature (Burgdorfer et al., 1991).

Tick-borne relapsing fever is transmitted by a number of different species of *Ornithodoros* ticks. Many are named after the species of *Ornithodoros* tick transmitting the infection. Numerous small animals serve as natural reservoirs for tick-borne relapsing fever borreliae. Relapsing fever borreliae are frequently vertically transmitted in infected ticks, occurring in up to 100% of offspring and in most but not all tick species (Barbour, 2005).

The causative agent of louse-borne relapsing fever, *Borrelia recurrentis*, is transmitted from human-to-human by the body louse *Pediculus humanus* subsp. *humanus*. Man acquires infection by crushing infected lice during scratching, thereby liberating borreliae which enter the body at the site of the louse bite or through skin abraded by scratching. Lice acquire *Borrelia recurrentis* by feeding on infected humans and remain infectious for the remainder of their relatively short lifespan.

The geographical distribution of the *Borrelia* species, specific arthropod vectors and hosts, are listed in Table 121.

Enrichment and isolation procedures

***In vitro* cultivation.** All Lyme disease borreliae and many species of relapsing fever borreliae (e.g., *Borrelia hermsii*, *Borrelia coriaceae*, and *Borrelia turicatae*) can be grown routinely in a cell-free liquid culture under microaerophilic conditions in Barbour–Stoenner–

Kelly II (BSK-II) medium (Barbour, 1984) or variations such as BSK-H (Pollack et al., 1993) or MKP medium (Preac-Mursic et al., 1986). These are modifications from the Kelly's medium that were used first for cultivation of certain relapsing fever borreliae (Kelly, 1971). Owing to the lack of or limited biosynthetic potential, complex nutritional requirements are necessary for cultivation of *Borrelia*. Typically, the culture medium contains serum, glucose, albumin, peptides, amino acids, vitamins, and a thickening agent such as gelatin. In addition, *N*-acetylglucosamine and long-chain saturated and unsaturated fatty acids are required. The optimum growth temperature for *Borrelia burgdorferi* is 30–34°C. The bacteria grow slowly, dividing every 8–12 h during the exponential growth phase *in vitro*. Culture-adapted isolates can usually reach cell densities of 10⁷–10⁸ per ml after cultivation *in vitro* for 5–7 d. *Borrelia burgdorferi* can also be grown on semi-solid BSK medium to obtain individual, pure clones (Preac-Mursic et al., 1991).

Isolation by animal inoculation. Some relapsing fever borreliae have yet to be cultivated in serial passage outside of a natural host or experimental animal. Animal inoculation remains the method of choice for isolation of these borreliae. A number of animals have been used for isolation of nonavian borreliae including mice, rats, rabbits, guinea pigs, and monkeys. Results have been variable depending on the species of *Borrelia* and the age and species of animals employed. The most consistent results have been obtained with suckling mice. Citrated blood or triturates of ticks or lice are inoculated in a volume of 0.1–0.2 ml via the subcutaneous or intraperitoneal route. At daily intervals, the mice are bled by clipping the tip of the tail with scissors to obtain a small drop of blood which is examined by darkfield microscopy or in smears stained by the Wright or Giemsa method.

Maintenance procedures

Suspensions of borreliae containing 10% glycerol retain viability for several years when stored at or below –70°C. Limited attempts to preserve borreliae by lyophilization have not been successful.

Tick-borne borreliae may also be maintained in the laboratory for several years in infected ticks with occasional feedings on experimental animals.

Differentiation of the genus *Borrelia* from other genera

Two other genera of spirochetes which may be present in biological fluids or tissues are species of *Treponema* and *Leptospira*. Borreliae stain readily and can be observed with conventional microscopy whereas leptospire and some treponemes are not visualized. The coils of borreliae are loose, coarse, and irregular. Leptospire are coiled so tightly that they are difficult to observe with darkfield microscopy. *Treponema* species are regularly and rigidly coiled and have a more uniformly helical structure than do borreliae species.

Taxonomic comments

The Lyme disease and relapsing fever borreliae are morphologically indistinguishable. However, these two major groups of *Borrelia* can be easily differentiated based on their arthropod vectors and 16S rRNA gene sequences with only a few exceptions. 16S rRNA and flagellin gene sequence analysis is reliable in discriminating members within the genus of *Borrelia* (Fukunaga et al., 1996b; Ras et al., 1996; Wang et al., 1999). In addition, several other molecular typing methods have been successfully employed for species differentiation of the Lyme disease *Borrelia*.

These include rRNA restriction analysis (ribotyping), pulsed-field gel electrophoresis, randomly amplified polymorphic DNA (RAPD) fingerprinting, PCR and PCR-based restriction fragment length polymorphism (RFLP), sequence analysis of the 5S–23S intergenic spacer, and multilocus sequence analysis (Margos et al., 2008; Richter et al., 2006; Wang et al., 1999).

Traditionally, relapsing fever borreliae are classified into species according to their arthropod vectors. Those borreliae transmitted by human body lice presently belong to the species *Borrelia recurrentis*; those transmitted by ticks are differentiated on the basis of the tick-spirochete specificity theory which states that borreliae carried by a given species of tick are specific for that vector and, therefore, constitute individual species of borreliae (Barbour and Hayes, 1986; Kelly, 1984). This theory, however, is flawed by the fact that some borreliae isolated from one species of tick are capable of infecting other tick species. Moreover, many species of tick-borne borreliae have been shown to develop in experimentally infected body lice. Consequently, classification according to the traditional scheme may or may not be correct. For example, the relapsing fever borreliae *Borrelia turicatae*, *Borrelia parkeri*, and *Borrelia hermsii* are transmitted by distinct soft-bodied ticks, but they may be a single species because their DNA–DNA similarity is greater than 70%. The isolation of *Borrelia miyamotoi*, a species more closely related to relapsing fever borreliae from hard ticks (*Ixodes persulcatus* and *Ixodes ricinus*), challenges the classical concept of tick-spirochete cospeciation. Additional studies will be necessary to determine if the present classification is in fact valid.

Acknowledgements

The authors thank their many collaborators during a decade and a half of *Borrelia* research. Special thanks to Dr Gary P. Wormser for numerous insights and enlightening discussions. The research in the authors' laboratory was supported by National Institutes of Health grants AR41511 and AI45801.

^aAdapted from Postic et al. (1994), Wang et al. (1999), and Masuzawa et al. (2001). For some *Borrelia* species, strain variations in the *MseI* restriction fragment sizes are documented but are not listed in this table.

List of species of the genus *Borrelia**

- Borrelia anserina*** (Sakharoff 1891) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 435^{AL} (*Spirochaeta anserina* Sakharoff 1891, 565; *Spiroschaudinna anserina* (Sakharoff 1891) Sambon 1907, 834)

an.se'ri.na. L. fem. adj. *anserina* pertaining to geese.

The organisms are 0.2–0.3 μm wide and 8–20 μm in length, and consist of 5–8 coils.

The organisms can be grown in BSK II medium at 30°C and embryonated duck or chicken eggs. They can also be maintained in young chickens or ducks. Not infective for mice, rats, or rabbits. There are a number of antigenically different strains. The most reliable distinguishing characteristic of this species is that it is infectious for birds but not for rodents. Considered as the agent of fowl spirochetosis. Biochemical characteristics have not been determined.

Source: naturally infected *Argas miniatus* ticks and has a worldwide distribution.

DNA G+C content (mol %): not known.

*See Table 121 for listing of species categorized as relapsing fever borreliae, *Borrelia burgdorferi sensu lato*, and "other borreliae".

Type strain: not designated.

Sequence accession no. (16S rRNA gene): U42284 (strain ES-1).

2. ***Borrelia afzelii*** Canica, Nato, du Merle, Mazie, Baranton and Postic 1994, 182^{VL}

af.ze'li.i. N.L. masc. gen. n. *afzelii* of Afzelius, named in honor of Arvid Afzelius, a Swedish physician who was the first to report the skin lesion characteristic of Lyme borreliosis in 1909.

It has been referred to as group VS461. Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. rRNA gene restriction patterns after digestion by *EcoRV* contain three fragments (6.7, 3.2, and 1.6 kb). rRNA gene restriction patterns after digestion by *HindIII* contain five fragments (3.7, 2.1, 1.5, 0.9, and 0.6 kb).

Source: humans and *Ixodes ricinus* ticks in Europe and Asia.

DNA G+C content (mol%): 27–28 (T_m), 28 (strain VS461).

Type strain: strain VS461, ATCC 51567, CIP 103469, DSM 10508.

Sequence accession no. (16S rRNA gene): U78151 (strain VS461^T), CP000395 (strain PKo).

3. ***Borrelia baltazardii*** corrig. (*ex* Karimi, Hovind-Hougen, Birch-Andersen and Asmar 1979) Karimi, Hovind-Hougen, Birch-Andersen and Asmar 1983, 438^{VL} ("*Borrelia baltazardii*" Karimi, Hovind-Hougen, Birch-Andersen and Asmar 1979) bal.ta.zar'di.i. N.L. masc. gen. n. *baltazardii* of Baltazard, named after Marcel Baltazard (1908–1971), a French doctor and biologist.

Resembles *Borrelia recurrentis* in morphology.

Source: a region of Iran.

DNA G+C content (mol%): not known.

Type strain: strain *Borrelia* "x".

Sequence accession no. (16S rRNA gene): no sequence available.

4. ***Borrelia brasiliensis*** Davis 1956, 476^{AL}

bra.si.li.en'sis. N.L. fem. adj. *brasiliensis* named after the specific epithet of the tick vector *Ornithodoros brasiliensis*.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in mice, rats, and guinea pigs. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: the tick *Ornithodoros brasiliensis*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

5. ***Borrelia burgdorferi*** Johnson 1984, 496^{VP} (*Borrelia burgdorferi sensu stricto*, emend. Baranton 1992, 378)

burg.dor'fe.ri. N.L. masc. gen. n. *burgdorferi* of Burgdorfer, named in honor of Willy Burgdorfer.

The organisms are flexible helical cells with dimension of 0.2–0.3 μm by 4–30 μm . Motile with both rotational and translational movements. Consists of 3–10 coils. The coiling of the cell is regular. Seven to 11 periplasmic flagella are located at each cell end, and these flagella overlap at the

central region of the cell. A multilayered outer membrane surrounds the protoplasmic cylinder, which consists of the peptidoglycan layer, cytoplasmic membrane, and the enclosed cytoplasmic contents. The diamino acid ornithine is present in the peptidoglycan. Cytoplasmic tubules are absent.

The cells are Gram-stain-negative and stain well with Giemsa and Warthin–Starry stains. Unstained cells are not visible by bright-field microscopy but are visible by dark-field or phase-contrast microscopy.

The organisms grow well in BSK II medium or its variants supplemented with *N*-acetylglucosamine and rabbit serum. The optimal growth temperature is 34–37°C, with a generation time of 8–12 h at 35°C. The cells are catalase-negative and microaerophilic. Use glucose as primary energy source, although other carbohydrates, including glycerol, glucosamine, fructose, and maltose, may be used in glycolysis. Pyruvate produced by glycolysis is converted to lactate. Chemo-organotropic.

The genome of *Borrelia burgdorferi* type strain B31 contains a linear chromosome of 910,725 bp and 21 plasmids (9 circular and 12 linear) with a combined size of 610, 694 bp. The chromosome contains 853 genes encoding a basic set of proteins for DNA replication, transcription, translation, solute transport, and energy metabolism, but no genes for cellular biosynthetic metabolic capacities. Differential expression of major surface proteins in tick vectors and mammalian hosts. It is pathogenic for humans and animals.

Source: several tick species of the genus *Ixodes* which are parasitized by the spirochete.

DNA G+C content (mol%): 28.6 (complete genome sequencing).

Type strain: strain B31, ATCC 35210, CIP 102532, DSM 4680.

Sequence accession no. (16S rRNA gene): NC_001318, U03396.

6. ***Borrelia caucasica*** (Kandelaki 1945) Davis 1957, 901^{VL} (*Spirochaeta caucasica* Kandelaki according to Maruashvili 1945, 24)

cau.ca'si.ca. N.L. fem. adj. *caucasica* pertaining to the Caucasus.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in mice, rats, and guinea pigs. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: unknown source in Russia.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

7. ***Borrelia coriaceae*** Johnson, Burgdorfer, Lane, Barbour, Hayes and Hyde 1987, 72^{VP}

co.ri.a.ce'ae. L. fem. adj. *coriacea* of leather, made of leather; N.L. fem. gen. n. *coriaceae* named after the specific epithet of the tick vector, *Ornithodoros coriaceus*, from which the organism was isolated.

Morphology as described for the genus. Growth *in vitro* in BSK II medium but is more fastidious than other cultivable *Borrelia* species. Only three isolates (Co53, CA434, and

CA435) have been cultivated and maintained *in vitro* since 1985. Low infectivity for infant Swiss White mice, BALB/c mice, and adult New Zealand White rabbits. Probable cause of epizootic bovine abortion.

Source: the soft tick *Ornithodoros coriaceus* from Northern California.

DNA G+C content (mol%): 32.4 (T_m).

Type strain: strain Co53, ATCC 43381, CIP 104208.

Sequence accession no. (16S rRNA gene): U42286.

8. **Borrelia crocidurae** (Leger 1917) Davis 1957, 903^{AL} (*Spirochaeta crocidurae* Leger 1917, 281)

cro.ci.du'rae. N.L. gen. n. *crocidurae* of *Crocidura*, a genus of Insectivora.

Resembles *Borrelia recurrentis* in morphology. Isolates from blood of patients have been grown *in vitro* in modified Kelly's medium. Isolated and maintained in young mice and rats. Four serovars have been recognized; however, the species has not been well characterized. Clusters phylogenetically with *Borrelia duttonii*, *Borrelia recurrentis*, and *Borrelia hispanica*. No biochemical data are available. Considered as one cause of tick-borne relapsing fever.

Source: isolated initially from the white-toothed shrew, *Crocidura*. The tick vector is *Alectorobius sonrai*.

DNA G+C content (mol%): not known.

Type strain: not designated.

Sequence accession no. (16S rRNA gene): U42283 (strain UESV/ACH).

9. **Borrelia dugesii** (Mazzotti 1949) Davis 1957, 902^{AL} (*Spirochaeta dugesii* Mazzotti 1949, 278)

du.ge'si.i. N.L. gen. n. *dugesii* of *dugesii*, the specific epithet of the tick vector, *Ornithodoros dugesi*.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in young mice or rats. Distinguishing characteristics: not well characterized. No biochemical data available. Considered as one cause of tick-borne relapsing fever.

Source: the argasid tick, *Ornithodoros dugesi*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

10. **Borrelia duttonii** (Novy and Knapp 1906) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 434^{AL} [*Spirillum duttoni* (*sic*) Novy and Knapp 1906, 296; *Spirochaeta duttoni* (Novy and Knapp 1906) Breinl 1906, 1691]

dut.to'ni.i. N.L. masc. gen. n. *duttonii* of Dutton, named after Joseph Everett Dutton (1876–1905), who died from relapsing fever during an investigative trip to the Congo.

Resembles *Borrelia recurrentis* in morphology. Cells contained 10 periplasmic flagella inserted at each end of the spirochete. Has been successfully cultivated in BSK II medium from patients with relapsing fever. Isolated and maintained in BSK II medium or young mice and rats. Genome consists of a chromosome of approximately 1 Mb, a large plasmid of approximately 200 kb, and 7–9 plasmids with sizes in the range 20–90 kb. Analysis of the SDS-PAGE

profiles of *Borrelia duttonii* strains revealed a high-molecular-mass band of 33.4–34.2 kDa (variable large protein, VLP) and a low-molecular-mass band of 22.3 kDa (variable small protein, VSP). The cause of East African tick-borne relapsing fever. Man is the only reservoir.

Source: humans and the *Ornithodoros* sp. soft ticks.

DNA G+C content (mol%): 27.6 (HPLC).

Type strain: no strain designated.

Sequence accession no. (16S rRNA gene): U42288.

11. **Borrelia garinii** Baranton, Postic, Saint Girons, Boerlin, Piffaretti, Assous and Grimont 1992, 382^{VP}

ga.ri'ni.i. N.L. masc. gen. n. *garinii* of Garin, in honor of Charles Garin, a French physician.

Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. rRNA gene restriction patterns after digestion by *EcoRV* contain three fragments (5.3, 3.2, and 1.6 or 1.5 kb). rRNA gene restriction patterns after digestion by *HindIII* contain three fragments (2.1, 1.3, and 0.6 kb). Some strains produce an additional weak fragment at 2.5 kb.

Source: humans and *Ixodes* ticks in Europe and Asia.

DNA G+C content (mol%): 27–28 (T_m).

Type strain: strain 20047, ATCC 51383, CIP 103362, DSM 10534.

Sequence accession no. (16S rRNA gene): D67018.

12. **Borrelia graingeri** (Heisch 1953) Davis 1957, 903^{AL} (*Spirochaeta graingeri* Heisch 1953, 133)

grain'ge.ri. N.L. gen. n. *graingeri* named after the specific epithet of the tick vector, *Ornithodoros graingeri*.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Animal pathogenicity: present in the blood of mice and rats only transiently after inoculation. Distinguishing characteristics: not well characterized. No biochemical data available.

Source: the tick, *Ornithodoros graingeri*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

13. **Borrelia harveyi** (Garnham 1947) Davis 1948, 316^{AL} (*Spirochaeta harveyi* Garnham 1947, 49)

har've.yi. N.L. masc. gen. n. *harveyi* of Harvey, named after A.E.C. Harvey.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. May be maintained in mice, rats, and monkeys. Distinguishing characteristics: not well characterized. No biochemical data available.

Source: louse-borne relapsing fever in Kenya.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

14. **Borrelia hermsii** (Davis 1942) Steinhaus 1946, 453^{AL} [*Spirochaeta hermsii* (*sic*) Davis 1942, 46]

herm'si.i. N.L. gen. n. *hermsii* of *hermsii*, the specific epithet of the tick vector *Ornithodoros hermsii*.

Resembles *Borrelia recurrentis* in morphology. Grows well in BSK II medium (Table 120). Readily isolated and maintained in young mice and rats. Distinguishing characteristics: ferments glucose, maltose, trehalose, starch, dextrin, and glycogen, but not raffinose.

Source: the tick *Ornithodoros hermsi*.

DNA G+C content (mol%): 29 (complete genome sequencing).

Type strain: strain HS1, ATCC 35209, CIP 104209, DSM 4682.

Sequence accession no. (16S rRNA gene): U42292.

15. **Borrelia hispanica** (de Buen 1926) Steinhaus 1946, 453^{AL} (*Spirochaeta hispanica* de Buen 1926, 185)

his.pa'ni.ca. L. fem. adj. *hispanica* Spanish.

Resembles *Borrelia recurrentis* in morphology. May be cultivated *in vitro*, but the yield of organisms (7×10^6 /ml) is low (Kelly, 1976). Can be maintained in guinea pigs. Causes a mild infection in young mice and rats. Can be transmitted via rat bite. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: the argasid ticks *Ornithodoros nicolleti* and *Ornithodoros erraticus*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): U42294.

16. **Borrelia japonica** Kawabata, Masuzawa and Yanagihara 1994, 595^{VL}

ja.po'ni.ca. N.L. fem. adj. *japonica* pertaining to Japan.

Morphology and cultural properties as described for *Borrelia burgdorferi*. rRNA gene restriction patterns after digestion by *Hind*III contain one fragment (2.1 kb). DNA homology between type strain HO14 and related Lyme disease borreliae: *Borrelia burgdorferi* B31^T (56%), *Borrelia garinii* 20047^T (63%), and *Borrelia afzelii* VS461^T (64%).

Source: the tick *Ixodes ovatus*, shrews, voles, and mice in Japan.

DNA G+C content (mol%): 27.9–28.3 (T_m).

Type strain: strain HO14, ATCC 51557, JCM 8951.

Sequence accession no. (16S rRNA gene): L46696, L40597.

17. **Borrelia latyschewii** (Sofiev 1941) Davis 1948, 315^{AL} [*Spirochaeta latyschewi* (sic) Sofiev 1941, 271]

la.ty.sche'wi.i. N.L. masc. gen. n. *latyschewii* of Latyschew, named after Latyschew (Latyshev).

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Maintained in young mice. Distinguishing characteristics: not well characterized. No biochemical data available.

Source: the argasid tick, *Ornithodoros tartakovskyi*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

18. **Borrelia lusitaniae** Le Fleche, Postic, Girardet, Peter and Baranton 1997, 924^{VP}

lu.si.ta.ni'ae. L. gen. n. *lusitaniae* of *Lusitania*, the Roman name for Portugal, where the organism was first isolated.

Morphology and cultural properties as described for *Borrelia burgdorferi*. Can be easily differentiated from other

Lyme disease borreliae by analysis of the *Mse*I restriction polymorphism of the 5S–23S rRNA spacer. Patterns after restriction of the 16S rRNA gene by *Bfa*I contain six fragments (689, 404, 159, 100, 78, and 58 bp).

Source: *Ixodes ricinus* ticks, lizards, and small rodents in Europe and North Africa, and from the skin lesion of one patient in Portugal.

DNA G+C content (mol%): not known.

Type strain: strain PotiB2, CIP 105366.

Sequence accession no. (16S rRNA gene): X98228.

19. **Borrelia mazzottii** Davis 1956, 17^{AL}

maz.zot'ti.i. N.L. masc. gen. n. *mazzottii* of Mazzotti, named after Luis Mazzotti, a Mexican physician who recovered a relapsing fever spirochete from *Ornithodoros talaje* in Mexico in 1953.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in young mice and rats. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: the argasid tick *Ornithodoros talaje*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence available.

20. **Borrelia miyamotoi** Fukunaga, Takahashi, Tsuruta, Matsushita, Ralph, McClelland and Nakao 1995, 809^{VP}

mi.ya.mo'to.i. N.L. masc. gen. n. *miyamotoi* of Miyamoto, in honor of Kenji Miyamoto, an entomologist who first isolated this organism from *Ixodes* ticks in Japan.

Morphology and cultural properties as described for *Borrelia burgdorferi*. The rRNA gene cluster contains only a single copy of 23S and 5S rRNA gene, which is separated from the 16S rRNA gene. Low levels of DNA relatedness (8–13%) between *Borrelia miyamotoi* HT31^T and Lyme disease borreliae: *Borrelia burgdorferi* B31^T (13%), *Borrelia garinii* 20047^T (13%), *Borrelia afzelii* VS461^T (8%), and *Borrelia japonica* HO14^T (9%). Moderate levels of DNA relatedness with *Borrelia hermsii* (44%), *Borrelia turicatae* (41%), *Borrelia parkeri* (51%), and *Borrelia coriaceae* Co53^T (41%). The pathogenicity of *Borrelia miyamotoi* is unknown.

Source: the hard tick *Ixodes persulatus*, vector of Lyme disease, and rodents in Japan. *Borrelia* strains closely related to *Borrelia miyamotoi* have been detected or cultured from *Amblyoma americanum* and *Ixodes scapularis* ticks in the United States and from *Ixodes ricinus* ticks in Sweden.

DNA G+C content (mol%): 28–29 (T_m).

Type strain: strain HT31, JCM 9579.

Sequence accession no. (16S rRNA gene): D45192.

21. **Borrelia parkeri** (Davis 1942) Steinhaus 1946, 453^{AL} (*Spirochaeta parkeri* Davis 1942, 46)

par'ke.ri. N.L. gen. n. *parkeri* named after the specific epithet of the tick vector *Ornithodoros parkeri*.

Resembles *Borrelia recurrentis* in morphology. Grows well in BSK II medium (Table 120). Animal pathogenicity: isolated and maintained in young mice and rats. Distinguishing characteristics: fermentation of carbohydrates is identical to that of *Borrelia hermsii*. This suggests that the two species are in fact variants of a single species.

Source: the argasid tick *Ornithodoros parkeri*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): U42296.

22. **Borrelia persica** (Dschunkowsky 1913) Steinhaus 1946, 453^{AL} (*Spirochaeta persica* Dschunkowsky 1913, 419)

per'si.ca. L. fem. adj. *persica* Persian.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Animal pathogenicity varies according to the strain. Most isolates can be maintained in mice or guinea pigs. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: the argasid tick *Ornithodoros moubata*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): U42297.

23. **Borrelia recurrentis** (Lebert 1874) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 433^{AL}. [*Spirochaeta recurrentis* Lebert 1874, 273; "*Spirochaete obermeieri*" Cohn 1875; *Spiroschaudinna recurrentis* (Lebert 1874) Sambon 1907, 833^{AL}]

re.cur.ren'tis. L. part. adj. *recurrens*, *recurrentis* recurring; N.L. gen. n. *recurrentis* intended to mean of a recurrent fever.

The organisms are 0.3–0.6 µm wide and 8–18 µm in length, and consist of 3–8 coils. Cells with pointed ends, a mean wavelength of 1.8 µm, an amplitude of 0.8 µm, and 8–10 periplasmic flagella.

May be cultivated *in vitro* in BSK II medium (Table 120). Most strains may also be maintained in young rats. Guinea pigs are not infected. DNA–DNA hybridizations and sequencing studies of both the flagellin and 16S RNA genes revealed that the greatest similarity was between *Borrelia recurrentis* and *Borrelia duttonii*. Causes louse-borne relapsing fever.

Source: the vector of this disease is the infected human body louse (*Pediculus humanus* subsp. *humanus*).

DNA G+C content (mol%): 28.4 (HPLC).

Type strain: strain A1, ATCC 700241.

Sequence accession no. (16S rRNA gene): U42300.

24. **Borrelia sinica** Masuzawa, Takada, Kudeken, Fukui, Yano, Ishiguro, Kawamura, Imai and Ezaki 2001, 1823^{VP}

si'ni.ca. M.L. fem. adj. *sinica* of China, the country from which the organism was isolated.

Morphology as described for the genus except for a maximum of four flagella at each end. Cultural properties as described for *Borrelia burgdorferi*. DNA homology of *Borrelia sinica* type strain CMN3 and other Lyme borreliiae: *Borrelia afzelii* VS461^T (43%), "*Borrelia andersonii*" 21123 (39%), "*Borrelia bissettii*" DN127 (47%), *Borrelia burgdorferi* B31^T (59%), *Borrelia garinii* 20047^T (53%), *Borrelia japonica* HO14^T (52%), *Borrelia lusitaniae* PotiB2^T (47%), *Borrelia tanukii* Fi81t (51%), *Borrelia turdi* Ya501^T (46%), and *Borrelia valaisiana* VS116^T (30%).

Source: the tick *Niviventer confucianus*.

DNA G+C content (mol%): 29.6 (CMN3^T) (HPLC).

Type strain: strain CMN3^T, JCM 10505.

Sequence accession no. (16S rRNA gene): AB022101.

25. **Borrelia spielmanii** Richter, Postic, Sertour, Livey, Matuschka and Baranton 2006, 880^{VP} (*Borrelia spielmani* Richter, Schlee, Allgower and Matuschka 2004)

spi.el.ma'ni.i. N.L. masc. gen. n. *spielmanii* of Spielman, in honor of Andrew Spielman, who first described the life cycle and biological relationships of *Borrelia burgdorferi*.

Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. It has pathogenic potential.

Source: *Ixodes ricinus* ticks feeding on garden and hazel dormice, in questing ticks, and in patients in France, Germany, The Netherlands, Denmark, Slovenia, Hungary, and the Czech Republic.

DNA G+C content (mol%): 27–32 (T_m).

Type strain: strain PC-Eq17N5, CIP 108855, DSM 16813.

Sequence accession no. (16S rRNA gene): AF102056 (strain A14S).

26. **Borrelia tanukii** Fukunaga, Hamase, Okada and Nakao 1997, 1274^{VL}

ta.nu'ki.i. N.L. gen. n. *tanukii* of/from *tanuki*, named after *Ixodes tanuki*, from which the organism was isolated.

Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. Less than 70% DNA homology with *Borrelia burgdorferi*, *Borrelia garinii*, *Borrelia afzelii*, *Borrelia japonica*, and *Borrelia turdi*. rRNA gene restriction patterns after digestion by *EcoRV* contain two fragments (6.2 and 3.2 kb). rRNA gene restriction patterns after digestion by *HincII* contain three fragments (6.5, 3.2, and 1.8 kb).

Source: *Ixodes tanuki* ticks and several species of rodents in Japan.

DNA G+C content (mol%): 28–31 (HPLC), 29 (strain Hk501^T).

Type strain: strain Hk501, ATCC BAA-127, JCM 9662.

Sequence accession no. (16S rRNA gene): D67023.

27. **Borrelia theileri** (Laveran 1903) Bergey, Harrison, Breed, Hammer and Huntoon 1925, 435^{AL}. (*Spirochaeta theileri* Laveran 1903, 941)

thei'le.ri. N.L. masc. gen. n. *theileri* of Theiler, named in honor of Arnold Theiler (1867–1936), a Swiss veterinarian and regarded as the father of veterinary science of South Africa.

The organisms are 0.25–0.30 µm wide and 20–30 µm in length in cattle; they are reported to be shorter in horses. *In vitro* cultivation has not been reported. May be maintained in cattle and horses. Distinguishing characteristics: not well characterized. No biochemical data available.

Source: the cattle tick *Boophilus microplus*.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): DQ872186.

28. **Borrelia tillae** Zumpt and Organ 1961, 33^{AL}

til'lae. N.L. fem. gen. n. *tillae* of Till, named after W. Till.

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in young mice and rats. Distinguishing characteristics are not well characterized. No biochemical data available.

Source: not known.

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence data available.

29. **Borrelia turcica** Güner, Watanabe, Hashimoto, Kadosaka, Kawamura, Ezaki, Kawabata, Imai, Kaneda and Masuzawa 2004, 1651^{VP}

tur.ci'ca. N.L. fem. adj. *turcica* of or belonging to Turkey, the country in which the organism was isolated.

Morphology is as described for the genus. Length of the cells is variable, about 10–25 µm, and the diameter is 0.2–0.28 µm, with 8–23 flagella. The mean number of flagella is 15–16. The optimal growth temperature in BSK II medium is between 34 and 37°C; cells can grow at 39°C. Fast-growing spirochete; doubling times at 34 and 37°C are 5.3 and 5.1 h, respectively.

Reactive with *Borrelia* genus-specific mAb H9326, but no reactivity with Lyme disease *Borrelia* OspA-specific mAb H5332.

The level of DNA relatedness in strain IST7^T was less than 20% when compared with the Lyme disease agent, *Borrelia burgdorferi*, or the relapsing fever agent, *Borrelia hermsii*. *Borrelia turcica* spirochetes formed a monophyletic cluster separated from both Lyme disease and relapsing fever-related *Borrelia* species on a phylogenetic tree based on 16S rRNA gene sequence data (Figure 87).

Source: hard tick *Hyalomma aegyptium* in Turkey.

DNA G+C content (mol%): 30 (T_m).

Type strain: strain IST7, DSM 16138, JCM 11958.

Sequence accession no. (16S rRNA gene): AB111849.

30. **Borrelia turdi** corrig. Fukunaga, Hamase, Okada and Nakao 1997, 1274^{VL}

tur'di. N.L. gen. n. *turdi* of/from *turdus*, named after *Ixodes turdus*, from which the organism was isolated.

Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. Less than 70% in DNA homology with *Borrelia burgdorferi*, *Borrelia garinii*, *Borrelia afzelii*, *Borrelia japonica*, and *Borrelia tanukii*. rRNA gene restriction patterns after digestion by *EcoRV* contain two fragments (6.3 and 3.2 kb). rRNA gene restriction patterns after digestion by *HindIII* contain three fragments (5.7, 3.2, and 2.3 kb). The pathogenicity of *Borrelia turdi* is unknown.

Source: *Ixodes turdus* ticks and passerine birds, *Emberiza spodocephala*, in Japan.

DNA G+C content (mol%): 28–32 (HPLC), 29 (strain Ya501^T).

Type strain: strain Ya501, ATCC BAA-126, JCM 9661.

Sequence accession no. (16S rRNA gene): D67022.

31. **Borrelia turicatae** (Brumpt 1933) Steinhaus 1946, 453^{AL} (*Spirochaeta turicatae* Brumpt 1933, 1369)

tu.ri.ca'tae. N.L. gen. n. *turicatae* of *turicata*, the specific epithet of the tick vector, *Ornithodoros turicata*.

Resembles *Borrelia recurrentis* in morphology. Grows well in BSK II medium (Table 120). Can also be isolated and maintained in young mice and rats. Distinguishing characteristics: Ferments only glucose, raffinose, and dextrin, thus differing from *Borrelia hermsii* and *Borrelia parkeri*.

Source: the argasid tick *Ornithodoros turicata*.

DNA G+C content (mol%): 29 (complete genome sequencing).

Type strain: none designated.

Sequence accession no. (16S rRNA gene): U42299.

32. **Borrelia valaisiana** Wang, van Dam, Le Fleche, Postic, Peter, Baranton, de Boer, Spanjaard and Dankert 1997, 931^{VP}

va.lai.si.a'na. N.L. fem. adj. *valaisiana* of or belonging to Valais, Switzerland, where this organism was first isolated.

Formerly *Borrelia* group VS116. Morphology as described for the genus. Cultural properties as described for *Borrelia burgdorferi*. rRNA gene restriction patterns after digestion by *EcoRV* contain three fragments (6.9, 3.2, and 1.4 kb). rRNA gene restriction patterns after digestion by *HindIII* contain four fragments (2.1, 1.2, 0.8, and 0.6 kb). It is probably pathogenic to humans.

Source: several species of *Ixodes* ticks in Europe and Asia.

DNA G+C content (mol%): 28–32 (T_m).

Type strain: strain VS116, CIP 105367.

Sequence accession no. (16S rRNA gene): X98232.

33. **Borrelia venezuelensis** (Brumpt 1921) Brumpt 1922b, 495^{AL} [*Treponema venezuelense* Brumpt 1921, 207; "*Spirochaeta neotropicalis*" Bates and St John 1922, "*Borrelia neotropicalis*" (Bates and St John 1922) Steinhaus 1946]

ve.ne.zu.e.len'sis. N.L. adj. *venezuelensis* named after the specific epithet of the tick vector, *Ornithodoros rudis* (*Ornithodoros venezuelensis*).

Resembles *Borrelia recurrentis* in morphology. *In vitro* cultivation has not been reported. Isolated and maintained in young mice or rats. Distinguishing characteristics: not well characterized. No biochemical data available.

Source: the argasid tick *Ornithodoros rudis* (*Ornithodoros venezuelensis*).

DNA G+C content (mol%): not known.

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): no sequence data available.

Species Candidatus

"*Candidatus Borrelia texasensis*": a *Borrelia* strain TXW-1, isolated from an adult male *Dermacentor variabilis* tick feeding on a coyote in Texas, USA. The levels of DNA relatedness between TXW-1 and previously described relapsing fever borreliae are extremely low (7.9–38.6%). It could not be revived from frozen cultures (Lin et al., 2005).

Other organisms belonging to the genus *Borrelia*

Three *Borrelia* species associated with Lyme disease, "*Borrelia andersonii*" sp. nov. (Marconi et al., 1995), "*Borrelia bissettii*" sp. nov. (Postic et al., 1998), and "*Borrelia californiensis*" sp. nov. (Postic et al., 2007), have been described. Their taxonomic status is not validated due to the lack of sufficient data.

"*Borrelia andersonii*" sp. nov. was chosen in honor of John Anderson, who was the first person to isolate and characterize strains in this group. It has been cultivated from *Ixodes dentatus* ticks and its wildlife host cottontail rabbits in North America. Isolates in this group possess a unique rRNA gene polymorphism (Marconi et al., 1995).

"*Borrelia bissetii*" sp. nov. was named in honor of Marjorie L. Bissett, who first described a member of this group. "*Borrelia bissetii*" sp. nov. has been isolated from *Ixodes spinipalpis* and some of its rodent hosts in the United States (Postic et al., 1998).

Several novel borreliial species or strains closely related to the relapsing fever borreliiae have been described. These include

an uncultivable "*Borrelia lonestari*" sp. nov. detected by PCR and 16S rRNA gene sequence analysis in the hard tick *Amblyomma americanum* in North America (Barbour et al., 1996) and possibly new *Borrelia* species in patients with relapsing fever in Spain (Anda et al., 1996) and in soft-bodied *Ornithodoros* ticks in Tanzania (Kisinza et al., 2003). Their taxonomic status and pathogenicity in humans remain to be determined.

Genus III. *Cristispira* Gross 1910, 44^{AL}

BRUCE J. PASTER AND JOHN A. BREZNAK

Cris.ti.spi'ra. L. fem. n. *crista* a crest; L. fem. n. *spira* a coil; N.L. fem. n. *Cristispira* a crested coil.

Helical cells are 0.5–3.0 μm in diameter \times 30–180 μm in length, displaying 2–10 helical turns. Ends of cells are blunt, rounded, or tapered. Round inclusions of unknown composition or function are seen in stained preparations or under phase microscopy. Multiple cytoplasmic vesicles bounded by a double membrane are observed in electron microscopy thin sections. Cells divide by transverse fission. Hundreds of periplasmic flagella are bundled together and wrap around the protoplasmic cylinder forming a ridge or crest (called *crista*). The cristae can be clearly seen under light microscopy when the cells stop moving. Cells flex, rotate, and swim rapidly at more than 100 $\mu\text{m}/\text{s}$. Under adverse environments, cells stop moving and form spherical bodies or lyse. Found in the crystalline style of the digestive tract of marine and freshwater mollusks. **Not known to be pathogenic and probably represent normal microflora. *Cristispira*-like cells have also been observed in gastropods, e.g., snails, and in nonmollusk species. *Cristispira* has not yet been grown in pure culture.**

DNA G+C content (mol%): not determined.

Type species: *Cristispira pectinis* Gross 1910, 44^{AL}.

Further descriptive information

Cristispira is found in the crystalline style (Figure 88), which is a mucoproteinaeous, rod-shaped organ of the digestive tract of marine and freshwater mollusks (e.g., clams, mussels,

and oysters). *Cristispira* cells can be seen in great numbers from crystalline style preparations as shown in Figure 89. Cells are more numerous and motile in the inner zone rather than in the firm cortical region of the crystalline style (Perrin, 1906). Typically, mollusks with soft textured styles tend to harbor the spirochetes more frequently (Noguchi, 1921). *Cristispires* have been observed to protrude through, or adhere to, the outer layer of the crystalline style as shown in Figure 90 (Bernard, 1970; Tall and Nauman, 1981). Swimming motility outside of the crystalline style is rapid, more than 100 $\mu\text{m}/\text{s}$. Within the crystalline style, *cristispires* move slower in a creeping or crawling type of motility. Cells tend to avoid the anterior (blunt) end of the style, which usually contains food debris formed by the grinding of the style on the gastric shield region of the stomach (Breznak, 1973). It is likely that the anterior end of the style may contain substances toxic (or repellent) to *cristispires* (Berkeley, 1933, 1959, 1962).

Cristispires have also been observed in regions of the host other than in the crystalline style, including the style pouch, gastric shield, and fluid of the pallial cavity, stomach, anterior intestine, cecum, and rectum (Bernard, 1970; Breznak, 1973). They have been observed in aquaria water used to incubate their hosts (Bosanquet, 1911; Fantham, 1908). Not all species of mollusks examined possess *Cristispira* (Bernard, 1970; Breznak, 1973).

FIGURE 88. Scanning electron micrograph of the crystalline style of the oyster *Crassostrea virginica* that was cut in two pieces. Bar = 1.0 μm . (Tall and Nauman, 1981. Appl. Environ. Microbiol. 42: 336–343; reproduced with permission from B.D. Tall.)

FIGURE 89. Phase-contrast micrograph of a cluster of *Cristispira* cells from the crystalline style of *Ostrea (Crassostrea) virginica*. Bar = 10 μm .

FIGURE 90. Scanning electron micrograph of *Cristispira* associated with the outer layer of the crystalline style. Differences in coiling of the spirochetes on the surface and those below the surface can be readily observed. Bar = 10 μm . (Tall and Nauman, 1981. *Appl. Environ. Microbiol.* 42: 336–343; reproduced with permission from B.D. Tall.)

In suspension, cells remain motile longer at 5–10°C than at temperatures above 20°C (Fantham, 1908; Noguchi, 1921; Perrin, 1906); glucosone inhibits motility (Berkeley, 1962); motility occurs under aerobic and putative anaerobic conditions (Berkeley, 1959). May be microaerophilic; a suspension of a high concentration of cristispires on a microscope slide will form a distinct zone, a ring, of cells near the edge of a coverslip with no cells present in the center of the slide (personal observation, BJP). Cells typically lyse in distilled water (Fantham, 1908; Perrin, 1906). Cells survive, and perhaps have limited growth, in media with proteinaceous substrates (Noguchi, 1921) and fructose (Kubomura, 1969).

Cells of *Cristispira* possess the ultrastructural characteristics typical of spirochetes, i.e., a bundle of periplasmic flagella is wrapped around the helical body of each cell. The bundle (called the crest for cells of *Cristispira*) consists of hundreds of periplasmic flagella (shown Figure 91) which are inserted near each end of the protoplasmic cylinder and appear to overlap in the central region of the cell. An outer sheath surrounds both the bundle of periplasmic flagella and the protoplasmic cylinder. *Cristispira* has the most periplasmic flagella of all the known spirochetes.

Cristispira is found usually in healthy, palatable, univalve and bivalve mollusks obtained from well aerated beds (Berkeley, 1959). It does not appear to be pathogenic to its host. In non-actively feeding mollusks or at cold temperatures, the crystalline style generally dissolves, and the numbers of *Cristispira* decrease dramatically or no *Cristispira* are found (Dimitroff, 1926; Kuhn, 1974).

The mollusk hosts that have been reported to harbor presumed *Cristispira* are listed in Table 124. *Cristispira*-like spirochetes have also been observed in starfish (Collier, 1921), tunicates (Hellmann, 1913), and termites (Hollande, 1922), however, their phylogenetic relationships to the molluscan cristispires are unknown.

FIGURE 91. Transmission electron micrograph of a negatively stained preparation. The “crest” has been somewhat dispersed revealing the numerous periplasmic flagella. Bar = 1.0 μm . (Tall and Nauman, 1981. *Appl. Environ. Microbiol.* 42: 336–343; reproduced with permission from B.D. Tall.)

Differentiation of the genus *Cristispira* from other genera

Since *Cristispira* has not yet been grown in culture, the genus can only be differentiated from other genera of spirochetes based on habitat, the presence of a crista with hundreds of periplasmic flagella, their relatively large size, and, more recently, 16S rRNA sequence comparison.

Taxonomic comments

16S rRNA genes amplified from DNA isolated from cristispire-laden crystalline styles of the common eastern oyster, *Crassostrea virginica*, were cloned into *Escherichia coli* and sequenced. Sequence comparisons indicated that *Cristispira* branches deeply among other spirochetal genera within the family *Spirochaetaceae*. *Cristispira* clearly represents a separate genus within this family (Figure 92). In situ hybridization experiments were used to verify that the sequence obtained was derived from the observed *Cristispira* cells (Paster et al., 1996). It is not known if there is more than one species of *Cristispira* since cells from only a single oyster were analyzed.

Consequently, the genus *Cristispira* is still considered monospecific until species can be grown or analyzed from different hosts by 16S rRNA gene sequence analysis. The early literature suggests many different specific epithets to reflect the molluscan host and subtle differences in ultrastructural traits (Breznak, 1973; Kuhn, 1974). These species have previously been referred to as species incertae sedis (Kuhn, 1974). In the 1st edition of *Bergey's Manual of Systematic Bacteriology* (Breznak, 1984), reviving such names was avoided until pure cultures could be obtained

TABLE 124. Mollusk hosts of *Cristispira*

Host	Geographical source	Reference
<i>Amphidesma australe</i> (Gm.)	Cheltenham Beach, Auckland, New Zealand (marine)	Judd (1979)

Host-associated, helical cells 0.1–0.7 μm in diameter and 1–20 μm in length. Cells have tight regular or irregular spirals and one or more **periplasmic flagella** (axial fibrils or axial filaments) inserted at each end of the protoplasmic cylinder. **Cytoplasmic filaments** are seen in the protoplasmic cylinder just under the cytoplasmic membrane and running parallel with the periplasmic flagella. Under unfavorable cultural or environmental conditions, spherical cells are formed. These can also be seen in old cultures. Gram-stain-negative. Cells stain well with silver impregnation methods. Most species stain poorly, if at all, with Gram or Giemsa stain. Best observed with darkfield or phase-contrast microscopy. **Motile. Cells have rotational movement in liquid media, and translational motion in media with high viscosity [e.g., those containing 1% (w/v) methyl cellulose].** In a semisolid or solid medium, cells exhibit a serpentine type movement, sometimes referred to as creeping motility. **Strictly anaerobic or microaerophilic.** Frank pathogens (*Treponema pallidum* subspecies, *Treponema carateum*, and the rabbit pathogen

Treponema paraluis-cuniculi) represent a closely related subset within this genus and are considered microaerophiles. Limited multiplication of *Treponema pallidum* subsp. *pallidum* strains has been obtained in a tissue culture system, but none of the pathogenic *Treponema* have been cultivated continuously in artificial media or in tissue culture. **Chemo-organotrophs**, using a variety of **carbohydrates or amino acids for carbon and energy sources.** Cultivated anaerobic species are catalase- and oxidase-negative. Some require long-chain fatty acids found in serum for growth, while other cultivated species require short-chain volatile fatty acids for growth. **Host-associated. Pathogenic *Treponema pallidum* subspecies cause skin lesions, and *Treponema pallidum* (particularly subspecies *pallidum*) can cause systemic infections that, if untreated, can last for years to decades. Other species are found in the oral cavity, intestinal tract, and genital areas of humans or other mammals, and in the gut contents of wood-feeding insects.**

DNA G+C content (mol%): 37–54.

Type species: ***Treponema pallidum* subsp. *pallidum*** (Schaudinn and Hoffman 1905) Schaudinn 1905, 1728^{AL}.

Further descriptive information

Phylogeny and genetics. Comparison of rRNA gene sequences (Figure 93) and additional genome information indicates that

*Portions of this chapter have been adapted from the previous version in Bergey's by Smibert (1984). To assure accuracy and completeness, many of the species descriptions from the defining publications are repeated with only minor modifications. We regret that space limitations preclude the inclusion of all references relevant to this chapter.

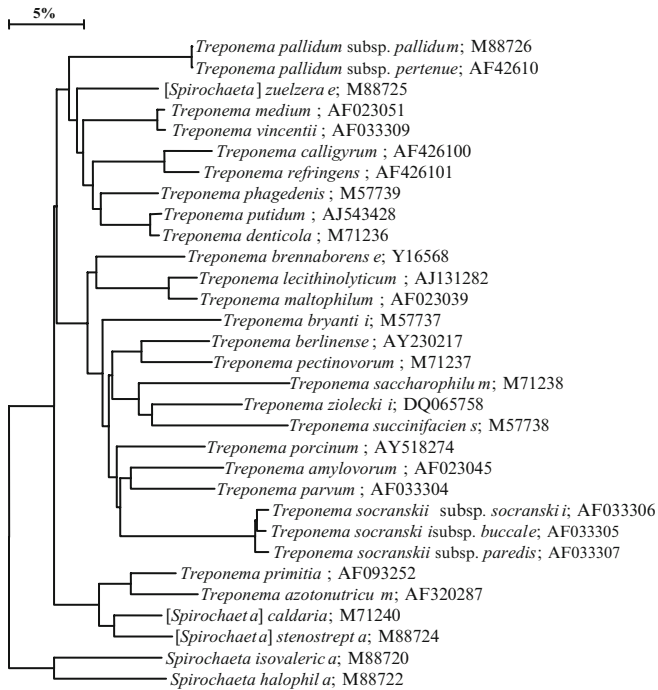

FIGURE 93. Phylogenetic tree of the genus *Treponema* and related organisms, based on 16S ribosomal RNA gene (rRNA) sequences. The distance corresponding to 5% sequence difference is indicated in the upper left corner. The GenBank accession number is provided for each organism. Approved species and candidati are not distinguished in this figure. Some of the *Spirochaeta* species shown ([*Spirochaeta*] *zuelzerae*, [*Spirochaeta*] *caldaria*, and [*Spirochaeta*] *stenostrepta*) are potential candidates for reclassification as *Treponema* species.

strains of the pathogenic species *Treponema pallidum* and *Treponema carateum* are closely related; *Treponema paraluiscluniculi*, while still a member of this group, diverges significantly from the human pathogens. In the 1984 edition of *Bergey's Manual*, Smibert (1984) reclassified the human pathogens as *Treponema pallidum* subsp. *pallidum* (venereal syphilis isolates), *Treponema pallidum* subsp. *endemicum* (endemic syphilis), and *Treponema pallidum* subsp. *pertenue* (yaws); *Treponema carateum* (pinta) has remained a separate species due to the lack of genetic information. This reclassification has withstood the test of time; indeed, the genomes of the *Treponema pallidum* subspecies differ by only a few hundred base pairs. The remaining *Treponema* species, although diverse, are clearly separated from the other genera of the family *Spirochaetaceae*.

The genome sequences of two strains (*Treponema pallidum* subsp. *pallidum* Nichols and *Treponema denticola* ATCC 35405) are available (Fraser et al., 1998; Seshadri et al., 2004). The genome size of *Treponema pallidum* is 1.138 Mb, whereas that of *Treponema denticola* is 2.843 Mb. The estimated genome sizes of other cultivatable *Treponema* species range from 2.3 to 3.9 Mb (Correia et al., 2004; Giacani et al., 2004).

The genome of *Treponema pallidum* subsp. *pallidum* Nichols does not contain any recognized extrachromosomal elements, bacteriophage sequences, or insertion elements (Fraser et al., 1998). The *Treponema denticola* chromosome contains at least one putative insertion element, a cryptic bacteriophage, and a “clustered regularly interspaced short palindromic repeat”

(CRISPR) region that is thought to represent a mobile element (Seshadri et al., 2004). Some *Treponema denticola* strains contain plasmids, and one of these (pTD1) has been sequenced and shown to contain bacteriophage-related sequences (Cheetham and Katz, 1995; MacDougall et al., 1992). Myovirus-like bacteriophage particles were detected by electron microscopy in cultures of an unclassified treponeme from a bovine digital dermatitis case (Demirkan et al., 2006). Otherwise, little is known about the existence of extrachromosomal elements, bacteriophage, and mobile DNA elements in the genus *Treponema*.

Morphology. Cells of all species are helical (Stepan and Johnson, 1981) and vary in cell diameter (0.1–0.7 μm). The structure of *Treponema pallidum* subsp. *pallidum* Nichols is shown in Figure 94. The outer envelope of treponemes contains lipid, protein, and carbohydrates and is similar to the outer

FIGURE 94. Structure of the type species *Treponema pallidum*, as exemplified by *Treponema pallidum* subspecies *pallidum* Nichols. 		<i>T. primitia</i>

membrane of Gram-stain-negative bacteria. The lipid is mainly phospholipid and glycolipid. In general, lipopolysaccharide (LPS) appears to be absent from *Treponema* spp., and the genomes of *Treponema pallidum* subsp. *pallidum* and *Treponema denticola* lack genes required for LPS biosynthesis (Fraser et al., 1998; Seshadri et al., 2004). It has, however, been reported that *Treponema vincentii* expresses LPS (Blanco et al., 1994; Kurimoto et al., 1990). The pathogenic treponemes are further distinguished by the paucity of proteins in the outer membrane (Radolf, 1995; Radolf et al., 1989b, 1991; Walker et al., 1989); these “rare outer-membrane proteins” have not been identified definitively. The cell walls contain muramic acid, glucosamine, ornithine, glycine, and alanine (Radolf et al., 1989a). Peptidoglycan represents 1% of the dry weight of cells. Several prominent lipoproteins are associated with the cytoplasmic membrane of *Treponema pallidum* (Norris, 1993) and are implicated in the induction of inflammatory reactions in the mammalian host.

As in other spirochetes, the periplasmic flagella of *Treponema* originate at both ends of the organism and extend proximally along the length of the bacterium within the periplasmic space. The basal body and proximal hook of periplasmic flagella are similar to those of flagella found in other bacteria (Murphy et al., 2006). In the *Treponema* species examined, the flagellar filaments consist of two or more core proteins homologous to flagellins of other bacteria (e.g., FlaB1, FlaB2, and FlaB3 of *Treponema pallidum*), as well as a single sheath protein (FlaA) (Norris, 1993; Norris et al., 1988).

Treponemes have cytoplasmic filaments that extend the length of the organism along the inner layer of the cytoplasmic membrane, underlying the periplasmic flagella (Hovind-Hougen

and Birch-Andersen, 1971; Izard, 2006; You et al., 1996). These ribbon-like filaments are ~5–7 nm×1 nm in cross section and occur in clusters of 4–6. The major subunit of cytoplasmic filaments is CfpA, with a molecular mass of 78–80 kDa. Most *Treponema* species examined have been found to contain cytoplasmic filaments. More recently, the cytoplasmic filaments have been shown to bridge the cytoplasmic cylinder constriction site in dividing cells, and may be anchored by a narrow plate-like structure (Izard et al., 2008).

Habitat and pathogenesis. Treponemes are primarily host-associated and are found in the microflora of humans and other animals (Table 125). The pathogenic treponemes in the *Treponema pallidum*/*Treponema carateum*/*Treponema paraluisuniculi* group cause syphilis, yaws, pinta, and nonvenereal endemic syphilis in humans and venereal spirochetosis in rabbits; these organisms have not been cultivated continuously *in vitro*, and are usually propagated in laboratory animals, e.g., in the testes of rabbits. These bacteria are transmitted by sexual contact in the case of syphilis and venereal spirochetosis of rabbits, and by skin-to-skin contact or shared utensils for the other treponematoses. The initial infection causes lesions in the skin or mucous membranes, but *Treponema pallidum* subsp. *pallidum* and some of the other subspecies disseminate and cause systemic infection and manifestations. *Treponema pallidum* is considered a microaerophile requiring low concentrations of oxygen (1.5–5.0%) for survival and multiplication (Cox, 1994, 1980; Norris et al., 1978). Many of the other *Treponema* species identified are localized in subgingival crevices surrounding the teeth of humans and other animals and are part of the polymicrobial infection that causes periodontal disease

(e.g., periodontitis) (Moore and Moore, 1994; Sela, 2001). *Treponema brennaborense* is associated with digital dermatitis in cattle, a painful ulcerative lesion occurring in the corona region of the hoof. The saprophytic *Treponema* species *Treponema minutum*, *Treponema phagedenis*, and *Treponema refringens* were isolated from material associated with the surface of the skin (smegma) in the anogenital region of humans and are nonpathogenic. *Treponema* species are also found in the intestinal tract of ruminant animals and swine, and have not as yet been implicated as pathogens. Another subset are intestinal symbionts important in the metabolism of termites.

Metabolism

The cultivated treponemes are strict anaerobes and require low redox conditions for growth. Some of these treponeme species ferment glucose and require a carbohydrate as an energy source, whereas other species gain energy from the fermentation of amino acids. Treponemes also differ in their requirement for fatty acids. Some species require long-chain fatty acids found in serum, while others require short-chain volatile fatty acids found in rumen fluid. All cultivated treponeme species require either long or short-chain fatty acids. Many of the oral organisms, including *Treponema denticola*, *Treponema vincentii*, and *Treponema scoliodontus*, require thiamine pyrophosphate in addition to serum.

Continuous culture of the pathogenic subspecies of *Treponema pallidum* has not been achieved. Limited multiplication of *Treponema pallidum* subsp. *pallidum* can be obtained in a culture system consisting of a modified tissue culture medium, Sf1Ep cottontail rabbit epithelial cell cultures, and an atmosphere containing 1.5% O₂, 5% CO₂, and 93.5% N₂ (Cox, 1994). Under these conditions, up to 100-fold increases in the number of *Treponema pallidum* over a 12-d period are observed; however, subculture does not lead to increased yields or prolonged survival (Norris and Edmondson, 1987). The genome sequence of *Treponema pallidum* subsp. *pallidum* Nichols indicates that the organism has little biosynthetic capacity (Fraser et al., 1998). The lack of continuous growth is likely due to a deficiency in required nutrients and/or irreversible damage resulting from toxic conditions in the *in vitro* environment. Cultivated treponemes (*Treponema phagedenis*, *Treponema refringens*, *Treponema denticola*, and *Treponema vincentii*) are inhibited by penicillin (100–1000 U/l), ampicillin (0.1–1.0 mg/l), oxacillin (0.1–10 mg/l), cloxacillin (0.1–1.0 mg/l), cephalothin (0.1–10 mg/l), vancomycin (0.1–10 mg/l), bacitracin (0.1–1.0 mg/l), erythromycin (0.1–1.0 mg/l), novobiocin (10–500 mg/l), tetracycline (1 mg/l), doxycycline (0.1–1.0 mg/l), chloramphenicol (100–500 mg/l), kanamycin (100–1000 mg/l), and viomycin (10–1000 mg/l). Bactericidal concentrations of antibiotics are usually much higher than inhibitory concentrations (Abramson and Smibert, 1971). All treponemes are resistant to cycloserine (500–1000 mg/l), polymyxin B (500–1000 mg/l), and nalidixic acid (500–1000 mg/l) (Abramson and Smibert, 1971). Oral and rumen treponemes are resistant to rifampicin at concentrations of 1–50 mg/l (Leschine and Canale-Parola, 1980b; Stanton and Canale-Parola, 1979), apparently due to an asparagine substitution at position 518 of the RNA polymerase β subunit RpoB (Stamm et al., 2001). Recent studies have shown that a substantial proportion of *Treponema pallidum* subsp. *pallidum* strains have a point mutation in the 16S rRNA genes that

renders the organism resistant to macrolides, including azithromycin (Lukehart et al., 2004; Marra et al., 2006; Mitchell et al., 2006; Stamm and Bergen, 2000).

Enrichment and isolation procedures

The cultivable treponemes can be isolated by two general methods. The first uses membrane filters placed on the surface of agar media. The second method uses rifampicin as a selective agent (Leschine and Canale-Parola, 1980b; Stanton and Canale-Parola, 1979).

A membrane filter with a pore size of 0.2 μ m is placed on an agar medium containing either 10% inactivated animal serum or 30% rumen fluid. The agar concentration should be no more than 1.3–1.4%. The sample is placed on the filter and the Petri dish quickly placed in an anaerobic jar or chamber and incubated. Treponemes and all other genera of spirochetes migrate through the filter whereas most other bacteria can not, resulting in a spirochetal enrichment. Incubation usually requires 1–2 weeks at 37°C. After incubation, the filter is removed and a white haze can be seen in the agar. Treponemes migrate through the filter and grow into the agar. A plug of agar is removed and inoculated into a pre-reduced culture medium.

In the second method, filter-sterilized rifampicin is added to either pre-reduced broth or molten agar medium in tubes to a final concentration of 1.0–2.0 mg/l. The tubes are inoculated and incubated at 37°C. Serial dilutions of samples can be made in the selective medium. The medium contains 1% agar and is allowed to solidify in the form of agar deeps. After incubation, white cottony colonies of treponemes are seen within the medium. These colonies can be removed with a Pasteur pipette and inoculated into pre-reduced medium.

The selective broth medium will contain treponemes and a few other kinds of bacteria because rifampicin does not inhibit all other bacteria. Treponemes can be isolated from the enriched selective culture by inoculating pre-reduced agar medium (1.3–1.4% agar) in 6- or 8-oz prescription bottles. The "bottle plates" can be streaked or the culture inoculated into molten agar (45°C) in the bottles, mixed, and the agar allowed to solidify on the flat side of the bottle. The gas phase in the bottle plates should be 90% N₂ and 10% CO₂.

The non-cultivable, pathogenic *Treponema* species can be propagated through animal inoculation (Miller, 1971; Turner and Hollander, 1957). Rabbits are the most widely used host for experimental infection, although primates, guinea pigs, and hamsters can also be infected with certain *Treponema pallidum* subspecies (Table 126). Early lesions (e.g., primary or secondary lesions of syphilis patients) sampled prior to the healing stages are most likely to yield infectious organisms. Either a tissue biopsy or lesion exudate can be used for inoculation. Tissue is minced and extracted in a serum-containing medium (e.g., 0.85% NaCl with 10% heat-inactivated rabbit serum). Organisms are highly susceptible to reactive oxygen species, so ideally, the medium should be pre-equilibrated with 95% N₂: 5% CO₂ and extraction carried out under anaerobic conditions. The extract should be monitored for the presence of spirochetes by darkfield microscopy. After 10–30 min, the extract should be centrifuged at 300 \times g for 7 min to remove tissue debris, and the supernate inoculated as soon as possible by needle and syringe into the testes (1 ml per testis) or intradermally into a

^cLesions are only slightly indurated and do not ulcerate (Turner and Hollander, 1957).

shaved area of the back (0.1 ml per site) of a rabbit. *Treponema pallidum* is highly temperature sensitive, so the rabbits should be maintained at 18–20°C and the skin inoculation sites kept free of hair. Rabbits should be examined daily for the presence of orchitis (testis swelling) or erythematous, indurated lesions at the skin inoculation sites. The infection can also be monitored by testing for Rapid Plasma Reagin (RPR) test reactivity. If lesions are not apparent at 3–4 weeks, blind passage of extracts from testicular tissue or popliteal lymph node to a naïve animal may yield positive results. Organisms can be maintained by extraction of organisms from infected tissue and inoculation of animals at 10–21-d intervals, depending on the strain. The inoculum for intratesticular inoculation should be 1–5×10⁷ cells; yields vary greatly according to the strain but will typically be in the range of 10⁹ to 10¹¹ cells per animal at the time of peak orchitis.

Maintenance procedures

Cultures of all species of treponemes can be stored in the frozen state using liquid nitrogen or mechanical freezers at -80°C. Cryoprotective agents such as 10–15% (v/v) glycerol or 10% (v/v) dimethyl sulfoxide are added to cultures just prior to freezing. Lyophilization has generally not been successful for preservation of treponemes.

Taxonomic comments

Named species of *Treponema* can be subdivided into the noncultivable, pathogenic species and the cultivatable species. Differentiation of the noncultivable species of *Treponema* is presented in Table 126. Characteristics useful for differentiating the cultivatable species are given in Tables 127–129.

The uncultivated species include *Treponema pallidum* (*Treponema pallidum* subsp. *pallidum*, *Treponema pallidum* subsp. *pertenue*, and *Treponema pallidum* subsp. *endemicum*), *Treponema carateum*, and *Treponema paraluisuniculi*. The primary distinguishing characteristics of these species and subspecies are the diseases that they cause: syphilis (subsp. *pallidum*), yaws (subsp. *pertenue*), endemic syphilis (subsp. *endemicum*), pinta (*Treponema carateum*), and venereal spirochetosis of rabbits (*Treponema paraluisuniculi*). To the extent they have been examined, these species and subspecies are indistinguishable in terms of morphology, *in vitro* characteristics (e.g., motility and survival under different conditions), protein content as determined by SDS-PAGE, and genomic DNA–DNA hybridization. Prior infection of animals with strains of different *Treponema* species or subspecies provides incomplete cross-protection from infection with other strains, indicating that antigenic differences are present (Turner and Hollander, 1957); however few such differences have been detected at the molecular level (Baker-Zander and Lukehart, 1983, 1984; Fohn et al., 1988; Noordhoek et al., 1990).

Centurion-Lara et al. (1998) found that the 5' and 3' regions flanking *tpp15* contained polymorphisms that could be used to distinguish *Treponema pallidum* subsp. *pallidum* from the other pathogenic *Treponema* species and subspecies, and *Treponema paraluisuniculi* from the human pathogens. PCR amplification followed by restriction fragment length polymorphism (RFLP) analysis revealed the presence of a unique *Eco47III* site in the 5' region in *Treponema pallidum* subsp. *pallidum* strains, and a *XcmI* site in the 3' region in *Treponema paraluisuniculi* strains. Subsequent studies by the same group (Centurion-Lara et al., 2006) showed that additional polymorphisms in the *Treponema*

pallidum repeat (*tpr*) genes *tprC* and *tprI* could be detected by RFLP analysis and used to distinguish each of the *Treponema pallidum* subspecies and a simian isolate, *Treponema* strain Fri-bourg-Blanc. These are currently the only systematic means for distinguishing the pathogenic *Treponema* species and subspecies. Additional approaches have been developed for the molecular subtyping of *Treponema pallidum* subsp. *pallidum* strains (Pillay et al., 1998), and have been used in epidemiologic studies of

syphilis transmission (Diclemente et al., 2004; Molepo et al., 2007; Pillay et al., 2002; Sutton et al., 2001).

Distinction of the cultivatable *Treponema* species is dependent on 16S rRNA gene sequence heterogeneity (Figure 93), phenotypic characteristics, some morphologic properties (e.g., cellular dimensions and number of flagella), and natural habitat. Little DNA–DNA reassociation data are available (Maio and Fieldsteel, 1978). 16S rRNA comparisons (Paster

^aSymbols: +, >85% positive; d, different strains give different reactions (16–84% positive); -, 0–15% positive.

^bResults from Wyss et al. (1996). Other results are from the defining publications.

and Dewhirst, 2000) and the available mol% G+C data indicate that the genus *Treponema* is an ancient, diverse phylogenetic group. There are instances where *Treponema* with high 16S rRNA similarity are from the same environment (e.g., *Treponema primitia* and *Treponema azotonutricum* from termite guts), and others where organisms with 16S rRNA relatedness are from different environments (e.g., *Treponema berlinense* from porcine intestinal tract and *Treponema pectinovorum* from human gingival crevices) (Figure 93). These results suggest that some *Treponema* strains may have “jumped” from one environment to another during evolution. Analyses of oral treponeme strains (Paster et al., 1998) from the Smibert collection indicate the difficulty in reconciling 16S rRNA and phenotypic data (such as fatty acid content), and the importance of using more global genotyping approaches, including DNA–DNA reassociation studies, for distinguishing phylotypes with $\geq 98\%$ 16S rRNA sequence identity.

As noted in the chapter on *Spirochaeta*, three species of *Spirochaeta*, namely *Spirochaeta stenostrepta*, *Spirochaeta zuelzeriae*, and *Spirochaeta caldaria*, belong with members of the genus *Treponema* rather than with other “free-living” *Spirochaeta* as indicated by 16S rRNA phylogeny (Figure 93) and single-base signature analysis (Paster et al., 1991). There has been no formal renaming, so they are described in the *Spirochaeta* chapter. As previously discussed, these “free-living” spirochetes may be descendants of precursors of host-associated treponemes or

may have been disseminated via fecal contamination (Paster et al., 1991).

Intestinal spirochetes previously classified as *Treponema hydysenteriae* and *Treponema innocens* have been reclassified as species of *Brachyspira*.

Further reading

Additional information regarding the genus *Treponema* is available in several recent books (Cabello et al., 2006; Radolf and Lukehart, 2006; Saier and Garcia-Lara, 2001), book chapters (Norris et al., 2003; Pope et al., 2006), and reviews (Antal et al., 2002; Cullen and Cameron, 2006; LaFond and Lukehart, 2006; Norris et al., 2001; Radolf et al., 1999).

Differentiation of the genus *Treponema* from other closely related genera

Characteristics useful for distinguishing *Treponema* from the other members of the family *Spirochaetaceae* are indicated in the key to the family. In terms of the pathogenic genera, *Borrelia* species are also host-dependent, but utilize arthropods (ticks or lice) as intermediate hosts and transmission agents. They are also somewhat larger in diameter and more loosely coiled than *Treponema*, and are facultative anaerobes. *Leptospira* are also associated with mammals, but are capable of surviving for prolonged periods in water or soil. They are more tightly coiled than either *Borrelia* or *Treponema*, and are obligate aerobes.

List of species of the genus *Treponema**†

1. ***Treponema pallidum*** (Schaudinn and Hoffman 1905) Schaudinn 1905, 1728^{AL}. (*Spirochaeta pallida* Schaudinn and Hoffman 1905, 528)

pal'li.dum. L. neut. adj. *pallidum* pale, pallid.

Tightly coiled, ~0.18 µm in diameter by 6–20 µm in length. The wavelength of coils is 1.1 µm and the amplitude is 0.2–0.3 µm. The ends of the cells are pointed, and a protrusion of the outer membrane at the end is often visible in well-preserved specimens by electron microscopy with negative staining (Figure 94). Two to four periplasmic flagella are inserted into each end of the cell, and overlap in the middle of the cell. Motile with graceful flexuous movements. Microaerophilic, with an optimal O₂ concentration in the range of 1–5%.

Obligate pathogens of humans. Can cause experimental infection and skin lesions in rabbits, guinea pigs, hamsters, and primates (Table 126). Sequence comparisons and DNA/DNA hybridization indicates that close to 100% DNA homology exists between the *Treponema* strains that cause syphilis, yaws, and endemic syphilis (Maio and Fieldsteel, 1980). Therefore, these organisms are considered subspecies of *Treponema pallidum* with distinctive clinical symptoms in humans and different patterns of infection in laboratory animals (Table 126). The subspecies can be distinguished by PCR and RFLP analysis of the *tpp15*, *tpnC*, and *tpnI* genes (Centurion-Lara et al., 1998, 2006).

Source: humans.

DNA G+C content (mol%): 52.4–53.7 (*T_m*).

Type strain: none designated.

- 1a. ***Treponema pallidum* subsp. *pallidum*** (Schaudinn and Hoffman 1905) Schaudinn 1905, 1728, subsp. nov.

The morphology and characteristics are as described for the species and as listed in Table 126. *Treponema pallidum* subsp. *pallidum* is the cause of venereal and congenital syphilis in humans. It has not been cultivated continuously in artificial media or in tissue culture. Propagated by intratesticular inoculation of rabbits.

Successful replication of *Treponema pallidum* subsp. *pallidum* (virulent Nichols strain) has been reported to occur on the surface of tissue culture cells of cottontail rabbit epithelium (SfIEP) growing in a monolayer in an atmosphere of 1.5% O₂. A 49-fold increase (mean value) in cell numbers was reported in primary cultures of *Treponema pallidum*, but increased or prolonged multiplication with subculture has not been obtained to date (Cox, 1994; Fieldsteel et al., 1981; Norris and Edmondson, 1987). *Treponema pallidum* cells show rapid attachment to cultured mammalian cells (Fitzgerald et al., 1977a; Hayes et al., 1977). Proteins that bind to the host extracellular matrix proteins laminin and fibronectin have been identified (Cameron, 2003, 2004, 2005).

Obligate pathogen of humans. Strains such as the Nichols pathogenic strain are propagated by intratesticular inoculation of rabbits. Cutaneous inoculation of rabbits produces skin lesions. Cutaneous inoculation of hamsters, mice, and guinea pigs produces no apparent infection or visible lesions. A slight lesion is occasionally seen at the point of injection of guinea pigs.

Microaerophilic. Survives in artificial media or tissue culture longest when incubated in an atmosphere of 1–5% O₂ (Cox, 1994; Fieldsteel et al., 1977; Fitzgerald et al., 1977b, 1980; Norris et al., 1978; Sandok et al., 1978). Glucose is metabolized by way of the Embden–Meyerhof–Parnas and hexose monophosphate pathways (Schiller and Cox, 1977). Oxygen uptake by *Treponema pallidum* has been reported and is glucose-dependent (Barbieri and Cox, 1981; Cox and Barber, 1974). Oxidation of pyruvate occurs only when oxygen is present (Barbieri and Cox, 1979). Major fermentation products of glucose are acetate and CO₂ (Nichols and Baseman, 1975).

Isolated from human patients with syphilis. The reference Nichols pathogenic strain was isolated from the cerebrospinal fluid of a patient with neurosyphilis (Nichols and Hough, 1913). Shows 100% DNA/DNA homology by saturation reassociation with *Treponema pallidum* subsp. *pertenue* (Gauthier strain) but no significant DNA–DNA reassociation with *Treponema phagedenis* or *Treponema refringens* (Maio and Fieldsteel, 1978, 1980).

Source: human patients with syphilis.

DNA G+C content (mol%): 52.8 (genome sequence); 52.4–53.7 (*T_m*).

Type strain: none designated.

Reference strain: Nichols pathogenic.

Sequence accession no. (16S rRNA gene): M88726.

- 1b. ***Treponema pallidum* subsp. *pertenue*** (Castellani 1905) subsp. nov. (*Spirochaeta pertenuis* Castellani 1905, 54)

per.te.nu'e. L. neut. adj. *pertenue* very thin, slender.

The morphology and characteristics as described for the species and as listed in Table 126. Pathogenic to humans. Causes yaws in humans, a contagious disease that is spread by skin-to-skin contact. *Treponema pallidum* subsp. *pertenue* has not been cultivated in artificial media or in tissue culture. Cutaneous lesions are produced at the point of inoculation in rabbits and Syrian hamsters, but not in guinea pigs. Sera from patients with yaws give positive results with serologic tests for syphilis. Attachment of *Treponema pallidum* subsp. *pertenue* to five different mammalian cell lines was compared to that of *Treponema pallidum* subsp. *pallidum* (Fieldsteel et al., 1979). *Treponema pallidum* subsp. *pertenue* attached to all five cell lines, as did *Treponema pallidum* subsp. *pallidum*. No preferential attachment was found with *Treponema pallidum* subsp. *pertenue* for nude mouse ear and cottontail rabbit epithelial (SfIEp) cells, but preferential attachment did occur with *Treponema pallidum* subsp. *pallidum*.

Inbred hamsters (LSH/Ss LAK) infected with *Treponema pallidum* subsp. *endemicum* (Bosnia A strain) were resistant to reinfection with both *Treponema pallidum* subsp. *pertenue* and *Treponema pallidum* subsp. *pallidum* (Schell et al., 1980).

Treponema pallidum subsp. *pertenue* (Gauthier strain) shows 100% DNA homology to *Treponema pallidum* (Nichols

*The 16S rRNA sequences of *Spirochaeta stenostrepta*, *Spirochaeta zuelzeriae*, and *Spirochaeta caldaria* (described in the section on *Spirochaeta*) are most similar to those of members of the genus *Treponema* (Figure 93).

†*Treponema pallidum*, *Treponema carateum*, and *Treponema paraluisuniculi* have not been cultivated continuously *in vitro*. The other species are anaerobes and have been cultivated; their characteristics are provided in Table 127, Table 128, and Table 129.

and KKJ strains) and no homology to *Treponema phagedenis* and *Treponema refringens* by DNA–DNA hybridization (Maio and Fieldsteel, 1980).

Source: Lesions from cases of yaws. Present in tropical areas of Africa, Southeast Asia, the Western Pacific Islands, and South and Central America (Antal et al., 2002).

DNA G+C content (mol %): 52–53.7 (T_m).

Type strain: none designated.

Reference strains: Gauthier or Haiti B.

Sequence accession no. (16S rRNA gene): AF42610.

1c. ***Treponema pallidum* subsp. *endemicum*** subsp. nov.

en.de'mi.cum. N.L. neut. adj. *endemicum* (from Gr. adj. *endēmos* -on native, dwelling in place), endemic.

The morphology and characteristics are as described for the species and as listed in Table 126. Pathogenic to humans. The cause of nonvenereal endemic syphilis in humans, a contagious disease spread in pre-pubertal years by contact with infected individuals or shared use of contaminated utensils. *Treponema pallidum* subsp. *endemicum* has not been successfully cultivated in artificial media or tissue culture. Propagated by intratesticular inoculation of rabbits or by intradermal inoculation of hamsters. The organisms can be isolated from inguinal lymph nodes 3–4 weeks after intradermal infection. Inbred hamsters (e.g., LSH/Ss LAK) are particularly useful for study of this organism (Schell et al., 1980). Produces cutaneous lesions in rabbits, hamsters, and guinea pigs but not in mice.

Sera from patients with nonvenereal epidemic syphilis give positive results with serologic tests for syphilis.

This subspecies was created (Smibert, 1984) because the organism is considered a variant of *Treponema pallidum* and has its own clinical symptoms in human infection as well as the ability to infect and produce skin lesions in different laboratory animals, as does the organism of venereal syphilis (Table 126).

Source: lesions from patients with nonvenereal endemic syphilis. Found in semi-arid areas of Africa, the Middle East, and some areas of Southeast Asia.

DNA G+C content (mol %): not determined.

Type strain: none designated.

Reference strain: Bosnia A.

Sequence accession no. (16S rRNA gene): not determined.

2. ***Treponema amylovorum*** Wyss, Choi, Schüpbach, Guggenheim and Göbel 1997, 844^{VP}

a.my.lo.vo'rum. Gr. n. *amylum* starch; N.L. neut. adj. *vorum* (from L. v. *voro* to devour), devouring; N.L. neut. adj. *amylovorum* starch-devouring.

Treponema amylovorum is an intermediate-sized, obligately anaerobic, helically coiled, motile treponeme (Wyss et al., 1997). The type strain HA2P^T was isolated from subgingival plaque of a deep human periodontal lesion. The cells are approximately 0.25 µm in diameter and 7 µm in length, with a wavelength of ~1.2 µm and an amplitude of ~0.3 µm. They have six periplasmic flagella (three at each end of the cell) that overlap in the center of the cell (i.e., flagellar arrangement of 3:6:3). In liquid media of low viscosity, cells exhibit active cellular rotation and jerky flexing but no directional motility. However, in media of higher viscosity or

when cells creep along the surface, they exhibit slow translational movement. Cells can be stored at temperatures below –70°C in medium supplemented with 10–20% glycerol.

When streaked onto OMIZ-Pat/HuS agarose plates (Wyss et al., 1997), *Treponema amylovorum* forms dense, off-white, subsurface colonies up to 3 mm in diameter within 5 d of inoculation. *Treponema amylovorum* does not grow in chemically defined OMIZ-W1 medium and requires the addition of yeast extract and/or Neopeptone (or fractions thereof). Addition of 1% human serum is highly stimulatory, whereas fetal bovine serum or higher concentrations of human serum are inhibitory. Growth of strain HA2P^T is accompanied by acid production as detected by phenol red indicator in the medium, and strictly depends on the presence of at least one of the following carbohydrates: D-glucose, maltose, starch, or glycogen. Acid is produced from these carbohydrates. None of the other carbohydrates tested (at a concentration of 2 g/l) support growth; these carbohydrates include D-arabinose, D-cellobiose, D-fructose, D-fucose, D-galactose, D-galacturonic acid, D-glucuronic acid, D-lactose, D-mannitol, D-mannose, D-melibiose, D-ribose, D-sucrose, D-trehalose, D-xylose, L-arabinose, L-fucose, L-rhamnose, L-sorbose, and L-xylose. Following the exponential growth phase, with an estimated doubling time of less than 4 h, cells of HA2P^T rapidly lose viability and disintegrate into small vesicles. Catalase-negative. With API ZYM strips, the only (weak) enzyme activities detected in cells grown on glucose are alkaline and acid phosphatases, naphtholphosphohydrolase, C4 esterase, and α-fucosidase. In cells grown on either maltose, starch, or glycogen, weak α-glucosidase activity is also detected. Strain HA2P^T is resistant to 1 mg/l rifampicin and 100 mg/l phosphomycin.

On the basis of a phylogenetic comparison of 16S rRNA sequences, *Treponema amylovorum* is a species that is genetically distinct from previously described treponemes. Its SDS-PAGE protein and antigen profiles and its Western blot profile are readily distinguished from those of other cultivable, oral *Treponema* species. Furthermore, size and flagellation, as well as rapid flexing motility, clearly distinguish *Treponema amylovorum* from other treponeme species, such as *Treponema denticola*, *Treponema maltophilum*, *Treponema pectinovorum*, and *Treponema socranskii*. In contrast to the growth of the two asaccharolytic oral species, *Treponema denticola* and *Treponema vincentii*, growth of strain HA2P^T is strictly carbohydrate-dependent, and the range of carbohydrates utilized is clearly distinct from the range of carbohydrates utilized by *Treponema maltophilum*, *Treponema pectinovorum*, and *Treponema socranskii*.

DNA G+C content (mol %): not determined.

Type strain: HA2P, ATCC 700288.

Sequence accession no. (16S rRNA gene): Y09959.

3. ***Treponema azotonutricium*** Graber, Leadbetter and Breznak 2004, 1319^{VP}

a.zo.to.nu.tri'ci.um. N.L. neut. n. *azotum* (from Fr. *azote*), nitrogen; L. neut. adj. *nutricium* nourishing; N.L. neut. adj. *azotonutricium* nourishing with nitrogen (symbiotic dinitrogen fixation).

Cells 0.2–0.3 µm in diameter by 10–12 µm in length, with a wavelength or body pitch of 1.2 µm. Motile by

two periplasmic flagella, inserted at opposite ends of the protoplasmic cylinder. Anaerobe. Catalase-negative. Yeast autolysate required for growth. Optimum temperature for growth is 30°C. Energy sources utilized for fermentative growth include D-glucose, D-fructose, D-ribose, D-xylose, D-maltose, and cellobiose. Maltose is fermented to acetate, ethanol, CO₂, and H₂ as major products. D-Mannitol, D- and L-arabinose, D-sucrose, D-trehalose, glycine, lactate, pyruvate, uric acid, and H₂ (plus CO₂) are not utilized. Exhibits nitrogenase activity and N₂-dependent growth in media low in combined N. Genome is 3901 kb and contains 50.0 mol% G+C and two *rrs* gene copies. Nucleotide sequence of the 16S rRNA places this spirochete within the "termite cluster" of the genus *Treponema*.

Source: hindgut contents of the Pacific dampwood termite *Zootermopsis angusticollis* (Hagen) (Isoptera: Termopsidae).

DNA G+C content (mol%): 50 (*T_m*).

Type strain: ZAS-9, ATCC BAA-888, DSM 13862.

Sequence accession no. (16S rRNA gene): AF320287.

4. ***Treponema berlinense*** Nordhoff, Taras, Macha, Tedin, Busse and Wieler 2005, 1678^{VP}

ber.li.nen'se. N.L. neut. adj. *berlinense* pertaining to Berlin, Germany, where the type strain was isolated.

Cells show typical spirochete morphology exhibiting two to three windings with two periplasmic, subterminally inserted flagella (Nordhoff et al., 2005). Cells are approximately 0.3 µm in width and 6 µm in length. Strictly anaerobic. Good growth is observed in liquid OMIZ-Pat medium at 37°C supplemented with 10% (v/v) BHI and 10% (v/v) TSYE. On OMIZ-Pat agar plates (1–3%, w/v) supplemented with 5% (v/v) sheep blood, 10% (v/v) BHI, and 10% (v/v) TSYE, species form small, irregular, grayish swarms up to 1–2 mm in diameter, visible after 3–4 d. Addition of galacturonic or glucuronic acid promotes growth, which is enhanced further by addition of any of the following carbohydrates: D-glucose, D-fructose, maltose, D-mannitol, D-mannose, D-arabinose, L-fucose, D-trehalose, D-sucrose, and L-rhamnose. No visible growth is observed with pectin as the sole carbon source. Using the API ZYM and Rapid ID 32A systems, positive enzyme reactions are obtained only for acid phosphatase and naphthol-AS-BI-phosphohydrolase. Negative in tests for alkaline phosphatase, esterase C4, esterase lipase C8, leucine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-fucosidase, urease, arginine dihydrolase, α-arabinosidase, mannose, and raffinose, glutamic acid decarboxylase, α-fucosidase, arginine arylamidase, proline arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, leucine arylamidase, pyroglutamic acid arylamidase, tyrosine arylamidase, alanine arylamidase, glycine arylamidase, histidine arylamidase, glutamyl glutamic acid arylamidase, and serine arylamidase. Reduction of nitrates and indole production are not detected. The polar lipid profile contains diphosphatidylglycerol, phosphatidylethanolamine, an unknown aminophospholipid, and an unknown highly hydrophobic compound as major components. Moderate or minor amounts of phosphatidylglycerol, several unknown aminophospholipids,

phospholipids, amino lipids, polar lipids, and a glycolipid are also present.

Source: swine feces in Berlin, Germany.

DNA G+C content (mol%): not determined.

Type strain: 7CPL208, ATCC BAA-909, CIP 108244, JCM 12341.

Sequence accession no. (16S rRNA gene): AY230217.

5. ***Treponema brennaboreense*** Schrank, Choi, Grund, Moter, Heuner, Nattermann and Göbel 1999, 49^{VP}

bren.na.bo.ren'se. N.L. neut. adj. *brennaboreense* of or belonging to Brennabor, where the cow was raised from which the organism was first isolated.

Treponema brennaboreense is an anaerobic, Gram-stain-negative, helically coiled, motile treponeme that was isolated initially from a digital dermatitis biopsy of a dairy cow. Bacterial cells are 5–8 µm long and 0.25–0.55 µm wide. One periplasmic flagellum originates subterminally at each cell pole, and the flagella overlap in the middle of the cell (i.e., have a 1:2:1 arrangement). In stationary-phase liquid cultures, the bacteria develop spherical forms. In liquid culture, the bacteria exhibit rotational movement. Growth of strain DD5/3^T is accompanied by acid production. The optimum growth temperature is 37°C and maximum cell density of approximately 8×10⁸ bacteria per ml is reached after 21 h incubation. Cells can be stored frozen (–80°C) in OMIZ-Pat medium (Wyss et al., 1996) supplemented with 15% (v/v) glycerol. On semi-solid agarose plates, *Treponema brennaboreense* forms diffuse, submersed white colonies up to 3 mm in diameter within 5-d incubation. Strain DD5/3^T ferments raffinose and mannose and exhibits the enzyme activities alkaline phosphatase, C₄ esterase, C₈ esterase lipase, acid phosphatase, naphtholphosphohydrolase, β-galactosidase, α-glucosidase, N-acetyl-β-glucosaminidase, and arginine arylamidase, as determined by the API ZYM and Rapid ID 32A systems. Catalase-negative. The addition of 2–10% (v/v) rabbit serum leads to decreased growth rate. The strain is resistant to rifampicin (1 mg/l) and phosphomycin (100 mg/l).

All previously described treponemes are genetically distinct from *Treponema brennaboreense* as determined by comparative 16S rRNA sequencing. *Treponema brennaboreense* is clearly distinguished by its morphology, protein pattern, and enzyme activities from the other cultivable *Treponema* species. Furthermore *Treponema brennaboreense* is distinguishable from *Treponema maltophilum* by the presence of N-acetyl-β-glucosaminidase activity and its lack of α-galactosidase activity. *Treponema brennaboreense* is clearly distinguishable from veterinary isolate 1-9185MED by its lack of trypsin and chymotrypsin activities.

Source: a digital dermatitis biopsy of a dairy cow in Brandenburg, Germany.

DNA G+C content (mol%): not determined.

Type strain: DD5/3, CIP 105900, DSM 12168.

Sequence accession no. (16S rRNA gene): Y16568.

6. ***Treponema bryantii*** Stanton and Canale-Parola 1981, 676^{VP} (Effective publication: Stanton and Canale-Parola 1980, 145).

bry.an'ti.i. N.L. masc. gen. n. *bryantii* of Bryant, named after Marvin P. Bryant.

Helical obligate anaerobe, 3–8 µm long and 0.3 µm wide. One periplasmic flagellum is inserted at each end of the cell. No translational motility occurs at 22°C. Motile at 37°C. Requires CO₂. Grows in chemically defined reduced medium containing isobutyrate, DL-2-methyl butyrate, pyridoxal, folic acid, niacinamide, biotin, thiamine, glucose, CO₂, salts, and ammonium sulfate (Stanton and Canale-Parola, 1981). Riboflavin is stimulatory. In 0.7% Noble agar (Difco), cells form colonies in agar deeps, which are spherical and white (resembling cotton balls), and 0.5–1.0 mm in diameter after 24–36 h incubation, and eventually reach 2–3 mm in diameter. Growth in broth medium containing rumen fluid, glucose, and sodium bicarbonate yields 1.9×10⁹ cells/ml. Does not utilize gluconate, succinate, acetate, formate, fumarate, sugar alcohols, or Tween 80. Grows in a medium containing cellulose and a cellulolytic bacterium such as *Bacteroides succinogenes* or *Ruminococcus albus*. No growth at 22 or 45°C.

End products of glucose fermentation (µmol/100 µmol of glucose and 84 µmol of CO₂ utilized) are acetate, 100; formate, 119; and succinate, 53. About 15% of glucose carbon is assimilated.

Growth is inhibited by penicillin (10 U disk), cephalothin (30 µg disk), tetracycline (30 µg disk), chloramphenicol (30 µg disk), erythromycin (15 µg disk), and vancomycin (30 µg disk), slightly inhibited by polymyxin B (100 U/disk), and not inhibited by rifampicin (5 µg disk or up to 10 mg/l in broth medium).

Source: bovine rumen contents.

DNA G+C content (mol%): 36±1 (*T_m*).

Type strain: RUS-1, ATCC 33254, DSM 1788.

Sequence accession no. (16S rRNA gene): M57737.

7. **Treponema carateum** (*ex* Brumpt 1939) sp. nov., nom. rev.

ca.ra'te.um. N.L. n. *carate* name of a South American disease, pinta; N.L. neut. adj. *carateum* of carate.

The cause of pinta or carate, a contagious disease of man transmitted by skin-to-skin contact. Morphologically similar to *Treponema pallidum*. Virulent strains have not been grown *in vitro*. Experimental transmission of the disease has been accomplished in man as well as in chimpanzees by intradermal inoculation and by direct exposure of scarified areas of skin to abraded human lesions. Has not been propagated successfully in rabbits, hamsters, or guinea pigs.

Source: exudate of cutaneous lesions of pinta. Occurs only in Mexico, Central America and parts of subtropical South America, the West Indies, and Cuba.

DNA G+C content (mol%): not determined.

Type strain: none designated.

Sequence accession no. (16S rRNA gene): not determined.

8. **Treponema denticola** (*ex* Brumpt 1922a) Chan, Siboo, Keng, Psarra, Hurley, Cheng and Iugovaz 1993, 201^{VP}

den.ti'co.la. L. masc. n. *dens*, *dentis* tooth; L. suff. *cola* from L. n. *incola* inhabitant dweller; N.L. n. *denticola* tooth-dweller.

A small to intermediate-sized spirochete. Many characteristics are listed in Tables 127 and 129. A 2:4:2 periplasmic flagellar arrangement is common, but *Treponema denticola* strains with higher numbers of flagella have been found. Cells are motile with a jerky, but fairly rapid motion. Cells are typically 7.74±0.94 µm in length, 0.20±0.02 µm in

diameter, with a wavelength and amplitude of 1.23±0.15 µm and 0.50±0.05 µm, respectively.

The organism grows well in a peptone-yeast extract-serum medium [e.g., New Oral Spirochete (NOS) medium; Leschine and Canale-Parola, 1980b) under anaerobic conditions. Surface and subsurface colonies are 0.3–1.0 mm in diameter, white, diffuse, and visible after 2 weeks incubation. *Treponema denticola* is primarily an amino acid fermenter and does not use the glycolytic pathway as a major source of energy, although it possesses genes encoding all of its enzymes (Seshadri et al., 2004). Amino acids in peptone-yeast extract-serum medium are fermented mainly to acetic acid, and to a lesser extent, lactic acid, succinic acid, and formic acid. Trace amounts of propionic acid, *n*-butyric acid, ethanol, *n*-propanol, and *n*-butanol may occasionally be found. Only 10% of the end products are from glucose. Alanine, cysteine, glycine, and serine are fermented. Arginine is metabolized to citrulline, NH₃, CO₂, proline, and small amounts of ornithine. Arginine iminohydrolase and ornithine carbamoyltransferase activity have been reported (Blakemore and Canale-Parola, 1976). Arginine can be an energy source and ornithine can be converted to putrescine and proline (Leschine and Canale-Parola, 1980a).

Treponema denticola ATCC 35405^T (Cheng et al., 1985) exhibits 76% DNA homology with *Treponema denticola* 33520 and 82% DNA homology with *Treponema denticola* ATCC 35404 (Chan et al., 1993). The genome sequence of *Treponema denticola* 35405^T has been determined (Seshadri et al., 2004). *Treponema denticola* ATCC 35405^T is susceptible to the antimicrobial agents spiramycin, metronidazole, tetracycline, penicillin G, and streptomycin but highly resistant to rifampicin (minimum inhibitory concentration, 50 mg/l).

Subdivided into biovar *denticola* (indole-positive) and biovar *comondonii* (indole-negative) (Smibert, 1984).

Methyl red-negative. Chopped meat-serum medium is neither blackened nor digested. No action on milk. Growth occurs at pH 6.5–8.0 but not at pH 6.0 or 9.6, and at 30–42°C; multiplication is minimal or absent at 25 and 45°C.

Source: oral cavity of humans and, perhaps, chimpanzees, typically from subgingival plaque.

DNA G+C content (mol%): 37.9 (genome sequence).

Type strain: ATCC 35405, CIP 103919, DSM 14222, JCM 8153.

Reference strains: ATCC 33520, ATCC 35404.

Sequence accession nos (16S rRNA gene): AE017226 (nt 610211–611726 and 1219839–1221354).

9. **Treponema lecithinolyticum** Wyss, Choi, Schüpbach, Moter, Guggenheim and Göbel 1999, 1337^{VP}

le.ci.thi.no.ly'ti.cum. Gr. n. *lekithos* egg yolk; Gr. adj. *lutikos* *ê*-on able to loosen, dissolve; N.L. neut. adj. *lecithinolyticum* effecting the breakdown of egg yolk.

An obligately anaerobic, helically coiled, motile treponeme. Cells are approximately 5×0.15 µm, with a wavelength of 0.7 µm and an amplitude of 0.3 µm. They contain two periplasmic flagella, one originating at each end and overlapping in the center of the cell. In liquid media, the cells flex and rotate but motility is not directional. However, in media of higher viscosity, or when cells creep along a surface, motility is directional.

Since dipalmitoyl phosphatidylcholine (lecithin) inhibits growth, it is omitted from OMIZ-Pat medium (Wyss et al., 1996) (yielding OMIZ-Pat-w/oPC). When streaked onto OMIZ-Pat-w/oPC agarose, *Treponema lecithinolyticum* forms off-white, diffuse subsurface colonies up to 3 mm in diameter within 7 d incubation at 37°C. Does not grow in the chemically defined medium OMIZ-W1 (Wyss, 1992) but requires addition of yeast extract and/or Neopeptone (or fractions thereof). Cells can be stored frozen (liquid nitrogen or mechanical freezer) in OMIZ-Pat-w/oPC medium supplemented with 10–20% glycerol. Growth is strictly dependent on *N*-acetylglucosamine, strongly enhanced by further addition of *D*-arabinose, *L*-fucose, or *D*-ribose, *D*-fructose (some strains excluding OMZ 684^T), and/or *D*-xylose (some strains including OMZ 684^T), and not influenced by *L*-arabinose, *D*-cellobiose, *D*-fucose, *D*-galactose, *D*-galacturonic acid, *D*-glucose, *D*-glucuronic acid, *D*-lactose, maltose, *D*-mannitol, *D*-melibiose, *L*-rhamnose, *L*-sorbose, sucrose, *D*-trehalose, or *D*-xylose. Heat-inactivated human serum (1% v/v) is tolerated or stimulatory, whereas 1% fetal bovine serum is completely inhibitory. All strains are resistant to rifampicin (1 mg/l) and phosphomycin (100 mg/l).

In all eight isolates examined (Wyss et al., 1999), activities of alkaline phosphatase, acid phosphatase, β -galactosidase, β -glucuronidase, *N*-acetyl- β -glucosaminidase, phospholipase A, and phospholipase C are prominent, whereas only intermediate activities of C4-esterase, C8-esterase, naphthol phosphohydrolase, and α -fucosidase are expressed. Catalase-negative. OMZ 684^T, OMZ 685, and BL2B have strong sialidase activity (the other five strains were not tested).

Phylogenetically distinct from other cultivable treponemes on the basis of its 16S rRNA sequence. Protein and antigen patterns (SDS-PAGE) are also readily distinguished from those of other cultivable treponemes, though more conventional criteria may suffice to distinguish it from the other characterized oral spirochetes. Simultaneous expression of strong activities of phospholipase C, phospholipase A, alkaline phosphatase, acid phosphatase, β -galactosidase, β -glucuronidase, *N*-acetyl- β -glucosaminidase, and sialidase and intermediate activities of C4-esterase, C8-esterase, naphthol phosphohydrolase, and α -fucosidase distinguish *Treponema lecithinolyticum* from all other oral spirochetes. Size, flagellation, and growth characteristics additionally distinguish it from *Treponema amylovorum*, *Treponema denticola*, *Treponema medium*, and *Treponema vincentii*. Finally, *Treponema lecithinolyticum* is phenotypically distinguished from the two other lecithinolytic isolates described by Wyss et al. (1999) (i.e., OMZ 702 and BL2A, which are phylogenetically classified as *Treponema maltophilum*) by its SDS-PAGE protein profile, a ~30-kDa antigen, and activities of phospholipase A, sialidase, β -glucuronidase, and *N*-acetyl- β -glucosaminidase.

Source: Only in human subgingival plaque, with a strong association suggested for diseased versus control sites in patients with adult periodontitis and rapidly progressive periodontitis. Strains OMZ 684^T and OMZ 685 were isolated from subgingival plaque of human deep periodontal lesions.

DNA G+C content (mol%): not determined.

Type strain: OMZ 684, ATCC 700332, CIP 107075.

Reference strains: OMZ 685, ATCC 700333.

Sequence accession no. (16S rRNA gene): AJ131282.

10. ***Treponema maltophilum*** Wyss, Choi, Schüpbach, Guggenheim and Göbel 1996, 751^{VP}

mal.to'phi.lum. N.L. n. *maltosum* maltose; Gr. adj. *philos ê-on* loving, friendly to; N.L. neut. adj. *maltophilum* intended to mean maltose-loving.

An obligately anaerobic, helically coiled, motile treponeme (5 μ m long, 0.2 μ m wide with a wavelength of 0.7 μ m and an amplitude of 0.3 μ m) isolated from human subgingival plaque (Wyss et al., 1996). One periplasmic flagellum originates at each end, overlapping in the center of each cell in a 1:2:1 arrangement. In low-viscosity liquid media, cellular rotation produces standing waves with amplitudes of up to 2 μ m, but this results in no directional motility. Translational movement, however, occurs in higher-viscosity media or when cells creep along a surface.

Cells can be stored frozen in liquid nitrogen or in a mechanical freezer in OMIZ-Pat (Wyss et al., 1996) supplemented with 10–20% glycerol.

On OMIZ-Pat agarose, off-white diffuse subsurface colonies (up to 3 mm in diameter) form within 5 d.

Treponema maltophilum does not grow in OMIZ-W1 and requires yeast extract and/or Neopeptone. Growth of most strains is strictly dependent on *N*-acetyl- β -glucosamine and at least one additional sugar. The most commonly used second sugars are *D*-arabinose, *L*-fucose, *D*-maltose, *L*-rhamnose, *D*-ribose, *D*-sucrose, and *D*-trehalose, but not *D*-glucose, which is totally ineffective. Some strains without α -fucosidase activity may not depend on *N*-acetyl- β -glucosamine. Growth is not influenced by *D*-cellobiose, *D*-fucose, *D*-lactose, *D*-mannitol, *L*-sorbose, or *L*-xylose. Fetal bovine serum at concentrations as low as 0.1% (v/v) prevents growth in OMIZ-Pat. Catalase-negative. API ZYM strips detected alkaline phosphatase, acid phosphatase, naphthol phosphohydrolase, C4 esterase, C8 esterase, and α -glucosidase activities in all strains, α - and β -galactosidase, β -glucosidase, and α -fucosidase activities in most strains, and α -fucosidase and β -glucuronidase activities in some strains. Strains with β -glucuronidase activity can grow on glucuronic acid. Immunoblotting with patient sera revealed an antigen only in strains with α -fucosidase activity. All strains examined are resistant to rifampicin (1 mg/l) and phosphomycin (100 mg/l). The type strain BR^T (α -fucosidase activity but no β -glucuronidase activity) differs markedly from reference strains HO2A (β -glucuronidase activity but no α -fucosidase activity) and PNA1 (neither α -fucosidase activity nor β -glucuronidase activity) (Wyss et al., 1996).

Phylogenetically distinct from previously described treponemes as determined by comparison of 16S rRNA sequences. Its protein and antigen patterns on SDS-PAGE differ from those of other cultivable treponemes. Clearly distinguish *Treponema maltophilum* differs from *Treponema vincentii* on the basis of size, morphology, enzyme activities, and growth characteristics, from the asaccharolytic organism *Treponema denticola* by its lack of trypsin activity, from *Treponema pectinovorum* by its lack of a requirement for either glucuronic acid or galacturonic acid, and from *Treponema socranskii* by synthesis of a wide spectrum of glycosidases and

utilization of a wide spectrum of carbohydrates. α -Glucosidase activity is characteristic of *Treponema maltophilum* and has never been observed in *Treponema socranskii*, although many strains of this species can ferment maltose.

Source: only in subgingival plaque samples of patients with periodontal disease.

DNA G+C content (mol%): not determined.

Type strain: BR, ATCC 51939, CIP 105146.

Sequence accession no. (16S rRNA gene): X87140.

11. ***Treponema medium*** Umemoto, Nakazawa, Hoshino, Okada, Fukunaga and Namikawa 1997, 71^{VP}

me'di.um. L. neut. adj. *medium* not very great or small, medium, referring to the cell size.

A Gram-stain-negative, anaerobic, motile, helically coiled, medium-sized treponeme. The cells (5–16 μ m long and 0.2–0.3 μ m wide) have cytoplasmic filaments and 5–7 periplasmic flagella (axial flagella) that originate subterminally at each end and in broth cultures exhibit rotational and translational movement. The optimum growth temperature is 37°C, and colonies on agar plates are white and translucent. Ferment D-glucose, D-fructose, maltose, D-mannose, D-galactose, sucrose, D-ribose, trehalose, inulin, salicin, and D-raffinose. Produce ammonia and hydrogen sulfate and hydrolyze esculin and hippuric acid. The major acid products of strain G7201^T grown in tryptone-yeast extract-gelatin-volatile fatty acids-serum (TYGVS) medium (Ohta et al., 1986) containing 0.1% glucose are acetic acid, *n*-butyric acid, and a trace of *n*-valeric acid. Phenotypic characteristics, DNA–DNA hybridization data, G+C content of the DNA, and 16S rRNA gene sequence data indicate that human oral spirochete strain G7201^T is a member of a novel species.

Source: subgingival plaque of patients with adult periodontitis.

DNA G+C content (mol%): 51 (HPLC).

Type strain: G7201.

Sequence accession no. (16S rRNA gene): D85437.

12. ***Treponema minutum*** Dobell 1912, 117^{AL}

mi.nu'tum. L. neut. adj. *minutum* small, tiny.

Many characteristics are listed in Table 127. Two to three periplasmic flagella are inserted into each end of the cell. Motile with sluggish movement. Colonies on pre-reduced peptone-yeast extract-serum agar (1.4%) are visible in 9–15 d, and are 0.5–1 mm in diameter, white, and round on the agar surface. Some colonies after longer incubation are white, fluffy, and up to 1.5 mm in diameter. Colonies grow on and below the surface of the medium. Size and texture of colonies will vary with the concentration of agar in the medium. Grow well in peptone-yeast extract-serum medium under anaerobic conditions. Require animal serum (inactivated at 56–60°C for 1 h) for growth.

Amino acids in peptone-yeast extract-serum medium are fermented to a large amount of acetic acid, moderate amount of succinic acid, smaller amount of lactic acid, and trace amounts of propionic, *n*-butyric, and formic acids (most strains). Trace amounts of ethanol, *n*-propanol, and

n-butanol are also produced by most strains. There are no additional end products in the presence of glucose.

Methyl red-negative. Skim milk is only slightly curdled. Ammonia produced by most strains. Grows at pH 6.5–8.0 but not at pH 6.0 or 9.6. Grows at 34–40°C. Chopped meat serum medium neither blackened nor digested. Slight putrid odor.

Dupouey (1963) reported that *Treponema minutum* was antigenically only slightly related to *Treponema refringens*. Not pathogenic.

Source: epidermal surfaces of male and female genital-urinary regions.

DNA G+C content (mol%): 37 (T_m).

Type strain: CIP 5162.

Sequence accession no. (16S rRNA gene): not available.

13. ***Treponema paraluis-cuniculi*** (Jacobsthal 1920) Smibert 1974, 177^{AL} (*Spirochaeta paraluis-cuniculi* Jacobsthal 1920, 571)

pa.ra.lu.is.cu.ni'cu.li. Gr. pref. *para* resembling; L. n. *lues* -is pestilences, plague, infection (here syphilis); L. n. *cuniculus* -i a rabbit; N.L. gen. n. *paraluis-cuniculi* of a syphilis-like (disease) of rabbits.

Produces venereal spirochetosis (rabbit spirochetosis or rabbit syphilis) in rabbits. Morphologically similar to *Treponema pallidum*. Transmitted by sexual contact. Has not been cultivated *in vitro*. The organism can be propagated by intratesticular inoculation of rabbits. Causes a latent infection of mice, guinea pigs, and hamsters. Treponemes are found in the lymph nodes of these animals. Cutaneous lesions are found only in guinea pigs and rabbits. Non-pathogenic to humans (Graves and Downes, 1981).

The cuniculi A strain has been shown to possess homologs of *tpr* genes found in *Treponema pallidum*, but many are predicted to be nonfunctional (Giacani et al., 2004). For additional information see Smith and Persetsky (1967).

Source: lesions in the genital area of rabbits. Primarily involves the genitalia, although cutaneous lesions often occur around the face, eyes, ears, and nose.

DNA G+C content (mol%): not determined.

Type strain: none has been designated.

Reference strain: Cuniculi A.

Sequence accession no. (16S rRNA gene): not determined.

14. ***Treponema parvum*** Wyss, Dewhirst, Gmür, Thurnheer, Xue, Schüpbach, Guggenheim and Paster 2001, 960^{VP}

par'vum. L. neut. adj. *parvum* small.

Small, obligately anaerobic, helically coiled, motile treponeme. Approximately 1 μ m long and 0.18 μ m wide, with a wavelength of 0.8 μ m and an amplitude of 0.3 μ m. In rapidly growing cultures, cells may be shorter than 1 wavelength, but chains of more than 10 wavelengths are also common. Cells contain two periplasmic flagella, one originating at each pole and overlapping in the center of the cell in a 1:2:1 arrangement. Although undulation, flexing, and rotation of cells occurs in liquid medium, motility does not appear to be directional. However, in media of higher viscosity or when cells creep along a surface, movement is translational.

Cells can be stored frozen (liquid nitrogen or mechanical freezer) in OMIZ-Pat/HuS medium supplemented with

10–20% glycerol. The four isolates OMZ 832, 833^T, 842, and 843 are strictly carbohydrate-dependent; either *N*-acetyl- β -glucosamine or *N*-acetyl- β -galactosamine is sufficient for growth, though growth is strongly promoted by addition of L-arabinose, D-galactose, D-glucose, D-fructose, D-mannitol, D-mannose, pectin, D-ribose, or D-xylose but not by D-arabinose, D-cellobiose, D-fucose, L-fucose, D-galacturonic acid, D-glucuronic acid, D-lactose, D-maltose, D-melibiose, L-rhamnose, L-sorbose, D-sucrose, D-trehalose, or L-xylose. The chemically complex (undefined) components of OMIZ-Pat, i.e., YEM (fractionated yeast extract) and DANP (fractionated peptone) (Wyss and Ermert, 1996), are not strictly required for growth but are strongly stimulatory. Similarly, human serum or FBS are not required but are growth-promoting at 1% (v/v). FBS is not inhibitory even at 10% (v/v). On OMIZPat/HuS agarose, *Treponema parvum* forms off-white diffuse subsurface colonies up to 3 mm in diameter after 5 d of anaerobic incubation at 37°C. The four OMZ isolates on API ZYM tests had weak alkaline phosphatase and esterase C₄ and C₈ activities, intermediate acid phosphatase and naphthol phosphohydrolase activities, and strong β -glucuronidase activity.

Although *Treponema parvum* and *Treponema pectinovorum* are similar, the former is clearly distinguishable phenotypically by the presence of a strong β -glucuronidase activity, inability to utilize pectin as sole source of carbohydrate, and marked differences in protein and antigen patterns revealed by SDS-PAGE. Very short and thin cells, though this is not strongly diagnostic, since all cultured treponemes show variation in morphology under different growth conditions. The “Smibert-2” isolates also differ from the 1:2:1 flagellated pectinolytic treponemes isolated from non-human primates by Sela et al. (1987) by virtue of their inability to grow on pectin. There are 16S rRNA sequence differences between *Treponema parvum* and other species of *Treponema*, including *Treponema pectinovorum*. *Treponema parvum* is the sole representative of Group 7 of oral *Treponema* as defined by Paster et al. (1998). Its closest relatives are *Treponema pectinovorum* (88% similarity) and *Treponema amylovorum* (90% similarity).

Source: OMZ 833^T was isolated from subgingival plaque of a human deep periodontal lesion. Strain OMZ 842 was isolated from acute necrotizing ulcerative gingivitis (ANUG) lesions of a patient in China.

DNA G+C content (mol%): not determined.

Type strain: OMZ 833, ATCC 700770, DSM 16260.

Reference strain: OMZ 842, ATCC 700773.

Sequence accession no. (16S rRNA gene): AF302937.

15. ***Treponema pectinovorum*** Smibert and Burmeister 1983, 853^{VP}

pec.ti.no'vo.rum. N.L. n. *pectinum* pectin; N.L. neut. adj. *vorum* (from L. v. *vor* to devour) devouring; N.L. neut. adj. *pectinovorum* pectin destroying and devouring.

Obligately anaerobic, motile helically coiled treponeme. The cells are 7–15 μ m long and 0.28–0.30 μ m wide. They are coiled and usually have straight, slightly pointed ends. The periplasmic flagella overlap in the center of the cell in a 2:4:2 arrangement. Secondary coils are observed in motile cultures. Movement is both rotational and translational.

Serpentine movement can be observed in a semisolid medium.

In Oral Treponeme Isolation (OTI) medium (Smibert and Burmeister, 1983) in bottle plates, colonies usually appear in the agar after 4–5 d. Colonies grow into the agar and are white and translucent with slightly denser centers and entire edges. The colonies spread out and become larger after additional incubation.

These organisms grow in PY-pectin broth containing either rumen fluid or a short-chain fatty acid-heme supplement. Serum and thiamine pyrophosphate are not required. Growth only occurs in the presence of a fermentable energy source, such as pectin, polygalacturonic acid, galacturonic acid, or glucuronic acid and is greatly stimulated by the addition of a fresh filter-sterilized yeast autolysate to the medium. Growth occurs at 37°C (optimum) but not at 25 or 42°C. Broth cultures become turbid with a granular sediment that can be seen after 4–5 d of incubation. Cultures can be stored frozen in liquid nitrogen or at –85°C in a mechanical freezer.

Pectin (final pH, 5.3–5.9) is utilized. Polygalacturonic acid, galacturonic acid, and glucuronic acid are also fermented and may be substituted for pectin in PY-rumen fluid broth. Growth and acid production occur in PY-rumen fluid broth supplemented with either autoclaved or filter-sterilized pectin. Growth and acid production also occur in PY-rumen fluid broth containing 0.5% polygalacturonic acid. The pH of this medium is 5.0 after 5 d of incubation at 37°C. Adonitol, amygdalin, arabinose, cellobiose, dextrin, starch, dulcitol, erythritol, esculin, fructose, galactose, glycerol, glycogen, inositol, inulin, lactose, mannitol, mannose, melezitose, melibiose, mucin, raffinose, rhamnose, ribose, salicin, sorbose, sorbitol, sucrose, trehalose, xylose, and glucose are not fermented; no growth occurs in PY-rumen fluid broth containing any of these substrates.

Negative for catalase and hydrogen sulfide production. Hydrogen gas was not detected by gas chromatography of the atmospheric phase of cultures in rubber-stopper sealed tubes; gas was not detected in agar deep cultures. Gelatin, esculin, glycogen, or starch is not hydrolyzed. Indole and acetylmethylcarbinol are not produced.

The major fermentation products from PY-pectin-rumen fluid broth are acetic acid (27.9 mM) and formic acid (8.5 mM). Only traces of pyruvic and lactic acids are detected. The products from polygalacturonic acid are acetic acid (39.5 mM) and formic acid (16.7 mM) with only traces of lactic and pyruvic acids.

Distinction from other *Treponema* species is based on 16S rRNA sequence, mol% G+C content, ability to ferment pectin, polygalacturonic acid, galacturonic acid, and glucuronic acid but not other carbohydrates, cellular dimensions, and the origin of the two periplasmic flagella attached at each end of the cell (Smibert and Burmeister, 1983).

Source: human supragingival and subgingival plaque specimens but not from adults with normal, healthy gingivae and no signs of gingivitis or periodontitis.

DNA G+C content (mol%): 39 (*T_m*).

Type strain: ATCC 33768^T, VPI D-36DR-2^T.

Sequence accession no. (16S rRNA gene): M71237.

16. **Treponema phagedenis** (*ex* Brumpt 1922a) sp. nov., nom. rev.

pha.ge.de'nis. Gr. gen. n. *phagedenis* of a cancerous sore.

Many characteristics are listed in Tables 127 and 128. Widest cells show double contours with darkfield microscopy. Ends of the cells are blunt with no covering sheath. Three-to-eight periplasmic flagella are inserted into each end of the cell. In old cultures, the flagella may be seen trailing from the ends of the cells.

Motility in culture media is jerky with slow rotational movement. Colonies in prereduced anaerobic peptone-yeast extract-serum medium containing 1.3–1.4% agar are white, annular, 0.5–1 mm in diameter with a dense center after incubation for 2–5 d at 37°C. Colonies can grow on the surface but mainly in the agar.

Requires animal serum (heat inactivated at 56–60°C for 0.5–1 h) for growth. Bovine serum albumin supplemented with a pair of fatty acids can substitute for serum (Johnson and Eggebraten, 1971). The pair includes (a) an unsaturated fatty acid such as oleic acid and (b) a saturated fatty acid such as palmitic acid. No growth with short-chain fatty acids or α -, β -, γ -globulins.

Fermentation of glucose is by the Embden–Meyerhof–Parnas pathway. Contains ferredoxin. End products of fermentation in a serum medium without glucose are mainly acetic and *n*-butyric acids with moderate-to-small amounts of propionic and formic acids and usually small-to-trace amounts of lactic and succinic acids. Trace amounts of alcohols are also produced. In a medium containing glucose, large amounts of ethanol and *n*-butanol and smaller amounts of *n*-propanol are produced.

A very slight curd is formed in skim milk. Weakly methyl-red-positive. Does not grow at a pH of 6.0 or 9.6. Grows at 30–42°C but not or only slightly at 25 and 45°C. Reduces neutral red. Chopped meat serum medium is neither blackened nor digested. A slight fetid odor is produced in cultures.

Subdivided into reiter and kazan biovars. Biovar reiter does not hydrolyze esculin, whereas biovar kazan does. Meyer and Hunter (1967) showed that the Reiter, Kazan, and English Reiter strains are antigenically closely related. Reiter and English Reiter contained the same antigens while the Kazan strain contained an antigen not shared by the Reiter treponemes. The Nichols strain of *Treponema refringens* was antigenically unrelated. Christiansen (1964) also reported that the Reiter and Kazan 11 strains were closely related but not identical. Dupouey (1963) reported that *Treponema phagedenis* and Reiter strain were closely related antigenically, sharing at least six common antigens. The Reiter strain has a large amount of an antigen that may be shared with a number of other species including *Treponema pallidum*. More than 40 water-soluble antigens have been demonstrated in the Reiter treponeme by crossed immunoelectrophoresis. Five antigens cross-reacted with antibodies in syphilitic sera (Strandberg-Pedersen et al., 1980, 1981).

Reiter and Kazan strains have high DNA/DNA homology to each other and no homology to *Treponema refringens* (Miao and Fieldsteel, 1978; Smibert, 1974). There is no DNA/DNA homology to *Treponema denticola* (Smibert,

1974). There is no detectable DNA homology between *Treponema phagedenis* (Reiter and Kazan 5) and pathogenic Nichols strain of *Treponema pallidum* subsp. *pallidum* (Maio and Fieldsteel, 1978). Additional information on *Treponema phagedenis* Reiter can be found in an excellent review by Wallace and Harris (1967).

Source: nonpathogenic. Phagedenic ulcer on human external genitalia. Reiter treponeme from a case of primary syphilis in man and also as normal flora in the anal and genital areas of normal male and female chimpanzees.

DNA G+C content (mol%): 38–39 (T_m).

Type strain: none designated.

Reference strain: Reiter.

Sequence accession no. (16S rRNA gene): M57739.

17. **Treponema porcinum** Nordhoff, Taras, Macha, Tedin, Busse and Wieler 2005, 1678^{VP}

por.ci'num. L. neut. adj. *porcinum* pertaining to swine, from which the type strain was isolated.

Cells exhibit typical spirochete morphology and are approximately 6–8 μ m in length and 0.3 μ m in width with 2–3 windings and 2:4:2 flagella arrangement. Strictly anaerobic. Best growth is obtained in liquid OMIZ-Pat medium at 37°C supplemented with 10% (v/v) BHI and 10% (v/v) TSYE. Growth is independent of glucuronic or galacturonic acid. D-Maltose is essential for growth, whereas any of the following carbohydrates (as the sole carbohydrate source) do not support growth: D-glucose, D-fructose, D-mannitol, D-mannose, D-arabinose, L-fucose, trehalose, sucrose, and L-rhamnose. Does not grow with pectin as a sole carbon source. On OMIZ-Pat (1–3% w/v) agar supplemented with 5% egg yolk, 10% BHI, and 10% TSYE, the species forms grayish, irregular swarms up to 2 mm in diameter, visible after 3–4 d. Reactions using the API ZYM and Rapid ID 32A system are positive for acid phosphatase, esterase C4, naphthol-AS-BI-phosphohydrolase, and α -glucosidase, and negative for alkaline phosphatase, esterase lipase C8, leucine arylamidase, cystine arylamidase, trypsin, α -chymotrypsin, α -galactosidase, β -galactosidase, β -glucuronidase, β -glucosidase, *N*-acetyl- β -glucosaminidase, α -fucosidase, urease, arginine dihydrolase, α -arabinosidase, mannose, and raffinose fermentation, glutamic acid decarboxylase, α -fucosidase, arginine arylamidase, proline arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, leucine arylamidase, pyroglutamic acid arylamidase, tyrosine arylamidase, alanine arylamidase, glycine arylamidase, histidine arylamidase, glutamyl glutamic acid arylamidase, and serine arylamidase. Reduction of nitrates and indole production are not detected. In the polar lipid profile, three unknown phospholipids and a highly hydrophobic compound predominate. Diphosphatidylglycerol, phosphatidylglycerol as well as phospholipids are present in moderate amounts. Additionally, a glycolipid and several phospholipids are present in minor amounts.

Source: swine feces in Berlin, Germany.

DNA G+C content (mol%): 38–39 (T_m).

Type strain: 14V28, ATCC BAA-908, CIP 108245, JCM 12342.

Sequence accession no. (16S rRNA gene): AY518274.

18. **Treponema primitia** Graber, Leadbetter and Breznak 2004, 1319^{VP}

pri.mi'ti.a. N.L. fem. sing. n. *primitia* (nominative in apposition), the first fruit (of isolation after long work).

Cells 0.2 µm in diameter by 3–7 µm long, with a wavelength or body pitch of 2.3 µm. Motile by two periplasmic flagella, inserted at opposite ends of the protoplasmic cylinder. Anaerobe. Possesses NADH and NADPH peroxidases but neither catalase nor superoxide dismutase. Optimum temperature for growth is 30°C. Optimum pH for growth is 7.2 (range, 6.5–7.8). Homoacetogen. Energy sources used for growth include glucose, maltose, mannitol, xylose, and H₂ (plus CO₂), which are fermented to acetate as the sole product. Strain ZAS-1 also uses arabinose and cellobiose, whereas strain ZAS-2 can grow slowly by acetogenic demethylation of methoxylated benzenoids (syringate, ferulate, vanillate, and trimethoxybenzoate). Ribose, methanol, formate, CO, lactate, pyruvate, glycine, betaine, and choline are not utilized. Growth by mixotrophy (i.e., simultaneous use of H₂ and organic substrates) has been demonstrated. Laboratory-prepared yeast autolysate or certain commercial yeast extracts are required for growth. Folate (formyltetrahydrofolate) is required for growth of strain ZAS-1, whereas folic acid or folinate is required for growth of strain ZAS-2. Cells possess homologs of the dinitrogenase reductase gene *nifH* and exhibit low levels of nitrogenase activity, but unambiguous N₂-dependent growth has not been demonstrated. Genome sizes are 3461 kb (ZAS-1) and 3835 kb (ZAS-2); G+C contents of DNA are 51.0 mol% (ZAS-1) and 50.9 mol% (ZAS-2) (by HPLC); each strain possesses 2 *rrs* gene copies. The 16S rRNA nucleotide sequences of strains ZAS-1 and ZAS-2 place them within the “termite cluster” of the genus *Treponema*.

Source: hindgut contents of the Pacific dampwood termite *Zootermopsis angusticollis* (Hagen) (Isoptera: Termopsidae).

DNA G+C content (mol%): 50.9–51.0 (HPLC).

Type strain: strain ZAS-2, ATCC BAA-887, DSM 12427.

Sequence accession no. (16S rRNA gene): AF093252 (ZAS-2^T), AF093251 (ZAS-1).

19. **Treponema putidum** Wyss, Moter, Choi, Dewhirst, Xue, Schüpbach, Göbel, Paster and Guggenheim 2004, 1121^{VP}

pu'ti.dum. L. neut. adj. *putidum* stinking, fetid.

Obligately anaerobic, helically coiled, motile, asaccharolytic, and proteolytic. The human oral cavity is so far its only known habitat. Approximately 0.25 µm in diameter and approximately 10 µm long, with a wavelength of approximately 3 µm and amplitude of approximately 1.5 µm. They contain four periplasmic flagella, two originating at each cell end and overlapping in the center of the cell in an arrangement of 2:4:2. In liquid media of low viscosity, cells appear highly active with cellular rotation and jerky flexing but no directional motility. Translational movement, however, is seen in media of higher viscosity or when cells creep along a surface. Cells can be stored at temperatures below –70°C in medium supplemented with 10–20% glycerol. Within 5 d of anaerobic incubation at 37°C when streaked onto OMIZ-Pat agar (Wyss et al., 1996), dense, off-white subsurface colonies up to 3 mm in diameter are formed. Does not grow in the chemically defined OMIZ-W1 medium, but

requires the addition of yeast extract and/or Neopeptone (or fractions thereof); addition of 1–10% human or fetal bovine serum is highly stimulatory. Growth is neither dependent on nor stimulated by any of the following carbohydrates, each tested at 2 g/l: D-arabinose, D-cellobiose, D-fructose, D-fucose, D-galactose, D-galacturonic acid, D-glucose, D-glucuronic acid, glycofen, D-lactose, D-maltose, D-mannitol, D-mannose, D-melibiose, D-ribose, starch, sucrose, D-trehalose, D-xylose, L-arabinose, L-fucose, L-rhamnose, L-sorbose, and L-xylose. Neuraminidase and dentilisin activities are not detected. Using API ZYM strips (Table 129), the following enzyme activities are always detected: esterase C4, esterase C8, leucyl arylamidase, trypsin, acid phosphatase, naphtholphosphohydrolase, β-galactosidase, and β-glucosidase; the following activities are never detected: lipase C14, valine arylamidase, β-glucuronidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Other enzyme activities detectable by API ZYM are present only in some strains. Growth is resistant to rifampicin (1 mg/l), phosphomycin (100 mg/l), nalidixic acid (30 mg/l), and polymyxin (5 mg/l).

Source: subgingival plaque of a deep human periodontal lesion.

DNA G+C content (mol%): not determined.

Type strain: JZC3, OMZ 758, ATCC 700334, CIP 108088, OMZ 758.

Sequence accession no. (16S rRNA gene): AJ543428.

20. **Treponema refringens** (ex Castellani and Chalmers 1919) sp. nov., nom. rev.

re.frin'gens. L. part. adj. *refringens* refringent, refractive.

Many characteristics are listed in Tables 127 and 128. The average cells are 5–8 µm long and 0.24 µm wide. Some cells may appear loosely coiled. Two to four periplasmic fibrils are inserted at each end of the cell. Motile, with a slow, sluggish movement. Rotation of cells is rare, and when observed, usually slow.

Colonies on prerduced anaerobic peptone-yeast extract-serum agar (1.4%) are visible in 9–15 d. They are white, round, surface colonies 0.5–1 mm in diameter. Some colonies after longer incubation are white, fluffy, and up to 1.5 mm in diameter. Colonies grow on and below the surface of the medium. Size and texture of colonies varies with the concentration of agar in the medium.

Grows well in peptone-yeast extract-serum medium under anaerobic conditions. Requires animal serum (inactivated at 56–60°C for 1 h) for growth. Amino acids in serum medium are fermented to mostly acetic acid, moderate amounts of succinic acid, and smaller amounts of lactic acid. Some strains produce trace amounts of propionic acid, *n*-butyric acid, formic acid, ethanol, *n*-propanol, and *n*-butanol. No additional end products are produced in the presence of D-glucose.

Methyl red-negative. Skim milk is only slightly curdled. Ammonia produced by most strains. Growth occurs at pH 6.5–8.0 but not at pH 6.0 or 9.6. Grows at 30–42°C but only very slightly or not at all at 25 or 45°C. Chopped meat serum medium is neither blackened nor digested. Only a very slight putrid odor is detectable.

Dupouey (1963) reported that strains labeled *Treponema refringens* and “*Treponema calligryum*” were closely related

antigenically, sharing 4–5 common antigens, but only slightly related to *Treponema minutum*. The three strains had only one antigen in common with *Treponema pallidum*.

DNA from *Treponema refringens* shows a high homology with DNA from the avirulent Nichols strain, the Noguchi strain, and “*Treponema calligyrum*”, and a very low homology with DNA from strains of *Treponema denticola* (R. M. Smibert and J. Johnson, unpublished data). No detectable DNA homology by hybridization to *Treponema phagedenis* or *Treponema pallidum* subsp. *pallidum* (Nichols) and *Treponema pallidum* subsp. *pertenue* (Maio and Fieldsteel, 1978). On this basis, “*Treponema calligyrum*” was designated a biovar of *Treponema refringens* by Smibert (1984). Biovar *refringens* does not grow with 1% glycine, whereas biovar *calligyrum* does grow in 5–6 d.

Source: condyloma acuminata lesions, occasionally from syphilitic lesions. Part of normal flora of male and female genitalia of man and animals. Not pathogenic.

DNA G+C content (mol%): 39–43 (T_m).

Type strain: none designated.

Reference strain for biovar refringens: *Treponema refringens*, Institut Pasteur, Paris.

Reference strain for biovar calligyrum: CIP 64.40.

Sequence accession nos (16S rRNA gene): AF426101 (*Treponema refringens* biovar *refringens*); AF426100 (*Treponema refringens* biovar *calligyrum*).

21. ***Treponema saccharophilum*** Paster and Canale-Parola 1985, 218^{VP}

sac.cha.ro.phi'lum. Gr. n. *sacchar* sugar; Gr. adj. *philus* -ê-on loving; N.L. neut. adj. *saccharophilum* sugar-loving.

Helical cells, 0.6–0.7 µm by 12–20 µm. Cell coiling is regular except when cells are in contact with solid surfaces. A bundle of periplasmic flagella is wrapped around the cell body. At least 16 periplasmic flagella are inserted near each end of the cell. Cells swim at velocities in excess of 60 µm/s in liquid media at 37°C, but no translational motility is observed at 23°C. Translational motility ceases 1–2 min after the cells are exposed to air. Cells in contact with solid surfaces exhibit creeping motility. Obligate anaerobe. Optimum growth is at 37–39°C. At these temperatures, the final growth yield in rumen fluid-glucose-sodium bicarbonate-salts broth is 7×10⁸ cells per ml and the population doubling time is 90 min. No growth at 23°C or 45°C. Subsurface colonies in agar media are spherical and opaque with diffuse edges. Utilizes as fermentable substrates for growth: L-arabinose, D-galactose, D-glucose, D-mannose, D-fructose, D-galacturonic acid, D-glucuronic acid, cellobiose, lactose, maltose, sucrose, D-raffinose, dextrin, inulin, starch, pectin, polygalacturonic acid, and arabinogalactan. Does not grow on: L-rhamnose, D-xylose, L-sorbose, D-ribose, cellulose, dextran, amino acids, D-arabitol, dulcitol, mannitol, ribitol, sorbitol, xylitol, glycerol, potassium galactonate, potassium gluconate, sodium acetate, sodium formate, sodium lactate, sodium succinate, potassium fumarate, Tween 80, glucosamine, and xylan. Exogenous isobutyric acid is required for growth, and valeric acid is stimulatory. Neither NaHCO₃ in media nor a CO₂-containing atmosphere is required for growth. Fermentation end products of growing cells (in micromoles per 100 pmol of glucose utilized):

formate, 150; acetate, 91.2; ethanol, 79.4. Approximately 15% of the glucose carbon consumed by growing cells is assimilated in cell material. Acetate and formate are major end products of pectin or glucuronic acid fermentation. Pyruvate is metabolized via a coliform-type clastic reaction. Isolated from bovine rumen fluid using an agar medium that contained rifampicin as a selective agent and pectin as a fermentable substrate.

Source: bovine rumen contents.

DNA G+C content (mol%): 54 (T_m).

Type strain: PB, ATCC 43261, DSM 2985.

Sequence accession no. (16S rRNA gene): M71238.

22. ***Treponema scoliodontus*** (ex Noguchi 1928) sp. nov., nom. rev.

sco.li.o.don'tus. Gr. adj. *skolios* crooked, bent; Gr. n. *odontos* tooth; N.L. neut. n. *scoliodontus* crooked tooth.

Many characteristics are listed in Tables 127 and 128. Very tightly coiled cells. Motile with a jerky but fairly rapid motion. Grows in peptone-yeast extract-serum medium under anaerobic conditions. Requires animal serum or ascitic fluid. Amino acids in a peptone-yeast extract-serum medium are fermented to moderate amounts of acetic acid and small amounts of formic, succinic, lactic, propionic, and *n*-butyric acids. No additional end products are produced in the presence of glucose.

Methyl red-negative. Ammonia is not produced from amino acids. No action on milk. Chopped meat serum medium is neither blackened nor digested. Produces a slight fetid odor. Grows at pH 6.5–8.0 but not at pH 6.0 or 9.6. Grows at 30–42°C.

Source: oral cavity of humans.

Type strain: none designated.

Reference strain: *Treponema scoliodontus* Institut Pasteur, Paris.

Sequence accession no. (16S rRNA gene): not determined.

23. ***Treponema socranskii*** (Noguchi 1928) Smibert, Johnson and Ranney 1984, 459^{VP}

so.crans'ki.i. N.L. masc. gen. n. *socranskii* of Socransky, named for Sigmund S. Socransky, Forsyth Dental Center, Boston, USA.

Cells are 6–15 µm long and 0.16–0.18 µm wide. They have tapered ends with a slight bend or “hook” at one or both ends of the cell. Obligately anaerobic, motile, helically coiled treponeme. The species is subdivided into three distinct subspecies based on DNA homology (by hybridization) and phenotypic characteristics: subspecies *socranskii*, *buccale*, and *paredis* (Smibert et al., 1984). The periplasmic flagella overlap in the center of the cell, in a 1:2:1 relationship. The cells form coccoid bodies in the late stationary growth phase. Cells in broth cultures have both rotational and translational movement. Serpentine movement of cells can be seen by darkfield microscopy of cultures grown in a semisolid medium.

Colonies usually appear in Oral Treponeme Isolation (OTI) agar (Smibert and Burmeister, 1983) in 7–10 d. The colonies grow into the agar, are white and translucent, and often have slightly denser centers and edges that can be

entire or irregular. The colonies spread and become larger after extended incubation. Growth occurs only in media containing a fermentable carbohydrate and either rumen fluid (20–30%) or a mixture of short-chain fatty acids. Serum is not required. Growth is optimum at 37°C and only slight at 25 or 42°C.

The phenotypic characteristics of representative strains (10–12 of each subspecies) were examined (Smibert et al., 1984). Fermentation of glucose by a majority of the strains leads to a pH ranging from 5.1 to 5.9. A few strains belonging to *Treponema socranskii* subsp. *buccale* do not reduce the pH below 6.0 when they are grown in glucose-containing broth. These cultures have a pH range of 6.2–6.7. Inulin, lactose, Melezitose, cellobiose, salicin, D-sorbitol, glycerol, amygdalin, adonitol, dulcitol, D-erythritol, inositol, and D-mannitol are not fermented, as indicated by only a slight change in the pH of the medium. Hydrogen sulfide is produced in SIM medium supplemented with rumen fluid by all but 1 of 32 strains tested.

A distinctive phenotypic trait found in all strains of all subspecies of *Treponema socranskii* (but not in any other oral spirochete) is the formation of intensely yellow colonies (or cell pellets after growth in liquid medium) in OMIZ-Pat agarose. Furthermore, live cells of *Treponema socranskii* can be recognized microscopically, since cells that are rotating around their axes have both cell tips markedly deflected, which gives the appearance of propellers on both ends of a straight helix.

None of the strains studied produces catalase, peroxidase, indole, or acetylmethylcarbinol. Esculin is not hydrolyzed. Hydrogen gas is not detected by gas chromatography of samples taken from the atmosphere above the broth medium in rubber-stoppered tubes.

The major acid fermentation products of all strains grown in PY-glucose-rumen fluid broth are acetic, lactic, and succinic acids. Trace amounts of formic acid occasionally can be found. The strains produce a mean of 8 mM lactic acid (range, 3–16 mM), 6.5 mM acetic acid (range, 2.6–10.4 mM), and 3 mM succinic acid (range, 1–6.5 mM).

Treponemes in homology group A1 are designated *Treponema socranskii* subsp. *socranskii*. The type strain of *Treponema socranskii* subsp. *socranskii* is ATCC 35536^T (= VPI DR56BR116). Treponemes in homology group A2 are designated *Treponema socranskii* subsp. *buccale* (*buc.ca'le*. L. n. *bucca* the mouth; L. neut. suff. *-ale* suffix denoting pertaining to; N.L. neut. adj. *buccale* buccal, pertaining to the mouth); the type strain is VPI D2B8^T (=ATCC 35534). The phenotypic characteristics of these subspecies are described in detail in the defining publication (Smibert et al., 1984).

Patterns of phenotypic reactions (Smibert et al., 1984) show that *Treponema socranskii* subsp. *socranskii* (homology group A1) cannot be readily differentiated from *Treponema socranskii* subsp. *buccale* (homology group A2). However, when a slide agglutination test with washed cells as the antigen was used, antisera against the type strain (strain ATCC 35536) and strain VPI D43BR1 agglutinated 11 of 12 *Treponema socranskii* subsp. *socranskii* strains (Smibert et al., 1984), and no strain of *Treponema socranskii* subsp. *buccale* or *Treponema socranskii* subsp. *paredis*. Antisera against the type strain (strain ATCC 35534) and strains VPI D11A1 and VPI

D40DPEI of *Treponema socranskii* subsp. *buccale* agglutinated 7 of 10 *Treponema socranskii* subsp. *buccale* strains. Antiserum against the type strain of *Treponema socranskii* subsp. *paredis* (strain ATCC 35535) agglutinated 7 of 9 *Treponema socranskii* subsp. *paredis* strains but no *Treponema socranskii* subsp. *socranskii* or *Treponema socranskii* subsp. *buccale* strains.

Treponemes in homology group K are designated *Treponema socranskii* subsp. *paredis* (*pa.re'dis*. Gr. n. *pareias* cheek; N.L. gen. n. *paredis* of a cheek). L-Arabinose and rhamnose are not fermented. Other characteristics of this subspecies are the same as those of the species. The type strain of *Treponema socranskii* subsp. *paredis* is strain ATCC 35535 (= VPI D46CPE1), which was isolated from a supragingival sample from a patient with severe periodontal disease.

Treponema socranskii subsp. *paredis* can be easily separated from *Treponema socranskii* subsp. *socranskii* and *Treponema socranskii* subsp. *buccale* by the inability of *Treponema socranskii* subsp. *paredis* to ferment L-arabinose and rhamnose.

Source: subgingival sample from a patient with severe periodontal disease. It is the most frequently isolated treponeme and is usually the most numerous of the cultivable treponemes in either supragingival or subgingival samples.

DNA G+C content (mol%): 50.5±2 (T_m).

Type strains: *Treponema socranskii* subsp. *socranskii* ATCC 35536, JCM 8157, VPI D56BR116; *Treponema socranskii* subsp. *buccale* ATCC 35534, JCM 8155, VPI D2B8; *Treponema socranskii* subsp. *paredis* ATCC 35535, JCM 8156, VPI D46CPE1.

Sequence accession nos (16S rRNA gene): AF033306 (*Treponema socranskii* subsp. *socranskii*); AF033305 (*Treponema socranskii* subsp. *buccale*); AF033307 (*Treponema socranskii* subsp. *paredis*).

24. ***Treponema succinifaciens*** Cwyk and Canale-Parola 1981, 383^{VP} (Effective publication: Cwyk and Canale-Parola 1979, 231.)

suc.ci.ni.fa'ci.ens. N.L. n. *acidum succinicum* succinic acid; L. part. adj. *faciens* making, producing; N.L. part. adj. *succinifaciens* succinic acid-producing.

Helical, anaerobic bacterium 0.3 µm wide by 4–8 µm long. Some cells may be up to 16 µm long. May form chains. Possesses a 2:4:2 flagellar arrangement. No transitional movement at 25°C. Motile at 37°C, requires carbon dioxide. Colonies in rumen fluid agar deeps are spheroid with an opaque center and diffuse peripheral growth. Colonies are 4–8 mm in diameter after 2 d growth at 37°C. In broth, cell yields are 1.5×10⁹ cells/ml with a mean generation time of 3.5 h.

The pH of a glucose culture after 48 h is about 6.0. Ferments glucose by the Embden–Meyerhof pathway. CO₂/bicarbonate and a carbohydrate are required for multiplication. Growth is supported by L-arabinose, D-xylose, D-glucose, D-mannose, D-galactose, maltose, lactose, cellobiose, dextrin, and starch, but not by D-ribose, L-sorbose, raffinose, L-rhamnose, D-fructose, sucrose, dextran, inulin, ball-milled cellulose, trehalose, glycerol, D-mannitol, D-sorbitol, dulcitol, xylitol, sodium acetate, sodium formate, sodium succinate, potassium pyruvate, sodium lactate, and potassium gluconate. Does not ferment acetate, formate, succinate, xylitol,

pyruvate, lactate, gluconate, and Tween 80. End products are (in $\mu\text{mol}/100 \mu\text{mol}$ glucose and $51 \mu\text{mol}$ of CO_2 utilized) acetate, 82; formate, 81; succinate, 58; lactate, 30; 2,3-butanediol, 5; pyruvate, 4; acetoin, 3. Catalase-negative. Poor growth occurs at 22 and 43°C .

Inhibited by penicillin G (4000 U/l), cephalothin (4 mg/l), and chloramphenicol (4 mg/l), not by erythromycin (4 mg/l), oxytetracycline (4 mg/l), polymyxin B (40,000 U/l), rifampicin (4 mg/l), streptomycin (4 mg/l), tetracycline (4 mg/l), and vancomycin (4 mg/l).

Source: colon of swine.

DNA G+C content (mol%): 36 (T_m).

Type strain: strain 6091, ATCC 33096, DSM 2489.

Sequence accession no. (16S rRNA gene): M57738.

25. **Treponema vincentii** (ex Brumpt 1922a) sp. nov., nom. rev.

vin.cen'ti.i. N.L. masc. gen. n. *vincentii* of Vincent, named after Jean-Hyacinthe Vincent (1862–1950), a French military physician.

Many characteristics are listed in Tables 127–129. Cells may have shallow and irregular spirals. Four to six periplasmic flagella are inserted at each end of cell. Motile with a rapid, jerky, vibratory motion. Colonies of strain N-9 are visible after incubation for 2 weeks. The colonies are white, 12–15 mm in diameter, appearing as a slight haze in the

agar. Unlike other *Treponema* species, *Treponema vincentii* is reported to produce LPS (Blanco et al., 1994; Kurimoto et al., 1990). Grows in a peptone-yeast extract medium under anaerobic conditions. Requires animal serum or ascitic fluid for growth.

Amino acids are fermented to mainly acetic and *n*-butyric acids, moderate amounts of lactic acid, and smaller amounts of succinic and formic acids, and trace amounts of propionic acid, ethanol, *n*-propanol, and *n*-butanol. No additional end products are produced in the presence of glucose.

Methyl red-negative. Skim milk is not changed. Ammonia is produced in cultures. Chopped meat is neither blackened nor digested. A slight fetid odor is produced in cultures. Grows at pH 6.5–7.5 and at $25\text{--}45^\circ\text{C}$.

Meyer and Hunter (1967) reported that *Treponema vincentii* strain N-9 was antigenically distinct from *Treponema denticola* (FM) and the Nichols and Noguchi strains of *Treponema refringens*. Antigens were shared with [*Spirochaeta*] *zuelerzae* and *Treponema phagedenis* (Reiter and Kazan strains).

Source: oral cavity of humans.

DNA G+C content (mol%): not known.

Type strain: none designated.

Reference strain: N-9.

Sequence accession no. (16S rRNA gene): AF033309.

Species *Candidatus**

1. “**Treponema suis**” (Molbak et al., 2006)

su'is. L. n. *sus suis* a swine, hog, pig, boar, sow; L. gen. n. *suis* of a pig.

This *Candidatus* was identified in paraffin-embedded biopsy specimens of porcine colon. Laser capture dissection and PCR amplification were used to determine the 16S rRNA sequence, and fluorescence *in situ* hybridization (FISH) was performed to show that the spirochetes were distributed within the colonic epithelium and lamina propria. The fact that the organism was identified by FISH in nearly equal proportions in pigs with colitis (60%) and in normal controls (43%) indicates that it is not a causative agent of colitis. The 16S rRNA sequence was most closely related to *Treponema bryantii*; however, the sequence identity was only 90.1%, making it likely that this organism, provisionally called “*Treponema suis*”, represents a separate species. By electron microscopy, “*Treponema suis*” is longer (6–11 μm) than other *Treponema* species identified in the porcine intestinal tract (*Treponema succinifaciens*, *Treponema berlinense*, and *Treponema porcinum*, 4–8 μm). In addition, “*Treponema suis*” has a total of 10–14 periplasmic flagella, as compared to two for the aforementioned species. The *in vitro* culture of this organism has not as yet been reported.

Source: porcine colon.

DNA G+C content (mol%): not known.

Type strain: none designated.

Sequence accession no. (16S rRNA gene): AM284386.

2. “**Treponema macrodentium**” Noguchi 1912, 82 [*Spirochaeta macrodentium* (Noguchi 1912) Pettit 1928, 182]

mac.ro.den'ti.um. Gr. adj. *makros* long; L. n. *dens dentis* tooth; N.L. gen. pl. n. *macrodentium* of large teeth.

Slender helical rods, 5–16 μm long and 0.1–0.25 μm wide. The ends of the cell are pointed. One periplasmic flagellum is inserted into each end of the cell. Motile with a fairly rapid motion. Young cells rotate rapidly on their long axis. Grows in peptone-yeast extract-medium or PPLO medium (BBL) containing 10% serum or ascitic fluid with cocarboxylase (5 mg/l), glucose (1 g/l), and cysteine (1 g/l). Requires animal serum for growth. This requirement can be replaced by isobutyric acid (20 mg/l), spermine (150 mg/l), and nicotinamide (400 mg/l). Will also grow in a medium supplemented with rumen fluid and cocarboxylase. Requires a fermentable carbohydrate as an energy source. Carbohydrates are fermented. Acid but no gas is produced. The final pH in glucose broth is 5.0–5.4. Ferments fructose, glucose, maltose, ribose, and sucrose. May ferment cellobiose, galactose, and xylose. Does not ferment mannose, rhamnose, sorbose, lactose, arabinose, trehalose, mannitol, inulin, sorbitol, or salicin. Starch is not hydrolyzed. Glucose is fermented mainly to lactic acid, moderate amounts of acetic and formic acids, and a trace of succinic acid. Gelatin is hydrolyzed. Indole-negative. Hydrogen sulfide is produced. Lactate is not used. Ammonia is not produced. Optimum temperature, 37°C . Grows at pH 7.0.

Source: subgingival crevice of humans.

DNA G+C content (mol%): 39 (T_m).

Type strain: no culture available.

Sequence accession no. (16S rRNA gene): not known.

*The following species have been described but can be found in the literature and are not yet classified formally. There are no known cultures of two of these species. They are listed so that if they are isolated again, the description can be used to aid in their identification. The names presently have no standing in nomenclature.

FIGURE 95. Phylogenetic tree illustrating the diversity of cultivable and not-yet-cultivable species of the genus *Treponema* based on 16S rRNA sequence comparisons. Environmental source or host for each species is noted in parentheses. Several clusters were apparent, e.g., mammalian clusters 1 and 2, termite clusters 1 and 2, and a waste water cluster 1. GenBank accession numbers for the 16S rRNA sequences of not yet cultivated species, or phylogenotypes, tested are shown. The scale bar represents a 5% difference in nucleotide sequence

3. “**Treponema orale**” Socransky, Listgarten, Hubersak, Cotmore and Clark 1969, 881 [*Treponema oralis* (*sic*) Socransky, Listgarten, Hubersak, Cotmore and Clark 1969, 881]

o.ra'le. L. n. *os*, *oris* the mouth; L. neut. suff. *-ale* suffix denoting pertaining to; N.L. neut. adj. *orale* pertaining to the mouth, of the mouth.

Slender helical cells, 6–16 μm long and 0.10–0.25 μm wide. Occasional chains are formed. One periplasmic flagellum is inserted into each end of the cell. Frequently end granules are seen in broth cultures. Motile with a jerky but fairly rapid motion. Grows in either PPLO medium without crystal violet (BBL) or peptone-yeast extract medium. Each medium contains glucose (1 g/l), cysteine (1 g/l), nicotinamide

(500 mg/l), cocarboxylase (5 mg/l), spermine tetrahydrochloride (150 mg/l), and sodium isobutyrate (20 mg/l), and each is further supplemented with 10% inactivated rabbit serum or ascitic fluid, or 0.05% α -globulin. Uniform turbidity occurs in liquid media. Does not grow well on surface cultivation. Does not require carbohydrates as an energy source. Carbohydrates not fermented. Amino acids are fermented. The final pH in glucose broth is 6.8–7.2. Amino acids are fermented to acetic and propionic acids. Hydrolyzes gelatin but not starch. Indole-positive. H_2S produced. Utilizes lactate. Does not produce ammonia in cultures. Grows at pH 7.0 and at 37°C.

Paster et al. (1998) reported that a strain labeled “*Treponema oralis*” in the Smibert collection had 16S rRNA sequence and

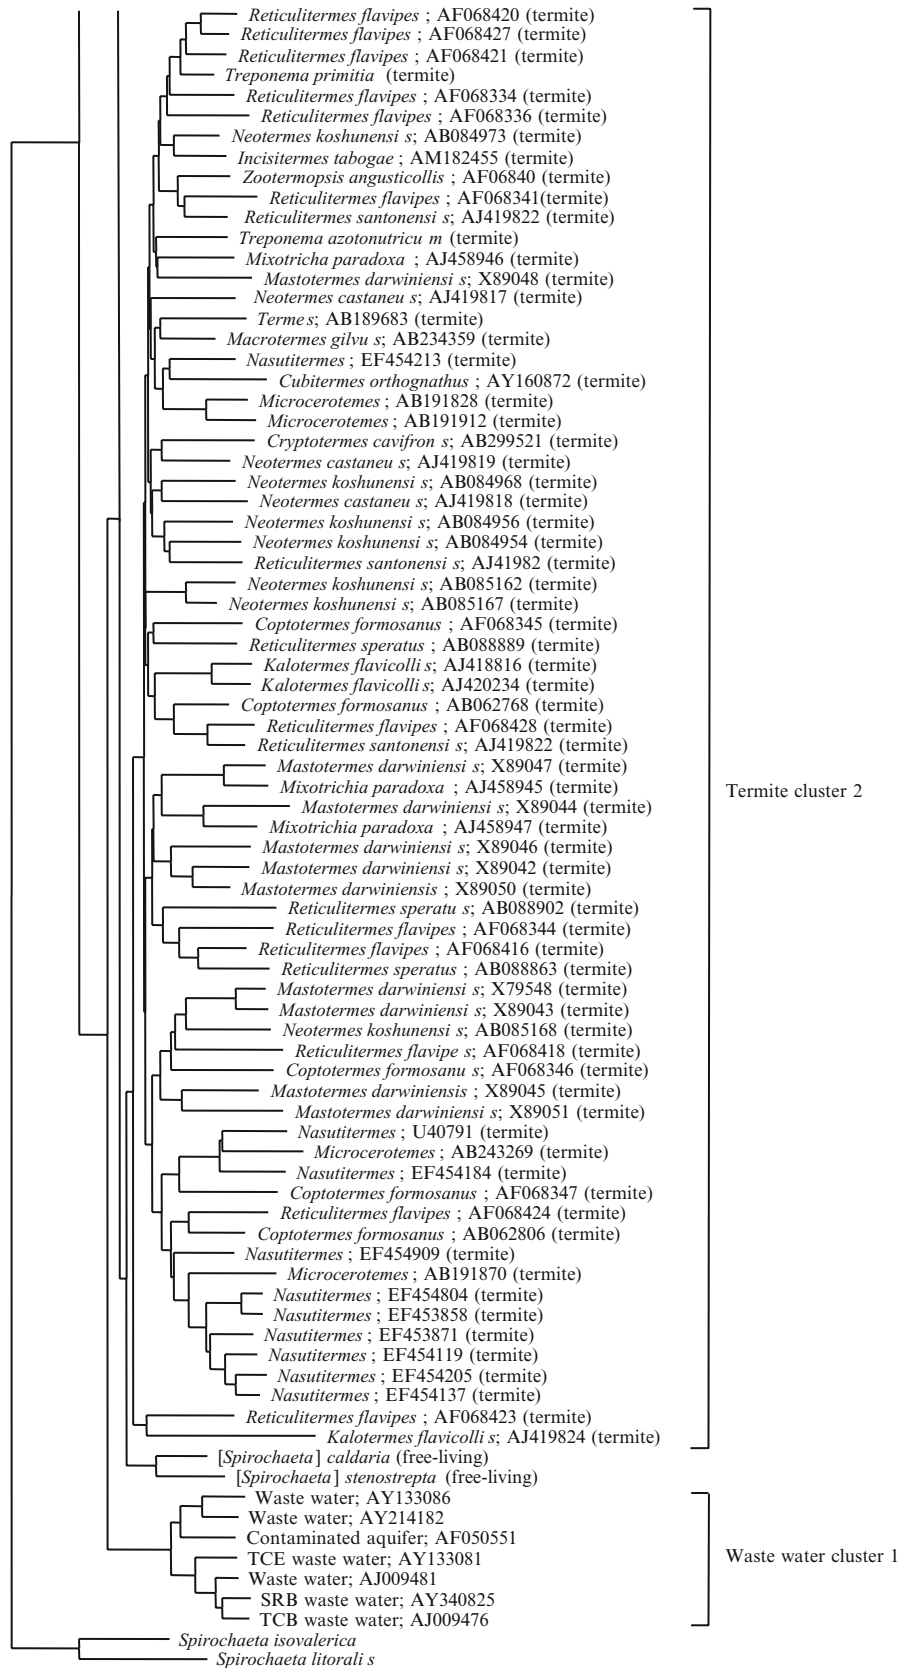

FIGURE 95. (continued)

other characteristics closely resembling those of *Treponema denticola*. The mol% G+C (37) is close to that determined for *Treponema denticola* (37.9). Therefore, this *Candidatus* species appears to be *Treponema denticola* and should be eliminated.

Source: subgingival crevice of humans.

DNA G+C content (mol%): 37.

Type strain: none.

Sequence accession no. (16S rRNA gene): none available.

4. “**Treponema zioleckii**” (Ziolecki, 1979; Ziolecki and Wojciechowicz, 1980)

zi.o.lec'ki.i. N.L. gen. masc. n. *zioleckii* of Ziolecki in honor of Alexander Ziolecki, Polish Academy of Sciences, in recognition of his contribution to the microbiology of rumen treponemes.

Cells are 0.5 µm in diameter by 5–11.5 µm in length. The number of periplasmic flagella per cell could not be estimated from electron microscopic observations, but it appears there are at least four per cell (Piknova et al., 2008). Utilizes fructan, inulin, sucrose, and various plant mono- and disaccharides as fermentable substrates. Produces formate, acetate, and ethanol as endproducts of glucose fermentation. The name *Treponema zioleckii* was recently formally proposed (Piknova et al., 2008). The 16S rRNA gene sequence of *Treponema zioleckii* was > 99% similarity to strain CA, which was previously isolated from bovine rumen contents (Paster and Canale-Parola, 1982). Cells of strain CA are similar in dimensions to *Treponema zioleckii*, have 16–20 periplasmic flagella per cell, are pectinolytic, have amyolytic activity, can grow on arabinogalactan, and have a G+C content of 42 mol% (Paster and Canale-Parola, 1982).

Source: sheep rumen contents.

DNA G+C content (mol%): not known for type strain.

Type strain: kT.

Sequence accession no. (16S rRNA gene): DQ065758; strain CA: M59294.

Diversity of not-yet-cultivated species

As with species of *Spirochaeta*, species of *Treponema* are broadly diverse. In addition to known species of *Treponema*, novel phylotypes, i.e., species that have not yet been cultivated *in vitro*, have been identified by analysis of 16S rRNA genes of DNA isolated from host-associated sources, such as the human oral cavity (Choi et al., 1994; Dewhirst et al., 2000; Paster et al., 2001), termite hindguts (Lilburn et al., 1999) and the bovine rumen (Tajima et al., 1999).

Representatives of treponemal phylotypes from each of these and other environments are included in Figure 95. In one study, Paster et al. (2001) identified 49 not-yet-cultivated species of *Treponema* in human subgingival plaque (see expanded phylogenetic trees of phylotypes in Dewhirst et al., 2000, and Paster et al., 2001). The termite hindgut has an especially diverse array of treponemal phylotypes, with hundreds of potentially new species of *Treponema* identified (Berlanga et al., 2007; Lilburn et al., 1999; Ohkuma et al., 1999). The diversity of treponemes in termite hindguts is likely even more extensive considering that there are over 2,000 species of termites. Bovine and ovine digital dermatitis cases have also yielded several treponemal phylotypes (Demirkan et al., 2006; Walker et al., 1995). It is likely that other environments such as the intestinal tracts of most mammals, birds, and other insects will also contain many additional *Treponema* phylotypes.

Figure 95 illustrates the phylogenetic diversity of representatives of treponemal species and not-yet-cultivable phylotypes from human, animal, insect, and waste water environments. Interestingly, several phylogenetic clusters based on host or environment are apparent, namely mammalian, termite, and waste water.

Family II. Brachyspiraceae

BRUCE J. PASTER

Bra.chy.spi.ra.ce'ae. N.L. fem. n. *Brachyspira* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Brachyspiraceae* the *Brachyspira* family.

The family *Brachyspiraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences. The family contains only one genus, *Brachyspira*. Description is the same as for the genus, *Brachyspira*.

Type genus: Brachyspira aalborgi Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1983, 896^{VP} (Effective publication: Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1982, 1135.).

Genus I. **Brachyspira** Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1983, 896^{VP} (Effective publication: Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1982, 1135.)

THADDEUS B. STANTON

Bra.chy.spi'ra. Gr. adj. *brachys* short; L. fem. n. *spira* a coil, spiral; N.L. fem. n. *Brachyspira* a short spiral, describing a bacterium that resembles a short spiral.

Brachyspira spirochetes are helical shaped bacteria with **regular coiling patterns**. Cells measure 2–11 µm by 0.2–0.4 µm. Unicellular, but dividing pairs and occasional chains of three or more cells can be observed in growing cultures. Under unfavorable growth conditions, spherical or round bodies are formed. Gram-stain negative. **Obligately anaerobic, aerotolerant**. Cell ends may be blunt or pointed. Cells have a typical spirochete cell ultrastructure, consisting of an outer sheath, helical protoplasmic cylinder, and internal flagella in the space between the protoplasmic cylinder and outer sheath. *Brachyspira* cells have 8–30 flagella per cell depending on the species (flagellar number usually correlates with cell size and species of smaller cells have fewer flagella). Flagella attach subterminally in equal numbers at each cell end, wrap around the protoplasmic cylinder, and their free ends overlap in the middle of the cells. Flexing and creeping motility at 22°C; translational movement in liquids at 37–42°C. Cultured anaerobically on commercially available media (trypticase soy or brain heart infusion broths) containing a carbohydrate growth substrate

and supplemented with defibrinated blood or animal (calf) serum. Grows at 36–42°C, optimally at 37–39°C. Population doubling times on glucose in broth cultures are 1–5 h (not reported for *Brachyspira aalborgi*). Chemoorganotrophic, using various carbohydrates for growth. **Possess NADH oxidase for reducing molecular oxygen. Consume oxygen during growth in culture broth beneath a 1% oxygen atmosphere. Acetate, butyrate, H₂, and CO₂ are major endproducts of glucose metabolism. Higher amounts of H₂ than CO₂ are produced.** Weakly hemolytic except for *Brachyspira hyodysenteriae* which exhibits β-hemolysis (strongly hemolytic). Associated with animal and human hosts. Some species are pathogenic. **The genus *Brachyspira* is distinguished from other spirochete genera based on 16S rRNA gene sequences.** *Brachyspira* species share high 16S rRNA sequence similarity with each other. Species can be differentiated by DNA–DNA relative reassociation and MLEE (multilocus enzyme electrophoresis) analyses. Similar to other spirochete genera, *Brachyspira* is insensitive to the antibiotic rifampin.

DNA G+C content (mol%): 24.5–27.1 (T_m).

Type species: *Brachyspira aalborgi* Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1983, 896^{VP} (Effective publication: Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1982, 1135^{VP}).

Further descriptive information

Cell morphology and ultrastructure. By phase-contrast microscopy, *Brachyspira* species appear helical shaped with regular coils (Figure 96). They have a typical spirochete ultrastructure with protoplasmic cylinder, enclosed flagella winding around the protoplasmic cylinder, and outer sheath (membrane) (Sellwood and Bland, 1997). The species can be divided into two groups based on cell size and flagellar numbers (Table 130). *Brachyspira* species with larger cell size, such as *Brachyspira hyodysenteriae*, *Brachyspira innocens*, *Brachyspira intermedia*, *Brachyspira murdochii*, and *Brachyspira alvinipulli*, have 20–30 flagella per cell. *Brachyspira pilosicoli* and *Brachyspira aalborgi* cells are shorter in length and have 8–12 flagella per cell. As with other spirochetes, the flagella attach in roughly equal numbers at each end of the cell (Figure 97).

The end shapes of cells of different species vary (Table 130). The pointed cell ends of *Brachyspira pilosicoli* and *Brachyspira aalborgi* may serve in the attachment of these spirochetes to

intestinal cells (Sellwood and Bland, 1997). Outer-membrane proteins of pathogenic *Brachyspira* species are frequently the targets of efforts to develop vaccines against intestinal spirochete diseases (Cullen et al., 2003; Cullen et al., 2004; La et al., 2004; McCaman et al., 2003; Trott et al., 2001, 2004).

Nutrition and growth conditions. Various anaerobic, nutritionally complex broth media have been described for *Brachyspira* species (Stanton, 1997). Incubation temperatures are 38–40°C. Shaking or stirring of broth cultures is important for optimum growth. BHIS broth and Kunkle's broth are commonly used for routine growth of *Brachyspira hyodysenteriae* (Kunkle et al., 1986; Stanton and Lebo, 1988). Both media support high growth yields ($1-4 \times 10^9$ cells/ml, direct microscope counts). In BHIS broth which contains glucose as a growth substrate, the population doubling times for most *Brachyspira* species are 1–5 h (Table 130).

HS broth (Heart infusion broth supplemented with serum) requires added carbohydrates to support optimum growth yields of *Brachyspira* species. Consequently, HS broth is useful for identifying metabolic end products (Table 130) and growth substrates (Table 131). NT broth, a serum-free medium with low protein content, supports *Brachyspira hyodysenteriae* growth (Humphrey et al., 1997).

Brachyspira species are generally aerotolerant and able to grow in sealed culture broth tubes beneath atmospheres containing 1–5% O₂. They will not initiate growth, however, in oxidized media, i.e., in media containing resazurin indicator dye that has become colored by exposure to air. A too low redox potential appears to be a controlling factor for *Brachyspira hyodysenteriae* growth (Stanton, 1997). This species can be difficult to culture in stringently prepared anaerobic broth media unless a small amount of oxygen (1%, v/v) is introduced into the culture atmosphere (Stanton and Lebo, 1988). *Brachyspira hyodysenteriae* cells can be cultured in a fermenter (12 l) beneath an air atmosphere (Stanton and Jensen, 1993).

Fermentation and growth substrates. Fermentation substrates have been identified by measuring acid production (medium pH decreases) in cultures to which the substrates have been added (Jones et al., 1986; Kinyon and Harris, 1979; Ochiai et al., 1998; Tompkins et al., 1986). Alternatively, carbon/energy sources of the spirochetes have been directly identified by measuring population density increases in HS broth, a culture medium that is growth limiting unless substrates are added (Table 131). The latter method is more sensitive for detecting substrates that support low growth yields. In HS broth, *Brachyspira hyodysenteriae*, *Brachyspira innocens*, *Brachyspira intermedia*, *Brachyspira murdochii*, *Brachyspira pilosicoli*, and *Brachyspira alvinipulli* cells use various monosaccharides, disaccharides, the trisaccharide trehalose, and amino sugars for growth (Table 131). The ability to ferment D-ribose distinguishes *Brachyspira pilosicoli* strains from other *Brachyspira* species (Fossi and Skrzypczak, 2006). *Brachyspira* strains do not use polysaccharides such as cellulose, hog gastric mucin, pectin, or glycogen. *Brachyspira hyodysenteriae* and *Brachyspira innocens* contain an inducible sucrase activity (Jensen and Stanton, 1994).

Cholesterol and phospholipids. *Brachyspira hyodysenteriae* requires cholesterol and phospholipid for growth (Lemcke and Burrows, 1980; Stanton, 1987, 1997). Cholesterol is likely required for outer membrane biosynthesis (Lemcke and

^bOnly one strain of *Brachyspira aalborgi* (513A^h) and *Brachyspira atomipulhi* (strain C1ⁱ) have been extensively studied. Data from Harris et al. (1972a, b), Kinyon and Harris (1979), Hovind-Hougen et al. (1982), Stanton and Lebo (1988), Stanton et al. (1991, 1996, 1997, 1998), Fellsstrom et al. (1995, 1997, 1999), Park et al. (1995), Troit et al. (1996a, b, 1997a–c), McLaren et al. (1997), Sellwood and Bland (1997), De Smet et al. (1998), Duhamel et al. (1998a, b), Kraaz et al. (2000), Fossi et al. (2004), and Jansson et al. (2004).

^cPure cultures of either the type strain or another strain have been shown to cause disease when inoculated into normal, healthy, natural host animals. *Brachyspira intermedia* infections of chickens are mild to moderate “economic loss” diseases associated with “wet litter” and “unthriftiness”, in contrast to the severe pathology of swine dysentery.

^dValues represent population doubling time in hours for broth cultures and days for colony development on agar-containing media at 37–39°C.

^eProduct yields of type strains after growth in HS broth containing glucose and beneath 1% O₂ atmosphere. All strains consumed O₂.

^fA unique signature sequence of nucleotides was identified within the 16S rDNA of *Brachyspira pilosicoli* and has been used to design specific PCR tests for this species (Fellsstrom et al., 1997; Park et al., 1995).

^gDetermined by using GenBank 16S rRNA gene sequences with accession numbers Z22781, U14930, U23033, U14920, U14927, U22838, and U23030. All sequences are for type strains except *Brachyspira murdochii* (strain 155-20).

^hAs reported by Fossi and Skrzypczak (2006).

FIGURE 97. Electron micrograph of one end of *Brachyspira alvinipulli* C1^T cell negatively stained with 2% phosphotungstic acid (pH 7.0). Disrupted outer sheath enables insertion sites of 15 periplasmic flagella to be seen (white arrowheads). Marker bar = 0.25 μ m. (Reproduced with permission from T.B. Stanton et al., 1998. *Int. J. Syst. Bacteriol.* 48: 669–676.)

Burrows, 1980; Plaza et al., 1997; Stanton, 1987; Stanton and Cornell, 1987). The cellular fatty acids of *Brachyspira hyodysenteriae* are distinct from those of *Borrelia* and *Leptospira* species (Livesley et al., 1993). The cellular phospholipids and glycolipids of *Brachyspira hyodysenteriae* and *Brachyspira innocens* contain acyl and alkenyl side chains and the spirochetes apparently have some capacity for fatty acid and lipid biosynthesis (Matthews and Kinyon, 1984; Matthews et al., 1980a, b).

Glucose and pyruvate metabolism. *Brachyspira hyodysenteriae* uses the Embden–Meyerhof–Parnas (EMP) pathway for converting glucose to pyruvate. Pyruvate is catabolized by a clostridial-type clastic reaction to acetyl-CoA, H₂, and CO₂. Acetyl-CoA is converted to either acetate or butyrate via a branched fermentation pathway. The ATP-yielding mechanisms are substrate-level phosphorylation reactions mediated by phosphoglycerate kinase and pyruvate kinase in the EMP pathway and by acetate kinase in the conversion of acetyl phosphate to acetate (Stanton, 1989, 1997).

In *Brachyspira hyodysenteriae* cells, NADH-H⁺ produced during glycolysis can be recycled or oxidized to NAD⁺ by three pathways: (a) 3-hydroxybutyryl-CoA dehydrogenase and butyryl-CoA dehydrogenase (butyrate pathway); (b) NADH-ferredoxin oxidoreductase plus hydrogenase; and (c) NADH oxidase (Stanton, 1997). The *Brachyspira hyodysenteriae* NADH oxidase is a water-forming, FAD-linked enzyme (Stanton and Jensen, 1993) and the *nox* gene has been cloned (GenBank no. U19610) (Stanton and Sellwood, 1999). *Brachyspira hyodysenteriae nox*-defective mutant strains are sensitive to oxygen and are avirulent (Stanton et al., 1999).

^bFermentation substrates for *Brachyspira aalborgi* were determined by phenol red measurements of acid production (Ochiai et al., 1997). Growth substrates for the other six *Brachyspira* species were determined by monitoring culture growth in HS broth to which the various substrates were added. Different substrates support different growth yields of cells. Data are for *Brachyspira aalborgi* NCTC 11492 (Ochiai et al., 1997), *Brachyspira hyodysenteriae* strains B78^T, B204, and B169 (Stanton and Lebo, 1988), *Brachyspira innocens* B256^T (Trott et al., 1996a), *Brachyspira pilosicoli* strains P43/6/78^T, 3295, 1648, Hrm7, Kar, WesB (Trott et al., 1996a, b), *Brachyspira intermedia* PWS/A^T (Stanton et al., 1997), *Brachyspira murdochii* 56-150^T (Stanton et al., 1997), and *Brachyspira alvinipulli* C1^T (Stanton et al., 1998). In the original studies, additional compounds were tested and were not substrates for any species.

^cIn a study of swine *Brachyspira* isolates, D-ribose fermentation was found to be a unique trait of *Brachyspira pilosicoli* strains (Fossi and Skrzypczak, 2006).

NADH oxidase is universally present in *Brachyspira* species (Atyeo et al., 1999; Stanton et al., 1995). *Brachyspira* species produce higher amounts of H₂ than CO₂, indicative of the NADH-ferredoxin oxidoreductase reaction. Ethanol is produced in cultures of *Brachyspira pilosicoli*, *Brachyspira alvinipulli*, *Brachyspira murdochii*, *Brachyspira intermedia*, and *Brachyspira innocens* (Stanton, 1989; Stanton et al., 1997, 1998; Stanton and Lebo, 1988; Trott et al., 1996b, c). The major endproducts of glucose metabolism by growing cells of various *Brachyspira* species are the same as those of *Brachyspira hyodysenteriae* (Table 130). For this reason, the species are likely to have similar catabolic routes.

Iron metabolism. Several observations suggest that specific iron uptake mechanisms are present and are important for brachyspire growth in animal hosts. *Brachyspira hyodysenteriae* cells grow in broth containing an iron chelator, 2,2'-dipyridyl, and increase the expression of three unidentified high molecular mass proteins, >200, 134, and 109 kDa (Li et al., 1995). A *Brachyspira hyodysenteriae* genome locus, designated *bit* ("*Brachyspira* iron transport"), encodes six proteins that are likely to form an iron ATP-binding transport system (Dugourd et al., 1999).

Genome properties. The *Brachyspira hyodysenteriae* B78^T chromosome is circular and 3.2 Mbp (megabase pairs) in size

(Zuerner and Stanton, 1994). *Brachyspira pilosicoli* P43/6/78^T has a circular chromosome approximately 2.4 Mb (Zuerner et al., 2004). The *Brachyspira hyodysenteriae* and *Brachyspira pilosicoli* genomes are currently being sequenced under proprietary circumstances by private corporations. The genomes of the spirochetes *Brachyspira hyodysenteriae*, *Leptospira interrogans*, *Borrelia* spp., *Treponema pallidum* and *Treponema denticola* differ from one another in terms of chromosomal conformation (linear and circular), chromosomal numbers (two for *Leptospira interrogans*), size (0.95–4.9 Mb), and number and arrangement of rRNA genes (Zuerner, 1997).

Plasmids. Uncharacterized plasmids and extrachromosomal DNAs have been reported for various *Brachyspira* species (Cattani et al., 1998; Combs et al., 1989; Turner and Sellwood, 1997). Some of the extrachromosomal DNAs (Combs et al., 1989; Turner and Sellwood, 1997) are likely to be DNA from VSH-1-like bacteriophage particles spontaneously produced in brachyspire cultures. Plasmid DNA was not detected for *Brachyspira hyodysenteriae* B78^T (Zuerner and Stanton, 1994).

Prophage-like gene transfer agent (VSH-1). When treated with mitomycin C, both *Brachyspira hyodysenteriae* and *Brachyspira innocens* cells lyse and release bacteriophage-like particles (Humphrey et al., 1995). One of these prophages was purified from *Brachyspira hyodysenteriae* strain B204 cultures and was named VSH-1 (Humphrey et al., 1997). VSH-1 virions package random, 7.5 kb linear fragments of bacterial DNA. The purified virions are noninfectious, that is, they do not lyse bacteria or form plaques, and behave like generalized transducing phages (Humphrey et al., 1997; Stanton et al., 2001). The VSH-1 genome (GenBank no. AY971355) encodes head, tail, and lytic proteins (Matson et al., 2005) and is 16.5 kb (substantially larger than the virion packaged DNA). Based on MLEE analysis of *Brachyspira hyodysenteriae* strains, Trott et al. (1997c) concluded that substantial genetic recombination, likely mediated by VSH-1 gene transfer, has shaped the overall population structure of this species. VSH-1 is the first natural gene transfer mechanism to be discovered for a spirochete.

Bacteriophages have also been detected by electron microscopy in both mitomycin C-treated and untreated cultures of weakly hemolytic human intestinal spirochetes (Calderaro et al., 1998a, b). These bacteriophages resemble VSH-1 in size and morphology.

Genetic techniques – mutagenesis. *Brachyspira hyodysenteriae* strains can be mutated by allelic exchange at specific loci (Li et al., 2000; Rosey et al., 1995, 1996; Stanton et al., 1999; ter Huurne et al., 1992). By this method, *Brachyspira hyodysenteriae* genes cloned in *Escherichia coli* are inactivated *in vitro* by inserting an antimicrobial (kanamycin, chloramphenicol) resistance marker into the gene. The constructs are then introduced as plasmids into *Brachyspira hyodysenteriae* cells by electroporation. The allelic exchange technique yields mutant strains that are isogenic, except for single genetic loci, to their progenitor strains. Such strains are invaluable in determining bacterial virulence traits.

UV mutagenesis has been used to generate coumermycin A1-resistant *Brachyspira hyodysenteriae* strains with mutations in *gyrB* (DNA gyrase) genes (Stanton et al., 2001). Coumermycin resistance is an antibiotic selection marker for genetic manipulations of *Brachyspira*. Another useful selection marker is tylosin resistance. Some *Brachyspira hyodysenteriae* strains are naturally

resistant to tylosin, owing to a nucleotide base change in the 23S rRNA gene (Karlsson et al., 1999).

Serotype analysis. *Brachyspira hyodysenteriae* strains have been subdivided into serotypes based on the immunological reactivities of lipo-oligosaccharides (LOS) in hot water-phenol extracts of whole cells (Baum and Joens, 1979; Li et al., 1991). A more elaborate system of immunological identification assigns *Brachyspira hyodysenteriae* strains to serogroups and subdivides the groups into serovars (Hampson et al., 1989, 1997; Lau and Hampson, 1992). This latter system has not been widely adopted because serogroups are not entirely consistent with genetic groupings based on MLEE analysis (Lee et al., 1993; Trott et al., 1997a). Enzyme-linked immunosorbent assay (ELISA) methods based on antibodies to LOS have been used to detect animal herd exposure to *Brachyspira hyodysenteriae* strains (Joens et al., 1982; Wright et al., 1989).

Antibiotic sensitivity. *Brachyspira hyodysenteriae* and other *Brachyspira* species are naturally insensitive to the antibiotics rifampin, spectinomycin, polymyxin B, and colistin at concentrations which limit growth of other intestinal bacteria (Buller and Hampson, 1994; Messier et al., 1990; Taylor and Trott, 1997; Trott et al., 1996c). Consequently, individual antibiotics or combinations of these antibiotics are useful for selectively culturing *Brachyspira hyodysenteriae* and other species (Jenkinson and Wingar, 1981; Kunkle and Kinyon, 1988).

There is evidence that *Brachyspira hyodysenteriae* and *Brachyspira pilosicoli* strains are becoming resistant to antimicrobials used to treat swine dysentery and porcine intestinal spirochetosis. These antimicrobials belong to the macrolide (i.e., tylosin, erythromycin), lincosamide (i.e., lincomycin, clindamycin), and pleuromutilin (i.e., tiamulin) classes of antibiotics (Duhamel et al., 1998a; Karlsson et al., 2003; Lobo et al., 2004; Pringle et al., 2006). Simultaneous resistance to both macrolide and lincosamide antimicrobials results from single nucleotide base changes in the 23S rRNA sequences of these spirochetes (Karlsson et al., 1999, 2004). Tiamulin resistance in a clinical isolate of *Brachyspira hyodysenteriae* has been associated with an amino acid change in ribosomal protein L3 (Pringle et al., 2004).

***Brachyspira* diseases and virulence-associated traits.** *Brachyspira hyodysenteriae*, *Brachyspira pilosicoli*, *Brachyspira intermedia*, and *Brachyspira alvinipulli* cause intestinal disease when inoculated into their healthy host animals (Table 130). Most disease-related research has focused on *Brachyspira hyodysenteriae*, the etiologic agent of swine dysentery. Several publications have described and reviewed brachyspire diseases from the viewpoints of host manifestations, clinical detection methods, therapies, and experimental models (Barrett, 1997; Galvin et al., 1997; Hampson et al., 1997; Hampson and Trott, 1999; Harris et al., 1999; Swayne, 2003; Swayne and McLaren, 1997; Taylor and Trott, 1997).

Swine dysentery (*Brachyspira hyodysenteriae*). Swine dysentery (bloody scours or black scours) is a severe intestinal disease that affects piglets, primarily in the postweaning stage of growth (8–14 weeks after birth). The disease has been reported worldwide in every major pig producing country. A typical sign of the disease is profuse bleeding into the large bowel lumen through lesions induced by *Brachyspira hyodysenteriae* cells. Afflicted animals pass loose stools containing blood and mucus and spirochetes readily seen by microscopy. These are presumptive signs of the disease. Culturing and identifying *Brachyspira*

hyodysenteriae cells, along with histopathological observations, provide conclusive evidence of swine dysentery. Up to 90–100% of a herd can become infected, and without effective treatment, 20–30% of infected animals may die. Economic losses result from death, poor weight gain/feed efficiency, and medication expenses. Swine management strategies, including segregation by age and prophylactic administration of antibiotics (such as tylosin, lincomycin, and carbadox), are credited with reducing swine dysentery in the United States. Swine dysentery can be experimentally produced by feeding or intragastrically inoculating normal swine with *Brachyspira hyodysenteriae* cultures (Kennedy et al., 1988; Kinyon et al., 1977). However, the type strain B78^T is weakly virulent and not useful for experimental infections (Jensen and Stanton, 1993). Various approaches have been used to develop whole cell or cell subunit-based vaccines for swine dysentery (Lee et al., 2000). A commercial vaccine for swine dysentery is based on pepsin-digested *Brachyspira hyodysenteriae* cells. The immunological properties of the vaccine are now being examined (Waters et al., 2000).

Swine are the common, but not the exclusive, animal hosts for *Brachyspira hyodysenteriae*. Strains of the spirochete also have been isolated from juvenile rheas with a severe necrotizing typhlitis (Buckles et al., 1997; Jensen et al., 1996; Sagartz et al., 1992). For experimental infections, mice (Joens and Glock, 1979; Nibbelink and Wannemuehler, 1992; Rosey et al., 1996; ter Huurne et al., 1992) and 1-day-old chicks (Sueyoshi et al., 1987) have been used. Nevertheless, nuances or inconsistencies are associated with the use of these surrogate animal models (Achacha et al., 1996; Jensen and Stanton, 1993). For this reason, conclusions regarding *Brachyspira hyodysenteriae* pathogenesis based on alternative animal models should be confirmed through the use of swine infections.

Several *Brachyspira hyodysenteriae* properties are putative or demonstrated virulence-associated traits. They include lipopoligosaccharide (Greer and Wannemuehler, 1989; Nibbelink and Wannemuehler, 1991; Nuessen et al., 1982, 1983), hemolysin/hemolytic activity (Hsu et al., 2001; Hutto and Wannemuehler, 1999; Kent et al., 1988; Lysons et al., 1991; Saheb et al., 1980, 1981; ter Huurne et al., 1992, 1994), chemotaxis/motility (Glock et al., 1974; Kennedy et al., 1988; Kennedy and Yancey, 1996; Milner and Sellwood, 1994), oxygen metabolism/NADH oxidase (Stanton, 1997; Stanton and Jensen, 1993), and variable surface proteins (Gabe et al., 1998). The swine host immune response also likely contributes to the pathology of swine dysentery (Hontecillas et al., 2005).

The ability to create strains with specific gene mutations has enabled direct evidence of a link between virulence and NADH oxidase activity, motility/flagella, and hemolytic activity. Mutant strains with specific deletions of *nox* (Stanton et al., 1999), *flaA* or *flaB* (Kennedy et al., 1997), or *tlyA* (Hyatt et al., 1994; Joens, 1997; ter Huurne et al., 1992) are avirulent compared to their isogenic wild-type counterparts. Although *tlyA*, *tlyB*, and *tlyC* were originally identified as hemolysin genes (Muir et al., 1992; ter Huurne et al., 1992, 1994), a subsequent study raises questions about that identification (Hsu et al., 2001).

Spirochetel colitis and spirochetel diarrhea (*Brachyspira pilosicoli*). Spirochetel colitis caused by *Brachyspira pilosicoli* is a mild to moderate diarrheal disease of swine, birds, and possibly humans (Hampson and Trott, 1999; Swayne and McLaren, 1997; Taylor and Trott, 1997). Spirochetel colitis of swine

resembles a mild case or early stage of swine dysentery. Watery, mucoid diarrhea and a reduction of growth rate of affected animals are common clinical signs. The disease has been experimentally produced by inoculating pure cultures of *Brachyspira pilosicoli* into healthy swine (Taylor and Alexander, 1971; Thomson et al., 1997; Trott et al., 1996a).

Evidence that *Brachyspira pilosicoli* is a pathogen of humans is circumstantial but multifarious. *Brachyspira pilosicoli* strains have been isolated from humans, including some (homosexual males and persons living in developing countries) with intestinal disorders and who are immunocompromised (Barrett, 1997; Trott et al., 1997a, b). Human strains are virulent for healthy piglets (Trott et al., 1996a). A human volunteer became colonized after drinking cultures of *Brachyspira pilosicoli* strain Wes B (Oxberry et al., 1998). Finally, *Brachyspira pilosicoli* has been isolated from the blood of human patients (Trott et al., 1997a). The significance and the capacity of *Brachyspira pilosicoli* cells to leave the intestinal tract and circulate throughout the host's body have not been sufficiently investigated.

Virulence factors of *Brachyspira pilosicoli* are unknown. By virtue of their location, outer-membrane proteins undoubtedly mediate interactions between spirochete cells and their environment and are logically involved in host colonization and virulence (Trott et al., 2001, 2004). Cell motility, chemotaxis, and spirochete end-on attachment to host tissues are likely to be associated with colonization of the intestinal tract and therefore important for pathogenesis. In the absence of gross lesions, extensive colonization of intestinal tissues by *Brachyspira pilosicoli* cells with associated damage to microvilli could interfere with intestinal absorptive processes and lead to diarrhea (Gad et al., 1977; Taylor and Trott, 1997).

Avian intestinal spirochetosis. Many studies of avian intestinal infections associated with spirochetes were made before *Brachyspira* species had been characterized and taxonomically defined (Davelaar et al., 1986; Dwars et al., 1989; Griffiths et al., 1987). Avian diarrheal diseases can be caused by different *Brachyspira* species (Swayne, 2003; Swayne and McLaren, 1997). In addition to *Brachyspira pilosicoli* and *Brachyspira hyodysenteriae*, *Brachyspira alvinipulli* C1^T, isolated from a diarrheic chicken, is a chicken enteropathogen. The C1^T cells colonize the ceca of 1-day-old chicks and 14-month-old hens and produce mild typhlitis with discolored and watery cecal contents (Swayne et al., 1995). *Brachyspira alvinipulli* has been isolated only from poultry and resembles an uncharacterized enteropathogenic spirochete (Davelaar et al., 1986).

Brachyspira intermedia appears to be another common avian enteropathogen, inasmuch as spirochetes of that species have been isolated from birds with moderate intestinal colitis (Stephens and Hampson, 2001; Swayne, 2003; Swayne and McLaren, 1997). One-day-old chicks inoculated with pure cultures of an intestinal spirochete strain 1380, later identified by MLEE analysis as a strain of *Brachyspira intermedia* (Swayne and McLaren, 1997), shed watery feces containing spirochetes and had body weight reduction compared to control birds (Dwars et al., 1992). Avian *Brachyspira intermedia* strain HB60 isolated from a hen with diarrhea causes reduced egg production and watery feces when inoculated into healthy hens (Hampson and McLaren, 1999). A *Brachyspira intermedia* strain, freshly isolated from a swine herd with diarrhea, however, was not pathogenic for swine (Jensen et al., 2000). Virulence traits of avian enteropathogenic *Brachyspira* species have yet to be determined.

Enrichment and isolation procedures. *Brachyspira hyodysenteriae* and other *Brachyspira* species can be isolated by inoculating intestinal contents or tissues onto solid agar culture media containing antibiotics selective for the growth of those spirochetes (Calderaro et al., 2001; Hovind-Hougen et al., 1982; Jenkinson and Wingar, 1981; Kunkle and Kinyon, 1988). Achacha and Messier (1992) compared various selective media and found BJ medium containing spiramycin, rifampin, vancomycin, colistin, and spectinomycin provided the highest rate of isolation of *Brachyspira hyodysenteriae* from feces of experimentally infected swine.

Physical methods (filtration, agar migration) can be used to isolate *Brachyspira* species from intestinal contents and tissues (Harris et al., 1972b; Olson, 1996; Taylor and Alexander, 1971). These methods take advantage of the small diameter of brachyspire cells and their active motility in agar-containing media.

Maintenance procedures

Broth cultures of most *Brachyspira* species remain viable when stored at 5°C for 1–2 weeks and can be used as “working” stock cultures to inoculate fresh cultures for experiments. The refrigerated cultures should be in exponential growth phase (approx. 2×10^8 cells/ml, direct microscope counts). Oxygen exposure must be prevented for example by sealing stoppered culture tubes with plastic tape (3M Scotch #471) before storage. Long-term *in vitro* passage of strains (with possible loss of virulence) should be avoided by starting fresh working stock cultures from long-term stock cultures every several months.

Agar plate cultures with colonies of *Brachyspira hyodysenteriae* can be stored at room temperature in an anaerobic atmosphere for at least a week. The plates should be sealed (Parafilm) to prevent desiccation. A slowly growing spirochete identified as *Brachyspira aalborgi* remained viable when kept at room temperature in an anaerobic jar for over 3 months (Kraaz et al., 2000).

For long-term storage, brachyspire broth cultures in the exponential phase of growth are harvested by centrifugation (15 min, $5000 \times g$). The pelleted bacteria are resuspended at 50–100 times their original concentration in fresh sterile broth medium containing dimethylsulfoxide [DMSO; 10% (v/v), final concentration]. The cell suspension is dispensed into Nunc cryovials (0.5–1.0 ml/vial). The sealed vials are placed upright in a beaker containing enough 95% ethanol to equal the fluid level of the suspensions (and well below the tops of the cryovials). The ethanol bath provides a more uniform rate of freezing of the cells and, with the DMSO as a cryoprotectant, prevents ice crystals from damaging the bacteria. The beaker is placed in an ultra-cold freezer (–75°C). After 24 h, the frozen stock cultures are transferred to storage boxes in the freezer. After 7–10 d, a cryovial should be examined to insure recovery of contaminant-free brachyspire cells. Brachyspire cells have remained viable in frozen stocks prepared in this way for over 20 years (T.B. Stanton, unpublished observations). Completely thawed stocks should not be refrozen. However, it is often possible to subculture without thawing the frozen stocks, by scraping the surface of a frozen cell suspension with a sterile inoculation loop and inoculating fresh media with the ice scrapings. *Brachyspira hyodysenteriae* cultures also have been preserved by lyophilization (Stanton and Lebo, 1988).

Taxonomic comments

In the past 25 years, there have been several taxonomic changes for spirochetes now assigned to the genus *Brachyspira*. Initially, the designation *Treponema hyodysenteriae* was applied to both patho-

genic (strongly hemolytic) and nonpathogenic (weakly hemolytic) strains of intestinal spirochetes from swine. Miao and colleagues (1978) found that these pathogenic and nonpathogenic strains share only 28% DNA homology, and the nonpathogenic strains were reclassified as a new species, *Treponema innocens* (Kinyon and Harris, 1979). In 1991, Stanton et al. proposed a reclassification of *Treponema hyodysenteriae* and *Treponema innocens* to a new genus “*Serpula*” on the basis primarily of 16S rRNA sequence and DNA homology analyses. The genus name *Serpula* was subsequently changed to *Serpulina* after it was determined that *Serpula* had prior use as a name for a genus of fungi (Stanton, 1992). More recently, Ochiai et al. (1997) proposed the unification of the genera *Serpulina* and *Brachyspira*. The genus name *Brachyspira* was first given to a human intestinal isolate, *Brachyspira aalborgi*, in 1982 (Hovind-Hougen et al., 1982). Due to the use of the genus name *Brachyspira* prior to the genus designation *Serpulina*, this proposed change is consistent with International Taxonomic rules governing bacterial nomenclature. This action raised *Brachyspira aalborgi*, currently considered a commensal member of the human intestinal microbiota, to the status of type species of the genus *Brachyspira*. *Brachyspira aalborgi* has been characterized to a limited extent (Hovind-Hougen et al., 1982; Ochiai et al., 1997) and additional biochemical, physiological, and genetic investigations of this *Brachyspira* type species are needed.

Ochiai et al. (1997) proposed the reassignment of *Serpulina hyodysenteriae* (the *Serpulina* type species), *Serpulina innocens*, and *Serpulina pilosicoli* to the genus *Brachyspira*. Unfortunately, prior to the publication of this proposal, the species *Serpulina intermedia* and *Serpulina murdochii* were described and validly named as two new species within the genus *Serpulina* based on their similarities to *Serpulina hyodysenteriae* (Stanton et al., 1997). For taxonomic and phylogenetic reasons, *Serpulina intermedia* and *Serpulina murdochii* should be reassigned to the genus *Brachyspira* and a proposal has been submitted for this reassignment (T.B. Stanton, unpublished). Thus, both species are included in this section describing the genus *Brachyspira*.

16S rRNA gene sequence comparisons indicate that members of the genus *Brachyspira* belong within the family *Spirochetaceae* and are clearly distinct from the other genera of spirochetes (Figure 98). Members of the genus *Brachyspira* cluster closely together, with several species at greater than 99% similarity. However, a phylogenetic tree with similar topology is also obtained for the phylogenetic analysis of the sequences of NADH (*nox*) genes (Mikoszka et al., 2004). Other methods described below, such as MLEE, have been used to better differentiate closely related members of the genus.

Differentiation of the species of the genus *Brachyspira*

For taxonomic purposes, *Brachyspira* species can be differentiated by MLEE (multilocus enzyme electrophoresis) and DNA homology methods. In the clinical laboratory, the cultivation of strongly (β -) hemolytic spirochete colonies from the feces of dysenteric animals has been used for reliable identification of *Brachyspira hyodysenteriae* when this hemolytic type is linked to histopathology and animal disease signs. It is more difficult to differentiate “non-*hyodysenteriae*” *Brachyspira* species, all of which form weakly hemolytic (nonhemolytic) colonies for several reasons. Nonpathogenic and pathogenic species which are both nonhemolytic can be present in the same clinical samples. Diseases caused by the weakly hemolytic species are often economic diseases associated with poor animal performance

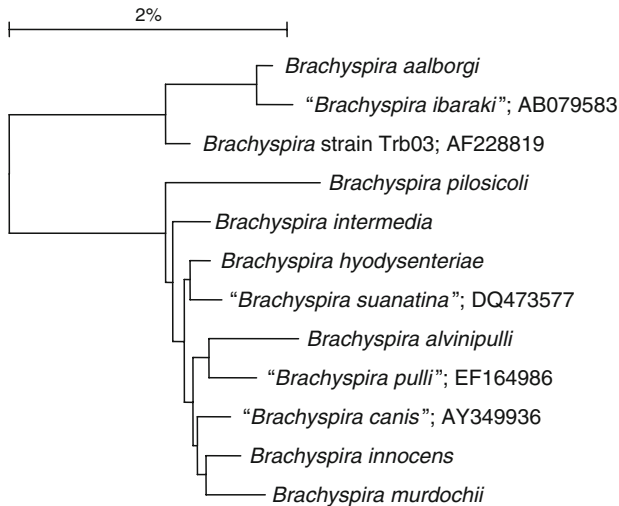

FIGURE 98. Dendrogram illustrating the phylogenetic positions of members of the genus *Brachyspira*. Species that have provisional names are indicated by quotation marks.

rather than diseases with high mortality and severe clinical signs. A further complicating factor for any clinical diagnostic test is that additional, uncharacterized *Brachyspira* species are likely to be in the intestinal tracts of humans and animals (Jansson et al., 2001; Pettersson et al., 2000).

Species differentiation based on biochemical tests (hippurate hydrolysis, indole production, and α -galactosidase and β -glucosidase) (Table 130) and 16S rRNA based RFLP-PCR methods have been proposed for differentiating swine brachyspires (Fellstrom et al., 1995, 1997). There is growing evidence, however, that *Brachyspira* species from swine at different geographical locations

and from different animal species give inconsistent results in these biochemical tests (Fellstrom et al., 1999; Fossi et al., 2004; Stephens et al., 2005). Both the 16S rRNA and 23S rRNA sequences of *Brachyspira* species are highly conserved, although a 16S rRNA signature region was identified for *Brachyspira pilosicoli* and has been used effectively in a PCR assay for that species (Park et al., 1995). Various PCR techniques based on the *nox* gene are currently being tested to differentiate *Brachyspira* species in poultry and swine (La et al., 2003; Rohde et al., 2002; Townsend et al., 2005).

List of species of the genus *Brachyspira*

- Brachyspira aalborgi*** Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1983, 896^{VP} (Effective publication: Hovind-Hougen, Birch-Andersen, Henrik-Nielsen, Orholm, Pedersen, Teglbjaerg and Thaysen 1982, 1135^{VP}.)

a.al.bor'gi. N.L. gen. n. *aalborgi* of Aalborg, named for the Danish town Aalborg in which the rectal biopsies containing the spirochete were taken from human diarrhetic patients.

Exhibit characteristics common to the genus *Brachyspira*. Additional characteristics of the species are given in Tables 130 and 131. Electron microphotographs of *Brachyspira aalborgi* cells have been published (Hovind-Hougen et al., 1982). Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation. *Brachyspira aalborgi* 513A exhibits 17–22% DNA–DNA relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira innocens* B256^T, and *Brachyspira pilosicoli* P43/6/78^T (filter hybridization method) (Ochiai et al., 1997).

Weakly hemolytic colonies on trypticase soy blood agar. Negative for indole production and positive for esculin hydrolysis. Ferments soluble carbohydrates (Table 131). Products of glucose metabolism have not been determined. Possess β -galactosidase and esterase, acid phosphatase, and phosphoamidase activities. Catalase-negative. *Brachyspira aalborgi* is not considered a pathogen.

Source: human intestinal tissues and contents.

DNA G+C content (mol%): 27.1 (T_m) for strain 513A.

Type strain: 513A, ATCC 43994, CIP 104603, NCTC 11492.

Sequence accession no. (16S rRNA gene): Z22781 (NCTC 11492).

- Brachyspira alvinipulli*** Stanton, Postic and Jensen 1998, 675^{VP}

al.vi.ni.pul'li. L. adj. *alvinus* -a -um suffering from diarrhea; L. n. *pullus* a young fowl, a chicken; N.L. gen. n. *alvinipulli* of a diarrhaeic chicken, referring to the host animal from which spirochete was isolated.

Exhibit characteristics common to the genus *Brachyspira*. A phase-contrast microphotograph and an electron micrograph of *Brachyspira alvinipulli* C1 cells have been published (Stanton et al., 1998). Additional characteristics of the species are given in Tables 130 and 131. Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation and MLEE analysis. Exhibits 24–39% DNA–DNA relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira innocens* B256^T, *Brachyspira pilosicoli* P43/6/78^T, *Brachyspira intermedia* PWS/A^T, and *Brachyspira murdochii* 56-150^T based on the S1 nuclease method (Stanton et al., 1998).

Weakly hemolytic colonies on trypticase soy blood agar. Grows optimally (3×10^8 to 10^9 cells/ml, direct cell counts) at 37–39°C in BHIS broth or HS broth containing carbohydrates (Table 131). Products of glucose metabolism include

acetate, butyrate, CO₂, H₂, and ethanol. Positive in tests for hippurate hydrolysis, β-glucosidase, β-galactosidase, alkaline phosphatase, indoxyl acetate hydrolysis, arginine aminopeptidase, alanine aminopeptidase, and glycine aminopeptidase. Negative for indole production and catalase activity.

Shares high 16S rRNA gene sequence similarity (96–99%) with other *Brachyspira* species. Intestinal pathogen of chickens.

DNA G+C content (mol%): 24.6 (*T_m*) (strain C1).

Type strain: C1 (91–1207/C1), ATCC 51933, CIP 105681.

Sequence accession no. (16S rRNA gene): U23030 (strain C1).

3. ***Brachyspira hyodysenteriae*** (Harris, Glock, Christensen and Kinyon 1972a) emend. Ochiai, Adachi and Mori 1998, 327^{VP} (*Treponema hyodysenteriae* Harris, Glock, Christensen and Kinyon 1972a, 64^{AL}). Other synonyms: *Serpula hyodysenteriae* (Harris, Glock, Christensen and Kinyon 1972a) Stanton, Jensen, Casey, Tordoff, Dewhirst and Paster 1991, 56; *Serpulina hyodysenteriae* (Harris, Glock, Christensen and Kinyon 1972a) Stanton 1992, 189

hyo.dy.sen.te.ri'ae. Gr. n. *hyos* hog, pig; L. n. *dysenteria* a flux, dysentery; N.L. gen. n. *hyodysenteriae* of hog dysentery. In recognition of the species as the etiologic agent of swine dysentery.

Exhibits characteristic common to the genus *Brachyspira*. Phase-contrast photomicrographs and electron photomicrographs of cells have been published (Kinyon et al., 1977; Trott et al., 1996b). Additional characteristics of the species are given in Tables 130 and 131. Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation, MLEE analysis. Strain B78^T exhibits 22% DNA–DNA relative reassociation with *Brachyspira aalborgi* NCTC 11492^T, based on the filter hybridization method (Ochiai et al., 1997). Strain B78^T exhibits 27–57% DNA–DNA relative reassociation with *Brachyspira innocens* B256^T, *Brachyspira pilosicoli* P43/6/78^T, *Brachyspira intermedia* PWS/A^T, *Brachyspira murdochii* 56-150^T, and *Brachyspira alvinipulli* C1^T, based on the S1 nuclease method (Stanton et al., 1998; Trott et al., 1996b). Unlike other *Brachyspira* species, *Brachyspira hyodysenteriae* cells form β-hemolytic (strongly hemolytic) colonies on trypticase soy blood agar and are positive for indole production. Strains have been differentiated according to serotypes, based on soluble antigens in the water phase of cells extracted with hot phenol-water.

Grows at 37–39°C in a variety of anaerobically prepared culture broth media, attaining population densities ≥10⁹ cells/ml (direct cell counts), under optimum conditions. Cholesterol in nutrient amounts is required for growth, presumably for cell membrane biosynthesis. Uses carbohydrates as growth substrates (Table 131). Products of glucose metabolism include acetate, butyrate, CO₂, and H₂. Although considered an anaerobic species, growing cells under certain conditions require low (1%) oxygen tensions and consume substrate amounts of oxygen.

Cells possess NADH oxidase, superoxide dismutase, NADH peroxidase, and inducible catalase activities. Hydrogen is produced via a clostridial-type phosphoroclastic mechanism and via NADH-ferredoxin oxidoreductase. Exhibits alkaline phosphatase, C4 esterase, C8 esterase, lipase, phosphatase acid, β-galactosidase, α-glucosidase, and β-glucosidase activities. Positive for esculin hydrolysis and most strains positive for indole production.

Isolated from intestinal contents and feces of swine, rheas, and other mammals (dogs) in contact with dysenteric feces. *Brachyspira hyodysenteriae* is an intestinal pathogen of swine and rheas. *Brachyspira hyodysenteriae* cells colonize within and between intestinal epithelial cells and the overlying intestinal mucus without cell attachment. The type strain B78 has become nonpathogenic for swine likely due to long-term passage in culture. Strain B204 (ATCC 31212) has commonly been used in the United States for experimental swine infections.

DNA G+C content (mol%): 25.7–25.9% (*T_m*) for strains B204 and A1.

Type strain: B78, ATCC 27164, CCUG 46668, NCTC 13041.

Sequence accession no. (16S rRNA gene): M57743, U14930 (B78).

4. ***Brachyspira innocens*** (Kinyon and Harris 1979, 108) emend. Ochiai, Adachi and Mori 1998, 327^{VP} (*Treponema innocens* Kinyon and Harris 1979, 108^{AL}). Other synonyms: *Serpula innocens* (Kinyon and Harris 1979) Stanton, Jensen, Casey, Tordoff, Dewhirst and Paster 1991, 56; *Serpulina innocens* (Kinyon and Harris 1979) Stanton 1992, 189

in'no.cens. L. fem. adj. *innocens* harmless, inoffensive (referring to non-pathogenic nature of the species for swine).

Exhibit characteristics common to the genus *Brachyspira*. Additional characteristics of the species are given in Tables 130 and 131. Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation and MLEE analysis. Strain B256 exhibits 19% DNA–DNA relative reassociation with *Brachyspira aalborgi* NCTC 11492, based on the filter hybridization method (Ochiai et al., 1997). Strain B256 exhibits 26–66% relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira pilosicoli* P43/6/78^T, *Brachyspira intermedia* PWS/A^T, *Brachyspira murdochii* 56-150^T, and *Brachyspira alvinipulli* C1^T based on the S1 nuclease method (Stanton et al., 1998; Trott et al., 1996b).

Weakly hemolytic colonies on trypticase soy blood agar. Uses carbohydrates as growth substrates (Table 131). Grows optimally (9 × 10⁸ to 1.5 × 10⁹ cells/ml, direct counts) at 37–39°C in BHIS broth or HS broth containing carbohydrates (Table 131). Products of glucose metabolism include acetate, butyrate, CO₂, H₂, and ethanol. Population doubling times are 3–5 h. Does not produce indole, hydrolyzes esculin.

Brachyspira innocens is not considered a pathogen.

Source: intestinal contents of healthy pigs, dogs, chickens.

DNA G+C content (mol%): 25.6–25.8% (*T_m*) (strain B256).

Type strain: B256, ATCC 29796, CCUG 17081.

Sequence accession no. (16S rRNA gene): M57744 (strain B256).

5. ***Brachyspira intermedia*** (Stanton, Fournié-Amazouz, Postic, Trott, Grimont, Baranton, Hampson and Saint Girons 1997) emend. Hampson and La 2006, 1011^{VP} (*Serpulina intermedia* Stanton, Fournié-Amazouz, Postic, Trott, Grimont, Baranton, Hampson and Saint Girons 1997, 1011)

in.ter.me'di.a. L. fem. adj. *intermedia* which is in the middle, referring to the fact that biochemical traits are intermediate between those possessed only by *Brachyspira hyodysenteriae* or by *Brachyspira innocens*.

Exhibit characteristics common to the genus *Brachyspira*. Additional characteristics of the species are given in Tables

130 and 131. Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation and MLEE analysis. Also called “*Serpulina intermedius*”. Some intestinal spirochetes referred to as “*Treponema hyodysenteriae* biotype 2” or “intermediate type” may be *Brachyspira intermedia* strains. Strain PWS/A exhibits 26–68% DNA–DNA relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira innocens* B256^T, *Brachyspira pilosicoli* P43/6/78^T, *Brachyspira murdochii* 56-150^T, and *Brachyspira alvinipullii* C1^T, based on the S1 nuclease method (Stanton et al., 1997, 1998).

Weakly to “intermediate” hemolytic colonies on trypticase soy blood agar. Uses carbohydrates as growth substrates (Table 131). Grows optimally (1.1×10^9 to 1.6×10^9 cells/ml, direct counts) at 37–39°C in BHIS broth or HS broth containing carbohydrates (Table 131). Products of glucose metabolism include acetate, butyrate, CO₂, H₂, and ethanol. Hydrolyzes esculin. Does not hydrolyze hippurate. Lacks α-galactosidase and possesses α-glucosidase and β-glucosidase activities.

Brachyspira intermedia strains have been isolated from swine, including swine with diarrhea and from commercial poultry flocks exhibiting diarrhea. Avian intestinal infections by *Brachyspira intermedia* are aptly described as “economic disease” due to production losses in flocks. Birds colonized by *Brachyspira intermedia* typically do not die and may even appear healthy. There is some thought that disease severity is either strain related or influenced by the animal diet or other environmental factors.

DNA G+C content (mol%): 25 (T_m) (strain PWS/A^T).

Type strain: PWS/A^T, ATCC 51140, CIP 105833.

Sequence accession no. (16S rRNA gene): U23033 (strain PWS/A).

6. ***Brachyspira murdochii*** (Stanton, Fournié-Amazouz, Postic, Trott, Grimont, Baranton, Hampson and Saint Girons 1997) emend. Hampson and La 2006, 1011^{VP} (*Serpulina intermedia* Stanton, Fournié-Amazouz, Postic, Trott, Grimont, Baranton, Hampson and Saint Girons 1997, 1011)

mur.do'chi.i. N.L. masc. gen. n. *murdochii* of Murdoch, named in recognition of work conducted at the Murdoch University in Western Australia where the type strain was identified.

Exhibit characteristics common to the genus *Brachyspira*. Additional characteristics of the species are given in Tables 130 and 131. Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation and MLEE analysis. Strain 56-150^T exhibits 27–66% DNA–DNA relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira innocens* B256^T, *Brachyspira pilosicoli* P43/6/78^T, *Brachyspira intermedia* PWS/A^T, and *Brachyspira alvinipullii* C1^T, based on the S1 nuclease method (Stanton et al., 1997, 1998).

Weakly hemolytic colonies on trypticase soy blood agar. Grows optimally (9×10^8 to 1.5×10^9 cells/ml, direct counts) at 37–39°C in BHIS broth or HS broth containing carbohydrates (Table 131). Products of glucose metabolism include acetate, butyrate, CO₂, H₂, and ethanol. Does not produce indole. Does not hydrolyze hippurate. Cells lack α-galactosidase, α-glucosidase, and possess β-glucosidase activities.

Not considered a pathogen.

Source: Intestinal contents of healthy swine and rats.

DNA G+C content (mol%): 27 (T_m) (strain 56-150).

Type strain: 56-150, ATCC 51254, CIP 105832, DSM 12563.

Sequence accession no. (16S rRNA gene): AY312492 (strain 56-150).

7. ***Brachyspira pilosicoli*** (Trott, Stanton, Jensen, Duhamel, Johnson and Hampson 1996b) emend. Ochiai, Adachi and Mori 1998, 327^{VP} (*Serpulina pilosicoli* Trott, Stanton, Jensen, Duhamel, Johnson and Hampson 1996b, 213)

pi.lo.si'co.li. L. adj. *pilosus* -a -um hairy, napped, shaggy; L. n. *colon* or *colum* the colon; N.L. gen. n. *pilosicoli*, of a hairy colon (referring to the fact that infection and attachment by this intestinal spirochete can result in the histological appearance of a hairy covering, false brush border, on the surface of the colon).

Exhibit characteristics common to the genus *Brachyspira*. Additional characteristics of the species are given in Tables 130 and 131. Phase-contrast photomicrographs and electron microphotographs of *Brachyspira pilosicoli* cells have been published (Trott et al., 1996b). Differentiated from other *Brachyspira* species by DNA–DNA relative reassociation, MLEE analysis, and by a signature nucleotide sequence (5'-AGUUUUUCGCUUCA-3') in the 16S rRNA. The 16S rRNA signature sequence has been useful in clinical identification of *Brachyspira pilosicoli*. Alternative designations are *Anguillina coli* and *Serpulina pilosicoli*. Strain P43/6/78 exhibits 17% DNA–DNA relative reassociation with *Brachyspira aalborgi* NCTC 11492 based on the filter hybridization method (Ochiai et al., 1997). Strains P43/6/78 and WES-B exhibit 21–28% DNA–DNA relative reassociation with *Brachyspira hyodysenteriae* B78^T, *Brachyspira innocens* B256^T, *Brachyspira intermedia* PWS/A^T, *Brachyspira murdochii* 56-150^T, and *Brachyspira alvinipullii* C1^T, based on the S1 nuclease method (Stanton et al., 1997, 1998).

Weakly hemolytic colonies on trypticase soy blood agar. Grows optimally (1.5×10^9 to $>2.0 \times 10^9$ cells/ml, direct counts) at 37–39°C in BHIS broth or HS broth containing carbohydrates (Table 131). Products of glucose metabolism include acetate, butyrate, CO₂, H₂, and ethanol. Strains lack β-glucosidase activity.

Brachyspira pilosicoli is considered an intestinal pathogen, the etiological agent of intestinal spirochetosis. Isolated from swine with watery, mucoid diarrhea. Swine intestinal spirochetosis clinically resembles early, mild stages of swine dysentery. Typical of the disease is the attachment of *Brachyspira pilosicoli* cells by one end to colonic epithelial cells. *Brachyspira pilosicoli* has been found in intestinal contents of birds, dogs, humans, and non-human primates. *Brachyspira pilosicoli* is being investigated as a possible enteropathogen of humans, dogs, and poultry.

DNA G+C content (mol%): 25 ± 1 (T_m) (strain P43/6/78).

Type strain: P43/6/78, ATCC 51139.

Sequence accession no. (16S rRNA gene): U23032 (strain P43/6/78).

Other organisms

There are reports of intestinal spirochetes that are likely to represent new *Brachyspira* species based on their MLEE profiles and comparative analyses of 16S rRNA and NADH oxi-

dase genes (Mikosza et al., 2004). The strains have only been partially characterized and some have been given provisional designations. For example, there are dog-associated spirochetes

- "*Brachyspira canis*" (Duhamel et al., 1998b), chicken-associated spirochetes "*Brachyspira pulli*" also known as group "d" spirochetes (McLaren et al., 1997; Stephens and Hampson, 1999), duck and pig-associated spirochetes "*Brachyspira suanatina*" (Råsbäck et al., 2007), and *Brachyspira aalborgi*-like spirochetes (Mikoszka et al., 2004).

Family III. **Brevinemataceae** fam. nov.

BRUCE J. PASTER

Bre.vi.ne.ma.ta.ce'ae. N.L. fem. n. *Brevinema* -atos type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Brevinemataceae* the *Brevinema* family.

The family *Brevinemataceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences. The family contains only one genus, *Brevinema*.

Description is the same as for the genus *Brevinema*.

Type genus: Brevinema Defosse, Johnson, Paster, Dewhirst and Fraser 1995, 83^{VP}.

Genus I. **Brevinema** Defosse, Johnson, Paster, Dewhirst and Fraser 1995, 83^{VP}

BRUCE J. PASTER

Bre.vi. ne'ma. L. adj. *brevis* short; Gr. neut. n. *nema* thread; N.L. neut. n. *Brevinema* a short thread.

Helical cells are 0.2–0.3 µm in diameter by 4–5 µm in length, displaying one to two helical turns. Irregular wavelengths of the cells range from 2 to 3 µm. Sheathed periplasmic flagella are in a 1:2:1 arrangement. No cytoplasmic tubules have been observed. Cells are motile by flexing, rotation, and translation. **Microaerophilic, host-associated**, isolated from blood and other tissues of short-tailed shrews (*Blarina brevicauda*) and white-footed mice (*Peromyscus leucopus*). Infectious for laboratory mice and Syrian hamsters.

DNA G+C content (mol%): 34–36 (T_m).

Type species: Brevinema andersonii Defosse, Johnson, Paster, Dewhirst and Fraser 1995, 83^{VP}.

Further descriptive information

Strains of *Brevinema andersonii* are homogeneous as based on enzymic, protein profile, and immunoblot data. Furthermore, there are no significant differences in fatty acid composition among the strains analyzed (Defosse et al., 1995). The major fatty acid components of *Brevinema* cells are myristic acid ($C_{14:0}$), palmitic acid ($C_{16:0}$), and oleic acid ($C_{18:1}$) with smaller amounts of stearic acid ($C_{18:0}$) and linoleic acid ($C_{18:2}$). Several fatty acids are present at low levels (less than 1%). Restriction enzyme analysis and SDS-PAGE patterns also demonstrate little or no differences among strains. Consequently, it was suggested that *Brevinema andersonii* represents a genetically homologous group, despite the diverse hosts and different geographic origins (Defosse et al., 1995).

Enrichment and isolation procedures

Brevinema andersonii has been isolated from blood and other tissues of the short-tailed shrew and the white-footed mouse using Shrew-Mouse Spirochete medium under microaerophilic conditions (Defosse et al., 1995). Fetal bovine serum, reducing agents, and peptones are required for growth. Neither supplemental bovine serum albumin, *N*-acetylglucosamine, nor pyruvate is required for growth. Optimal growth is at 30–34°C at pH 7.4 with a generation time of 11–14 h.

Differentiation of the genus *Brevinema* from other genera

Brevinema andersonii is serologically distinct from other spirochetes (Anderson et al., 1987; Defosse et al., 1995). There is little or no DNA–DNA hybridization between *Brevinema andersonii* and members of other spirochetal genera using Southern blot analysis (LeFebvre and Perng, 1989; LeFebvre et al., 1989). At the species level, *Brevinema andersonii* is differentiated using restriction enzyme analysis, SDS-PAGE, or fatty acid composition.

Taxonomic comments

Brevinema andersonii is the only named species for the genus. Based on 16S rRNA gene sequence comparisons, *Brevinema* belongs within the family *Spirochetaceae* and is clearly distinct from the other genera of spirochetes (Paster and Dewhirst, 2000). 16S rRNA sequences of *Brevinema andersonii* do not possess a 20- to 30-base extension at the 5' end, which is typical of 16S rRNA sequences of species of *Treponema*, *Spirocheta*, *Leptospira*, and *Leptonema* (Defosse et al., 1995; Paster et al., 1991).

List of species of the genus *Brevinema*1. ***Brevinema andersonii*** Defosse, Johnson, Paster, Dewhirst and Fraser 1995, 83^{VP}

an.der.so'ni.i. N.L. masc. gen. n. *andersonii* of Anderson, named for John F. Anderson, who first described the organism.

The characteristics are as described for the genus. Chemoorganotrophic. Microaerophilic and catalase-negative. Growth occurs in modified BSK medium at an optimal growth temperature of 30–34°C and an optimal pH of 7.4; under these conditions the generation time is 11–14 h. Does not grow at

25°C. Exhibits the following enzymic activities: C4, C5, C6, C8, C9, and C10 esterases, C4 esterase lipase, alkaline phosphatase, acid phosphatase, and β-glucuronidase.

Source: tissues of a short-tailed shrew (*Blarina brevicauda*) captured in West Haven, Connecticut, USA (Anderson et al., 1987).

DNA G+C content (mol%): 34–36 (T_m).

Type strain: ATCC 43811, CT11616.

Sequence accession no. (16S rRNA gene): M59179.

Family IV. **Leptospiraceae** Hovind-Hougen 1979, 245^{AL} emend. Levett, Morey, Galloway, Steigerwalt and Ellis 2005, 1499

RICHARD L. ZUERNER

Lep.to.spi.ra.ce'ae. N.L. fem. n. *Leptospira* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Leptospiraceae* the *Leptospira* family.

Helical cells, 0.1–0.3 µm in diameter and 3.5–20 µm in length. Cells have right-handed helical conformation. Cells at rest and those that are fixed have hooked ends. Actively motile cells have a spiral anterior end and a hook at the posterior end of the cell. One periplasmic flagellum (historically also referred to as axial filaments, endoflagella, or flagella), is inserted subterminally at each end of cell, but flagella rarely overlap in the center of the cell. Periplasmic flagella lie along the helix axis. **The diamino acid in peptidoglycan is α,ε-diaminopimelic acid.**

Obligate aerobes or microaerophilic. Chemoorganotrophic. **Utilize long-chain fatty acids and fatty alcohols as carbon and energy sources.** Do not use carbohydrates/amino acids as carbon or energy sources.

Free-living or in association with animal and human hosts. Some species are pathogenic.

Species examined by 16S rRNA sequence analysis are distinct from members of *Spirochetaceae*.

DNA G+C content (mol%): 33–53.

Type genus: **Leptospira** Noguchi 1917, 755^{AL}.

Key to the genera of the family *Leptospiraceae*

1. DNA G+C content (mol%) is 33–43% (T_m and genomic sequence analysis). Cells are 0.1 µm in diameter and 6–20 µm in length. Aerobe or microaerophilic. Long-chain fatty acids and long-chain fatty alcohols serve as carbon and energy

sources. Free-living in aquatic environments, including mud, sediments, and water of ponds, lakes, and streams. May be found in fresh water and marine environments. Some species are found in association with animals. Some species are pathogenic.

→Genus I. *Leptospira*

2. DNA G+C content (mol%) is 54% (T_m and Bd). Cells are 0.1–0.2 µm in diameter and 13–15 µm in length, with wavelength of 0.7 µm. Aerobe. Long-chain fatty acids and long-chain fatty alcohols serve as carbon and energy sources. Can grow on trypticase broth. Free-living in aquatic environments, including mud, sediments, and water of ponds, lakes, and streams. May be found in fresh water and marine environments. Type strain was found in association with animals (cattle). Nonpathogenic for hamsters.

→Genus II. *Leptonema*

3. DNA G+C content (mol%) is 48% (T_m and Bd). Cells are 0.3 µm in diameter and 3.5–7.5 µm in length, with wavelength of 0.3–0.5 µm. Obligate aerobe. One periplasmic flagellum. Long-chain fatty acids and long-chain fatty alcohols serve as carbon and energy sources. Oxidase-positive. Found in tap water and in association with animals. Not pathogenic for hamsters.

→Genus III. *Turneriella*

Genus I. **Leptospira** Noguchi 1917, 755^{AL} emend. Faine and Stallman 1982, 461

RICHARD L. ZUERNER

Lep.to.spi'ra. Gr. adj. *leptos* thin, narrow, fine; L. fem. n. *spira* a coil, helix; N.L. fem. n. *Leptospira* a thin helix or coil, referring to the morphology of the bacterium.

Leptospira are **long, thin, flexible rods, 0.1 µm in diameter and 6–12 µm in length**, with a regular right-handed helical coiling pattern (Carleton et al., 1979). These bacteria are unicellular but may be observed as dividing pairs or short chains of three or more cells in actively growing cultures. Resting stages are not known, but long term survival in water, with the appearance of aggregates has been described (Trueba et al., 2004). Spherically

shaped cells form under unfavorable growth conditions. Bacteria stain as Gram-negative. Due to the small diameter of these bacteria, **unstained cells are not visible by bright-field microscopy**. Dark-field or phase-contrast microscopy is required for visualization of unstained cells. These are highly motile aerobic or microaerophilic bacteria. Optimum growth temperature is 28–30°C, with a generation time of 6–16 h, although **many**

primary pathogenic isolates may grow slower. Chemoorganotrophic bacteria that consume long-chain fatty acids and alcohols as primary carbon and energy sources, and carry out respiration with oxygen as the terminal electron acceptor. Optimal growth occurs in semi-solid (0.1–0.2%) agar media. Growth on 1–2% solid agar results in the formation of clear to turbid surface or subsurface colonies. Colony formation is enhanced by the addition of pyruvate. Oxidase, catalase, and/or peroxidase-positive. Some strains are β -hemolytic. Some strains are pathogenic for humans and animals, while other strains are saprophytic and found in freshwater and marine environments. **The genus *Leptospira* forms a deep unique branch of spirochetes, separate from other genera based on comparison of 16S rRNA gene sequences.** Species are differentiated by DNA–DNA relative reassociation analysis and by unique sequence polymorphisms in 16S rRNA.

DNA G+C content (mol%): 35–43.

Type species: Leptospira interrogans (Stimson 1907) Wenyon 1926, 1281 emend. Faine and Stallman 1982, 462 (*Spirochaeta interrogans* Stimson 1907, 541).

Further descriptive information

Taxonomic history. The taxonomy of *Leptospira* has undergone substantial revisions in the past 20 years with the use of 16S rRNA sequence comparison and DNA–DNA reassociation studies. DNA–DNA reassociation studies helped differentiate pathogenic and saprophytic species (Haapala et al., 1969). Subsequent studies by Brendle et al. (1974), Ramadass et al. (1992), and Yasuda et al. (1987) helped to revise and better define *Leptospira* species. The key paper by Brenner et al. (1999) compared 303 strains of *Leptospira*, leading to a refined definition of 12 different species and identification of five new genomospecies, one of which was given the designation *Leptospira alexanderi*. One of the species included in the Brenner et al. (1999) study was *Leptospira parva*, originally described by Hovind-Hougen et al. (1981). Due to extensive DNA sequence and 16S rRNA differences from other *Leptospira* species and to the difference from *Leptonema illini*, it was placed in a new genus of *Leptospiroaceae*, *Turneriella parva* (Levett et al., 2005). Three new *Leptospira* species have been described, *Leptospira broomii* (Levett et al., 2006), *Leptospira licerasiae* (Matthias et al., 2008), and *Leptospira wolffii* (Slack et al., 2008). Thus, at the current time, the genus *Leptospira* contains 15 named species and the Subcommittee on the taxonomy of *Leptospiroaceae* has recommended names for four genomospecies identified by Brenner et al., (1999) (Levett and Smythe, 2008).

Following the initial use of 16S rRNA sequence comparisons to define taxonomic relationships among spirochete genera (Paster et al., 1984, 1991); Hookey et al. (1993) expanded these analyses to help differentiate *Leptospira* species and differentiate

the genera *Leptonema* and *Leptospira*. Comparison of 16S rRNA sequences and DNA–DNA reassociation studies suggest the presence of three groups of pathogenic species; Group I contains *Leptospira interrogans* and *Leptospira kirschneri*, Group II contains *Leptospira weilii*, *Leptospira borgpetersenii*, and *Leptospira santarosai*, and Group III contains *Leptospira noguchi* and *Leptospira meyeri* (Hookey, 1993). There are five species having intermediate pathogenicity: *Leptospira fainei*, *Leptospira inadai*, *Leptospira broomii*, *Leptospira licerasiae*, and *Leptospira wolffii*. The latter three species were recently recognized by the Subcommittee on the taxonomy of *Leptospiroaceae* (Levett and Smythe, 2008). Saprophytic species include *Leptospira biflexa* and *Leptospira wolbachii* (Yasuda et al., 1987). The status of *Leptospira meyeri* is unclear because strains fit into both saprophytic (Yasuda et al., 1987) and pathogenic groups (Hookey et al., 1993; Victoria et al., 2008). Many of the diverse free-living strains of *Leptospira* described by Ramadass et al. (1992) and halophiles described by Cinco et al. (1975) were not included in the study by Brenner et al. (1999), so the taxonomic status of these strains is unknown. Brenner et al. (1999) discovered and described four *Leptospira* genomospecies tentatively named *Leptospira alstonii* (genomospecies 1), *Leptospira vanthielii* (genomospecies 3), *Leptospira terpstrae* (genomospecies 4), and *Leptospira yanagawae* (genomospecies 5) (Levett and Smythe, 2008).

Cell morphology, motility, and ultrastructure. *Leptospira* cells are typically visualized by dark-field light microscopy due to their long slender cell dimensions. The basic cell morphology of *Leptospira* resembles other members of the order *Spirochetales*; *Leptospira* species typically appear as long helical cells with loose coils (Figure 99). One flagellum is inserted subterminally at each end of the cell and lies along the helix axis in the periplasmic space (Goldstein et al., 1996). Scanning electron microscopic analysis shows these cells form right-handed helices, and helical handedness may affect cell motility (Carleton et al., 1979). During translational movement, the trailing end of the cell bends to form a hook thought to function as a propeller, with the leading end maintaining a spiral twist, guiding the forward movement of the bacterium (Charon et al., 1984; Charon et al., 1981). Translational movement increases with the viscosity of the medium (Greenberg and Canale-Parola, 1977a, b), a finding that suggests these bacteria are viscotaxic (Petrino and Doetsch, 1978).

Leptospira have a typical spirochete ultrastructure, having an outer membrane surrounding a protoplasmic cylinder. The cell wall contains peptidoglycan containing the diamino acid alpha, epsilon diaminopimelic acid (Azuma et al., 1975). Two flagella (also referred to as axial filaments) are inserted subterminally at each end of the cell, and wrap around the protoplasmic cylinder in the periplasmic space. The ends of the flagella rarely overlap near the midpoint of the cell. The outer membrane is

FIGURE 99. Transmission electron micrograph of *Leptospira biflexa* serovar Patoc. Bar = 500 nm.

loosely attached to the cell and easily removed by detergents (Haake et al., 1991; Zuerner et al., 1991). Rapid displacement of antibody-coated latex beads adhered to *Leptospira* cells suggests the outer membrane is quite fluid (Charon et al., 1981).

Outer membrane composition. Protein composition of the *Leptospira* outer membrane varies depending on virulence and growth conditions. For example, few proteins have been detected on the surface of virulent *Leptospira kirschneri*, while outer-membrane protein density is substantially higher in avirulent strains (Haake et al., 1991). LipL36 is expressed under normal *in vitro* growth conditions, but down-regulated during mammalian infection (Haake et al., 1998). Changes in osmolarity also alter outer-membrane protein expression. For example, expression of LigA and LigB, two bacterial immunoglobulin-like proteins increase as osmolarity rises (Choy et al., 2007; Matsunaga et al., 2007a, b; Matsunaga et al., 2005).

Under normal *in vitro* growth, the most predominant proteins on the surface of pathogenic *Leptospira* are LipL32, LipL21, and LipL41 (Cullen et al., 2002, 2003, 2005). LipL32 is the major outer-membrane protein and is unique to pathogenic *Leptospira* species. LipL32 is heat labile and, in the absence of calcium ions, is degraded by an endogenous protease to two smaller peptides (Haake et al., 2000; Zuerner et al., 1991). Although the original report describing LipL21 identified this protein as unique to pathogenic *Leptospira* species (Cullen et al., 2003), genome analysis of the *Leptospira biflexa* genome revealed the presence of a gene encoding a protein with extensive similarity to LipL21 (Picardeau et al., 2008). Protein OmpLI is an integral transmembrane porin (Haake et al., 1993). Access to genomic sequences for three species of *Leptospira*, including two pathogenic species, has resulted in cloning and analysis of many previously unknown outer-membrane proteins. Of particular interest are proteins from pathogenic strains that interact with the host. LigA and Lsa24 (also referred to as LfhA) bind extracellular matrix proteins (Barbosa et al., 2006; Choy et al., 2007), and Lsa24 binds complement factor H (Verma et al., 2006).

The leptospiral LPS is thought to be the primary antigen associated with determining serovar, and variation in LPS biosynthetic genes may occur via lateral transfer (de la Pena-Moctezuma et al., 1999) or mutation (Zuerner and Trueba, 2005), resulting in expression of antigenically distinct LPS. Leptospiral LPS is not as complex in structure as often found in typical Gram-stain-negative bacteria, and does not resolve as a ladder of variable sized products during polyacrylamide gel electrophoresis. Purified leptospiral LPS activates mouse cells via TLR2 and TLR4 (Nahori et al., 2005; Werts et al., 2001). Purified *Leptospira interrogans* Lipid A, the membrane anchor for LPS, does not induce *Limulus* amebocyte lysates to gel (Nahori et al., 2005; Que-Gewirth et al., 2004). The *Leptospira interrogans* lipid A has unusual features including a methylated 1-phosphate group (Nahori et al., 2005).

Nutrition and growth conditions. *Leptospira* are obligate aerobes but vary greatly in their ability to grow *in vitro*. Although many *Leptospira* can grow in a defined medium of relatively simple composition referred to as EMJH (Ellinghausen and McCullough, 1965; Johnson and Harris, 1967a), addition of rabbit serum is often necessary for growth of many pathogenic strains, and early attempts to grow *Leptospira* utilized media rich in rabbit serum (Fletcher, 1928; Stuart, 1946). Growth yields in

EMJH media vary from 3 to 5×10^8 to $\sim 10^{10}$ cells/ml, with generation times of 6–16 h, depending on the strain. *Leptospira* consume long chain fatty acids or alcohols as primary carbon and energy sources, which are metabolized by beta-oxidation (Baseman and Cox, 1969; Henneberry and Cox, 1970). Fatty acids are commonly added to *Leptospira* media preparations through the addition of polysorbate (e.g., Tweens), nonionic detergents derived from long chain fatty acids. Tween 80, predominantly containing oleic acid, is used most commonly, but addition of Tween 40 (primarily palmitic acid) and/or Tween 60 (primarily steric acid) can be useful to support growth of fastidious strains of *Leptospira* (e.g., *Leptospira borgpetersenii* serovar Hardjo) (Ellinghausen, 1983). Leptospiral media often contains purified bovine serum albumin to bind free fatty acids and reduce their toxicity. Protein-free media for growth of some strains of *Leptospira* have been reported (Bey and Johnson, 1978; Shenberg, 1967), but these media do not support prolonged propagation of many pathogenic species. Vitamins B₁ and B₁₂ are typically included in the growth medium for *Leptospira*. However, *Leptospira* synthesize heme (Guegan et al., 2003), consistent with possessing vitamin B₁₂ biosynthesis genes. Furthermore, *de novo* synthesis of B₁₂ may be required as genomic analysis suggests *Leptospira* may be deficient in the ability to transport exogenous B₁₂ (Rodionov et al., 2003). Ammonium is provided by addition of ammonium salts to the media as amino acids do not appear to be a significant source of ammonia for *Leptospira* (Johnson and Rogers, 1964c). *Leptospira* appear to synthesize all amino acids except isoleucine by standard pathways (Charon et al., 1974). Isoleucine is synthesized either by the standard pathway, being derived from threonine, or by a pathway involving condensation of pyruvate with acetyl-S-coenzyme A (Charon et al., 1974). *Leptospira* synthesize isoleucine either by a combination of threonine and pyruvate pathways or by exclusive use of the threonine or pyruvate pathways (Westfall et al., 1983). Exogenous purines are incorporated by *Leptospira* (Johnson and Rogers, 1964a). However, *Leptospira* do not incorporate exogenous pyrimidines, thus incorporation of pyrimidine analogs such as 5-fluorouracil is a useful method for suppressing the growth of other bacteria and providing an enrichment method for isolating *Leptospira* (Johnson and Rogers, 1964b). Iron is required for growth of *Leptospira* (Faine, 1959) and is usually supplied as iron sulfate in the media. Recent analysis of iron transport in *Leptospira* revealed that iron sulfate-free media supports growth of *Leptospira interrogans*, presumably by supplying trace iron, but *Leptospira biflexa* requires addition of exogenous iron to the media for growth (Louvel et al., 2006).

Leptospira are rarely grown on agar plate media due to their slow growth. Colony formation can be observed in about 10 days for saprophytic species, but it may take 6–8 weeks for pathogenic species to form colonies. Colonies are diffuse, non-pigmented, clear to turbid, and may form below the surface. Growth, especially on solid agar media, is enhanced by the addition of pyruvate (Johnson et al., 1973). Optimal growth conditions include pH 7.2–7.4, 30°C, and media containing low salt (17–60 mM), although halophilic strains require 0.22–0.44 M for growth (Cinco and Cociancich, 1975).

Genome properties. Physical mapping of *Leptospira interrogans* serovars Pomona and Icterohemorrhagiae using pulsed-field gel electrophoresis (PFGE) and DNA hybridization revealed the presence of two chromosomal replicons in this

species (Baril et al., 1992; Zuerner, 1991). Comparative mapping revealed extensive rearrangements that alter genetic organization within the same species (Zuerner et al., 1993). The genomes of four pathogenic *Leptospira* strains have been published: *Leptospira interrogans* serovar Copenhageni (Nascimento et al., 2004) and *Leptospira interrogans* serovar Lai (Ren et al., 2003), and two strains of *Leptospira borgpetersenii* serovar Hardjo (Bulach et al., 2006). Genome size ranges from 3.9 to 4.7 Mbp, consisting of one large and one small chromosome. Genome sequencing of the free-living *Leptospira biflexa* serovar Patoc shows the presence of three stable replicons, corresponding to the large and small chromosomes of pathogenic *Leptospira*, and a third replicon of unknown function (Picardeau et al., 2008). Comparative analysis of *Leptospira interrogans* serovar Lai and Copenhageni confirm previous mapping studies that suggest recombination between transposable elements contribute to changes in genetic organization by identifying an inversion flanked at both ends by insertion sequences that differentiates genetic organization of these two serovars (Nascimento et al., 2004). Extensive rearrangements differentiate the organization of *Leptospira interrogans* from *Leptospira borgpetersenii*, and strains of *Leptospira borgpetersenii* are likewise differentiated by the presence of chromosomal rearrangements. Approximately 7% of the *Leptospira borgpetersenii* serovar Hardjo genome is comprised of transposable elements, and nearly 17% of pseudogenes in *Leptospira borgpetersenii* are associated with insertion sequences (IS), leading to the conclusion that the genome of this species is undergoing IS-mediated genome erosion (Bulach et al., 2006). A primary consequence of genome erosion in *Leptospira borgpetersenii* is the apparent loss of viability in water (Bulach et al., 2006), thereby limiting dissemination of viable organisms via the environment, a common means of disease transmission for *Leptospira interrogans*. Additional variability in *Leptospira interrogans* may result from lateral transfer of genomic islands (Bourhy et al., 2007).

An unusual feature of *Leptospira* genomes is the organization of rRNA genes (Fukunaga and Mifuchi, 1989a, b). Individual rRNA genes are not linked closely to each other in *Leptospira*, but are dispersed around the large chromosome (Zuerner et al., 1993). There are two copies each of the 16S and 23S rRNA genes in *Leptospira*; there is one copy of the 5S rRNA gene in pathogenic *Leptospira*, but two copies of the 5S rRNA gene in free-living *Leptospira* (Fukunaga and Mifuchi, 1989b).

Phage, plasmid, and transposable elements and genetic manipulation in *Leptospira*. Although naturally occurring mechanisms for genetic exchange are not yet defined for *Leptospira*, several recent discoveries and advances in genetic manipulation of members of this genus suggest lateral transfer of DNA contributes to genetic variation. Bacteriophages have been detected by electron microscopy of *Leptospira* cultures. Saint Girons et al. (Saint Girons et al., 1990) described the first successful isolation and propagation of bacteriophage that infect *Leptospira biflexa*. The replication origin of bacteriophage LE1 can direct autonomous replication of a plasmid in *Leptospira biflexa*, and this discovery led to development of an *Escherichia coli*-*Leptospira biflexa* shuttle vector facilitating genetic manipulation of *Leptospira* (Girons et al., 2000). In a similar manner, discovery of genetic islands in *Leptospira interrogans* led to development of a limited-host range shuttle vector (Bourhy et al., 2007). Autonomous replication of these genetic islands

may contribute to lateral transfer of DNA in nature and affect pathogenicity by spreading virulence determinants (Bourhy et al., 2007). Recent demonstration of conjugative transfer of a shuttle vector from *Escherichia coli* to *Leptospira* is consistent with evidence for lateral transfer of genetic material into *Leptospira* (Picardeau, 2008).

Intervening sequences are inserted into the 23S rRNA gene in some *Leptospira* species (Ralph and McClelland, 1993). During post-transcriptional processing, the intervening sequences are excised without ligation, therefore bacterial strains containing these elements lack an intact 23S rRNA and instead have 14S and 17S rRNA species (Hsu et al., 1990).

As noted above, genetic rearrangements occur frequently in *Leptospira* strains, and these rearrangements are often associated with transposable elements including IS-elements. There are several different IS-like elements found in *Leptospira* (Boursaux-Eude et al., 1995; Bulach et al., 2006; Nascimento et al., 2004; Ralph and McClelland, 1993; Zuerner, 1994; Zuerner and Huang, 2002; Zuerner and Trueba, 2005) that share substantial sequence similarity to elements found in diverse bacterial genera, yet lateral transfer of these elements has not been demonstrated. The presence of high numbers (~90 copies) of IS1533 in *Leptospira borgpetersenii* serovar Hardjo is hypothesized to have a prominent role in genome degradation by generating non-functional pseudogenes that restrict serovar Hardjo to a host to host transmission cycle (Bulach et al., 2006). Transposition of the genetic elements derived from the eukaryotic transposon *himar1* provides a means to generate selectable random mutants in *Leptospira* species (Bourhy et al., 2005), opening up new possibilities in genetic manipulation and analysis in this genus.

Serotype analysis. *Leptospira* are antigenically diverse and are clustered by serological analysis into serogroups. Serogroups are further subdivided into serovars, which are considered the primary serotype taxon. Serovar determination is achieved by agglutination reactions using a microscopic agglutination test (Cole et al., 1973; Ryu, 1970). Serovars are differentiated by cross-absorption agglutination reactions using high titer sera. Two strains are designated different serovars if, after sufficient cross-absorption with each sera using the heterologous strain, at least one of the sera retains 10% or more of the initial homologous agglutination titer (Stallman, 1984). Use of monoclonal antibodies can also help differentiate strains belonging to different serovars (Terpstra et al., 1985; World Health Organization, 2003). Serovar designation has historical relevance and may be essential in understanding the relationships between these bacteria and their normal maintenance hosts; maintenance hosts appear to have a stable relationship with bacteria in the same serovar but may undergo acute infection with a different serovar (Faine et al., 1999). Likewise, the same strain in its normal maintenance host rarely displays signs of acute infection, but accidental infection by that strain of a non-maintenance host can result in severe acute infection (Faine et al., 1999). Complicating the importance and relevance of serovar designation is the discovery of several serovars represented by strains belonging to different *Leptospira* species (Levett, 2001).

Antibiotic sensitivity. *Leptospira* exhibit *in vitro* sensitivity to a large number of antibiotics, including beta-lactams (penicillin, ampicillin, and amoxycillin), rifampin, tetracycline and doxycycline, cephalosporins (cefotaxime and ceftizoxime),

aminoglycosides including streptomycin (Oie et al., 1983), macrolides (erythromycin and azithromycin), and fluoroquinolones including ciprofloxacin (Hospenthal and Murray, 2003). Immediate treatment of suspected infections is recommended. Traditionally, leptospirosis has been treated with intravenous penicillin for severe cases, or oral antibiotics including amoxicillin, ampicillin, doxycycline, and erythromycin (Terpstra et al., 1985; World Health Organization, 2003). There is limited clinical data on effective use of newer antibiotics to treat leptospirosis.

Environmental range. Pathogenic *Leptospira* species cause leptospirosis, one of the most widespread zoonosis known. Wild and domesticated animals are reservoirs of infection, and animal to human transmission may occur either through direct exposure to blood or urine from an infected animal, or indirectly from urine-contaminated water. After infection, the bacteria disseminate via the blood and concentrate in the kidney. *Leptospira* are voided in the urine (Figure 100), facilitating infection of new hosts (Faine et al., 1999). Leptospirosis ranges in severity from a mild influenza-like infection to a severe acute infection often resulting in death from organ failure. Chronically infected animal maintenance hosts often do not exhibit clinical signs of infection. Several *Leptospira* species exhibit an intermediate pathogenicity in humans and animal hosts, and may be opportunistic pathogens.

The normal environment for saprophytic *Leptospira* species is water or moist soil (Henry and Johnson, 1978). Cinco et al. (1975) have reported isolation of halophilic *Leptospira*, but these have not been subjected to taxonomic characterization. Recent surveys using 16S rRNA sequence analysis to assess the diversity of microbes in different environments suggest *Leptospira*

FIGURE 100. *Leptospira* in urine. A sample of urine was obtained from a dog exhibiting clinical signs of leptospirosis and stained with FITC-conjugated anti-*Leptospira* rabbit sera, counterstained with Flazo-orange, then visualized using a 60× objective on an Olympus fluorescent microscope (final magnification 600×). Under these conditions, the bacteria appear green. Individual cells and cell masses are visible.

and *Leptonema* are widely distributed, including in petroleum contaminated soil (Kasai et al., 2005), marine sediments (GenBank accession EU386041), and geothermal regions (GenBank accession EF205465).

Leptospirosis and virulence-associated traits. Virulence determinants of pathogenic *Leptospira* remain poorly characterized. This is due, in part, to the limited tools available for genetic manipulation; until quite recently, genetic manipulation of pathogenic *Leptospira* species was not possible. Thus, to date, only one protein has been clearly shown to have an effect on virulence. Mutation of the gene encoding Loa22, a protein localized in the outer membrane, resulted in attenuation of *Leptospira interrogans* (Ristow et al., 2007). Genetic complementation of a Loa22⁻ mutant partially restored virulence near the level seen with the wild-type parental strain (Ristow et al., 2007). Hemolysins, including phospholipase C, sphingomyelinase-like proteins, and pore-forming proteins, are potential virulence factors (Artushin et al., 2004; Bernheimer and Bey, 1986; del Real et al., 1989; Lee et al., 2000, 2002; Matsunaga et al., 2007b; Segers et al., 1990, 1992). Several proteins, including bacterial immunoglobulin-like proteins LigA and LigB (Choy et al., 2007), a group of endostatin-like proteins (Barbosa et al., 2006; Stevenson et al., 2007), and the major outer-membrane protein LipL32 (Hoke et al., 2008), facilitate attachment of pathogenic *Leptospira* to mammalian extracellular matrix proteins and probably have important roles during infection. Lsa24 may also help the pathogenic *Leptospira* evade the antibacterial effects of complement by binding factor H (Verma et al., 2006), consistent with earlier findings that virulent *Leptospira* are resistant to serum (Johnson and Harris, 1967b). The unusual ability of *Leptospira* to undergo translational movement in highly viscous media (Greenberg and Canale-Parola, 1977a) may be an important factor in tissue penetration.

Enrichment and isolation procedures

Pathogenic *Leptospira* can be isolated from blood and, occasionally, spinal fluid during the early stages of infection (1–2 weeks) by growth in semi-solid (0.1–0.2% agar) or liquid growth media. Blood treated with heparin to prevent coagulation or untreated blood added directly to transport media (1% bovine serum albumin in phosphate buffer) can be used to inoculate growth media. One to two weeks after infection, and for several weeks to months following infection, *Leptospira* can be isolated from urine. *Leptospira* reside primarily in kidney and liver, therefore inoculation of media with tissue homogenates prepared from these organs collected during necropsy often results in successful isolation of bacteria. Addition of 5'-fluorouracil (100 µg/ml) to the isolation medium is useful for primary isolation of pathogenic *Leptospira*, especially from urine, by helping to suppress growth of contaminating bacteria. Primary isolation of pathogenic strains may require incubation of cultures up to 6 months with periodic microscopic evaluation. Direct intraperitoneal inoculation of weanling Golden Syrian hamsters using tissue, soil, or water samples is an alternative method to enrich for pathogenic *Leptospira* (Brendle and Alexander, 1974; Glosser et al., 1974).

Saprophytic *Leptospira* reside in streams, lakes, and moist soil (Henry and Johnson, 1978). To prepare environmental samples for culture, suspend soil in sterile distilled water, or use surface water directly, and filter through 0.45 or 0.22 µm filters before inoculating culture media. Incorporation of 5'-fluorouracil

during initial isolation of environmental samples is important for restricting growth of non-*Leptospira* bacteria. Isolation of *Leptospira* from contaminated cultures can be achieved either by filtration through 0.22 µm filters or by spotting a few microliters of culture on solid culture medium. *Leptospira* will tend to migrate away from the spot, forming a halo of growth from which the bacteria can be isolated.

Leptospira growth in semi-solid media typically results in formation of a dense zone of growth (referred to as a Dinger disk) a few millimeters below the surface of the media.

Maintenance procedures

Leptospira cultures are maintained in semi-solid (0.1–0.2% agar) media at 30°C. The frequency of subculture varies greatly, dependent upon strain specific growth characteristics; some fastidious strains may take 6 months of incubation before visible growth, while more vigorous strains can be subcultured weekly. Long term cultivation of pathogenic *Leptospira* may result in loss of virulence, and therefore pathogenic strains should be frozen and stored in liquid nitrogen after initial isolation or within 1–2 *in vitro* subcultures. To prepare cultures for cryopreservation, mix a fresh Dinger disk of *Leptospira* growth in semi-solid media with an equal volume transport media and freeze at –70°C before placing in liquid nitrogen. Free-living *Leptospira* may be frozen or kept in semi-solid media for long term storage. Storage of *Leptospira* cultures by lyophilization is not recommended.

Differentiation of the genus *Leptospira* from other closely related taxa

Leptospira are obligate aerobes that consume fatty acids or alcohols as primary carbon and energy sources, distinguishing this genus from other spirochetes. Although morphologically similar to other spirochetes, *Leptospira* form tighter coils, often with at least one hooked end. These bacteria are resistant to 5'-fluorouracil, whereas other spirochetes are sensitive to this compound. The cell wall contains diaminopimelic acid vs ornithine in other spirochetes.

Differentiation of species of the genus *Leptospira*

Characteristics that differentiate species of *Leptospira* are shown in Table 132. *Leptospira* species are defined by DNA–DNA reassociation analysis. In addition, 16S rRNA sequence comparison (Hookey, 1993), mapped-restriction site polymorphisms of amplified rRNA sequences (Ralph et al., 1993), and *secY* sequence comparison (Ahmed et al., 2006; Victoria et al., 2008)

are also useful for differentiating *Leptospira* species. Several methods have proven helpful for strain and serovar differentiation, including restriction endonuclease analysis (Marshall et al., 1981; Robinson et al., 1982) and macrorestriction endonuclease analysis by pulsed-field gel electrophoresis (Galloway and Levett, 2008; Herrmann et al., 1991, 1992). The results of strain comparison using restriction endonuclease DNA digestion patterns usually correlate with serological analysis that separates strains based on agglutination reactions using specific sera (Ellis et al., 1991, 1988; Robinson et al., 1982, 1986; Thiermann et al., 1985). There are several examples of serovars found in more than one species (Levett, 2001), indicating the need to characterize strains by both serological and DNA-based techniques. Extensive phenotypic diversity precludes use of differential growth characteristics for differentiation of *Leptospira* species.

Taxonomic comments

The previous edition of the *Manual* described three species of *Leptospira*, namely *Leptospira interrogans*, representing pathogens, *Leptospira biflexa*, representing free-living leptospirae, and *Leptospira illini species incertae sedis*. DNA–DNA renaturation studies have revealed substantial diversity within the previous classifications of *Leptospira interrogans* and *Leptospira biflexa*, and have supported the establishment of two new genera, *Leptonema*, in which *Leptonema illini species incertae sedis* now resides, and *Turneriella parva*. The taxonomic status of halophilic *Leptospira* has not been determined. Environmental surveys using 16S rRNA sequence analysis to monitor bacterial populations suggests the distribution of *Leptospira* and *Leptonema* species is diverse, and additional species are likely to be discovered.

The serovar is the primary *Leptospira* taxon, but this classification scheme is distinct from molecular taxonomy based on DNA–DNA reassociation kinetics or 16S rRNA sequence analysis. Strains representing the same serovar occur in two or more species. Likewise, serogroups also occur in different species (Table 133).

Differentiation of *Leptospira* species is difficult because these bacteria are morphologically similar and there is substantial variation in biochemical and growth characteristics within each species. Generally, free-living *Leptospira* and *Leptonema illini* share the ability to grow at 13°C. *Leptonema* is the only genus in *Leptospiroaceae* that can grow on trypticase media and possesses cytoplasmic tubules. Pathogenic *Leptospira* are sensitive to 8-azaguanine, but nonpathogenic and strains with intermediate pathogenic status can vary in their capacity to grow in the presence of this compound. Likewise, 2,6-diaminopurine or copper sulfate inhibits growth of most pathogenic strains, but nonpathogenic strains and strains with intermediate pathogenic status vary in their ability to grow in the presence of these compounds. Therefore, accurate differentiation of *Leptospira* species must rely on molecular characterization comparing 16S rRNA sequences or DNA–DNA reassociation analysis (Levett and Smythe, 2006).

List of species of the genus *Leptospira*

1. ***Leptospira interrogans*** (Stimson 1907) Wenyon 1926, 1281^{AL} emend. Faine and Stallman 1982, 462 (*Spirocheta interrogans* Stimson 1907, 541)
in.ter'ro.gans. L. part. adj. *interrogans* asking, inquiring, interrogating, here meaning shaped like a question mark.

Exhibits morphological and cultural features common to the genus *Leptospira* (Figure 101). Grows at 30°C, but does not grow at 13°C. Growth is inhibited by 8-azaguanine (225 µg/ml) or CuSO₄ (100 p.p.m.). Growth of some strains is inhibited by 2,6-diaminopurine (10 µg/ml). Production

of lipase varies among strains of this species. Pathogenic in mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection.

The genome sequences for two strains of *Leptospira interrogans* have been determined: serovar Copenhageni strain Fiocruz LI-130 (GenBank accession nos AE016823 and AE016824) and serovar Lai strain 56601 (GenBank accession nos AE010300 and AE010301).

Source: bacteria localize in the kidneys of mammals, facilitating shedding via urine.

DNA G+C content (mol%): 35 (T_m).

Type strain: *Leptospira interrogans* serogroup Icterohaemorrhagiae, serovar Icterohaemorrhagiae, strain RGA, ATCC 23581, ATCC 43642, CUG 5117, KCTC 2880.

Sequence accession no. (16S rRNA gene): AY631894, FJ154549.

2. *Leptospira alexanderi* Brenner, Kaufmann, Sulzer, Steigerwalt, Rogers and Weyant 1999, 856^{VP}

a.le.xan.de'ri. N.L. masc. gen. n. *alexanderi* of Alexander, named to honor Aaron D. Alexander, an American microbiologist.

FIGURE 101. Silver-stained *Leptospira interrogans* serovar Pomona in situ. Sections of hamster kidney were isolated after infection with *Leptospira interrogans* serovar Pomona, fixed with formalin, then processed for histology. The tissue was stained with a modified PAS Steiner process. Bacteria appear black due to the precipitation of silver on the bacterial surface. A final magnification of 400 \times is shown. Bar = 25 μ m.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11 or 37°C. Growth is inhibited by 8-azaguanine (225 μ g/ml) or 2,6-diaminopurine (10 μ g/ml). Strains vary in the ability to grow in the presence of CuSO₄ (100 p.p.m.), and production of lipase activity is variable. Pathogenicity for animals not reported.

Source: isolated in China from an unknown source.

DNA G+C content (mol%): 38 (T_m).

Type strain: L 60 serovar Manhao 3, ATCC 700520.

Sequence accession no. (16S rRNA gene): AY631880.

3. *Leptospira biflexa* (Wolbach and Binger 1914) Noguchi 1918, 585^{AL} emend. Faine and Stallman 1982, 462 (*Spirocheta biflexa* Wolbach and Binger 1914, 23)

bi.fle'xa. L. adv. num. *bis* twice; L. part. adj. *flexus* -a -um (from. L. v. *flecto*) bent, winding; N.L. fem. adj. *biflexa* bent twice.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 13°C and at 30°C. Strains often grow in the presence of 8-azaguanine (225 μ g/ml), 2,6-diaminopurine (10 μ g/ml), and CuSO₄ (100 p.p.m.). All strains produce lipase. Strains are typically found in flowing or still freshwater sources, tap water, and occasionally animals. Pathogenicity not demonstrated, thought to be nonpathogenic for mammals.

The genome sequence for the type strain and one of its derivatives has been determined (GenBank accession nos CP00777–CP00779 and CP007786–CP007788).

Source: a stream in Italy.

DNA G+C content (mol%): 38.9 (genomic sequencing).

Type strain: *Leptospira biflexa* serovar Patoc strain Patoc I, ATCC 23582.

Sequence accession no. (16S rRNA gene): AY631876, Z12821.

4. *Leptospira borgpetersenii* Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 414^{VP}

borg.pe'ter.sen'i.i. N.L. masc. gen. n. *borgpetersenii* of Borg-Petersen, named for C. Borg-Petersen, the Danish physician who made significant early contributions to the epidemiology and microbiology of leptospirosis in Europe.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml) or CuSO₄ (100 p.p.m.), but not by 2,6-diaminopurine (10 µg/ml). Does not produce lipase. The type strain was isolated from a Java house rat in Indonesia. Pathogenic in mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine.

The genome sequences for two strains of *Leptospira borgpetersenii* serovar Hardjo (L550 and JB197) have been determined (GenBank accession nos. CP000348-CP000351).

Source: a Java house rat in Indonesia.

DNA G+C content (mol%): 39.8 (T_m).

Type strain: Veldrat Bataviae 46 serovar Javanica, ATCC 43292.

Sequence accession no. (16S rRNA gene): AY461862, AY887899, AM050572, DQ991483, FJ154600, Z21630.

5. ***Leptospira broomii*** Levett, Morey, Galloway and Steigerwalt 2006, 673^{VP}

bro.o'mi.i. N.L. masc. gen. n. *broomii* of Broom, named for John Constable Broom (1902–1960), a Scottish bacteriologist who made substantial contributions to the study of leptospirosis.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but growth at other temperatures not reported. Pathogenic in mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine. However, clusters with other species (*Leptospira fainei*, *Leptospira inadai*, and *Leptospira licerasiae*) considered intermediate in pathogenicity based on 16S rRNA sequence comparison.

Source: blood of human patient with leptospirosis; additional isolates from blood, cerebrospinal fluid, and urine of human patients with leptospirosis.

DNA G+C content (mol%): 42 (T_m).

Type strain: 5399, ATCC BAA-1107, KIT 5399.

Sequence accession no. (16S rRNA gene): AY796065.

6. ***Leptospira fainei*** Perolat, Chappel, Adler, Baranton, Bulach, Billingham, Letocart, Merien and Serrano 1998, 857^{VP}

fai'ne.i. N.L. masc. gen. n. *fainei* of Faine, named for Solomon Faine, an Australian medical microbiologist who made definitive contributions to the knowledge of the physiopathology and epidemiology of leptospirosis.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 13°C and 30°C. Growth is partially inhibited by 8-azaguanine (225 µg/ml, 30°C). May induce disease manifestations ranging from mild influenza-like symptoms to acute, potentially lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine. Clusters with other species (*Leptospira broomii*,

Leptospira inadai, and *Leptospira licerasiae*) considered intermediate in pathogenicity based on 16S rRNA sequence comparison. Species contains a single serovar, Hurstbridge.

Source: the uterus of a sow in Australia; strains isolated from chronic human infections also reported.

DNA G+C content (mol%): not reported.

Type strain: BUT 6 serovar Hurstbridge.

Sequence accession no. (16S rRNA gene): AY631885, FJ154578, U60594.

7. ***Leptospira inadai*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 414^{VP}

i.na'da.i. N.L. masc. gen. n. *inadai* of Inada, named for Ryokichi Inada, the Japanese microbiologist who is regarded by some to have first isolated leptospires from human patients.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but no growth at 11°C. Growth of some strains is inhibited by 8-azaguanine (225 µg/ml), CuSO₄ (100 p.p.m.), or 2,6-diaminopurine (10 µg/ml). Some strains produce lipase. Strains of this species are considered to have intermediate pathogenic status, but clinical manifestations and pathogenicity have not been clearly demonstrated. Clusters with other species (*Leptospira broomii*, *Leptospira fainei*, and *Leptospira licerasiae*) considered intermediate in pathogenicity based on 16S rRNA sequence comparison.

Source: the skin of a patient with a concurrent, unrelated Lyme disease infection; strains have been isolated from a variety of rodents.

DNA G+C content (mol%): 42.6 (T_m).

Type strain: 10 serovar Lyme, ATCC 43289.

Sequence accession no. (16S rRNA gene): AY631896, Z21634.

8. ***Leptospira kirschneri*** Ramadass, Jarvis, Corner, Penny and Marshall 1992, 219^{VP}

kirsch'ne.ri. N.L. masc. gen. n. *kirschneri* of Kirschner, named for Leopold Kirschner, a Dutch medical microbiologist who worked on leptospirosis research in Indonesia before coming to New Zealand to work at the Otago Medical School in Dunedin and whose pioneering work on leptospirosis helped focus attention on the human and animal health problem that existed at the time.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but no growth at 13°C. Growth is inhibited by 8-azaguanine (225 µg/ml). Most strains are inhibited by CuSO₄ (100 p.p.m.) or 2,6-diaminopurine (10 µg/ml). Lipase is not produced. Strains of this species are pathogenic for mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine.

Source: Indonesia, from a short-headed fruit bat.

DNA G+C content (mol%): not reported.

Type strain: 3522 C serovar Cynopteri, ATCC 49945.

Sequence accession no. (16S rRNA gene): AY631895, DQ991475, FJ154546, Z21628.

9. ***Leptospira licerasiae*** Matthias, Ricaldi, Cespedes, Diaz, Galloway, Saito, Steigerwalt, Patra, Ore, Gotuzzo, Gilman, Levett and Vinetz 2009, 1^{VP} (Effective publication: Matthias,

Ricaldi, Cespedes, Diaz, Galloway, Saito, Steigerwalt, Patra, Ore, Gotuzzo, Gilman, Levett and Vinetz 2008, 11.)

li.ce.ra.si'ae. N.L. fem. gen. n. *licerasiae* of Liceras, named to honor Julia Liceras de Hidalgo, who obtained the first leptospiral isolates in Peru.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C. Growth at other temperatures not reported. Growth is inhibited by 8-azaguanine (225 µg/ml). However, clusters with other species (*Leptospira broomi*, *Leptospira fainei*, and *Leptospira inadai*) considered intermediate in pathogenicity based on 16S rRNA sequence comparison. Although these strains are associated with human infections, experimental inoculation of hamsters and guinea pigs did not induce clinical signs of leptospirosis.

Source: blood obtained from human patients with undifferentiated fever.

DNA G+C content (mol%): not reported.

Type strain: VAR010 serovar Varillal, ATCC BAA-1110, KIT VAR 010, WPR VAR 010.

Sequence accession no. (16S rRNA gene): EF612284.

10. ***Leptospira meyeri*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 414^{VP}

me.ye'ri. N.L. masc. gen. n. *meyeri* of Meyer, named to honor Karl F. Meyer, the veterinarian who established veterinary public health in the United States through his broad interests in the zoonoses, including leptospirosis.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but not at 11°C. Grows in the presence 8-azaguanine (225 µg/ml), 2,6-diaminopurine (10 µg/ml), or CuSO₄ (100 p.p.m.). Produces lipase. Virulence has not been demonstrated, but some strains share genetic and antigenic similarity to pathogens.

Source: United States, from a leopard frog.

DNA G+C content (mol%): 33.5 (*T_m*).

Type strain: Iowa City Frog serovar Ranarum, ATCC 43782.

Sequence accession no. (16S rRNA gene): AY631878.

11. ***Leptospira noguchii*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 413^{VP}

no.gu'chi.i. N.L. masc. gen. n. *noguchii* of Noguchi, named to honor Hideyo Noguchi, the Japanese microbiologist who named the genus *Leptospira*.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but no growth at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml), 2,6-diaminopurine (10 µg/ml), or CuSO₄ (100 p.p.m.). Lipase is usually produced. Thought to be pathogenic with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine.

Source: parasitic strains isolated from mammals.

DNA G+C content (mol%): 36.5 (*T_m*).

Type strain: CZ 214 serovar Panama, ATCC 43288.

Sequence accession no. (16S rRNA gene): AY631886, DQ991500, Z21635.

12. ***Leptospira santarosai*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 413^{VP}

san.ta.ro'sa.i. N.L. masc. gen. n. *santarosai* of Santa Rosa, named to honor Carlos A. Santa Rosa, the Brazilian veterinary microbiologist who was a pioneer in the study of leptospirosis as a human and animal health problem in Brazil.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml) or CuSO₄ (100 p.p.m.). Growth of some strains is inhibited by 2,6-diaminopurine (10 µg/ml). Lipase is not produced. Pathogenic in mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine.

Source: the Panama Canal Zone, from a spiny rat.

DNA G+C content (mol%): 40.7 (*T_m*).

Type strain: LT 821 serovar Shermani, ATCC 43286.

Sequence accession no. (16S rRNA gene): AY461889, AY631883.

13. ***Leptospira weilii*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 413^{VP}

weil'i.i. N.L. masc. gen. n. *weilii* of Weil, named to honor Adolph Weil, a German physician who was among the first to clinically differentiate leptospirosis (Weil's disease) from other types of infectious jaundice.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml), 2,6-diaminopurine (10 µg/ml), or CuSO₄ (100 p.p.m.). Lipase is not produced. Pathogenic in mammals with disease manifestations ranging from mild influenza-like symptoms to acute, lethal infection. Bacteria localize in the kidneys of their host, facilitating shedding via urine.

Source: Australia, from blood of a patient with leptospirosis.

DNA G+C content (mol%): 40.5 (*T_m*).

Type strain: Celledoni serovar Celledoni, ATCC 43285.

Sequence accession nos (16S rRNA gene): AY631877, DQ991486, FJ154580, U12676, Z21637.

14. ***Leptospira wolbachii*** Yasuda, Steigerwalt, Sulzer, Kaufmann, Rogers and Brenner 1987, 414^{VP}

wol.ba'chi.i. N.L. masc. gen. n. *wolbachii* of Wolbach, named to honor Simeon Burt Wolbach (1880–1954), the American microbiologist who first identified *Leptospira* [*Spirochaeta*] *biflexa*.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Grows in the presence of 8-azaguanine (225 µg/ml) or 2,6-diaminopurine (10 µg/ml), but does not grow in the presence of CuSO₄ (100 p.p.m.). All strains produce lipase. Pathogenicity not demonstrated; thought to be nonpathogenic for mammals.

Source: water in the United States.

DNA G+C content (mol%): 37.2 (*T_m*).

Type strain: CDC serovar Codice, ATCC 43284.

Sequence accession no. (16S rRNA gene): AY631879.

15. ***Leptospira wolffii*** Slack, Kalambaheti, Symonds, Dohnt, Galloway, Steigerwalt, Chaicumpa, Bunyaraksyotin, Craig, Harrower and Smythe 2008, 2307^{VP}

wolffii. N.L. masc. gen. n. *wolffii* of Wolff, named to honor Jan Wolff, a Dutch bacteriologist.

Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C and 37°C, but does not grow at 13°C. Grows in the presence of 8-azaguanine (225 µg/ml). Pathogenicity not demonstrated, but thought to be of intermediate pathogenicity based on 16S rRNA

and DNA:DNA reassociation similarity to *Leptospira broomii*, *Leptospira fainei*, and *Leptospira inadai*.

Source: urine of a human patient with symptoms consistent with leptospirosis.

DNA G+C content (mol%): 41.8 (T_m).

Type strain: Khorat-H2, KIT Khorat-H2, WHO LT1686.

Sequence accession no. (16S rRNA gene): EF025496.

Other organisms

1. “**Leptospira genomospecies 1**” Brenner, Kaufmann, Sulzer, Steigerwalt, Rogers and Weyant 1999, 857
Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml), 2,6-diaminopurine (10 µg/ml), or CuSO₄ (100 p.p.m.). Does not produce lipase. Pathogenicity not reported.
Source: a frog in China.
DNA G+C content (mol%): 39.8 (T_m).
Type strain: 79601 serovar Sichuan, ATCC 700521. Note: ATCC does not list this strain.
Sequence accession no. (16S rRNA gene): AY631881.
Taxonomic note: the Subcommittee on the taxonomy of *Leptospiraceae* proposed this species be named *Leptospira alstonii*.
2. “**Leptospira genomospecies 3**” Brenner, Kaufmann, Sulzer, Steigerwalt, Rogers and Weyant 1999, 857
Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 8-azaguanine (225 µg/ml), 2,6-diaminopurine (10 µg/ml), or CuSO₄ (100 p.p.m.). Does not produce lipase. Pathogenicity not reported.
Source: water in the Netherlands.
DNA G+C content (mol%): 43.4 (T_m).
Type strain: WaZ Holland serovar Holland, ATCC 700522.
Sequence accession no. (16S rRNA gene): AY631897.
Taxonomic note: the Subcommittee on the taxonomy of *Leptospiraceae* proposed this species be named *Leptospira vanthielii*.
3. “**Leptospira genomospecies 4**” Brenner, Kaufmann, Sulzer, Steigerwalt, Rogers and Weyant 1999, 857
Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 2,6-diaminopurine (10 µg/ml), but growth is not inhibited by 8-azaguanine (225 µg/ml) or CuSO₄ (100 p.p.m.). Does not produce lipase. Pathogenicity not reported.
Source: China from an unknown source.
DNA G+C content (mol%): 38.9 (T_m).
Type strain: H 2 serovar Hualin, ATCC 700522. Note ATCC lists this strain as genomospecies 3.
Sequence accession no. (16S rRNA gene): AY631888.
Taxonomic note: the Subcommittee on the taxonomy of *Leptospiraceae* proposed this species be named *Leptospira terpstrae*.
4. “**Leptospira genomospecies 5**” Brenner, Kaufmann, Sulzer, Steigerwalt, Rogers and Weyant 1999, 857
Exhibits morphological and cultural features common to the genus *Leptospira*. Grows at 30°C, but does not grow at 11°C. Growth is inhibited by 2,6-diaminopurine (10 µg/ml), but growth is not inhibited by 8-azaguanine (225 µg/ml) or CuSO₄ (100 p.p.m.). Does not produce lipase. Pathogenicity not reported.
Source: China from an unknown source.
DNA G+C content (mol%): 37.9 (T_m).
Type strain: Sao Paulo serovar Saopaulo, ATCC 700523.
Sequence accession no. (16S rRNA gene): AY631882.
Taxonomic note: the Subcommittee on the taxonomy of *Leptospiraceae* proposed this species be named *Leptospira yanagawae*.

Genus II. **Leptonema** Hovind-Hougen 1983, 439^{VP} (Effective publication: Hovind-Hougen 1979, 250.)

RICHARD L. ZUERNER

Lep.to.ne'ma. Gr. adj. *leptos* thin, narrow, fine; Gr. neut. n. *nema* a filament or thread; N.L. neut. n. *Leptonema* a thin filament or thread, describing a bacterium that resembles a thin filament or thread.

Long, thin, flexible rods, 0.1–0.2 µm in diameter and 13–21 µm in length, with a regular helical coiling pattern having a wavelength of 0.6–0.7 µm. Unicellular but may be observed as dividing pairs or short chains in actively growing cultures. Resting stages are not known. Gram-stain-negative. Due to small diameter, unstained cells are **not visible by bright-field microscopy**. Dark-field or phase-contrast microscopy is required for visualization of unstained cells. Highly motile. **Obligate aerobes**. Growth temperatures range between 13 and 30°C, with optimal growth at 28–30°C. **Chemoorganotrophic; consume long-chain**

fatty acids and fatty alcohols as primary carbon and energy sources. Can grow on trypticase media. Uses respiration with oxygen as the terminal electron acceptor. Optimal growth occurs in semi-solid (0.2%) agar media. Growth on 1–2% solid agar results in the formation of clear to turbid subsurface colonies. Oxidase-positive. Lipase-positive. Nonpathogenic for cattle, gerbils, guinea pigs, hamsters, and mice. **Free-living in aquatic environments and soil**. Some strains found in association with animals. Does not share significant levels of sequence similarity with other *Leptospiraceae* as determined by DNA

hybridization analysis. The 16S rRNA sequence is distinct from other *Leptospiraceae*.

DNA G+C content (mol%): 51–54%

Type species: *Leptonema illini* (Hanson, Tripathy, Evans and Alexander 1974) Hovind-Hougen 1983, 439 (Effective publication: Hovind-Hougen 1979, 251.) (*Leptospira illini* Hanson, Tripathy, Evans and Alexander 1974, 355).

Further descriptive information

Taxonomic history. The previous taxonomic designation for *Leptospira illini* as *Leptospira interrogans* serovar Illini and *Leptospira illini* has led to considerable confusion in the literature. In the previous edition of this manual, the taxonomic status of the genus *Leptonema* was uncertain, and the species *illini* was designated a *species incertae sedis*. The International Committee on Systematic Bacteriology Subcommittee on the Taxonomy of *Leptospira* approved the genus designation at its meeting in 1986 (Stallman, 1987).

Leptonema illini strain 3055, the type strain for this genus and species, was originally isolated from the urine of a healthy bull in Illinois (Hanson et al., 1974). An antigenically similar strain, A177, was isolated from a turtle in the same geographical region in the year following isolation of strain 3055^T. Early DNA hybridization studies led to the discovery that strain 3055^T lacked significant homology to either the “pathogenic” complex (*Leptospira interrogans sensu lato*), or the “saprophytic” complex (*Leptospira biflexa sensu lato*) (Brendle et al., 1974). Furthermore, the DNA G+C content (51–54 mol%) of *Leptonema illini* is substantially higher than known *Leptospira* strains (Brendle et al., 1974). Subsequent DNA hybridization studies by Ramadass et al. (1990) and Brenner et al. (1999), and analyzes of *Leptospiraceae* 16S rRNA sequences (Hookey et al., 1993; Morey et al., 2006; Paster et al., 1991) support a familial relationship between *Leptospira* and *Leptonema*, while supporting formation of a distinct genus *Leptonema* with a single known species, *Leptonema illini*.

Cell morphology, ultrastructure, and motility. Analysis of *Leptonema illini* has played a critical role in understanding cell structure and motility of the *Leptospiraceae*. *Leptonema illini* cells have a typical spirochete ultrastructure including a long slender helical morphology (Figure 102), forming right-handed helices (Carleton et al., 1979). Cells undergoing translational movement have a spiral anterior end and a hooked posterior end (Goldstein and Charon, 1990). The ability to form hooked ends is essential for translational movement and is governed by

the shape of the two periplasmic flagella inserted subterminally at each end of the cell (Bromley and Charon, 1979). Nonhelical mutants are nonmotile and have periplasmic flagella with no defined shape, whereas wild-type cells and motile revertants have hooked ends and highly coiled flagella (Bromley and Charon, 1979), indicating these structures are rigid. *Leptonema* cells retain a gentle helical morphology regardless of whether the periplasmic flagella are straight or coiled (Bromley and Charon, 1979), and this is consistent with a model suggesting that the periplasmic flagella lie along the helical axis of the cell (Goldstein et al., 1996). Rotation of the periplasmic flagella is thought to cause the cytoplasmic cylinder to rotate around the axis of the flagella, and, depending on the direction of flagellar rotation, induce either a spiral or hook shape (Berg et al., 1978; Charon et al., 1984; Goldstein and Charon, 1990). A coordinated change in the cell ends from spiral to hook or from hook to spiral, enables the bacteria to rapidly change direction during translational movement (Charon et al., 1984).

A feature unique to *Leptonema* among the *Leptospiraceae* is the presence of cytoplasmic tubules that start near the insertion of the periplasmic flagella, and are about the same length as the flagella (Hovind-Hougen, 1979). These structures are also seen in species of *Treponema* and *Spirocheta*, but have not been observed in other members of *Leptospiraceae*.

Nutrition and growth conditions. Although *Leptonema* is traditionally grown on bovine serum albumin, Tween-based media used to cultivate *Leptospira*, e.g., EMJH (Ellinghausen and McCullough, 1965; Johnson and Harris, 1967a), members of this genus are distinguished by the ability to grow on trypticase media (Hanson et al., 1974). Large (8–10 mm) colonies appear on solid EMJH agar media within 7–10 d. Little information is known about the specific nutritional requirements of *Leptonema illini*. However, physiological profiles of *Leptospiraceae* using aminopeptidase substrates clustered the *Leptonema* strains together in a distinct pattern separate from either *Leptospira* or *Turneriella* (Neill et al., 1987).

Leptonema illini and *Leptospira biflexa* are more resistant to killing by UV or mitomycin C treatments than pathogenic *Leptospira* (Stamm and Charon, 1988).

rRNA sequence analysis. As noted above, 16S rRNA sequence analysis is useful for distinguishing *Leptonema* from *Leptospira* or *Turneriella* (Hookey et al., 1993; Morey et al., 2006; Paster et al., 1991). Unlike *Leptospira* species, which have one gene encoding 5S rRNA (*rrm*) and two genes each encoding 16S (*rrs*) and 23S (*rrl*) rRNA species, *Leptonema* has two genes

FIGURE 102. Transmission electron micrograph of *Leptonema illini* strain 3055^T. Bar = 2 μm.

encoding each rRNA species (Fukunaga et al., 1991). In addition, the two *Leptonema rrn* genes are closely linked to each other (Fukunaga and Mifuchi, 1989b), and the *rrs* and *rrl* genes are separated by a 435 bp intergenic spacer (Woo et al., 1996). In contrast, the rRNA genes in *Leptospira* species are dispersed throughout the large chromosome.

Bacteriophage. Early electron microscopy studies of *Leptonema illini* strain 3055^T cultures revealed the presence of bacteriophage-like particles with 45–50 nm heads and 60–65 × 15–20 nm tails (Hanson et al., 1974; Ritchie and Ellinghausen, 1969). Intracellular forms of these phage-like particles were also detected. Subsequent studies to characterize these particles have not been reported.

Ecology. The initial isolations of *Leptonema illini* were from cattle and turtles. Subsequent isolations of *Leptonema illini* having distinctly different antigenic profiles from the original isolates have been reported from fresh water (Bazovska et al., 1983) and a lymphocyte culture from a HIV-I infected human patient (Rocha et al., 1993). Several spirochete isolates from animal and water sources by Neill et al. (1987) have

aminopeptidase substrate profiles similar to *Leptonema illini*, but these have not been characterized further by either DNA hybridization or 16S rRNA sequence analysis. Recent studies using 16S rRNA sequence analysis to profile microbial communities suggest *Leptonema illini* is broadly distributed in nature; 16S rRNA sequences matching *Leptonema illini* were detected in petroleum-contaminated soil in Japan (Kasai et al., 2005) and diseased coral communities near the Bahamas (Sekar et al., 2006).

Pathogenesis and antigenicity. Although serological surveys of cattle and swine in Illinois showed >60% positive reaction with strain 3055^T (Tripathy and Hanson, 1973a), this strain is not pathogenic for a wide variety of animal species including cattle, gerbils, guinea pigs, hamsters, and mice (Tripathy and Hanson, 1973b). Serological testing of strains 3055^T and A177 showed these strains comprised a novel antigenic group, distinct from known *Leptospira* serovars (Hanson et al., 1974). The discovery of additional serovars of *Leptonema illini* suggests this genus may also be antigenically diverse (Rocha et al., 1993).

List of species of the genus *Leptonema*

1. ***Leptonema illini*** (Hanson, Tripathy, Evans and Alexander 1974) Hovind-Hougen 1983, 439^{VP} (Effective publication: Hovind-Hougen 1979, 251.) (*Leptospira illini* Hanson, Tripathy, Evans and Alexander 1974, 355)

il.li'ni. N.L. gen. n. *illini* of Illinois, named after the state of Illinois, USA, where the first isolate was obtained.

Morphologically similar to *Leptospira*. Cytoplasmic tubules extend from near the insertion of periplasmic flagella and are about the same length. Aerobe. Long-chain fatty acids and long-chain fatty alcohols serve as carbon and energy sources. Can grow on trypticase media, unlike *Leptospira* or *Turneriella*.

Three serovars described. Lacks significant homology to *Leptospira* or *Turneriella* as measured by DNA hybridization analysis. Has a unique 16S rRNA sequence profile. Not pathogenic for cattle, gerbils, guinea pigs, hamsters, and mice.

Source: urine of a clinically normal bull in Illinois, USA, in 1965 (Hanson et al., 1974); free living in soil or aquatic environments; some strains are found in association with animals.

DNA G+C content (mol%): 51–54% (*T_m* and Bd).

Type strain: 3055, NCTC 11301.

Sequence accession no. (16S rRNA gene): AY714984, Z21632.

Genus III. *Turneriella* Levett, Morey, Galloway, Steigerwalt and Ellis 2005, 1499^{VP}

RICHARD L. ZUERNER

Tur.ne.ri'el.la. N.L. fem. dim. n. *Turneriella* named after Leslie Turner, an English microbiologist who made definitive contributions to the knowledge of leptospirosis.

Flexible helical rods, 0.3 × 3.5–7.5 μm with a wavelength of 0.3–0.5 μm. Gram-stain-negative. Unicellular. Resting stages are not known. Dark-field or phase-contrast microscopy is required for visualization of unstained cells. **Obligate aerobes.** Grows slowly at 13, 30, and 37°C, with temperature optimum of 28–30°C. **Chemorganotrophic bacteria that consume long-chain fatty acids and fatty alcohols as primary carbon and energy sources.** Optimal growth occurs in semi-solid (0.2%) agar media. Oxidase-positive. Lipase-positive. Isolated from contaminated culture medium, tap water, and uterus of a sow. DNA hybridization and 16S rRNA sequence analyzes show this genus is distinct from other *Leptospiroaceae*.

DNA G+C content (mol%): 47–48.

Type species: ***Turneriella parva*** (Hovind-Hougen, Ellis and Birch-Andersen 1981) Levett, Morey, Galloway, Steigerwalt and

Ellis 2005, 1499^{VP} (*Leptospira parva* Hovind-Hougen, Ellis and Birch-Andersen 1981, 352).

Further descriptive information

Taxonomic history. The type strain was isolated from contaminated bovine serum albumin culture media and provisionally named *Leptospira parva* (Hovind-Hougen et al., 1981). Analysis of 16S rRNA sequence data indicated that this strain was different from other *Leptospira* and *Leptonema* species, and distinct from *Spirochetaceae* (Hookey et al., 1993). Additionally, this strain has an unusual aminopeptidase profile as compared to other *Leptospiroaceae* (Neill et al., 1983, 1987). These data were consistent with DNA hybridization studies that showed no significant sequence similarity to other *Leptospiroaceae* (Brenner et al., 1999). Furthermore, the G+C content of genomic DNA,

at 47–48 mol% (Hovind-Hougen et al., 1981; Neill et al., 1987), is inconsistent with known *Leptospira* and *Leptonema* species. The unique position of the type strain among *Leptospiroaceae* led to a proposal for a new genus, *Turneria* that was approved by the International Committee on Systematic Bacteriology Subcommittee on the Taxonomy of *Leptospiroaceae* in 1990 (Marshall, 1992). However, the genus name *Turneria* was found to be illegitimate due to its use as genus names for plants and animals. A description of this bacterial genus was not published in a timely manner, leading to further confusion in the literature, with references to “*Turneria*” and *Leptospira parva incertae sedis*. The accepted name of *Turneriella* was approved by the taxonomic subcommittee in 2005 (Levett and Smythe, 2006) and a description published by Levett et al. (2005).

Enrichment and isolation procedures

The type strain and original isolate was obtained from contaminated bovine serum albumin (BSA) based media used for the cultivation of *Leptospira* (Hovind-Hougen et al., 1981).

Presumably, the metabolic capabilities are similar to other *Leptospiroaceae*. Cells grow slowly at 13, 30, and 37°C in liquid, solid, and semi-solid BSA-Tween based media (EMJH) capable of supporting the growth of *Leptospira*.

Maintenance procedures

These bacteria are maintained in liquid nitrogen by placing fresh growth in semi-solid BSA-Tween media, e.g., EMJH (Ellinghausen and McCullough, 1965; Johnson and Harris, 1967a), in sterile cryogenic vials. Cultures are frozen slowly to –70°C before long-term storage in liquid nitrogen.

Differentiation of *Turneriella* from other genera

The G+C content of genomic DNA is 47–48 mol%, which is distinct from *Leptospira* (33–43%) and *Leptonema* (54%). Phylogenetic analysis of 16S rRNA sequences distinguish *Turneriella* from other *Leptospiroaceae* (Levett et al., 2005). Morphologically, *Turneriella* cells are shorter and have a shorter wavelength than other *Leptospiroaceae*.

List of species of the genus *Turneriella*

1. ***Turneriella parva*** (Hovind-Hougen, Ellis and Birch-Andersen 1981) Levett, Morey, Galloway, Steigerwalt and Ellis 2005, 1499^{VP} (*Leptospira parva* Hovind-Hougen, Ellis and Birch-Andersen 1981, 352)

par'va. L. fem. adj. *parva* small.

In addition to the description of the genus, this species has the following characteristics. Growth is

inhibited by 200 µg 8-azaguanine/ml and 10 µg 2,6-diaminopurine/ml.

Source: contaminated bovine serum albumin (BSA)-based media.

DNA G+C content (mol%): 47–48 (T_m).

Type strain: H, ATCC BAA-1111, NCTC 11395.

Sequence accession no. (16S rRNA gene): AY293856, Z21636.

Hindgut spirochetes of termites and *Cryptocercus punctulatus*

BRUCE J. PASTER AND JOHN A. BREZNAK

Spirochetes are commonly observed in the hindguts of termites (Table 134) and the wood-eating cockroach *Cryptocercus punctulatus* (Grimstone, 1963). Early workers referred to these motile bacteria as spirilla (Leidy, 1877) or vibrios (Leidy, 1881), assigned them to currently recognized spirochete genera (see *Taxonomic comments*), or “spirochetes” (Damon, 1926). Later studies using electron microscopy confirmed that these bacteria were indeed true spirochetes in that they possessed ultrastructural characteristics typical of spirochetes. (Bermudes et al., 1988). Hindgut spirochetes occur free in the gut fluid as well as attached to the surfaces of hindgut protozoa. Recently, two species of spirochetes from termite hindguts have been grown in pure culture and, on the basis of 16S rRNA sequence comparisons, were determined to be species of *Treponema*, namely *Treponema azotonutricium* and *Treponema primitia* (Graber et al., 2004; see chapter on *Treponema*, in this volume). However, most of spirochetes from the termite and cockroach hindguts have not been isolated and grown in pure or mixed culture.

The size of free hindgut spirochetes ranges from about 0.2 μm in diameter \times 3 μm long (Breznak and Pankratz, 1977) to as large as 1.0 μm in diameter \times 100 μm long (Hollande and Gharagozlou, 1967). Likewise, the number of periplasmic flagella ranges from a few per cell to as many as 100 or more in the larger forms (Bermudes et al., 1988; To et al., 1978; Wier et al., 2000). However, the multiple periplasmic flagella in most of the large forms do not generally occur in a tight bundle as in *Cristispira*.

Bermudes et al. (1988) presented taxonomic considerations of the large uncultivable hindgut spirochetes as based on size,

number of flagella, amplitude and wavelength of coils, and other ultrastructural traits. These distinctive features include the following: (a) a crenulated outer sheath (Hollande and Gharagozlou, 1967) (Figure 103); (b) a helicoidal groove or “sillon”, an invagination of the outer membrane that appears to be in contact to the inner membrane (Gharagozlou, 1968; Hollande and Gharagozlou, 1967) (Figure 104); (c) the thickness of the outer and inner coat of the outer membrane (Bermudes et al., 1988); (d) a polar organelle (Bermudes et al., 1988); and (e) cytoplasmic tubules (Bermudes et al., 1988).

Some hindgut spirochetes attach by one end to the surface of certain flagellate protozoa found only in the lower termites (i.e., families Mastotermitidae, Kalotermitidae, Hodotermitidae, Serritermitidae, and Rhinotermitidae) and *Cryptocercus punctulatus*. These spirochetes may be uniformly distributed over the surface or localized to specific regions (Ball, 1969; Kirby, 1941). Some spirochetes have a structural modification of one end of the cell in their attachment to the surfaces of *Pyronympha* (from *Reticulitermes flavipes* and *Reticulitermes tibialis*) and *Barbulanympha* (from *Cryptocercus punctulatus*) (Bloodgood and Fitzharris, 1976; Bloodgood et al., 1974). In contrast, some protozoa have structural modifications to facilitate spirochetal attachment. For example, in *Mixotrichia paradoxa* in the termite *Mastotermes darwiniensis*, bracket-like elements in the plasma membranes serve as attachment points (Cleveland and Grimstone, 1964), whereas in polymastigotes from *Reticulitermes flavipes* the attachment points are screw-like structures (Smith et al., 1975a, b). In other termite species, both the protozoan plasma

membrane and the spirochetal poles are modified to form an attachment complex (Smith and Arnott, 1974).

Cleveland and Grimstone (1964) demonstrated that adherent spirochetes serve a locomotory function for *Mixotrichia paradoxa*, although not likely for propulsion. Based on these observations, Margulis et al. (1979) proposed that eukaryotic flagella and cilia evolved from ectosymbiotic spirochetes. However, antibiotic treatment of *Mixotrichia paradoxa* reduces the number of ectobionts and leads to a disintegration of the attachment systems rendering the protozoan immotile (Radek and Nitsch, 2007). Furthermore, the antibiotic treatment causes attached spirochetes to lose their helical shape and form round bodies (Radek and Nitsch, 2007).

From the data on the two cultivable hindgut spirochetes (Graber et al., 2004), *Treponema azotonutricium* ferments carbo-

hydrates to acetate, ethanol, CO₂, and H₂ as major products and is noteworthy in that this species does have nitrogenase activity. On the other hand, *Treponema primitia* ferments carbohydrates only to acetate, with little or no nitrogenase activity. *Treponema azotonutricium* and *Treponema primitia* are obligate anaerobes, and it is likely that other hindgut spirochetes are anaerobic as they become nonmotile and begin to disintegrate when exposed to air. Hindgut spirochetes do not invade the hindgut epithelium, and the insects harboring them appear vigorous and healthy. It has been suggested that hindgut spirochetes may benefit the host. Eutick et al. (1978) observed that *Nasutiterme)s exitiosus* termites had a reduced life span when spirochetes were eliminated from the hindgut.

Motile spirochetes have been observed within the cytoplasm of hindgut protozoa (Kirby, 1941; Margulis et al., 1979;

FIGURE 103. Transmission electron micrograph of transverse section of large spirochete from the hindgut of *Reticulitermes flavipes*, showing the proposed genus "*Pillotina*" with a crenulated outer sheath (OS), sillon or groove (G) and periplasmic flagella (PF). Scale bar = 0.2 μ m.

To et al., 1978). However, it is not clear whether these intracellular spirochetes are truly symbiotic or were endocytosed into food vacuoles.

Taxonomic comments

Early workers classified spirochete-like organisms from termite hindguts as belonging to known spirochete genera such as "*Spirochaeta termitis*" (Dobell, 1910), "*Spirochaeta minei*" (von Prowazek, 1910), "*Spirochaeta leucotermidis*" (Hollande, 1922), and "*Spirochaeta staphylini*" (Ghidini and Archetti, 1939); "*Treponema termitis*" and "*Treponema minei*" (Dobell, 1912); and "*Cristispira termitis*" (Hollande, 1922). Electron microscopy was later used to confirm that these organisms possessed ultrastructural features characteristic of spirochetes such as a protoplasmic cylinder, periplasmic flagella (internal organelles), and an outer sheath (Margulis and Hinkle, 1992). Based on morphology and electron microscopic studies, new generic and specific epithets for true spirochetes of termite hindguts have been proposed. The framework for the morphometric analysis of large uncultivable spirochetes was formally proposed to revive four earlier-proposed species, namely *Pillotina calotermidis*, *Diplocalyx calotermidis*, *Hollandina pterotermidis*, and *Clevelandina*

FIGURE 104. Transmission electron micrograph of transverse section of large spirochete from the hindgut of *Reticulitermes flavipes*, showing the proposed genus "*Clevelandina*" with sillon or groove (G), outer sheath (OS), and periplasmic flagella (PF). Scale bar = 0.2 μ m.

reticulitermitidis (Bermudes et al., 1988; Margulis and Hinkle, 1992). More recently, also on the basis of morphometric analysis, two new, large pillotinaceous spirochetes, "*Canaleparolina darwiniensis*" and "*Diplocalyx cryptotermidis*", have been proposed (Wier et al., 2000). "*Canaleparolina darwiniensis*", the large spirochete attached to the protozoan *Mixotrichia paradoxa*, is 0.5 μ m \times 25 μ m in length and has multiple flagella in a 16:32:16 flagellar arrangement (Wier et al., 2000). "*Diplocalyx cryptotermidis*", observed in the hindguts of the dry wood-eating termite *Cryptotermes cavifrons*, is smaller in diameter and has fewer flagella than the other large hindgut spirochetes.

Spirochetal sequences have been obtained from 16S rRNA clonal analysis of enrichments of *Mixotrichia paradoxa* and are deposited in GenBank under the accession numbers AJ458944, AJ458945, AJ458946, and AJ458947. These sequences represent four separate phylotypes that cluster deeply with the genus *Treponema* at about 90% similarity to treponemal phylotypes from termite hindguts. However, *in situ* hybridization experiments have not yet been performed to verify that the sequences obtained were derived from the spirochetes attached to *Mixotrichia paradoxa*. Consequently, these large spirochetes from the hindguts of termites and *Cryptocercus punctulatus* will be included in the family *Spirochaetaceae* until pure cultures are obtained and the phylogenetic placement among the spirochetal genera has been verified.

Phylum XVI. *Tenericutes* Murray 1984a, 356^{VP} (Effective publication: Murray 1984b, 33.)

DANIEL R. BROWN

Ten.er'i.cutes. L. adj. *tener* tender; L. fem. n. *cutis* skin; N.L. fem. n. *Tenericutes* prokaryotes of a soft pliable nature indicative of a lack of a rigid cell wall.

Members of the *Tenericutes* are **wall-less bacteria that do not synthesize precursors of peptidoglycan.**

Further descriptive information

The nomenclatural type by monotypy (Murray, 1984a) is the class *Mollicutes*, which consists of very small prokaryotes that are devoid of cell walls. Electron microscopic evidence for the absence of a cell wall was mandatory for describing novel species of mollicutes until very recently. Genes encoding the pathways for peptidoglycan biosynthesis are absent from the genomes of more than 15 species that have been annotated to date. Some species do possess an extracellular glycocalyx. The absence of a cell wall confers such mechanical plasticity that most mollicutes are readily filterable through 450 nm pores and many species have some cells in their populations that are able to pass through 220 nm or even 100 nm filters. However, they may vary in shape from coccoid to flask-shaped cells or helical filaments that reflect flexible cytoskeletal elements.

Taxonomic comments

To provide greater definition and formal nomenclature for vernacular names used in the 8th edition of *Bergey's Manual of Determinative Bacteriology* (Bergey VIII; Buchanan and Gibbons, 1974), Gibbons and Murray (1978) proposed that the higher taxa of prokaryotes be subdivided primarily according to the presence and character, or absence, of a rigid or semirigid cell wall as reflected in the determinative Gram reaction. Similar to the non-hierarchical groupings of Bergey VIII, which were based on a few readily determined criteria, the "wall-deficient" organisms grouped together in the first edition of *The Prokaryotes* included the mollicutes (Starr et al., 1981). While acknowledging the emerging 16S rRNA-based evidence that indicated a phylogenetic relationship between mollicutes and certain Gram-stain-positive bacteria in the division *Firmicutes*, Murray (1984b) proposed the separate division *Tenericutes* for the stable and distinctive group of wall-less species that are not simply an obvious subset of the *Firmicutes*.

The approved divisional rank of *Tenericutes* and the assignment of class *Mollicutes* as its nomenclatural type (Murray, 1984a) were adopted by the International Committee on Systematic Bacteriology's Subcommittee on the Taxonomy of *Mollicutes* (Tully, 1988) and subsequent valid taxonomic descriptions assigned novel species of mollicutes to the *Tenericutes*. However, the second (1992) and third (2007) editions of *The Prokaryotes* described the mollicutes instead as *Firmicutes* with low G+C DNA. The Subcommittee considered this to be an unfortunate grouping: "While

the organisms are evolutionarily related to certain clostridia, the absence of a cell wall cannot be equated with Gram reaction positivity or with other members of the *Firmicutes*. It is unfortunate that workers involved in determinative bacteriology have a reference in which wall-free prokaryotes are described as Gram-positive bacteria" (Tully, 1993a). Despite numerous valid assignments of novel species of mollicutes to the *Tenericutes* during the intervening years, the class *Mollicutes* was still included in the phylum *Firmicutes* in the most recent revision of the *Taxonomic Outline of Bacteria and Archaea* (TOBA), which is based solely on the phylogeny of 16S rRNA genes (Garrity et al., 2007). The taxon *Tenericutes* is not recognized in the TOBA, although paradoxically it is the phylum consisting of the *Mollicutes* in the most current release of the Ribosomal Database Project (Cole et al., 2009). Mollicutes are specifically excluded from the most recently emended description of the *Firmicutes* in *Bergey's Manual of Systematic Bacteriology* (2nd edition, volume 3; De Vos et al., 2009) on the grounds of their lack of rigid cell walls plus analyses of strongly supported alternative universal phylogenetic markers, including RNA polymerase subunit B, the chaperonin GroEL, several different aminoacyl tRNA synthetases, and subunits of F₀F₁-ATPase (Ludwig et al., 2009; Ludwig and Schleifer, 2005). The taxonomic dignity of *Tenericutes* bestowed by its original formal validation, and upheld by a quarter of a century of valid descriptions of novel species of mollicutes, has therefore been respected in this volume of *Bergey's Manual*.

Type order: Mycoplasmatales Freundt 1955, 71^{AL} emend. Tully, Bové, Laigret and Whitcomb 1993b, 382.

Class I. *Mollicutes* Edward and Freundt 1967, 267^{AL}

DANIEL R. BROWN, MEGHAN MAY, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

Mol'li.cutes or Mol.li.cu'tes. L. adj. *mollis* soft, pliable; L. fem. n. *cutis* skin; N.L. fem. pl. n. *Mollicutes* class with pliable cell boundary.

Very small prokaryotes totally **devoid of cell walls**. Bounded by a plasma membrane only. Incapable of synthesis of peptidoglycan or its precursors. Consequently resistant to penicillin and its derivatives and sensitive to lysis by osmotic shock, detergents, alcohols, and specific antibody plus complement. **Gram-stain-negative** due to lack of cell wall, but constitute a distinct phylogenetic lineage within the Gram-stain-positive bacteria (Woese et al., 1980). **Pleomorphic**, varying from spherical or flask-shaped structures to branched or helical filaments. The coccoid and flask-shaped cells usually range from 200–500 nm in diameter, although cells as large as 2000 nm have been seen. Replicate by binary fission, but genome replication may precede cytoplasmic division, leading to the formation of multinucleated filaments. Colonies on solid media are very small, usually much less than 1 mm in diameter. The organisms tend to penetrate and grow inside the solid medium. Under suitable conditions, almost all species **form colonies that have a characteristic fried-egg appearance**. Usually nonmotile, but some species show **gliding motility**. Species that occur as helical filaments show **rotary, flexional, and translational motility**. No resting stages are known.

The species recognized so far can be grown on artificial cell-free media of varying complexity, although certain strains may be more readily isolated by cell-culture procedures. Many “*Candidatus*” species have been proposed and characterized at the molecular level, but not yet cultivated axenically. Most cultivable species **require sterols** and fatty acids for growth. However, members of some genera can grow well in either serum-free media or serum-free media supplemented with polyoxyethylene sorbitan. Most species are **facultative anaerobes**, but some are **obligate anaerobes** that are killed by exposure to minute quantities of oxygen. No tricarboxylic acid cycle enzymes, quinones, or cytochromes have been found.

All mollicutes are commensals or parasites, occurring in a wide range of vertebrate, insect, and plant hosts. Many are significant

pathogens of humans, animals, insects, or plants. Genome sizes range from 580 to 2200 kbp, among the smallest recorded in prokaryotes. The genomes of more than 20 species have been completely sequenced and annotated to date (Table 135). The G+C content of the DNA is usually low, ~23–34 mol%, but in some species is as high as ~40 mol% (Bd, *T_m*). Can be distinguished from other bacteria in having only one or two rRNA operons (one species of *Mesoplasma* has three) and an RNA polymerase that is resistant to rifampin. The 5S rRNA contains fewer nucleotides than that of other bacteria and there are fewer tRNA genes. In some genera, instead of a stop, the UGA codon encodes tryptophan. Plasmids and viruses (phage) occur in some species.

Type order: Mycoplasmatales Freundt 1955, 71^{AL} emend. Tully, Bové, Laigret and Whitcomb 1993, 382.

Further descriptive information

Table 136 summarizes the present classification of the *Mollicutes* into families and genera and provides the major distinguishing characteristics of these taxa. The trivial term mycoplasma has been used to denote any species included in the class *Mollicutes*, but the term mollicute(s) is now considered most appropriate as the trivial name for all members of the class, so that the trivial name mycoplasma can be retained only for members of the genus *Mycoplasma*. Hemotropic mycoplasmas are referred to by the trivial name hemoplasmas. The trivial names ureaplasma, entomoplasma, mesoplasma, spiroplasma, acholeplasma, anaeroplasma, and asteroleplasma are commonly used when reference is made to members of the corresponding genus.

Their 16S rRNA gene sequences usefully place the mollicutes into phylogenetic groups (Johansson, 2002; Weisburg et al., 1989) and an analysis of 16S rRNA gene sequences is now mandatory for characterization of novel species (Brown et al., 2007). 16S rRNA gene sequences have also shown that certain hemotropic bacteria, previously considered to be members of the *Rickettsia*, belong to the order *Mycoplasmatales*.

TABLE 136. Description of the class *Mollicutes*^a

Order	Family	Genus	Species ^b	Genome size range (kbp)	Cholesterol requirement	Habitat ^c	Defining features
I. <i>Mycoplasmatales</i>	<i>Mycoplasmataceae</i>	<i>Mycoplasma</i>	116, 9, 1, 4	580–1,350	+	H, A	
I. <i>Mycoplasmatales</i>	<i>Mycoplasmataceae</i>	<i>Ureaplasma</i>	7, 0, 0, 0	760–1,140	+	H, A	Urea hydrolysis

III. <i>Acholeplasmatales</i>	<i>Acholeplasmataceae</i>	<i>Acholeplasma</i>	18, 0, 0, 0	1,500–1,650	–	A, N, P	
III. <i>Acholeplasmatales</i>	<i>Incertae sedis</i>	<i>Candidatus Phytoplasma</i> ^e	0, 27, 0, 0	530–1,350	nd	N, P	Not yet cultured <i>in vitro</i>
IV. <i>Anaeroplasmatales</i>	<i>Anaeroplasmataceae</i>	<i>Anaeroplasma</i>	4, 0, 0, 0	1,500–1,600	+	A	Strictly anaerobic
IV. <i>Anaeroplasmatales</i>	<i>Anaeroplasmataceae</i>	<i>Asteroleplasma</i>	1, 0, 0, 0	1,500	–	A	Strictly anaerobic

^and, Not determined; PES, polyoxyethylene sorbitan.^bNumbers of species: valid, *Candidatus, incertae sedis*, invalid.^cH, human; A, vertebrate animal; N, invertebrate animal; P, plant.^dAffiliation of the constituent genera within the *Mycoplasmatales* has not been formalized.

The phytoplasmas, a large group of uncultivated mollicutes occurring as agents that can cycle between plant and invertebrate hosts, have been given a provisional “*Candidatus* Phytoplasma” genus designation. The 16S rRNA gene sequences from at least ten unique phylotypes, recently discovered among the human microbial flora through global 16S rRNA gene PCR (Eckburg et al., 2005), cluster distinctly enough to suggest the existence of a yet-uncircumscribed order within the class (May et al., 2009).

Non-helical mollicutes isolated from insects and plants have been placed in the order *Entomoplasmatales*, the two genera of which are distinguished by their requirement for cholesterol (Tully et al., 1993). Members of the genus *Entomoplasma* require cholesterol; those of the genus *Mesoplasma* do not. However, sterol requirements do not correlate well with phylogenetic analyses in other groups. At least four species of spiroplasmas do not require sterol for growth, but they do not form a phylogenetic group. Within the order including the obligately anaerobic mollicutes *Anaeroplasmatales*, members of the genus *Anaeroplasma* require sterols for growth, whereas members of the genus *Asteroleplasma* do not (Robinson et al., 1975; Robinson and Freundt, 1987). Thus, sterol requirement is a useful phylogenetic marker only in the *Acholeplasmatales* and *Anaeroplasmatales*.

In the past, there was some risk of confusing mollicutes with wall-less “L (Lister)-phase” variants of certain other bacteria, but simple PCR-based analyses of 16S rRNA or other gene sequences now obviate that concern. Wall-less members of the genus *Thermoplasma*, previously assigned to the *Mollicutes*, are *Archaea* and differ from all other members of this class in their 16S rRNA nucleotide sequences plus a number of important features relating to their mode of life and metabolism. Thus, they are quite unrelated to this class (Fox et al., 1980; Razin and Freundt, 1984; Woese et al., 1980). Members of the *Erysipelothrix* line of descent, also formerly assigned to the *Mollicutes*, are now assigned to the class *Erysipelotrichi* in the phylum *Firmicutes* (Stackebrandt, 2009; Verbarg et al., 2004).

Taxonomic comments

The origin of mollicutes and their relationships to other prokaryotes was controversial for many years, especially since their small genomes and comparative phenotypic simplicity suggested that they might have descended from a primitive organism. The first comparative phylogenetic analysis of the origin of mollicutes was carried out by oligonucleotide mapping of 16S rRNA gene sequences by Woese et al. (1980). The organisms then assigned to the genera *Mycoplasma*, *Spiroplasma*, and *Acholeplasma* seemed to have arisen by reductive evolution as a deep branch of the clostridial lineage leading to the genera *Bacillus* and *Lactobacillus*. This relationship had been proposed earlier (Neimark, 1979) because the low G+C mollicutes, streptococci, and lactic acid bacteria share characteristic enzymes. In particular, acholeplasma and streptococcus aldolases show high amino acid sequence similarity.

These findings were generally confirmed by studies of 5S rRNA gene sequences (Rogers et al., 1985), which included a number of acholeplasmas, anaeroplasmas, mycoplasmas, ureaplasmas, and *Clostridium innocuum*. Dendrograms constructed from evolutionary distance matrices indicated that the mollicutes form a coherent phylogenetic group that developed as

a branch of the *Firmicutes*. The initial event in this evolution was proposed to be the formation of the *Acholeplasma* branch, although the position of the *Anaeroplasma* species (*Anaeroplasma bactoclasticum* and *Anaeroplasma abactoclasticum*) was not definitely established within these dendrograms. Formation of the acholeplasmas may have coincided with a reduction in genome size to about 1500–1700 kb and loss of the cell wall. With a genome size similar to the acholeplasmas, the spiroplasmas may have formed from the acholeplasmas. Later independent genome reductions to 500–1000 kb may have led to the origins of the sterol-requiring mycoplasma and ureaplasma lineages. The more extensive phylogenetic analysis of Weisburg et al. (1989) examined the 16S rRNA gene sequences of about 50 species of mollicutes and confirmed a number of these observations and provided additional insights into mollicute evolution. These results also indicated that the acholeplasmas formed upon the initial divergence of mollicutes from clostridial ancestors. Further divergence of this stem led to the sterol-requiring, anaerobic *Anaeroplasma* and the non-sterol-requiring *Asteroleplasma* branches. The *Spiroplasma* branch also appeared to originate from within the acholeplasmas, with further evolution leading to a series of repeated and independent genome reductions from nearly 2000 kb to 600–1200 kb to yield the *Mycoplasma* and *Ureaplasma* lineages.

Based on the phylogeny of 16S rRNA genes, the class *Mollicutes* was included in the phylum *Firmicutes* in the most recent revision of the *Taxonomic Outline of Bacteria and Archaea* (Garrity et al., 2007). However, the *Mollicutes* are excluded from the most recently emended description of the *Firmicutes* (De Vos et al., 2009) based on alternative phylogenetic markers, including RNA polymerase subunit B, the chaperonin GroEL, several different aminoacyl tRNA synthetases, and subunits of F₀F₁-ATPase (Ludwig and Schleifer, 2005).

The Weisburg et al. (1989) study also proposed five additional phylogenetic groupings within the mollicutes, including the anaeroplasma, asteroleplasma, spiroplasma, pneumoniae, and hominis groups (Figure 105). Phytoplasmas are similar to acholeplasmas in their 16S rRNA gene sequences and UGA codon usage (IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004). They probably diverged from acholeplasmas at about the same time as the split of spiroplasmas into helical and non-helical lineages (Maniloff, 2002). The modern species concept for mollicutes is justified principally by DNA–DNA hybridization, serology, and 16S rRNA gene sequence similarity (Brown et al., 2007). A large number of individual species have been assigned to phylogenetic groups, clusters, and subclusters that also share other characteristics, although the cluster boundaries are sometimes subjective (Harasawa and Cassell, 1996; Johansson, 2002; Pettersson et al., 2000, 2001).

Lastly, the type order *Mycoplasmatales* is assigned to the class as this clearly appeared to be the intention of Edward and Freundt (1967) in their paper entitled “Proposal for *Mollicutes* as name of the class established for the order *Mycoplasmatales*”.

Acknowledgements

Order I. **Mycoplasmatales** Freundt 1955, 71^{AL} emend. Tully, Bové, Laigret and Whitcomb 1993, 382

DANIEL R. BROWN, MEGHAN MAY, JANET M. BRADBURY, KARL-ERIK JOHANSSON AND HAROLD NEIMARK

My.co.plas.ma.ta'les. N.L. neut. n. *Mycoplasma*, -*atos* type genus of the order; -*ales* ending to denote an order; N.L. fem. pl. n. *Mycoplasmatales* the *Mycoplasma* order.

The first order in the class *Mollicutes* is assigned to a group of sterol-requiring, wall-less prokaryotes that occur as commensals or pathogens in a wide range of vertebrate hosts. The description of the order is essentially the same as for the class. A single family *Mycoplasmataceae* with two genera, *Mycoplasma* and *Ureaplasma*, recognizes the prominent and distinct characteristics of the assigned organisms, based on their sterol requirements for growth, the capacity of some to hydrolyze urea, and conserved 16S rRNA gene sequences.

Type genus: **Mycoplasma** Nowak 1929, 1349 nom. cons. Jud. Comm. Opin. 22, 1958, 166.

Further descriptive information

The entire class *Mollicutes* was encompassed initially by a single order. The elevation of acholeplasmas to ordinal rank (*Acholeplasmatales* Freundt, Whitcomb, Barile, Razin and Tully 1984) recognized their major distinctions in nutritional, biochemical, physiological, and genetic characteristics from other members of the class *Mollicutes*. Subsequently, additional orders were proposed to recognize the anaerobic mollicutes and the wall-less prokaryotes from plants and insects which were phylogenetically related to the remaining *Mycoplasmatales*. Thus, the *Anaeroplasmatales* (Robinson and Freundt, 1987) recognized the strictly anaerobic, wall-less prokaryotes first isolated from the bovine and ovine rumen, and *Entomoplasmatales* (Tully et al., 1993) provided a classification for a number of the mollicutes regularly associated with plant and insect hosts. On the basis of 16S rRNA gene sequence similarities (Johansson and

Pettersson, 2002), the *Mycoplasmatales* and *Entomoplasmatales* represent a clade deeply split from the *Acholeplasmatales* and *Anaeroplasmatales*.

A growth requirement for cholesterol or serum is shared by the organisms assigned to the order *Mycoplasmatales*, as well as most other organisms within the class *Mollicutes*. Therefore, tests for cholesterol requirements are essential to classification. Earlier assessments of the growth requirements for cholesterol were based upon the capacity of organisms to grow in a number of serum-free broth preparations to which various concentrations of cholesterol were added (Edward, 1971; Razin and Tully, 1970). In this test, species that do not require exogenous sterol usually show no significant growth response to increasing cholesterol concentrations. Polyoxyethylene sorbitan (Tween 80) and palmitic acid should be included in the base medium because acholeplasmas such as *Acholeplasma axanthum* and *Acholeplasma morum* require additional fatty acids for adequate growth. A modified method utilizing serial passage in selective medium has been applied successfully to a large number of mollicutes (Rose et al., 1993; Tully, 1995). The *Acholeplasmatales* grow through end-point dilutions in serum-containing medium and in serum-free preparations, or occasionally in serum-free medium supplemented with Tween 80. Mesoplasmas from the order *Entomoplasmatales* grow in serum-containing medium and in serum-free medium supplemented only with Tween 80. Most spiroplasmas, also from the *Entomoplasmatales*, and all members of the order *Mycoplasmatales* grow only in serum-containing medium.

My.co.plas.ma.ta.ce'ae. N.L. neut. n. *Mycoplasma*, -atos type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Mycoplasmataceae* the *Mycoplasma* family.

Pleomorphic usually coccoid cells, 300–800 nm in diameter, to **slender branched filaments** of uniform diameter. Some cells have a **terminal bleb or tip structure** that mediates adhesion to certain surfaces. **Cells lack a cell wall** and are bounded only by a plasma membrane. Gram-stain-negative due to the absence of a cell wall. Usually **nonmotile**. **Facultatively anaerobic** in most instances, possessing a truncated flavin-terminated electron transport chain devoid of quinones and cytochromes. Colonies of *Mycoplasma* are usually less than 1 mm in diameter and colonies of *Ureaplasma* are much smaller than that. The typical colony has a **fried-egg or “cauliflower head” appearance**. Usually catalase-negative. **Chemo-organotrophic**, usually using either sugars or arginine, but sometimes both, or having an obligate requirement for urea as the major energy source. **Require cholesterol** or related sterols for growth. **Commensals or pathogens** of a wide range of **vertebrate hosts**. The **genome size** ranges from about **580 to 1350 kbp**, as measured by pulsed field gel electrophoresis (PFGE) or complete DNA sequencing.

DNA G+C content (mol%): about 23–40 (Bd, T_m).

Type genus: Mycoplasma Nowak 1929, 1349 nom. cons. Jud. Comm. Opin. 22, 1958, 166.

Further descriptive information

This family and its type genus *Mycoplasma* are polyphyletic. Two genera, *Mycoplasma* and *Ureaplasma*, are currently accepted within the family. The genus *Mycoplasma* is further divisible into phylogenetic groups on the basis of 16S rRNA gene sequence similarities (Johansson and Pettersson, 2002), including an ecologically, phenotypically, and genetically cohesive group called the mycoides cluster, which includes the type species *Mycoplasma mycoides* and other major pathogens of ruminant animals. The taxonomic position of the mycoides cluster is an important anomaly because molecular markers based upon rRNA and other gene sequences indicate that it is closely related to other genera usually associated with plant and insect hosts and currently classified within the order *Entomoplasmatales*. Members of the genus *Ureaplasma* are distinguished by their tiny colony size and capacity to hydrolyze urea.

DANIEL R. BROWN, MEGHAN MAY, JANET M. BRADBURY, MITCHELL F. BALISH, MICHAEL J. CALCUTT, JOHN I. GLASS, SÉVERINE TASKER, JOANNE B. MESSICK, KARL-ERIK JOHANSSON AND HAROLD NEIMARK

My.co.plas'ma. Gr. masc. n. *myces* a fungus; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Mycoplasma* fungus form.

Pleomorphic cells, 300–800 nm in diameter, varying in shape from spherical, ovoid or flask-shaped, or twisted rods, to slender branched filaments ranging in length from 50 to 500 nm. **Cells lack a cell wall** and are bounded by a single plasma membrane. Gram-stain-negative due to the absence of a cell wall. Some have a complex internal cytoskeleton. Some have a specific **tip structure** that mediates attachment to host cells or other surfaces. **Usually nonmotile**, but gliding motility has been demonstrated in some species. **Aerobic or facultatively anaerobic**. Optimum growth at 37°C is common, but permissive growth temperatures range from 20 to 45°C. **Chemo-organotrophic**, usually using either sugars or arginine as the major energy source. **Require cholesterol** or related sterols for growth. Colonies are usually less than 1 mm in diameter. The typical colony has a **fried-egg appearance**. The **genome size** of species examined ranges from **580 kbp to about 1350 kbp**. The codon UGA encodes tryptophan in all species examined. **Commensals or pathogens** in a wide range of vertebrate hosts.

DNA G+C content (mol%): 23–40.

Type species: Mycoplasma mycoides (Borrel, Dujardin-Beaumetz, Jeantet and Jouan 1910) Freundt 1955, 73 (*Astero-coccus mycoides* Borrel, Dujardin-Beaumetz, Jeantet and Jouan 1910, 179).

Further descriptive information

The shape of these organisms (trivial name, mycoplasmas) can depend on the osmotic pressure, nutritional quality of the

culture medium, and the growth phase. Some mycoplasmas are filamentous in their early and exponential growth phases or when attached to surfaces or other cells. This form can be transitory, and the filaments may branch or fragment into chains of cocci or individual vegetative cells. Many species are typically coccoid and never develop a filamentous phase. Some species develop specialized attachment tip structures involved in colonization and virulence (Figure 106). In Romanowsky-type stained blood smears, hemotropic species (trivial name, hemoplasmas) appear as round to oval cells on the surface of erythrocytes (Figure 107). They may be found individually or, during periods of high parasitemia, in pairs or chains giving the appearance of pleomorphism. Their small size and the absence of cell wall components provide considerable plasticity to the organisms, so that cells of most species are readily filterable through 450 nm pores, and many species have some cells in the population that are able to pass through 220 nm or even 100 nm filters (Tully, 1983). Descriptions of the morphology, ultrastructure, and motility of mycoplasmas should be based on correlation of the appearance of young exponential-phase broth cultures under phase-contrast or dark-field microscopy with their appearance using negative-staining or electron microscopy (Biberfeld and Biberfeld, 1970; Boatman, 1979; Carson et al., 1992; Cole, 1983). Special attention to the osmolarity of the fixatives and buffers is required since these may alter the size and shape of the organisms. The classical isolated colony is umbonate with a fried-egg appearance, but others may have

either cauliflower-like or smooth colony surfaces (Figure 108), with smooth, irregular or scalloped margins, depending on the species, agar concentration, and other growth conditions.

A significant minority of species exhibit cell polarization. This depends on Triton X-100-insoluble cytoskeletal structures

involved in morphogenesis, motility, cytoadherence, and cell division (Balish and Krause, 2006). In the distantly related species *Mycoplasma pneumoniae* and *Mycoplasma mobile*, the cytoskeleton underlies a terminal organelle. This prominent extension of the cytoplasm and cell membrane is the principal focus of adherence

FIGURE 108. Diverse colonial morphology in the genus *Mycoplasma*. Original magnification 25×. Images provided by Helena Windsor and David Windsor.

and is the leading end of cells engaged in gliding motility. In *Mycoplasma pneumoniae*, adhesin proteins are located either all over the surface of the organelle or at its distal tip; an unrelated adhesin is concentrated at the base of the terminal organelle in *Mycoplasma mobile* (Balish, 2006). Both the formation of this attachment organelle of *Mycoplasma pneumoniae* and the localization of the adhesins depend upon cytoskeletal proteins that form an electron-dense core within its cytoplasm, which is surrounded by an electron-lucent space (Krause and Balish, 2004). The overall appearance of this core is that of two parallel, flat rods of differing thickness, with a bend near the cell-proximal end (Henderson and Jensen, 2006; Seybert et al., 2006). A bilobed button constitutes its distal end and its proximal base terminates in a bowl-like structure. Overall, both the core and the attachment organelle are 270–300 nm in length (Hatchel and Balish, 2008). Around the onset of DNA replication, a second attachment organelle is constructed (Seto et al., 2001). The motile force provided by the first organelle reorganizes the cell such that the new organelle is moved to the opposite cell pole before cell division (Hasselbring et al., 2006). These observations suggest that complex coordination exists between attachment organelle biogenesis, motor activity, the DNA replication machinery, and the cytokinetic machinery. Similar structures are present in other species of the *Mycoplasma pneumoniae* cluster, but in most cases the attachment organelle is shorter, resulting in much of the core protruding into the cell body (Hatchel and Balish, 2008). In *Mycoplasma mobile*, the terminal organelle is completely dissimilar, consisting of a cell-distal sphere with numerous tentacle-like strands extending into the cytoplasm (Nakane and Miyata, 2007). It is comprised of proteins unrelated to those

found in *Mycoplasma pneumoniae*, suggesting that it has evolved independently. Further distinct cytoskeletal structures appear in *Mycoplasma penetrans* (Jurkovic and Balish, unpublished), “*Mycoplasma insons*” (Relich et al., 2009), and several species of the mycoides cluster (Peterson et al., 1973).

Attachment to eukaryotic host cells is important for the natural survival and transmission of mycoplasmas. The prominent attachment organelle of species in the *Mycoplasma pneumoniae* cluster is the most extensively characterized determinant of cytodherence. In other species, multiple adhesin proteins are involved in cytodherence. When one adhesin is blocked, cytodherence is reduced, but not completely lost. For this reason, the adhesins appear to be functionally redundant rather than synergistic in action. Numerous species possess multigene families of antigenically variable proteins, some of which have been implicated in host cell attachment or hemagglutination. While this attachment may serve as a supplemental binding mechanism in species such as *Mycoplasma gallisepticum* and *Mycoplasma hominis*, variable surface proteins are currently the only known mechanism for cytodherence and hemagglutination of *Mycoplasma synoviae* and *Mycoplasma pulmonis*. The avidity of adherence may differ among variants in *Mycoplasma pulmonis* and *Mycoplasma hominis*. Though one or more attachment mechanisms have been described for numerous species, there remains a greater number of species with no documented system for cytodherence. Strains that lose the capacity to cytodhere are almost invariably unable to survive in their hosts, but highly invasive species such as *Mycoplasma alligatoris* may not require host cell attachment for infection.

The mycoplasmas possess a typical prokaryotic plasma membrane composed of amphipathic lipids and proteins

(McElhane, 1992a, b, c; Smith, 1992; Wieslander et al., 1992). At one time, demonstration of a single unit membrane was mandatory for defining all novel species of mollicutes (Tully, 1995a). Now, when the 16S rRNA gene sequence of a novel species is determined and the candidate is placed in one of the phylogenetic clusters of mollicutes, in the majority of cases it can be safely inferred that the organism lacks a cell wall, because the majority of others in that cluster will have been shown to be solely membrane-bound (Brown et al., 2007). The lack of a cell wall explains the resistance of the organisms to lysis by lysozyme and their susceptibility to lysis by osmotic shock and various agents causing the lysis of bacterial protoplasts (Razin, 1979, 1983). In certain species, the extracellular surface is textured with capsular material or a nap, which can be stained with ruthenium red in some cases (Rosenbusch and Minion, 1992).

These organisms represent some of the most nutritionally fastidious prokaryotes, as expected from their greatly reduced or minimalist genomes, close association with vertebrate hosts as commensals and pathogens, and total dependence upon the host to meet all nutritional requirements. They have very limited capacity for intermediary metabolism, which restricts the utility of conventional biochemical tests for identification. Detailed information on carbohydrate (Pollack, 1992, 1997, 2002; Pollack et al., 1996), lipid (McElhane, 1992a), and amino acid (Fischer et al., 1992) metabolism is available. All species examined have truncated respiratory systems, lack a complete tricarboxylic acid cycle, and lack quinones or cytochromes, which precludes their capacity to carry out oxidative phosphorylation. Instead only low levels of ATP may be generated through glycolysis or the arginine dihydrolase pathway (Miles, 1992a, b). Fermentative species catabolize glucose or other carbohydrates to produce ATP and acid and, consequently, lower the pH of the medium. Non-fermentative species hydrolyze arginine to yield ammonia, some ATP, and carbon dioxide, and consequently raise the pH of the medium. Species such as *Mycoplasma fermentans* have both pathways. Species such as *Mycoplasma bovis* evidently lack both pathways, but are capable oxidizing pyruvate or lactate to yield ATP (Miles, 1992a; Taylor et al., 1994). Some species cause a pronounced "film and spots" reaction on media incorporating heat-inactivated horse serum or egg yolk: a wrinkled film composed of cholesterol and phospholipids forms on the surface of the medium and dark spots containing salts of fatty acids appear around the colonies.

Most mycoplasmas are aerobes or facultative anaerobes, but some species such as *Mycoplasma muris* prefer an anaerobic environment. The optimum growth of species isolated from homeothermic hosts is commonly at 37°C and the permissive temperature range of species from poikilothermic fish and reptiles is always above 20–25°C. Thus, growth of the mycoplasmas is restricted to mesophilic temperatures. Growth in liquid cultures usually produces at most light turbidity and few sedimented cells, except for the heavy turbidity and sediments usually observed with members of the *Mycoplasma mycoides* cluster. Tully (1995b) described in detail the most commonly used culture media formulations. Although colonies are occasionally first detected on blood agar, complex undefined media such as American Type Culture Collection (ATCC) medium 988 (SP-4) are usually required for primary isolation and maintenance. Cell-wall-targeting antibiotics are included to discourage growth of other bacteria. Phenol red facilitates detection of species that excrete acidic or alkaline metabolites. Growth of

arginine-hydrolyzing species can be enhanced by supplementing media with arginine. Commonly used alternatives such as Frey's, Hayflick's and Friis' media differ from SP-4 mainly in the proportions of inorganic salts, amino acids, serum sources, and types of antibiotics. For species that utilize both sugars and arginine as carbon sources, the pH of the medium may initially decrease before rising later during the course of growth (Razin et al., 1998). Defined mycoplasma culture media have been described in detail (Rodwell, 1983), but provision of lipids and amino acids in the appropriate ratios is difficult technically (Miles, 1992b).

Many mobile genetic elements occur in the genus. Four plasmids have been identified in members of the mycoides cluster (Bergemann and Finch, 1988; Djordjevic et al., 2001; King and Dybvig, 1994). Each plasmid is apparently cryptic, with no discernible determinants for virulence or antibiotic resistance. DNA viruses have been isolated from *Mycoplasma bovirhinis* (Howard et al., 1980), *Mycoplasma hyorhinis* (Gourlay et al., 1983) *Mycoplasma pulmonis* (Tu et al., 2001), and *Mycoplasma arthritidis* (Voelker and Dybvig, 1999). The *Mycoplasma pulmonis* P1 virus and the lysogenic bacteriophage MAV1 of *Mycoplasma arthritidis* do not share sequence similarity (Tu et al., 2001; Voelker and Dybvig, 1999), whereas the *Mycoplasma fermentans* MFV1 prophage is strikingly similar in genetic organization to MAV1 (Röske et al., 2004). No role in pathobiology has been demonstrated for any virus or prophage.

The most abundant mobile DNAs in *Mycoplasma* are insertion sequence (IS) elements. The first identified units (IS1138 of *Mycoplasma pulmonis*, IS1221 of *Mycoplasma hyorhinis*, IS1296 of *Mycoplasma mycoides* subsp. *mycoides* and ISM1 of *Mycoplasma fermentans*) are members of the IS3 family (Bhugra and Dybvig, 1993; Ferrell et al., 1989; Frey et al., 1995; Hu et al., 1990). More recently, multiple IS elements of divergent subgroups have been identified. Members of the IS4 family include IS1634 and ISMmy1 of *Mycoplasma mycoides* subsp. *mycoides* (Vilei et al., 1999; Westberg et al., 2002), ISMhp1 of *Mycoplasma hyopneumoniae*, ISMhp1-like unit of *Mycoplasma synoviae*, and four distinct elements of *Mycoplasma bovis* (Lysnyansky et al., 2009). Among the IS30 family members identified are IS1630 of *Mycoplasma fermentans*, ISMhom1 from *Mycoplasma hominis*, ISMag1 of *Mycoplasma agalactiae* (Pilo et al., 2003), and two IS units of *Mycoplasma bovis*. IS-like elements have also been identified in *Mycoplasma leachii*, *Mycoplasma penetrans* (belonging to four different families), *Mycoplasma hyopneumoniae*, *Mycoplasma flocculare*, and *Mycoplasma orale*. Transposases that reside within IS units are also discernable in the genome of *Mycoplasma gallisepticum* (Papazisi et al., 2003). In select instances, almost identical IS units have been found in species from different phylogenetic clades, which strongly suggests lateral gene transfer between species. Despite their widespread distribution, IS elements are not ubiquitous in the genus. Although the type strains of *Mycoplasma bovis* (54 IS units of seven different types) and *Mycoplasma mycoides* subsp. *mycoides* (97 elements of three different types) possess large numbers of elements, the sequenced genomes of *Mycoplasma arthritidis*, *Mycoplasma genitalium*, *Mycoplasma pneumoniae*, and *Mycoplasma mobile* lack detectable IS units.

Although IS units only encode genes related to transposition, large integrating elements have also been identified in diverse *Mycoplasma* species. The Integrative Conjugal Elements (ICE) of *Mycoplasma fermentans* strain PG18^T comprise >8% of the genome and related units have been identified in *Mycoplasma*

agalactiae, *Mycoplasma bovis*, *Mycoplasma capricolum*, *Mycoplasma hyopneumoniae*, and *Mycoplasma mycoides* subsp. *mycoides*. In general, such units encode 18–30 genes, can be detected in extra-chromosomal forms, and are strain-variable in distribution and chromosomal insertion site. Two additional large mobile DNAs, designated Tra Islands, were identified in *Mycoplasma capricolum* California kid^T. The presence of putative conjugation genes and the variability in genomic location of Tra Islands and ICE suggest that these are agents of lateral gene transfer.

The best-studied mycoplasmas are primary pathogens of humans or domesticated animals (Baseman and Tully, 1997). About half of the listed species occur in the absence of disease, but are occasional opportunistic or secondary pathogens. The principal human pathogens are *Mycoplasma pneumoniae*, *Mycoplasma hominis*, and *Mycoplasma genitalium*, with *Mycoplasma penetrans* added to this list due to its association with HIV infections (Blanchard, 1997; Blanchard et al., 1997; Tully, 1993; Waites and Talkington, 2005). *Mycoplasma pneumoniae* is one of the main agents of community-acquired pneumonia, bronchitis, and other respiratory complications (Atkinson et al., 2008). *Mycoplasma pneumoniae* infections can also involve extra-pulmonary complications including central nervous system, cardiovascular, and dermatological manifestations. Outbreaks cause considerable morbidity and require rapid and effective therapeutic intervention (Hyde et al., 2001; Meyer and Clough, 1993). *Mycoplasma hominis* occurs more frequently in the urogenital tract of women than men and is often found in the genital tract of women with vaginitis, bacterial vaginosis, or localized intrauterine infections (Keane et al., 2000). The organism can gain access to a fetus from uterine sites and it is associated with perinatal morbidity and mortality (Gonçalves et al., 2002; Waites et al., 1988). It is also clearly associated with septicemias and respiratory infections and with transplant or joint infections in immunosuppressed persons (Brunner et al., 2000; Busch et al., 2000; Fernandez Guerrero et al., 1999; Garcia-Porrúa et al., 1997; Gass et al., 1996; Hopkins et al., 2002; Mattila et al., 1999; Tully, 1993; Zheng et al., 1997). *Mycoplasma genitalium* has been associated with non-gonococcal urethritis in men (Gambini et al., 2000; Jensen, 2004; Jensen et al., 2004; Taylor-Robinson et al., 2004; Taylor-Robinson and Horner, 2001; Totten et al., 2001) and urogenital disease in women (Baseman et al., 2004; Blaylock et al., 2004). *Mycoplasma genitalium* occurs more frequently in the vagina than in the cervix or urethra, but it may be involved in cervicitis (Casin et al., 2002; Manhart et al., 2001). Mycoplasmas are common agents of chronic joint inflammation in a wide variety of hosts (Cole et al., 1985). Species associated with arthritis in humans include *Mycoplasma hominis*, *Mycoplasma fermentans*, *Mycoplasma genitalium*, *Mycoplasma salivarium*, and possibly *Mycoplasma pneumoniae* in juvenile arthritis (Waites and Talkington, 2005). Humans are also susceptible to opportunistic zoonotic mycoplasmosis; immunosuppressed persons are highly susceptible. The recent molecular confirmation of a *Mycoplasma haemofelis*-like infection in an HIV-positive patient (dos Santos et al., 2008) highlights the zoonotic potential of the hemoplasmas.

Mycoplasmas colonize fish, reptiles, birds, and terrestrial and aquatic mammals. Some cause significant diseases of cattle and other ruminants, swine, poultry, or wildlife, and others are opportunistic or secondary veterinary pathogens (Simecka et al., 1992; Tully and Whitcomb, 1979). The principal bovine pathogens include the serovars historically called “Small Colony”

types of *Mycoplasma mycoides* subsp. *mycoides*, and *Mycoplasma bovis*. *Mycoplasma mycoides* subsp. *mycoides* has caused major losses of livestock globally in the twentieth century due to contagious bovine pleuropneumonia and currently remains a problem in Asia and Africa (Lesnoff et al., 2004). *Mycoplasma bovis* is a widespread agent of otitis media, pneumonia, mastitis, polyarthritides, and urogenital disease in cattle and buffaloes. *Mycoplasma mycoides* subsp. *capri*, *Mycoplasma capricolum* subsp. *capricolum*, and *Mycoplasma agalactiae* are important causes of arthritis, mastitis, and agalactia in goats and sheep. *Mycoplasma mycoides* subsp. *capri* (type strain PG3^T) properly includes all of the serovars historically called “Large Colony” types of subspecies *mycoides* (Manso-Silvan et al., 2009; Shahram et al., 2010). *Mycoplasma capricolum* subsp. *capripneumoniae* (type strain F38^T) causes severe contagious pleuropneumonia in goats (Leach et al., 1993; McMartin et al., 1980). Contagious bovine and caprine pleuropneumonia, and mycoplasmal agalactia of sheep or goats are subject to control through listing in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>) as well as strict notification and export regulations by individual countries. *Mycoplasma hyopneumoniae*, one of the most difficult species to cultivate, causes primary enzootic pneumonia in pigs and exacerbates other porcine respiratory diseases leading to substantial economic burdens. *Mycoplasma hyosynoviae* is carried in the upper respiratory tract, but causes nonsuppurative polyarthritides, usually without other serositis, especially in growing pigs.

The most important poultry pathogens are *Mycoplasma gallisepticum*, *Mycoplasma synoviae*, and *Mycoplasma meleagridis*, but more than 20 other species have been isolated from birds as diverse as ostriches, raptors, and penguins (Bradbury and Morrow, 2008). *Mycoplasma gallisepticum* can be transmitted vertically, venereally, by other direct contact, or by aerosol to cause respiratory disease and its sequelae in chickens, turkeys, and other birds. It also causes decreased egg production and egg quality in chickens. *Mycoplasma synoviae* can cause a syndrome of synovitis, tendonitis, and bursitis in addition to respiratory disease in chickens and turkeys, whereas the developmental abnormalities and airsacculitis associated with congenital or acquired *Mycoplasma meleagridis* infection seem restricted to turkeys. *Mycoplasma gallisepticum* and *Mycoplasma synoviae* are also listed in the OIE’s Terrestrial Animal Health Code.

Pathogenicity of specific mycoplasmas has also been reported for companion animals (Chalker, 2005; Lemcke, 1979; Messick, 2003) and a number of wild animal hosts (Brown et al., 2005). The respiratory, reproductive, and joint diseases caused in rodents by *Mycoplasma pulmonis* and *Mycoplasma arthritidis* (Schoeb, 2000) are important models of infection and immunity in humans and other animals.

Hemoplasmas infect a variety of wild and domesticated animals and are relatively host-specific, although cross-infection of related hosts has been reported. Transmission can be achieved by ingestion of infected blood or by percutaneous inoculation. Arthropod vector transmission of some species is also supported by experimentation and by the clustered geographic distribution of hemoplasmosis in some studies (Sykes et al., 2007; Willi et al., 2006a). The pathogenicity of different hemoplasma species is variable and strain virulence also likely plays a key role in the development of disease. For example, *Mycoplasma haemofelis* can induce acute clinical disease in non-splenectomized, immunocompetent cats, whereas *Mycoplasma haemocanis* appears able

to induce disease only in immunosuppressed or splenectomized dogs. Clinical syndromes range from acute fatal hemolytic anemia to chronic insidious anemia and ill-thrift. Signs may include anemia, pyrexia, anorexia, dehydration, weight loss, and infertility. The presence of erythrocyte-bound antibodies (including cold agglutinins), indicated by positive Coombs' testing, has been demonstrated in some hemoplasma-infected animals and may contribute to anemia. Animals can remain chronic asymptomatic carriers of hemoplasmas after acute infection. PCR is the diagnostic test of choice for hemoplasma infection.

Contamination of eukaryotic cell cultures with mollicutes is still a common and important yet often unrecognized problem (Tully and Razin, 1996). More than 20 species have been isolated from contaminated cell lines, but more than 90% of the contamination is thought to be caused by just five species of mycoplasma: *Mycoplasma arginini*, *Mycoplasma fermentans*, *Mycoplasma hominis*, *Mycoplasma hyorhinis*, and *Mycoplasma orale*, plus *Acholeplasma laidlawii*. *Mycoplasma pirum* and *Mycoplasma salivarium* account for most of the remainder (Drexler and Uphoff, 2002). Culture medium components of animal origin, passage of contaminated cultures, and laboratory personnel are likely to be the most significant sources of cell culture contaminants. PCR-based approaches to detection achieve sensitivity and specificity far superior to fluorescent staining methods (Masover and Becker, 1996). Another method of detection is based on mycoplasma-specific ATP synthesis activity present in contaminated culture medium (Robertson and Stemke, 1995; MycoAlert, Lonza Group). Eradication through treatment of contaminated cultures with antibiotics (Del Giudice and Gardella, 1996) is rarely successful. Strategies for prevention and control of mycoplasmal contamination of cell cultures have been described in detail (Smith and Mowles, 1996).

Several categories of potential virulence determinants are encoded in the metagenome of pathogenic mycoplasmas. Some species possess multiple types of virulence factors. Determinants such as adhesins and accessory proteins, extracellular polysaccharide structures, and pro-inflammatory or pro-apoptotic membrane lipoproteins are produced by multiple species. Several species excrete potentially toxic by-products of intermediary metabolism, including hydrogen peroxide, superoxide radicals, or ammonia. Other determinants such as extracellular endopeptidases, nucleases, and glycosidases seem irregularly distributed in the genus, whereas the ADP-ribosylating and vacuolating cytotoxin (pertussis exotoxin S1 subunit analog) of *Mycoplasma pneumoniae* and the T-lymphocyte mitogen (superantigen) of *Mycoplasma arthritidis* are evidently unique to those species. Reports of a putative exotoxin elaborated by *Mycoplasma neurolyticum* have not been substantiated by later work (Tryon and Baseman, 1992).

Candidate virulence mechanisms, such as motility, biofilm formation, or facultative intracellular invasion, are expressed by a range of pathogenic species. Several species possess systems of variable surface antigens that are thought to be important in evasion of the hosts' adaptive immune responses. In addition, a large number of species can suppress or inappropriately stimulate host immune cells and their receptors and cytokines through diverse, poorly characterized mycoplasmal components. Although candidate virulence factor discovery has accelerated significantly in recent years through whole genome annotation, the molecular basis for pathogenicity and causal relationships with disease still remain to be definitively established for most of these factors (Razin and Herrmann, 2002; Razin et al., 1998).

Because they lack lipopolysaccharide and a cell wall, and do not synthesize their own nucleotides, mycoplasmas are intrinsically resistant to polymyxins, β -lactams, vancomycin, fosfomicin, sulfonamides, and trimethoprim. They are also resistant to rifampin because their RNA polymerase is not affected by that antibiotic (Béb ear and Kempf, 2005). Individual species exhibit an even broader spectrum of antibiotic resistance, such as the resistance to erythromycin and azithromycin exhibited by several species, which is apparently mediated by mutation in the 23S rRNA (Pereyre et al., 2002). Treatment of mycoplasmosis often involves the use of antibiotics that inhibit protein synthesis or DNA replication. Certain macrolides or ketolides are used when tetracyclines or fluoroquinolones are inappropriate. Fluoroquinolones, aminoglycosides, pleuromutlins, and phenicols are not widely used to treat human mycoplasmosis at present, with the exception of chloramphenicol for neonates with mycoplasmosis of the central nervous system unresponsive to other antibiotics (Waites et al., 1992), but their use in veterinary medicine is more common. The long-term antimicrobial therapy often required may be due to mycoplasmal sequestration in privileged sites, potentially including inside host cells. Mycoplasmosis in immunodeficient patients is very difficult to control with antibiotic drugs (Baseman and Tully, 1997).

Enrichment and isolation procedures

Techniques for isolation of mycoplasmas from humans, various species of animals, and from cell cultures have been described (Neimark et al., 2001; Tully and Razin, 1983). Typical steps in the isolation of mycoplasmas were outlined in the recently revised minimal standards for descriptions of new species (Brown et al., 2007). Initial isolates may contain a mixture of species, so cloning by repeated filtration through membrane filters with a pore size of 450 or 220 nm is essential. The initial filtrate and dilutions of it are cultured on solid medium and an isolated colony is subsequently picked from a plate on which only a few colonies have developed. This colony is used to found a new cultural line, which is then expanded, filtered, plated, and picked two additional times. Hemoplasmas have not yet been successfully grown in continuous culture *in vitro*, although recent work (Li et al., 2008) suggests that *in vitro* maintenance of *Mycoplasma suis* may be possible.

Maintenance procedures

Cultures of mycoplasma can be preserved by lyophilization or cryogenic storage (Leach, 1983). The serum in the culture medium provides effective cryoprotection, but addition of sucrose may enhance survival following lyophilization. Hemoplasmas can be frozen in heparin- or EDTA-anticoagulated blood cryopreserved with dimethylsulfoxide. Most species can be recovered with little loss of viability even after storage for many years.

Taxonomic comments

This polyphyletic genus is divisible on the basis of 16S rRNA and other gene sequence similarities into a large paraphyletic clade of over 100 species in two groups called hominis and pneumoniae (Johansson and Pettersson, 2002; Figure 109), plus the ecologically, phenotypically, and genetically cohesive "mycoides cluster" of five species including the type species *Mycoplasma mycoides* (Cottew et al., 1987; Manso-Silv an et al., 2009; Shahram et al., 2010). The priority of *Mycoplasma mycoides* as the type species of the genus *Mycoplasma* and, hence, the family *Mycoplasmataceae* and the order *Mycoplasmatales* is, in retrospect, unfortunate.

The phylogenetic position of the mycoides cluster is eccentrically situated to the remaining species of the order *Mycoplasmatales*, amidst genera that are properly classified in the order *Entomoplasmatales*. When the order *Entomoplasmatales* was established, a century after the discovery of *Mycoplasma mycoides*, it was explicitly accepted that the taxonomic anomaly created by the phylogenetic position of the mycoides cluster will remain impractical to resolve (Tully et al., 1993). The few species in the mycoides cluster cannot simply be renamed, because confusion and peril would result, especially regarding “Small Colony” PG1^T-like strains of *Mycoplasma mycoides* subsp. *mycoides* and F38^T-like strains of *Mycoplasma capricolum* subsp. *capripneumoniae*, which are highly virulent pathogens and subject to strict international regulations.

Another controversy involves the nomenclature of uncultivated hemotropic bacteria originally assigned to the genera *Eperythrozoon* or *Haemobartonella*. It is now undisputed that, on the bases of their lack of a cell wall, small cell size, low G+C content, use of the codon UGA to encode tryptophan, regular association with vertebrate hosts, and 16S rRNA gene sequences that are most similar (80–84%) to species in the pneumoniae group of *Mycoplasma*, these organisms are properly affiliated with the *Mycoplasmatales*. However, the proposed transfers of *Eperythrozoon* and *Haemobartonella* species to the genus *Mycoplasma* (Neimark et al., 2001, 2005) were opposed on the grounds that the degree of 16S rRNA gene sequence similarity is insufficient (Uilenberg et al., 2004, 2006). The principal objection to establishing the hemoplasmas in a third genus in the *Mycoplasmataceae* (Uilenberg et al., 2006) is that this would compound the polyphyly within the pneumoniae group solely on the basis of a capacity to adhere to erythrocytes *in vivo*. In addition, the transfer of the type species *Eperythrozoon coxcooides* to the genus *Mycoplasma* is complicated by priority because *Eperythrozoon* predates *Mycoplasma*. The alternative, to transfer all mycoplasmas to the genus *Eperythrozoon*, would be completely impractical and perilous in part because the epithet *Eperythrozoon* does not indicate an affiliation with *Mycoplasmatales*. The Judicial Commission of the International Committee on Systematics of Prokaryotes (ICSP) declined to rule on a request for an opinion in this matter (Neimark et al., 2005) during their 2008 meeting, but a provisional placement in the genus *Mycoplasma* has otherwise been embraced by specialists in the molecular biology and clinical pathogenicity of these and similar hemotropic organisms. At present, the designation “*Candidatus*” must still be used for new types.

Mycoplasma feliminutum was first described during a time when the only named genus of mollicutes was *Mycoplasma*. Its publication coincided with the first proposal of the genus *Acholeplasma* (Edward and Freundt, 1969, 1970), with which *Mycoplasma feliminutum* is properly affiliated through established phenotypic (Heyward et al., 1969) and 16S rRNA gene sequence (Brown et al., 1995) similarities. This explains the apparent inconsistencies with its assignment to the genus *Mycoplasma*. The name *Mycoplasma feliminutum* should therefore be revised to *Acholeplasma feliminutum* comb. nov. The type strain is Ben^T (=ATCC 25749^T; Heyward et al., 1969).

Recent work at the J. Craig Venter Institute, including complete chemical synthesis and cloning of an intact *Mycoplasma genitalium* chromosome (Gibson et al., 2008) and other work with *Mycoplasma mycoides* “Large Colony” (Lartigue et al., 2009), suggests that *de novo* synthesis of two species of mollicute is imminent. Transplantation of isolated deproteinized tet^R-selectable chromosomes from donor *Mycoplasma mycoides* “Large Colony” into recipient *Mycoplasma capricolum* cells displaced the recipient genome and conferred the genotype and phenotype of the donor

(Lartigue et al., 2007). Cloning in yeast and subsequent resurrection of *Mycoplasma mycoides* “Large Colony” genomes as living bacteria demonstrate that it is possible to enliven a prokaryotic genome constructed in a eukaryotic cell (Lartigue et al., 2009). The ICSP subcommittee on the taxonomy of *Mollicutes* may be the first to accommodate a system of nomenclature and classification for species of novel prokaryotes that originate by entirely artificial speciation events (Brown and Bradbury., 2008).

Differentiation of the genus *Mycoplasma* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. Aerobic or facultatively anaerobic growth in artificial medium and a growth requirement for sterols exclude assignment to the genera *Anaeroplasmata*, *Asteroleplasmata*, *Acholeplasmata*, or “*Candidatus* Phytoplasma”. Non-spiral cellular morphology and regular association with a vertebrate host or fluids of vertebrate origin support exclusion from the genera *Spiroplasma*, *Entomoplasmata*, or *Mesoplasmata*. The inability to hydrolyze urea excludes assignment to the genus *Ureaplasma*.

Differentiation of the species of the genus *Mycoplasma*

Glucose fermentation and arginine hydrolysis are discriminating phenotypic markers (Table 137), but the pleomorphism and metabolic simplicity of mycoplasmas has led to a current reliance principally on the combination of 16S rRNA gene sequencing and reciprocal serology for species differentiation. Failure to cross-react with antisera against previously recognized species provides substantial evidence for species novelty. For this reason, deposition of antiserum against a novel type strain into a recognized collection is still mandatory for novel species descriptions (Brown et al., 2007). Preliminary differentiation can be by PCR and DNA sequencing using primers specific for bacterial 16S rRNA genes or the 16S–23S intergenic region. A similarity matrix relating the candidate strain to its closest neighbors, usually species with >94% 16S rRNA gene sequence similarity, will suggest related species that should be examined for serological cross-reactivities.

FIGURE 109. (Continued)

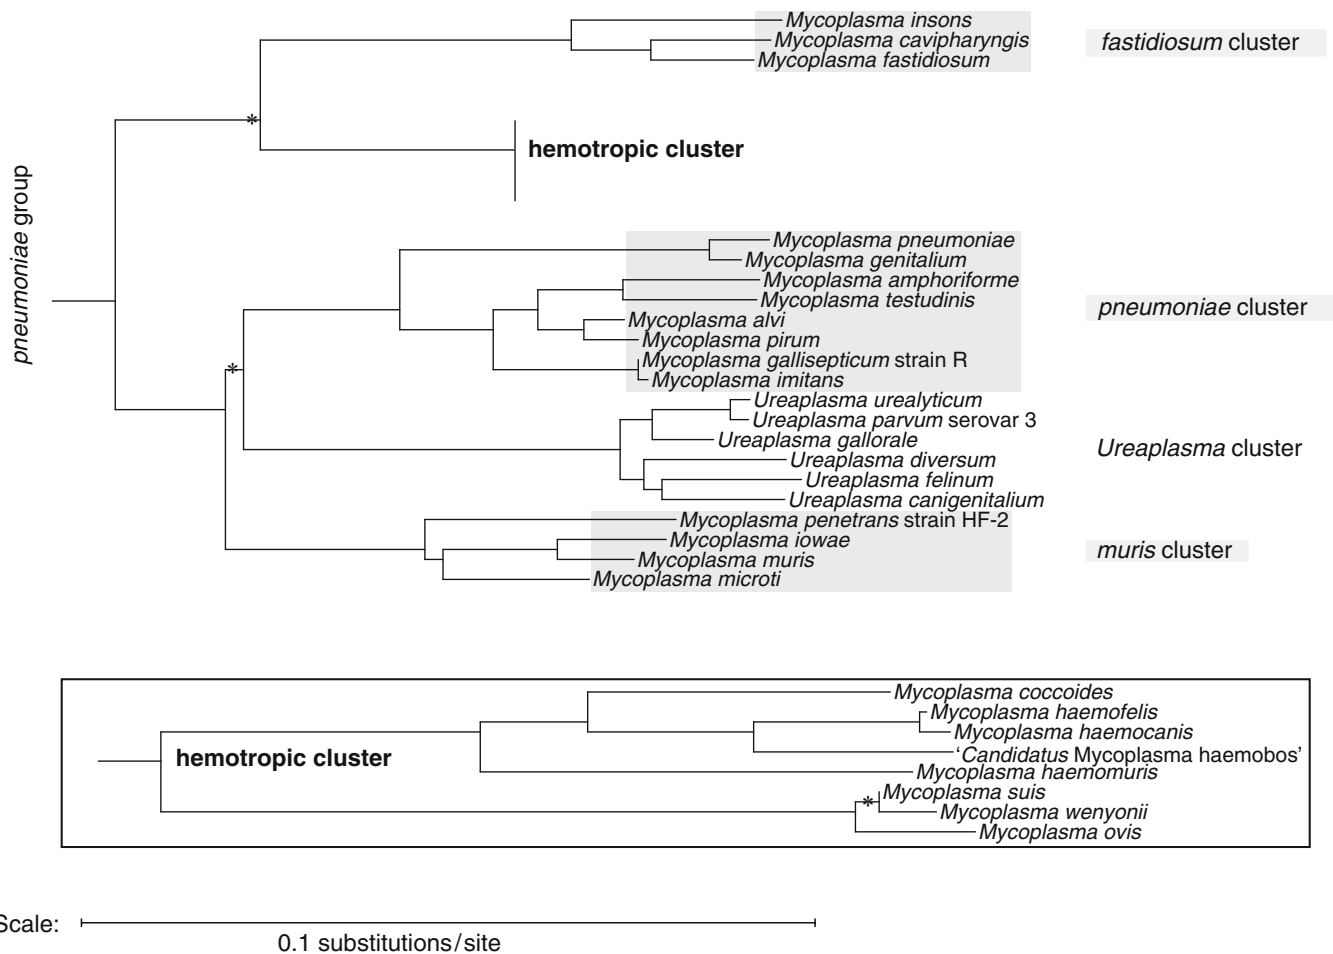

FIGURE 109. Phylogenetic relationships in the *Mycoplasma hominis* and *Mycoplasma pneumoniae* groups of the order *Mycoplasmatales*. The phylogram was based on a Jukes–Cantor corrected distance matrix and weighted neighbor-joining analysis of the 16S rRNA gene sequences of the type strains, except where noted. *Acholeplasma* (formerly *Mycoplasma*) *feliminutum* was the outgroup. The major groups and clusters are defined in terms of positions in 16S rRNA showing characteristic base composition and signature positions, plus higher-order structural synapomorphies (Johansson and Pettersson, 2002; Weisburg et al., 1989). Bootstrap values (100 replicates) <50% are indicated (*); the branching order is considered to be equivocal.

List of species of the genus *Mycoplasma*

1. ***Mycoplasma mycoides*** (Borrel, Dujardin-Beaumetz, Jeantet and Jouan 1910) Freundt 1955, 73^{AL} (*Asterococcus mycoides* Borrel, Dujardin-Beaumetz, Jeantet and Jouan 1910, 179) my.co.i'des. Gr. n. *mukês-êtos* mushroom or other fungus; L. suff. *-oides* (from Gr. suff. *-eides*, from Gr. n. *eidos* that which is seen, form, shape, figure) resembling, similar; N.L. neut. adj. *mycoides* fungus-like.
This is the type species of the genus. Cells are pleomorphic and capable of forming long filaments. Nonmotile. An extracellular capsule can be visualized by electron microscopy following staining with ruthenium red. Colonies on solid agar have a characteristic fried-egg appearance. Grows in modified Hayflick medium supplemented with glucose at 37°C.
The species has subsequently been divided as follows.
 - 1a. ***Mycoplasma mycoides* subsp. *capri*** Manso-Silvan, Vilei, Sachse, Djordjevic, Thiaucourt and Frey 2009, 1357^{VP} (*Asterococcus mycoides* var. *capri* Edward 1953, 874; *Mycoplasma mycoides* subsp. *mycoides* var. large colony Cottew and Yeats 1978, 294)

ca'pri. L. n. *caper*, *-pri* goat; L. gen. n. *capri* of the goat.

Cells are pleomorphic and capable of forming long filaments and long, helical rods known as rho forms. Nonmotile. An extracellular capsule can be visualized by electron microscopy following staining with ruthenium red. Colonies on solid agar have a characteristic fried-egg appearance and are notably larger than those of *Mycoplasma mycoides* subsp. *mycoides*. Grows in modified Hayflick medium supplemented with glucose at 37°C. Formation of biofilms has been demonstrated (McAuliffe et al., 2006).

Pathogenic; causes polyarthritis, mastitis, conjunctivitis (a syndrome collectively termed contagious agalactia), pneumonia, peritonitis, and septicemia in goats; and balanitis and vulvitis in sheep. Transmission occurs via direct contact between animals or with fomites, or can be vector-borne by the common ear mite (*Psoroptes cuniculi*).

Tetracyclines are effective therapeutic agents. Eradication from herds is difficult due to the tendency of healthy animals to harbor the organism in the ear canal without seroconverting. Antigenic cross-reactivity with *Mycoplasma*

^anr, Not reported; na, not applicable; G, glucose; R, arginine; OH, alcohols; OA, organic acids; U, undefined; A, acidic pH shift; K, alkaline pH shift; N, pH remains neutral; V, pH shift can be acidic or alkaline depending on the energy source provided; FB, fetal bovine serum; E, equine serum; P, porcine serum.

^bNot yet cultivated in cell-free artificial medium. The putative organism "*Candidatus M. haemotandarangiferis*" remains to be definitively established and the name has no standing in nomenclature.

^cHas been grown only in co-culture with eukaryotic cells.

mycoides subsp. *mycoides* precludes the exclusive reliance on serological-based diagnostics. Experimental vaccines using formalin-inactivated *Mycoplasma mycoides* subsp. *capri* appear to protect goats from subsequent challenge (Bar-Moshe et al., 1984; de la Fe et al., 2007). This organism is under certain quarantine regulations in most non-endemic countries and is a List B pathogen in the World Organization for Animal Health (OIE) disease classification (<http://oie.int>).

Source: isolated from the synovial fluid, synovial membranes, udders, expelled milk, conjunctivae, lungs, blood, and ear canals of goats; and the urogenital tract of sheep (Bergonier et al., 1997; Cottew, 1979; Kidanemariam et al., 2005; Thiaucourt et al., 1996).

DNA G+C content (mol%): 24 (T_m).

Type strain: PG3, NCTC 10137, CIP 71.25.

Sequence accession nos (16S rRNA gene): U26037 (strain PG3^T), U26044 (strain Y-goat).

Further comment: *Mycoplasma mycoides* subsp. *capri* now refers to strains once known as *Mycoplasma mycoides* subsp. *mycoides* var. large colony as well as strains known as *Mycoplasma mycoides* subsp. *capri* (Manso-Silvan et al., 2009; Shahram et al., 2010).

- 1b. ***Mycoplasma mycoides* subsp. *mycoides*** Manso-Silvan, Vilei, Sachse, Djordjevic, Thiaucourt and Frey 2009, 1356^{VP} (*Mycoplasma mycoides* subsp. *mycoides* var. small colony Cottew and Yeats 1978, 294)

my.co.i'des. Gr. n. *mukes*-etos mushroom or other fungus; L. suff. -oides (from Gr. suff. -oides from Gr. n. *eidōs* that which is seen, form, shape, figure) resembling, similar; N.L. neut. adj. *mycoides* fungus-like.

Cells are pleomorphic and capable of forming long filaments, but do not produce rho forms. Nonmotile. An extracellular capsule can be visualized by electron microscopy following staining with ruthenium red. Colonies on solid agar have a characteristic fried-egg appearance and are notably smaller than those of *Mycoplasma mycoides* subsp. *capri*. Grows in modified Hayflick medium supplemented with glucose at 37°C. Formation of biofilms has been demonstrated (McAuliffe et al., 2008).

Pathogenic; causes a characteristic, highly lethal fibrinous interstitial pneumonia and pleurisy known as contagious bovine pleuropneumonia (CBPP) in adult cattle and severe polyarthritis in calves. Transmission occurs primarily via direct contact, but can occur by droplet aerosol as well.

Tetracyclines, chloramphenicol, and fluoroquinolones are effective chemotherapeutic agents; however, treatment of endemic herds is often counterproductive as resistance can develop in carrier animals. Organisms are often sequestered in areas of coagulative necrosis in subclinically infected animals and can serve as a reservoir for reintroduction of resistant clones of *Mycoplasma mycoides* subsp. *mycoides* into a herd. Culling of infecting herds and restricting the movement of infected animals are more effective strategies for controlling spread of the disease (Windsor and Masiga, 1977). Killed and live vaccines are available for the prevention of infection, but suffer from low antigenicity, poor efficacy, and residual pathogenesis (Brown et al., 2005). Antigenic cross-reactivity with *Mycoplasma mycoides* subsp. *capri* and *Mycoplasma leachii* preclude the exclusive reliance on serological-based diagnostics. Multiple molecular diagnostics have been described (Gorton et al., 2005; Lorenzon et al., 2008; Persson et al., 1999) and many additional

molecular tools such as insertion sequence typing have led to a greater understanding of the epidemiology of outbreaks (Cheng et al., 1995; Frey et al., 1995; Vilei et al., 1999). This organism is under certain quarantine regulations in most non-endemic countries and is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>).

Source: isolated from the lungs, pleural fluid, lymph nodes, sinuses, kidneys, urine, synovial fluid, and synovial membranes of cattle and water buffalo (Gourlay and Howard, 1979; Scanziani et al., 1997; Scudamore, 1976); the respiratory tract of bison; the respiratory tract of yak; and the lungs, nasopharynx, and pleural fluid of sheep and goats (Brandao, 1995; Kusiluka et al., 2000).

DNA G+C content (mol%): 26.1 (T_m), 24.0 (strain PG1^T complete genome sequence).

Type strain: PG1, NCTC 10114, CCUG 32753.

Sequence accession nos: U26039 (16S rRNA gene), BX293980 (strain PG1^T complete genome sequence).

Further comment: *Mycoplasma mycoides* subsp. *mycoides* now refers exclusively to the agent of CBPP (Manso-Silvan et al., 2009).

2. ***Mycoplasma adleri*** Del Giudice, Rose and Tully 1995, 31^{VP} ad'le.ri. N.L. masc. gen. n. *adleri* of Adler, referring to Henry Adler, a Californian veterinarian whose studies contributed much new information concerning the pathogenic role of caprine and avian mycoplasmas.

Cells are primarily coccoid. Nonmotile. Colonies on solid media have a typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine at 35–37°C.

Pathogenic; associated with suppurative arthritis and joint abscesses. Mode of transmission is unknown.

Source: isolated from an abscessed joint of a goat with suppurative arthritis (Del Giudice et al., 1995).

DNA G+C content (mol%): 29.6 (Bd).

Type strain: G145, ATCC 27948, CIP 105676.

Sequence accession no. (16S rRNA gene): U67943.

3. ***Mycoplasma agalactiae*** (Wroblewski 1931) Freundt 1955, 73^{AL} (*Anulomyces agalaxiae* Wroblewski 1931, 111) a.ga.lac.ti'ae. Gr. n. *agalactia* want of milk, agalactia; N.L. gen. n. *agalactiae* of agalactia.

Cells are primarily coccoid, but are occasionally branched and filamentous. Nonmotile. Colonies on solid media have a typical fried-egg appearance. Grows well in SP-4 or Hayflick medium supplemented with glucose at 37°C. Formation of biofilms has been demonstrated (McAuliffe et al., 2006).

Pathogenic; causes polyarthritis, mastitis, conjunctivitis (a syndrome collectively termed contagious agalactia; Bergonier et al., 1997), nonsuppurative arthritis, pneumonia, abortion, and granular vulvovaginitis (Cottew, 1983; DaMassa, 1996) in goats and sheep. Transmission occurs via direct contact, most commonly during feeding (kids and lambs) or milking (dams and ewes).

Macrolides and fluoroquinolones are effective chemotherapeutic agents; however, antimicrobial therapy is not often utilized in widespread outbreaks due to the potential for infected animals to develop carrier states with resistant

strains and the tendency of antimicrobials to be excreted in milk. Control measures such as disinfection of fomites (endemic areas) and culling of infected animals (acute outbreaks) are more common practices. *Mycoplasma agalactiae* reportedly shares surface antigens with *Mycoplasma bovis* and *Mycoplasma capricolum* subsp. *capricolum* (Alberti et al., 2008; Boothby et al., 1981), potentially complicating serology-based diagnosis of infection. Molecular diagnostics that can distinguish *Mycoplasma agalactiae* from *Mycoplasma bovis* have been described (Chavez Gonzalez et al., 1995). Commercially available vaccines are widely used, but exhibit poor efficacy. Numerous experimental vaccines have been described. This organism is under certain quarantine regulations in some countries and is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>).

Source: isolated from the joints, udders, milk, conjunctivae, lungs, vagina, liver, spleen, kidneys, and small intestine of sheep and goats.

DNA G+C content (mol%): 30.5 (T_m), 29.7 (strain PG2^T complete genome sequence).

Type strain: PG2, NCTC 10123, CIP 59.7.

Sequence accession nos: M24290 (16S rRNA gene), NC_009497 (strain PG2^T complete genome sequence).

4. ***Mycoplasma agassizii*** Brown, Brown, Klein, McLaughlin, Schumacher, Jacobson, Adams and Tully 2001c, 417^{VP}

a.gas.si'zi.i. N.L. masc. gen. n. *agassizii* of Agassiz, referring to Louis Agassiz, a naturalist whose name was assigned to a species of desert tortoise (*Gopherus agassizii*) from which the organism was isolated.

Cells are coccoid to pleomorphic, with some strains appearing to possess a rudimentary terminal structure. Cells exhibit gliding motility. Colony forms on solid medium vary from those with a fried-egg appearance to some with mulberry characteristics. Grows well in SP-4 medium supplemented with glucose at 30°C.

Pathogenic; causes chronic upper respiratory tract disease characterized by severe rhinitis in desert tortoises, gopher tortoises, Russian tortoises, and leopard tortoises. Mode of transmission appears to be intranasal inhalation (Brown et al., 1994).

Source: isolated from the nares and choanae of desert tortoises, gopher tortoises, Russian tortoises, and leopard tortoises (Brown et al., 2001c).

DNA G+C content (mol%): not determined.

Type strain: PS6, ATCC 700616.

Sequence accession no. (16S rRNA gene): U09786.

5. ***Mycoplasma alkalescens*** Leach 1973, 149^{AL} al.ka.les'cens. N.L. v. *alkalesco* to make alkaline, referring to the reaction produced in arginine-containing media; N.L. part. adj. *alkalescens* alkaline-making.

Coccoid to coccobacillary cells. Motility and colony morphology have not been described for this species. Grows well in SP-4 medium supplemented with arginine at 37°C.

Pathogenic; causes febrile arthritis and sometimes mastitis, pneumonia, and otitis in cattle (Kokotovic et al., 2007; Lamm et al., 2004; Leach, 1973). Mode of transmission has not been established.

Tetracyclines and pleuromutilins are effective chemotherapeutic agents (Hirose et al., 2003). *Mycoplasma alkalescens* reportedly shares surface antigens with many arginine-fermenting *Mycoplasma* species; however, this is only likely to interfere with accurate diagnosis of infection in the case of *Mycoplasma arginini*.

Source: isolated from the synovial fluid, expelled milk, lungs, ears, prepuce, and semen of cattle.

DNA G+C content (mol%): 25.9 (T_m).

Type strain: D12, PG51, NCTC 10135, ATCC 29103.

Sequence accession no. (16S rRNA gene): U44764.

Further comment: Bovine serogroup 8 of Leach (1967).

6. ***Mycoplasma alligatoris*** Brown, Farley, Zacher, Carlton, Clipinger, Tully and Brown 2001a, 423^{VP}

al.li.ga.to'ris. N.L. n. *alligator*, -*oris* an alligator; N.L. gen. n. *alligatoris* of/from an alligator.

Cells are primarily coccoid. Nonmotile. Colonies on solid medium exhibit typical fried-egg morphology. Growth is very rapid in SP-4 medium supplemented with glucose at 30°C.

Pathogenic; causes a multisystemic inflammatory illness with a lethality unprecedented among mycoplasmas. Pathologic lesions in infected animals include meningitis, interstitial pneumonia, fibrinous pleuritis, polyserositis, fibrinous pericarditis, myocarditis, endocarditis, synovitis, and splenic and hepatic necrosis. A high level of mortality of naturally and experimentally infected American alligators (*Alligator mississippiensis*) and broad-nosed caimans (*Caiman latirostris*) occurs. In contrast, *Mycoplasma alligatoris* colonizes the tonsils of experimentally infected Siamese crocodiles (*Crocodylus siamensis*) without causing overt pathology. Such findings led to the hypothesis that *Mycoplasma alligatoris* is a natural commensal of a species more closely related to crocodiles than alligators and that the extreme disease state observed in alligators results from an enzootic infection (Brown et al., 1996; Pye et al., 2001). The natural mode of transmission has not been established definitively; however, animals can be experimentally infected via inoculation of the glottis.

Source: isolated from the blood, synovial fluid, cerebrospinal fluid, lungs, brain, heart, liver, and spleen of naturally and experimentally infected American alligators, experimentally infected broad-nosed caimans, and from the tonsils of experimentally infected Siamese crocodiles.

DNA G+C content (mol%): not determined.

Type strain: A21JP2, ATCC 700619.

Sequence accession no. (16S rRNA gene): U56733.

Further comment: the name *Mycoplasma alligatoris* was assigned for this organism in consideration of the initial isolation from an alligator (Order: Crocodylia). The English word "alligator" is from the Spanish *el lagarto* (Latin *ille lacertu* the lizard). However, the specific epithet *lacerti*, originally proposed for this taxon, was ultimately rejected because of the modern phylogenetic distinction between lizards (Order: Lacertilia) and crocodylians.

7. ***Mycoplasma alvi*** Gourlay, Wyld and Leach 1977, 95^{AL}

al'vi. L. n. *alvus* bowel, womb, stomach; L. gen. n. *alvi* of the bowel.

Cells are primarily coccoid; however, subsets of the population display elongated, flask-shaped cells with well-defined terminal structures. Unlike most species that exhibit polar structures, *Mycoplasma alvi* appears to be nonmotile (Bredt, 1979; Hatchel and Balish, 2008). Colonies on solid medium exhibit typical fried-egg morphology. Grows well in SP-4 medium supplemented with either glucose or arginine at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the lower alimentary tract, feces, bladder, and vagina of cows, and the intestinal tract of voles (Gourlay and Howard, 1979).

DNA G+C content (mol%): 26.4 (Bd).

Type strain: IIsley, NCTC 10157, ATCC 29626.

Sequence accession no. (16S rRNA gene): U44765.

8. ***Mycoplasma amphoriforme*** Pitcher, Windsor, Windsor, Bradbury, Yavari, Jensen, Ling and Webster 2005, 2592^{VP}

am.pho.ri.for'me. L. n. *amphora* amphora; L. adj. suff. -*formis* -*e* like, of the shape of; N.L. neut. adj. *amphoriforme* amphora-shaped, having the form of an amphora.

Cells are flask-shaped with a distinct terminal structure reminiscent of *Mycoplasma gallisepticum*. Cells exhibit low-speed gliding motility and move in the direction of the terminal structure (Hatchel et al., 2006). Colony morphology variable, from a typical fried-egg morphology to a "ground glass" appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenicity and mode of transmission have not been established definitively.

Despite showing sensitivity to fluoroquinolones, tetracyclines, and macrolides *in vitro*, *Mycoplasma amphoriforme* appears to be successfully evasive during treatment of patients with these antibiotics. The veterinary antibiotic valnemulin is successful at controlling infection (Webster et al., 2003).

Source: isolated from the sputum of immunocompromised humans with bronchitis and related lower respiratory tract disease (Pitcher et al., 2005; Webster et al., 2003). The prevalence of *Mycoplasma amphoriforme* in the general human population is unsubstantiated.

DNA G+C content (mol%): 34.0 (fluorescent intensity).

Type strain: A39, NCTC 11740, ATCC BAA-992.

Sequence accession no. (16S rRNA gene): FJ226575.

9. ***Mycoplasma anatis*** Roberts 1964, 471^{AL}

a.na'tis. L. n. *anas*, -*atis* a duck; L. gen. n. *anatis* of a duck.

Cells have been described as coccoid with ring forms, but cellular and colony morphology is generally poorly described. Motility for this species has not been assessed. Grows well in SP-4 medium supplemented with glucose 37°C.

Isolated from pathologic lesions, but attempts to reproduce disease following experimental infection have been equivocal (Amin and Jordan, 1978; Roberts, 1964). The mode of transmission has not been established definitively.

Source: isolated from pathologic lesions, the respiratory tract, hock joint, pericardium, cloaca, and meninges of ducks (Goldberg et al., 1995; Ivanics et al., 1988; Tiong, 1990).

DNA G+C content (mol%): 26.6 (Bd).

Type strain: 1340, ATCC 25524, NCTC 10156.

Sequence accession no. (16S rRNA gene): AF412970.

10. **Mycoplasma anseris** Bradbury, Jordan, Shimizu, Stipkovits and Varga 1988, 76^{VP}

an'se.ris. L. gen. n. *anseris* of the goose.

Cells are primarily spherical. Nonmotile. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine at 37°C.

Opportunistic pathogen; associated with balanitis of geese, but can be isolated from clinically normal animals. Mode of transmission has not been established definitively.

Source: isolated from the phallus and cloaca of geese (Hinz et al., 1994; Stipkovits et al., 1984a).

DNA G+C content (mol%): 24.7–26.0 (Bd/ T_m).

Type strain: 1219, ATCC 49234.

Sequence accession no. (16S rRNA gene): AF125584.

11. **Mycoplasma arginini** Barile, Del Giudice, Carski, Gibbs and Morris 1968, 490^{AL}

ar.gi.ni'ni. N.L. n. *argininum* arginine, an amino acid; N.L. gen. n. *arginini* of arginine, referring to its hydrolysis.

Cells are primarily coccoid. Motility for this species has not been assessed. Colonies have either the typical fried-egg morphology or a granular, “berry-like” appearance. Grows well in modified Hayflick medium supplemented with arginine at 37°C.

Pathogenic; associated with pneumonia, vesiculitis, keratoconjunctivitis, and mastitis in cattle; pneumonia and keratoconjunctivitis in sheep; possibly with arthritis in goats; and septicemia in immunocompromised humans (Tully and Whitcomb, 1979; Yechouron et al., 1992). Modes of transmission have not been definitively assessed and likely vary by anatomical site.

Mycoplasma arginini is commonly associated with contamination of eukaryotic cell culture and is frequently removed by treatment of cells with antibiotics and/or maintenance of cell lines in antibiotic-containing medium. The most effective classes of antibiotics for cell culture eradication are tetracyclines, macrolides, and fluoroquinolones. Additionally, passage of eukaryotic cells in hyperimmune serum raised against *Mycoplasma arginini* has been shown to be an effective method of eradication (Jeansson and Brorson, 1985).

Source: isolated from a wide array of mammalian hosts including cattle, sheep, goats, pigs, horses, domestic dogs, domestic cats, lions, lynxes, cheetahs, chamois, camels, ibexes, humans, and mice.

DNA G+C content (mol%): 27.6 (T_m).

Type strain: G230, ATCC 23838, NCTC 10129, CIP 71.23, NBRC 14476.

Sequence accession no. (16S rRNA gene): U15794.

12. **Mycoplasma arthritis** (Sabin 1941) Freundt 1955, 73^{AL} (*Murimycetes arthritis* Sabin 1941, 57)

ar.thri'ti.dis. Gr. n. *arthritis -idos* gout, arthritis; N.L. gen. n. *arthritis* of arthritis.

Cells are filamentous and vary in length. Motility for this species has not been assessed. Colonies on solid medium

have a typical fried-egg appearance. Grows well in SP-4 medium supplemented with arginine.

Pathogenic; causes purulent polyarthritis, rhinitis, otitis media, ocular lesions, and abscesses in rats. *Mycoplasma arthritis* is also known to superinfect lung lesions initiated by *Mycoplasma pulmonis*. Experimental inoculations via various routes can result in septicemia, acute flaccid paralysis, and pyelonephritis in rats, and chronic arthritis in mice and rabbits. *Mycoplasma arthritis* is unique among mycoplasmas in harboring the lysogenized bacteriophage MAV1, whose contribution to virulence is equivocal, and producing the potent mitogen MAM, which appears to confer increased toxicity and lethality but to be irrelevant to arthritogenicity (Clapper et al., 2004; Luo et al., 2008; Voelker et al., 1995). The mechanism of transmission is largely dependent on the tissue infected.

Source: isolated from the synovial membranes, synovial fluid, middle ear, eye, abscessed bone, abscessed ovary, and oropharynx of wild and captive rats. Isolations have also been reported from non-human primates including rhesus monkeys and bush babies (Somerson and Cole, 1979); and from joint fluid of wild boars (Binder et al., 1990). The true origins of putative isolates from the human urethra, prostate, and cervix have been questioned (Cassell and Hill, 1979; Washburn et al., 1995).

DNA G+C content (mol%): 30.0 (T_m ; strain PG6^T), 30.7 (strain 158L3-1 complete genome sequence).

Type strain: PG6, ATCC 19611, NCTC 10162, CIP 104678, NBRC 14860.

Sequence accession nos: M24580 (16S rRNA gene), CP001047 (strain 158L3-1 complete genome sequence).

13. **Mycoplasma auris** DaMassa, Tully, Rose, Pitcher, Leach and Cottew 1994, 483^{VP}

au'ris. L. gen. n. *auris* of the ear, referring to the provenance of the organism, the ears of goats.

Cells are coccoid to pleomorphic. Nonmotile. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine at 37°C.

No evidence of pathogenicity. Mechanism of transmission has not been established.

Source: isolated from the external ear canals of goats (Damassa et al., 1994).

DNA G+C content (mol%): 26.9 (T_m).

Type strain: UIA, ATCC 51348, NCTC 11731, CIP 105677.

Sequence accession no. (16S rRNA gene): U67944.

14. **Mycoplasma bovigentialium** Freundt 1955, 73^{AL}

bo.vi.ge.ni.ta'li.um. L. n. *bos*, *bovis* the ox, bull, cow; L. pl. n. *genitalia* the genitals; N.L. pl. gen. n. *bovigentialium* of bovine genitalia.

Cells range from coccoid to filamentous. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in SP-4 broth supplemented with glucose and/or arginine at 37°C and produces a “film and spots” reaction.

Pathogenic; causes vulvovaginitis, vesiculitis, epididymitis, abortion, infertility, mastitis, pneumonia, conjunctivitis,

and arthritis in cattle; and pneumonia and conjunctivitis in domestic dogs. Mode of transmission is via sexual contact and/or droplet aerosol.

Control measures during outbreaks of *Mycoplasma bovis* infection include suspension of natural breeding in favor of artificial insemination with disposable instruments and, in severe cases, culling of infected animals.

Source: isolated from the udders, seminal vesicles, prepuce, semen, vagina, cervix, lungs, conjunctivae, and joint capsule of cattle; and from the lungs, prepuce, prostate, vagina, cervix, and conjunctivae of domestic dogs (Chalker, 2005; Gourlay and Howard, 1979).

DNA G+C content (mol%): 30.4 (T_m).

Type strain: PG11, ATCC 19852, NCTC 10122, NBRC 14862.

Sequence accession nos (16S rRNA gene): M24291, AY121098.

Further comment: the collection of strains formerly referred to as “*Mycoplasma ovine/caprino* serogroup 11” have been reclassified as *Mycoplasma bovis* (Nicholas et al., 2008).

15. ***Mycoplasma bovirhinis*** Leach 1967, 313^{AL}

bo.vi.rhi'nis. L. n. *bos, bovis* the ox; Gr. n. *rhis, rhinos* nose; N.L. gen. n. *bovirhinis* of the nose of the ox.

Cell and colony morphology and motility for this species are poorly defined. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes pneumonia, otitis, conjunctivitis, and mastitis in cattle. *Mycoplasma bovirhinis* is often found in co-infections with other pathogens, leading to speculation that it often acts as a superinfecting agent. Mode of transmission has not been established definitively.

Source: isolated from the lungs, nasopharynx, trachea, udders, expelled milk, ears, conjunctivae, and rarely from the urogenital tract of cattle (Gourlay and Howard, 1979).

DNA G+C content (mol%): 27.3 (T_m).

Type strain: PG43, ATCC 27748, NCTC 10118, CIP 71.24, NBRC 14857.

Sequence accession no. (16S rRNA gene): U44766.

16. ***Mycoplasma bovis*** (Hale, Hemboldt, Plastring and Stula 1962) Askaa and Ernø 1976, 325^{AL} (*Mycoplasma agalactiae* var. *bovis* Hale, Hemboldt, Plastring and Stula 1962, 591; *Mycoplasma bovimastitidis* Jain, Jasper and Dellinger 1967, 409)

bo'vis. L. n. *bos* the ox; L. gen. n. *bovis* of the ox.

Cells range from coccoidal to short filaments. Nonmotile. Formation of biofilms has been demonstrated (McAuliffe et al., 2006). Colonies on solid medium have the typical fried-egg appearance, with notably large centers. Grows well in SP-4 medium supplemented with glucose at 37°C and produces a “film and spots” reaction.

Pathogenic; causes mastitis, polyarthritis, keratoconjunctivitis (Gourlay and Howard, 1979), pneumonia, and otitis media (Caswell and Archambault, 2007; Maeda et al., 2003), and is rarely associated with infertility, abortion, endometritis, salpingitis, and vesiculitis (Doig, 1981; Gourlay and Howard, 1979) in cattle; pneumonia and polyarthritis in bison (Dyer et al., 2008); and is rarely associated with pneumonia,

mastitis, and arthritis in goats (Egwu et al., 2001; Gourlay and Howard, 1979). Mode of transmission is via direct contact with infected animals or fomites, most commonly during feeding (suckling or trough), milking (cows), aerosol, or sexual contact.

Macrolides and fluoroquinolones are effective chemotherapeutic agents *in vitro*; however, antimicrobial therapy is not often utilized in animals with advanced disease due to poor efficacy and the tendency of antimicrobials to be excreted in milk. Control measures such as disinfection of fomites, isolation of infected animals, and euthanasia of animals showing clinical signs are more common practices. *Mycoplasma bovis* reportedly shares surface antigens with *Mycoplasma agalactiae* (Boothby et al., 1981), potentially complicating serology-based diagnosis of infection. Molecular diagnostics that can distinguish *Mycoplasma agalactiae* from *Mycoplasma bovis* have been described (Chávez Gonzalez et al., 1995). Several vaccines are commercially available, but exhibit poor efficacy in that they tend to allow for the establishment of infection while only preventing overt clinical signs.

Source: isolated from the udders, expelled milk, synovial fluid, synovial membranes, conjunctivae, lungs, ear canals, tympanic membranes, aborted calves, uterus, cervix, vagina, and semen of cattle; from the lungs and synovial fluid of bison; and from the lungs and udders of goats.

DNA G+C content (mol%): 32.9 (T_m).

Type strain: Donetta, PG45, ATCC 25523, NCTC 10131.

Sequence accession no. (16S rRNA gene): AJ419905.

Further comment: Bovine serotype 5 of Leach (1967).

17. ***Mycoplasma bovoculi*** Langford and Leach 1973, 1443^{AL}

bo.vo'cu.li. L. n. *bos, bovis* ox, bull, cow; L. n. *oculus* the eye; N.L. gen. n. *bovoculi* of the bovine eye.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick medium supplemented with glucose at 37°C.

Pathogenic; causes conjunctivitis and keratoconjunctivitis in cattle. Face flies are the suggested mechanism of transmission, though this has yet to be established definitively. Topical application of oxytetracycline is an effective treatment for infection.

Source: isolated from the conjunctivae and semen of cattle, and from aborted calves (Langford and Leach, 1973; Singh et al., 2004).

DNA G+C content (mol%): 29.0 (T_m).

Type strain: M165/69, NCTC 10141, ATCC 29104.

Sequence accession no. (16S rRNA gene): U44768.

Further comment: *Mycoplasma bovoculi* was originally described as *Mycoplasma oculi* by Leach in 1973, wherein the defining publication referring to the species as *Mycoplasma bovoculi* (Langford and Leach, 1973) was cited as “in press”.

18. ***Mycoplasma buccale*** Freundt, Taylor-Robinson, Purcell, Chanock and Black 1974, 252^{AL}

buc.ca'le. L. n. *bucca* the mouth; L. neut. suff. *-ale* suffix denoting pertaining to; N.L. neut. adj. *buccale* buccal, pertaining to the mouth.

Cells range from coccoid to filamentous. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine and herring sperm DNA at 37°C.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the oropharynx of humans, rhesus macaques, chimpanzees, orangutans, baboons, African green monkeys, crab-eating macaques, and patas monkeys (Somerson and Cole, 1979).

DNA G+C content (mol%): 26.4 (T_m).

Type strain: CH20247, ATCC 23636, NCTC 10136, CIP 105530, NBRC 14851.

Sequence accession no. (16S rRNA gene): AF125586.

19. ***Mycoplasma buteonis*** Poveda, Giebel, Flossdorf, Meier and Kirchhoff 1994, 97^{VP}

bu.te.o'nis. L. masc. n. *buteo*, -onis buzzard; L. masc. gen. n. *buteonis* of the buzzard.

Cells are coccoid. Motility for this species has not been assessed. Colonies on solid medium have typical fried-egg appearance. Grows well in modified Frey's medium supplemented with glucose at 37°C.

Mycoplasma buteonis may be pathogenic for saker falcons, as it was found in the respiratory tract, nervous system, and bone of a nestling with pneumonia, hepatitis, ataxia, and dyschondroplasia. No evidence of pathogenicity for buzzards. Mode of transmission has not been assessed.

Source: isolated from the trachea of buzzards; from the eggs of the lesser kestrel; and the trachea, lungs, brain, and bone marrow of the saker falcon. Has been detected in the common kestrel and the Western marsh harrier (Erdélyi et al., 1999; Lierz et al., 2008a, 2008c).

DNA G+C content (mol%): 27.0 (Bd).

Type strain: Bb/T2g, ATCC 51371.

Sequence accession no. (16S rRNA gene): AF412971.

20. ***Mycoplasma californicum*** Jasper, Ernø, Dellinger and Christiansen 1981, 344^{VP}

ca.li.for'ni.cum. N.L. neut. adj. *californicum* pertaining to California.

Cells are coccoid to filamentous. Motility for this species has not been assessed. Colonies are conical in shape with distinct small centers. Grows well in modified Hayflick broth at 37°C.

Pathogenic; causes purulent mastitis in cows and rarely in sheep. Mode of transmission has not been established definitively.

Source: isolated from the udders and expelled milk of cows and ewes.

DNA G+C content (mol%): 31.9 (Bd).

Type strain: ST-6, ATCC 33461, AMRC-C 1077, NCTC 10189.

Sequence accession no. (16S rRNA gene): M24582.

21. ***Mycoplasma canadense*** Langford, Ruhnke and Onoviran 1976, 218^{AL}

ca.na.den'se. N.L. neut. adj. *canadense* pertaining to Canada.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid agar have a characteristic fried-egg appearance. Grows well in SP-4 medium supplemented with arginine at 37°C.

Pathogenic; causes mastitis and arthritis, and may be associated with infertility, abortion, and pneumonia of cattle. Mode of transmission has not been established definitively.

Source: isolated from the udders, expelled milk, synovial membranes, aborted calves, vagina, semen, and lungs (Boughton et al., 1983; Friis and Blom, 1983; Gourlay and Howard, 1979; Jackson et al., 1981).

DNA G+C content (mol%): 29.0 (T_m).

Type strain: 275C, NCTC 10152, ATCC 29418.

Sequence accession no. (16S rRNA gene): U44769.

22. ***Mycoplasma canis*** Edward 1955, 90^{AL}

ca'nis. L. n. *canis*, -is a dog; L. gen. n. *canis* of a dog.

Cells are pleomorphic, exhibiting branched and filamentous forms. Motility for this species has not been assessed. Colonies on solid medium exhibit two stable forms: "smooth" colonies with a nongranular appearance and round edges; and "rough" colonies with a granular appearance and irregular or crenated edges. Each form maintains its characteristic appearance during repeated subculturing. Grows well in SP-4 medium supplemented with glucose at 37°C.

Opportunistic pathogen; associated with infertility and adverse pregnancy outcomes, endometritis, epididymitis, urethritis, cystitis, and pneumonia of domestic dogs (Chalker, 2005); pneumonia of cattle (ter Laak et al., 1992b); and pneumonia in immunocompromised humans (Armstrong et al., 1971). Mode of transmission is via sexual contact or aerosol. *Mycoplasma canis* appears to have a greater tendency toward upper respiratory tract commensalism and urogenital tract pathogenicity in dogs, while exhibiting pathogenicity for the respiratory tract of cattle.

Source: isolated from the cervix, vagina, prepuce, epididymis, prostate, semen, urine, bladder, oropharynx, nares, lungs, trachea, conjunctivae, kidneys, spleen, pericardium, liver, and lymph nodes of domestic dogs; from the lungs and oropharynx of cattle; from the lungs and pharynx of humans; and from the throat and rectum of baboons and African green monkeys.

DNA G+C content (mol%): 28.4 (T_m).

Type strain: PG14, ATCC 19525, NCTC 10146, NBRC 14846.

Sequence accession no. (16S rRNA gene): AF412972.

23. ***Mycoplasma capricolum*** Tully, Barile, Edward, Theodore and Ernø 1974, 116^{AL}

ca.pri.co'lum. L. n. *caper*, -pri the male goat; N.L. -suff. *colus*, -a, -um (from L. v. *incolere* to dwell) dwelling; N.L. neut. adj. *capricolum* dwelling in a male goat.

Cells are coccobacillary. Nonmotile. Colonies on solid agar have a characteristic fried-egg appearance. Grows in SP-4 or modified Hayflick medium supplemented with glucose at 37°C.

DNA G+C content (mol%): 24.1 (T_m).

Type strain: California kid, ATCC 27343, NCTC 10154, CIP 104620.

The species has subsequently been divided as follows.

23a. **Mycoplasma capricolum subsp. capricolum** (Tully, Barile, Edward, Theodore and Ernø 1974) Leach, Ernø and MacOwan 1993, 604^{VP} (*Mycoplasma capricolum* Tully, Barile, Edward, Theodore and Ernø 1974, 116)

ca.pri.co'lum. L. n. *caper*, -*pri* the male goat; N.L. -suff. *colus*, -*a*, -*um* (from L. v. *incolere* to dwell) dwelling; N.L. neut. adj. *capricolum* dwelling in a male goat.

Cells are coccobacillary and can produce long, helical rods known as rho forms. Nonmotile. Colonies on solid agar have a characteristic fried-egg appearance. Grows in SP-4 or modified Hayflick medium supplemented with glucose at 37°C.

Pathogenic; causes fibrinopurulent polyarthritis, mastitis, conjunctivitis (a syndrome collectively termed contagious agalactia) and septicemia in goats. Transmission occurs via direct contact between animals or with fomites.

Tetracyclines, macrolides, and tylosin are effective chemotherapeutic agents. Treatment of acutely infected animals often leads to the eradication of the organism, whereas treatment of chronically infected animals does not. Early intervention with antibiotics and improved sanitation are effective control measures (Thiaucourt et al., 1996). Antigenic cross-reactivity with *Mycoplasma capricolum* subsp. *capripneumoniae* and *Mycoplasma leachii* preclude the exclusive reliance on serological-based diagnostics. Multiple molecular diagnostics have been described (Fitzmaurice et al., 2008; Greco et al., 2001). This organism is under certain quarantine regulations in some countries and is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>).

Source: isolated from the synovial fluid, synovial membranes, udders, expelled milk, conjunctivae, spleen, nasopharynx, oral cavity, and ear canal of goats; and the nasopharynx of sheep (Cottew, 1979).

DNA G+C content (mol%): 24.1 (T_m), 23 (strain California kid^T complete genome).

Type strain: California kid, ATCC 27343, NCTC 10154, CIP 104620.

Sequence accession nos: U26046 (16S rRNA gene), NC_007633 (strain California kid^T complete genome).

23b. **Mycoplasma capricolum subsp. capripneumoniae** Leach, Ernø and MacOwan 1993, 604^{VP}

ca.pri.pneu.mo.ni'ae. L. n. *capra*, -*ae* a goat; Gr. n. *pneumonia* disease of the lungs, pneumonia; N.L. gen. n. *capripneumoniae* of a pneumonia of a goat.

Cells are coccobacillary. Nonmotile. Colonies on solid agar have a characteristic fried-egg appearance. Grows in SP-4 or modified Hayflick medium supplemented with glucose at 37°C.

Pathogenic; causes characteristic, highly lethal fibrinous pleuropneumonia known as contagious caprine pleuropneumonia (CCPP) in goats (McMartin et al., 1980). A respiratory tract disease of similar pathology found in association with *Mycoplasma capricolum* subsp. *capripneumoniae* has been reported in sheep, mouflon, and ibex (Arif et al., 2007; Shiferaw et al., 2006). Transmission occurs via droplet aerosol.

Tetracyclines and tylosin are effective chemotherapeutic agents; however, treatment of endemic herds is not often

undertaken. Culling of infected herds and restricting the movement of infected animals are more common strategies for controlling spread of the disease (Thiaucourt et al., 1996). Live and killed vaccines have been described; however, each appear to afford delayed or partial protection from morbidity, and few have been completely successful at preventing infection (Browning et al., 2005). Antigenic cross-reactivity with *Mycoplasma capricolum* subsp. *capricolum* and *Mycoplasma leachii* preclude the exclusive reliance on serological-based diagnostics. Multiple molecular diagnostics have been described (Lorenzon et al., 2008; March et al., 2000; Woubit et al., 2004). This organism is under certain quarantine regulations in some countries and is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://www.oie.int>).

Source: isolated from the lower respiratory tract of goats, sheep, mouflon, and ibex.

DNA G+C content (mol%): 24.4 (Bd).

Type strain: F38, NCTC 10192.

Sequence accession no. (16S rRNA gene): U26042.

Further comment: previously known as the F38-type caprine mycoplasmas.

24. **Mycoplasma caviae** Hill 1971, 112^{AL}

ca.vi'ae. N.L. n. *cavia* guinea pig (*Cavia cobaya*); N.L. gen. n. *caviae* of a guinea pig.

Cell morphology for this species has not been described and motility has not been assessed. Colonies on solid agar have a characteristic fried-egg appearance. Grows in SP-4 medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the nasopharynx and urogenital tract of guinea pigs (Hill, 1971).

DNA G+C content (mol%): not determined.

Type strain: G122, ATCC 27108, NCTC 10126.

Sequence accession no. (16S rRNA gene): AF221111.

25. **Mycoplasma cavipharyngis** Hill 1989, 371^{VP} (Effective publication: Hill 1984, 3187)

ca.vi.pha.ryn'gis. N.L. n. *cavia* the guinea pig (*Cavia cobaya*); N.L. n. *pharynx-yngis* (from Gr. n. *pharugx pharuggos* throat) throat; N.L. gen. n. *cavipharyngis* of the throat of a guinea pig.

Cells are highly filamentous and filaments are twisted at intervals along their length. Regular helical forms like those of *Spiroplasma* species are not produced. Nonmotile. Growth on solid medium shows small, granular colonies with poorly defined centers. Grows in Hayflick medium supplemented with glucose at 35°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the nasopharynx of guinea pigs (Hill, 1984).

DNA G+C content (mol%): 30 (T_m).

Type strain: 117C, NCTC 11700, ATCC 43016.

Sequence accession no. (16S rRNA gene): AF125879.

26. **Mycoplasma citelli** Rose, Tully and Langford 1978, 571^{AL}

ci.tel'li. N.L. n. *Citellus* a genus of ground squirrel; N.L. gen. n. *citelli* of *Citellus*.

Cells are highly pleomorphic. Motility for this species has not been assessed. Colonies on solid agar have a characteristic fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the trachea, lung, spleen, and liver of ground squirrels (Rose et al., 1978).

DNA G+C content (mol%): 27.4 (Bd).

Type strain: RG-2C, ATCC 29760, NCTC 10181.

Sequence accession no. (16S rRNA gene): AF412973.

27. **Mycoplasma cloacale** Bradbury and Forrest 1984, 392^{VP}

clo.a.ca'le. L. neut. adj. *cloacale* pertaining to a cloaca.

Cells are primarily spherical. Nonmotile. Colonies on solid medium exhibit typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the cloaca of a turkey; from the lungs, trachea, ovaries, and eggs of ducks; and from chickens, pheasants, and geese (Benčina et al., 1987, 1988; Bradbury et al., 1987; Goldberg et al., 1995; Hinz et al., 1994).

DNA G+C content (mol%): 26 (Bd).

Type strain: 383, ATCC 35276, NCTC 10199.

Sequence accession no. (16S rRNA gene): AF125592.

28. **Mycoplasma collis** Hill 1983b, 849^{VP}

col'lis. L. gen. n. *collis* of a hill, alluding to the author who described the species.

Cells are primarily coccoidal and are nonmotile. Growth on a solid medium shows colonies with a typical fried-egg appearance. Grows in Hayflick medium supplemented with glucose at 35–37°C.

No evidence of pathogenicity. Mode of transmission has not been assessed.

Source: isolated from the conjunctivae of captive rats and mice (Hill, 1983b). References to isolation of *Mycoplasma collis* from domestic dogs appear to have been in error (Chalker and Brownlie, 2004).

DNA G+C content (mol%): 28 (T_m).

Type strain: 58B, NCTC 10197, ATCC 35278.

Sequence accession no. (16S rRNA gene): AF538681.

29. **Mycoplasma columbinasale** Jordan, Ernø, Cottew, Hinz and Stipkovits 1982, 114^{VP}

co.lum.bi.na.sa'le. L. n. *columbus* a pigeon; L. n. *nasus* nose; L. neut. suff. *-ale* suffix used with the sense of pertaining to; N.L. neut. adj. *nasale* pertaining to the nose; N.L. neut. adj. *columbinasale* pertaining to the nose of a pigeon.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium exhibit typical fried-egg appearance. Grows well in SP-4 medium supplemented with arginine at 35–37°C. Produces a “film and spots” reaction.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the turbinates of rock pigeons, racing pigeons, and fantail pigeons (Benčina et al., 1987; Keymer et al., 1984; Nagatomo et al., 1997; Yoder and Hofstad, 1964).

DNA G+C content (mol%): 32 (Bd).

Type strain: 694, ATCC 33549, NCTC 10184.

Sequence accession no. (16S rRNA gene): AF221112.

Further comment: previously known as avian serovar (serotype) L (Yoder and Hofstad, 1964).

30. **Mycoplasma columbinum** Shimizu, Ernø and Nagatomo 1978, 545^{AL}

co.lum.bi'num. L. neut. adj. *columbinum* pertaining to a pigeon.

Cells are pleomorphic and vary from coccoid to ring forms. Motility for this species has not been assessed. Colonies on solid medium have typical fried-egg morphology. Grows in Frey's medium supplemented with arginine at 37°C. Produces a “film and spots” reaction.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the trachea and oropharynx of feral pigeons and from the brain and lungs of racing pigeons (Benčina et al., 1987; Jordan et al., 1981; Keymer et al., 1984; Reece et al., 1986).

DNA G+C content (mol%): 27.3 (Bd).

Type strain: MMP1, ATCC 29257, NCTC 10178.

Sequence accession no. (16S rRNA gene): AF221113.

31. **Mycoplasma columborale** Shimizu, Ernø and Nagatomo 1978, 545^{AL}

co.lum.bo.ra'le. L. n. *columba* pigeon; L. n. *os, oris* the mouth; L. neut. suff. *-ale* suffix used with the sense of pertaining to; N.L. neut. adj. *orale* of or pertaining to the mouth; N.L. neut. adj. *columborale* of the pigeon mouth.

Cells are pleomorphic but predominantly coccoid or exhibiting ring forms. Motility for this species has not been assessed. Growth on solid medium yields medium to large colonies with very small central zones. Grows in Frey's medium supplemented with glucose at 37°C.

Pathogenicity for pigeons is unconfirmed, but one report described airsacculitis in experimentally inoculated chickens. Mode of transmission has not been assessed definitively.

Source: isolated from the trachea and oropharynx of feral pigeons and fantail pigeons; from the oropharynx and sinuses of racing pigeons; and from corvids and house flies (Benčina et al., 1987; Bradbury et al., 2000; Jordan et al., 1981; Kempf et al., 2000; Keymer et al., 1984; MacOwan et al., 1981; Nagatomo et al., 1997; Reece et al., 1986).

DNA G+C content (mol%): 29.2 (Bd).

Type strain: MMP4, ATCC 29258, NCTC 10179.

Sequence accession no. (16S rRNA gene): AF412975.

32. **Mycoplasma conjunctivae** Barile, Del Giudice and Tully 1972, 74^{AL}

con.junc.ti'va.e. N.L. n. *conjunctiva* the membrane joining the eyeball to the lids; N.L. gen. n. *conjunctivae* of conjunctiva.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies grown on solid medium may have elevated centers and a greenish, brownish, or olive color. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes infectious keratoconjunctivitis that can either resolve into a carrier state or result in complete

or near-complete blindness in goats, sheep, chamois, and ibex (Cottew, 1979; Mayer et al., 1997). Mode of transmission is via direct contact.

Though tetracyclines are an effective antimicrobial therapy *in vivo*, treatment to eradicate *Mycoplasma conjunctivae* from herds is not often attempted as the economic burden of infection is low. Topical treatment of secondary infections is often necessary (Slatter, 2001). Several commercial diagnostic assays have been described.

Source: isolated from the conjunctivae of goats, sheep, chamois, and Alpine ibex.

DNA G+C content (mol%): not determined.

Type strain: HRC581, ATCC 25834, NCTC 10147.

Sequence accession no. (16S rRNA gene): AY816349.

33. ***Mycoplasma corogypsi*** Panangala, Stringfellow, Dybvig, Woodard, Sun, Rose and Gresham 1993, 589^{VP}

co.ro.gyp'si. Gr. n. *korax-acos* a raven (black); Gr. n. *gyps gypos* a vulture; N.L. gen. n. *corogypsi* (*sic*) of a raven vulture.

Cells are highly pleomorphic and show small circular budding processes abutting elongated cells. Motility for this species has not been assessed. Colonies on solid medium have a fried-egg appearance. Grows in Frey's medium supplemented with glucose at 37°C.

Pathogenicity has not been established, although associated with abscess formation in a black vulture. *Mycoplasma corogypsi* has been isolated from clinically normal captive falcons, and may represent a commensal of this species. Mode of transmission has not been assessed definitively.

Source: isolated from the abscessed footpad of a black vulture, and from captive falcons (Lierz et al., 2002; Panangala et al., 1993).

DNA G+C content (mol%): 28 (Bd).

Type strain: BV1, ATCC 51148.

Sequence accession no. (16S rRNA gene): L08054.

34. ***Mycoplasma cottewii*** DaMassa, Tully, Rose, Pitcher, Leach and Cottew 1994, 483^{VP}

cot.te'wi.i. N.L. masc. gen. n. *cottewii* of Cottew, named for Geoffrey S. Cottew, an Australian veterinarian who was a co-isolator of the organism.

Cells are primarily coccoid. Nonmotile. Formation of biofilms has been demonstrated (McAuliffe et al., 2006). Growth on solid medium shows colonies with a typical fried-egg appearance. Grows well in Hayflick medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established.

Source: isolated from the external ear canals and rarely the sinuses of goats (Damassa et al., 1994).

DNA G+C content (mol%): 27 (T_m).

Type strain: VIS, ATCC 51347, NCTC 11732, CIP 105678.

Sequence accession no. (16S rRNA gene): U67945.

35. ***Mycoplasma cricetuli*** Hill 1983a, 117^{VP}

cri.ce.tu'li. N.L. n. *Cricetulus* generic name of the Chinese hamster, *Cricetulus griseus*; N.L. gen. n. *cricetuli* of *Cricetulus*.

Cells are coccoid to pleomorphic. Nonmotile. Colony growth on solid medium has a fried-egg appearance with

markedly small centers. Grows well in Hayflick broth supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established.

Source: isolated from the conjunctivae and nasopharynx of Chinese hamsters (Hill, 1983a).

DNA G+C content (mol%): not determined.

Type strain: CH, NCTC 10190, ATCC 35279.

Sequence accession no. (16S rRNA gene): AF412976.

36. ***Mycoplasma crocodyli*** Kirchhoff, Mohan, Schmidt, Runge, Brown, Brown, Foggin, Muvavarirwa, Lehmann and Flossdorf 1997, 746^{VP}

cro.co.dy'li. N.L. n. *Crocodylus* (from L. n. *crocodilus* crocodile) generic name of the crocodile; N.L. gen. n. *crocodyli* of *Crocodylus*.

Cells are coccoid. Nonmotile. Colonies on solid medium show a typical fried-egg appearance. Grows very rapidly in SP-4 medium supplemented with glucose at 30°C.

Pathogenic; causes exudative polyarthritides and rarely pneumonia in crocodiles. The natural mode of transmission has not been assessed definitively; however, experimental infection resulting in the reproduction of disease was achieved by intracoelomic and/or intrapulmonary inoculation.

Tetracyclines are effectively used to alleviate clinical signs in farmed crocodiles. A bacterin vaccine effective at controlling infection and preventing disease has been described (Mohan et al., 2001).

Source: isolated from the joints and lungs of Nile crocodiles (Mohan et al., 1997).

DNA G+C content (mol%): 27.6 (Bd).

Type strain: MP145, ATCC 51981.

Sequence accession no. (16S rRNA gene): AF412977.

37. ***Mycoplasma cynos*** Røsendal 1973, 53^{AL}

cy'nos. Gr. n. *cyon*, *cynos* a dog; N.L. gen. n. *cynos* of a dog.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium have defined centers and scalloped perimeters. Grows well in SP-4 medium supplemented with arginine at 37°C.

Pathogenic; causes pneumonia, bronchitis, and rarely cystitis in domestic dogs. The mode of transmission is via droplet aerosol, as demonstrated by studies housing infected and sentinel dogs (Røsendal and Vinther, 1977).

Source: isolated from the lungs, trachea, nasopharynx, urine, prepuce, prostate, cervix, vagina, and conjunctivae of domestic dogs (Chalker, 2005).

DNA G+C content (mol%): 25.8 (Bd).

Type strain: H 831, ATCC 27544, NCTC 10142.

Sequence accession no. (16S rRNA gene): AF538682.

38. ***Mycoplasma dispar*** Gourlay and Leach 1970, 121^{AL}

dis'par. L. neut. adj. *dispar* dissimilar, different.

Cells range from coccoid to short and filamentous. Motility for this species has not been assessed. An extracellular capsule can be visualized by electron microscopy following staining with ruthenium red. Colonies on solid medium have a granular, lacy, or reticulated appearance with no or a poorly defined central area. Grows in SP-4 medium or

modified Friis medium supplemented with glucose and calf thymus DNA at 37°C.

Pathogenic; causes pneumonia and rarely mastitis in cattle. Mode of transmission is by droplet aerosol.

Source: isolated from the lower respiratory tract and udders of cattle (Gourlay and Howard, 1979; Hodges et al., 1983).

DNA G+C content (mol%): 28.5–29.3 (T_m).

Type strain: 462/2, ATCC 27140, NCTC 10125.

Sequence accession no. (16S rRNA gene): AF412979.

39. **Mycoplasma edwardii** Tully, Barile, Del Giudice, Carski, Armstrong and Razin 1970, 349^{AL}

ed.war'di.i. N.L. masc. gen. n. *edwardii* of Edward, named after Derrick Graham ff. Edward (1910–1978), who first isolated this organism.

Cells are coccobacillary to short and filamentous. Motility for this species has not been assessed. Colonies on solid medium show a typical fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

Opportunistic pathogen; commonly found as a commensal of the oral and/or nasal cavities and urogenital tract of domestic dogs. *Mycoplasma edwardii* is rarely associated with pneumonia, arthritis, and septicemia of domestic dogs, often as a secondary pathogen compounding an existing lesion. Mode of transmission has not been established definitively.

Source: isolated from the oropharynx, nasopharynx, trachea, lungs, prepuce, vagina, cervix, blood, and synovial fluid of domestic dogs (Chalker, 2005; Stenske et al., 2005).

DNA G+C content (mol%): 29.2 (T_m).

Type strain: PG-24, ATCC 23462, NCTC 10132.

Sequence accession no. (16S rRNA gene): U73903.

40. **Mycoplasma elephantis** Kirchhoff, Schmidt, Lehmann, Clark and Hill 1996, 440^{VP}

e.le.phan'tis. L. n. *elephas*, -antis elephant; L. gen. n. *elephantis* of the elephant.

Cells are coccoidal. Nonmotile. Colonies on solid medium show a typical fried-egg appearance. Grows well in Hayflick medium supplemented with glucose at 37°C.

Probable commensal. No pathology was observed at the site of isolation (i.e., the vagina and urethra); however, isolation was achieved almost exclusively from arthritic animals with evidence of rheumatoid factor. The possibility thus exists that the clinical status of the animals was due to sexually acquired reactive arthritis, which has been observed with other *Mycoplasma* species known to parasitize the urogenital tract (Blanchard and Bébéar, 2002). Mode of transmission has not been established definitively.

Source: isolated from the vagina and urethra of captive elephants (Clark et al., 1980, 1978).

DNA G+C content (mol%): 24 (Bd).

Type strain: E42, ATCC 51980.

Sequence accession no. (16S rRNA gene): AF221121.

41. **Mycoplasma equigenitalium** Kirchhoff 1978, 500^{AL}

e.qui.ge.ni.ta'li.um. L. n. *equus*, *equi* the horse; L. pl. n. *genitalia* the genitals; N.L. pl. gen. n. *equigenitalium* of equine genitalia.

Cells are pleomorphic. Motility for this species has not been assessed. Colonies on solid medium show a typical fried-egg appearance. Grows in Hayflick medium supplemented with glucose at 37°C.

Opportunistic pathogen. Associated with endometritis, vulvitis, balanoposthitis, impaired fecundity, and abortion in horses; however, *Mycoplasma equigenitalium* is highly prevalent in clinically normal horses (Spergser et al., 2002). Mode of transmission is via sexual contact.

Source: isolated from the cervix, semen, and aborted foals, and rarely from the trachea, of horses (Lemcke, 1979).

DNA G+C content (mol%): 31.5 (Bd).

Type strain: T37, ATCC 29869, NCTC 10176.

Sequence accession no. (16S rRNA gene): AF221120.

42. **Mycoplasma equirhinis** Allam and Lemcke 1975, 405^{AL}

e.qui.rhi'nis. L. n. *equus*, *equi* a horse; Gr. n. *rhis*, *rhinos* nose; N.L. gen. n. *equirhinis* of the nose of a horse.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium show a typical fried-egg appearance. Grows in SP-4 or Hayflick medium supplemented with arginine at 37°C.

Opportunistic pathogen; associated with rhinitis and pneumonitis in horses, but can also be found in clinically normal animals. Mode of transmission is via droplet aerosol.

Source: isolated from the nasopharynx, nasal turbinates, trachea, tonsils, and semen of horses, and from the nasopharynx of cattle (Lemcke, 1979; Spergser et al., 2002; ter Laak et al., 1992a).

DNA G+C content (mol%): not determined.

Type strain: M432/72, ATCC 29420, NCTC 10148.

Sequence accession no. (16S rRNA gene): AF125585.

43. **Mycoplasma falconis** Poveda, Giebel, Flossdorf, Meier and Kirchhoff 1994, 97^{VP}

fal.co'nis. L. gen. n. *falconis* of the falcon, the host from which the organism was first isolated.

Cells are coccoid. Motility for this species has not been assessed. Colonies on solid medium have a fried-egg appearance. Grows well in modified Frey's medium supplemented with arginine at 37°C.

Pathogenicity has not been established. Associated with respiratory tract infections of saker falcons, although can also be isolated from clinically normal birds. Mode of transmission has not been established definitively.

Source: isolated from the trachea of falcons (Lierz et al., 2002, 2008a, b).

DNA G+C content (mol%): 27.5 (Bd).

Type strain: H/T1, ATCC 51372.

Sequence accession no. (16S rRNA gene): AF125591.

44. **Mycoplasma fastidiosum** Lemcke and Poland 1980, 161^{VP}

fas.ti.di.o'sum. L. neut. adj. *fastidiosum* fastidious, referring to the nutritionally fastidious nature of the organism on primary isolation.

Cells are highly filamentous and filaments are twisted at regular intervals along their length. Helical forms like those of *Spiroplasma* species are not produced. Nonmotile. Colonies on solid medium show a typical fried-egg appearance.

Grows in SP-4 or Frey's medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the nasopharynx of horses (Lemcke and Poland, 1980).

DNA G+C content (mol%): 32.3 (Bd).

Type strain: 4822, NCTC 10180, ATCC 33229.

Sequence accession no. (16S rRNA gene): AF125878.

45. **Mycoplasma faucium** Freundt, Taylor-Robinson, Purcell, Chanock and Black 1974, 253^{AL}

fau'ci.um. L. pl. n. *fauces*, -ium the throat; L. gen. pl. n. *faucium* of the throat.

Cells are coccoidal. Motility for this species has not been assessed. Colonies on solid medium show a typical fried-egg appearance, but are more loosely attached to the agar surface than are the colonies of most other mycoplasmas. Grows well in SP-4 medium supplemented with arginine at 37°C. Produces a "film and spots" reaction.

Probable commensal. Most commonly found as a commensal of the human oropharynx; however, recent isolations of *Mycoplasma faucium* have been made from brain abscesses (Al Masalma et al., 2009). Mode of transmission has not been established definitively.

Source: isolated from the oropharynx and brain of humans, and from the oral cavity of numerous species of nonhuman primates (Freundt et al., 1974; Somerson and Cole, 1979).

DNA G+C content (mol%): not determined.

Type strain: DC-333, ATCC 25293, NCTC 10174.

Sequence accession no. (16S rRNA gene): AF125590.

46. **Mycoplasma felifaucium** Hill 1988, 449^{VP} (Effective publication: Hill 1986, 1927)

fe.li.fau'ci.um. L. n. *felis* cat; L. pl. n. *fauces*, -ium throat; N.L. gen. pl. n. *felifaucium* of the feline throat.

Cells are primarily coccoidal. Nonmotile. Colonies on solid medium show a typical fried-egg appearance. Grows well in SP-4 or Hayflick medium supplemented with arginine at 37°C. Produces a "film and spots" reaction.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the oropharynx of captive pumas (*Felis concolor*; Hill, 1986).

DNA G+C content (mol%): 31 (T_m).

Type strain: PU, NCTC 11703, ATCC 43428.

Sequence accession no. (16S rRNA gene): U15795.

47. **Mycoplasma feliminutum** Heyward, Sabry and Dowdle 1969, 621^{AL}

fe.li.mi.nu'tum. L. n. *felis* a cat; L. neut. part. adj. *minutum* small; N.L. neut. adj. *feliminutum* a small colony organism isolated from cats.

Morphology is poorly defined. Motility for this species has not been assessed. Colonies are relatively small and irregular in shape. Grows well in SP-4 medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the oropharynx of domestic cats; from the nasopharynx, lungs, and urogenital tract of domestic dogs; and from the respiratory tract of horses (Chalker, 2005; Heyward et al., 1969; Lemcke, 1979).

DNA G+C content (mol%): 29.1 (Bd).

Type strain: Ben, ATCC 25749, NCTC 10159.

Sequence accession no. (16S rRNA gene): U16758.

Further comment: this organism was first described during a time when the only named genus of mollicutes was *Mycoplasma*. Its publication coincided with the first proposal of the genus *Acholeplasma* (Edward and Freundt, 1969, 1970), with which *Mycoplasma feliminutum* is properly affiliated through established phenotypic (Heyward et al., 1969) and 16S rRNA gene sequence (Brown et al., 1995) similarities. This explains the apparent inconsistencies with its assignment to the genus *Mycoplasma*. The name *Mycoplasma feliminutum* should therefore be revised to *Acholeplasma feliminutum* comb. nov.

48. **Mycoplasma felis** Cole, Golightly and Ward 1967, 1456^{AL}
fe'lis. L. n. *felis* a cat, L. gen. n. *felis* of a cat.

Cells are coccobacillary to filamentous. Motility for this species has not been assessed. Colonies on solid media display the typical fried-egg morphology. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; associated with conjunctivitis, rhinitis, ulcerative keratitis, and polyarthritis in domestic cats, and upper and lower respiratory tract infection in horses. *Mycoplasma felis* can also be isolated from clinically normal domestic cats, domestic dogs, and horses. The mode of transmission has not been established definitively.

Source: isolated from the conjunctivae, nasopharynx, lungs, and urogenital tract of domestic cats; from the lungs, tonsils, trachea nasopharynx of horses; from the oropharynx and trachea of domestic dogs; and from the synovial fluid of an immunocompromised human (Lemcke, 1979) Røsendal, 1979; (Bonilla et al., 1997; Gray et al., 2005; Hooper et al., 1985).

DNA G+C content (mol%): 25.2 (T_m).

Type strain: CO, ATCC 23391, NCTC 10160.

Sequence accession no. (16S rRNA gene): U09787.

Further comment: the proposed species "*Mycoplasma equipharyngis*" (Kirchoff, 1974) has been reported in horses. Further characterization has demonstrated unequivocally that these isolates are *Mycoplasma felis* and all mention of "*Mycoplasma equipharyngis*" should be considered equivalent to *Mycoplasma felis* (Lemcke, 1979).

49. **Mycoplasma fermentans** Edward 1955, 90^{AL}

fer.men'tans. L. part. adj. *fermentans* fermenting.

Cells are filamentous. Motility has not been established for this species. Colonies on solid media display typical fried-egg morphology. Grows well in SP-4 or Hayflick medium supplemented with either arginine or glucose at 37°C.

Pathogenicity unclear; associated with balanitis, vulvovaginitis, salpingitis, respiratory distress syndrome, pneumonia, and development of rheumatoid arthritis. *Mycoplasma fermentans* has also been tenuously linked with the progression of AIDS, chronic fatigue syndrome, Gulf War syndrome, Adamantides-Behçet's disease, and fibromyalgia.

The connection of the preceding clinical syndromes with *Mycoplasma fermentans* is highly equivocal, as different studies have reached markedly different conclusions. Mode of transmission has not been established definitively.

Source: isolated from the urine, urethra, rectum, penis, cervix, vagina, fallopian tube, amniotic fluid, blood, synovial fluid, and throat of humans; from the cervix of an African green monkey (*Chlorocebus* sp.); and from the vagina of a sheep (Blanchard et al., 1993; Nicholas et al., 1998; Taylor-Robinson and Furr, 1997; Waites and Talkington, 2005).

DNA G+C content (mol%): 28.7 (T_m)

Type strain: PG18, ATCC 19989, NCTC 10117, NBRC 14854.

Sequence accession no. (16S rRNA gene): M24289.

50. ***Mycoplasma flocculare*** Meyling and Friis 1972, 289^{AL}

floc.cu.la're. L. dim. n. *flocculus* a small flock or tuft of wool; L. neut. suff. *-are* suffix denoting pertaining to; N.L. neut. adj. *flocculare* resembling a small floc of wool, referring to the tendency of the organism to form clumps of flocculent material in broth culture.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid media are slightly convex with a coarsely granular surface and lack a defined center. Aggregates of cells may be produced during growth in broth, appearing as small floccular elements upon gentle shaking of the culture. Grows slowly in Friis medium at 37°C.

Opportunistic pathogen; normally regarded as a commensal of the nasopharynx that can cause pneumonia in association with other pathogens, most notably *Mycoplasma hyopneumoniae*. Mode of transmission is via droplet aerosol. *Mycoplasma flocculare* reportedly shares surface antigens with *Mycoplasma hyopneumoniae*, potentially complicating serology-based diagnosis of infection (Whittlestone, 1979).

Source: isolated from the nasopharynx, lungs, pericardium, and conjunctivae of pigs.

DNA G+C content (mol%): 33 (Bd).

Type strain: Ms42, ATCC 27399, NCTC 10143.

Sequence accession no. (16S rRNA gene): L22210.

51. ***Mycoplasma gallinaceum*** Jordan, Ernø, Cottew, Hinz and Stipkovits 1982, 114^{VP}

gal.li.na'ce.um. L. neut. adj. *gallinaceum* pertaining to a domestic fowl.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium have typical fried-egg morphology although some are devoid of a central core. Grows well in Frey's medium supplemented with glucose at 37°C.

Opportunistic pathogen associated with tracheitis, airsacculitis, or conjunctivitis in chickens, turkeys, ducks, and pheasants. *Mycoplasma gallinaceum* has been reported to complicate cases of infectious synovitis due to *Mycoplasma synoviae* in chickens. The mode of transmission has not been assessed definitively.

Source: isolated from upper and lower respiratory tract of chickens, turkeys, pheasants, partridges, and ducks; from the conjunctivae of pheasants; and from the synovial fluid of chickens (Bradbury et al., 2001; Tiong, 1990; Welchman et al., 2002; Yagihashi et al., 1983).

DNA G+C content (mol%): 28 (Bd).

Type strain: DD, ATCC 33550, NCTC 10183.

Sequence accession no. (16S rRNA gene): L24104.

Further comment: previously known as avian serotype D (Kleckner, 1960).

52. ***Mycoplasma gallinarum*** Freundt 1955, 73^{AL}

gal.li.na'rum. L. n. *gallina* a hen; L. gen. pl. n. *gallarum* of hens.

Cells are coccoid to coccobacillary. Nonmotile. Colonies on solid medium have a typical fried-egg appearance. Grows well in Frey's medium supplemented with arginine at 37°C. The organism shares some antigens in immunodiffusion tests with *Mycoplasma iners*, *Mycoplasma columbinasale*, and *Mycoplasma meleagridis*.

Commensal of gallinaceous birds; little evidence exists for the pathogenicity of isolates in such hosts. *Mycoplasma gallinarum* may have a role in airsacculitis of geese and participate in complex infection of chickens. Mode of transmission has not been assessed definitively.

Source: isolated from the respiratory tract of chickens, turkeys, ducks, geese, red jungle fowl, bamboo partridge, sparrow, swan, and demoiselle crane; and from sheep (Kisary et al., 1976; Kleven et al., 1978; Shimizu et al., 1979; Singh and Uppal, 1987).

DNA G+C content (mol%): 26.5–28.0 (T_m , Bd).

Type strain: PG16, ATCC 19708, NCTC 10120.

Sequence accession no. (16S rRNA gene): L24105.

Further comment: previously known as avian serotype B (Kleckner, 1960).

53. ***Mycoplasma gallisepticum*** Edward and Kanarek 1960, 699^{AL}

gal.li.sep'ti.cum. L. n. *gallus* rooster, chicken; L. adj. *septicus-a-um* producing a putrefaction, putrefying, septic; N.L. neut. adj. *gallisepticum* hen-putrefying (infecting).

Cells are coccoid, ovoid, and elongated pear-shaped with a highly structured polar body, called the bleb. Cells are motile and glide in the direction of the terminal bleb. Gliding speed varies among strains. Colonies on solid medium may be small and not necessarily of typical fried-egg appearance. Grows well in SP-4 or Hayflick medium supplemented with glucose at 37°C (Balish and Krause, 2006; Hatchel et al., 2006; Nakane and Miyata, 2009).

Pathogenic. Causes a characteristic combination of pneumonia, tracheitis, and airsacculitis (collectively termed chronic respiratory disease); salpingitis and atrophy of the ovaries, isthmus, and cloaca resulting in poor egg quality and reduced hatchability; arthritis or synovitis; and keratoconjunctivitis in chickens; infectious sinusitis, coryza, airsacculitis, arthritis or synovitis, encephalitis, meningitis, ataxia, and torticollis in turkeys; conjunctivitis and coryza featuring a high mortality rate in finches and grosbeaks; and respiratory disease in additional game birds including quail, partridges, pheasants, and peafowl. Lesions established by *Mycoplasma gallisepticum* are often complicated by additional avian pathogens including *Mycoplasma synoviae*, avian strains of *Escherichia coli*, Newcastle disease virus, and infectious bronchitis virus. Established mechanisms of transmission include droplet

aerosols, direct contact with infected animals or fomites, and vertical transmission.

Tetracyclines, macrolides, aminoglycosides, fluoroquinolones, and pleuromutilins are effective chemotherapeutic agents; however, treatment is typically only sought for individual birds, as medicating a commercial flock is not considered an effective control strategy. Vaccination and management strategies (i.e., single age “all in/all out” systems and culling of endemic flocks) are more commonly utilized. Multiple live and killed vaccines are commercially available, but suffer from residual pathogenicity, the need to develop a carrier state to provide protective immunity, adverse reactions, or low efficacy. Experimental vaccines have also been described. *Mycoplasma gallisepticum* shares surface antigens with *Mycoplasma imitans* and *Mycoplasma synoviae*, potentially complicating serology-based diagnosis of infection. Numerous molecular diagnostics have been described. This organism is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>; Yogev et al., 1989; Kempf, 1998; Markham et al., 1999; Gautier-Bouchardon et al., 2002; Ferguson et al., 2004; Browning et al., 2005; Crespo and McMillan, 2008; Gates et al., 2008; Gerchman et al., 2008; Kleven, 2008).

Source: isolated from the trachea, lungs, air sacs, ovaries, oviducts, brain, arterial walls, synovial membranes, synovial fluid, conjunctivae, and eggs of chickens; from the infraorbital sinuses, air sacs, brain, meninges, conjunctivae, synovial membranes, and synovial fluid of turkeys; from the conjunctivae, infraorbital sinuses, and trachea of finches; and from the respiratory tract of quail, partridges, pheasants, peafowl, ducks, grosbeak, crows, robins, and blue jays (Benčina et al., 2003, 1988; Bradbury and Morrow, 2008; Bradbury et al., 2001; Dhondt et al., 2005, 2007; Levisohn and Kleven, 2000; Ley et al., 1996; Mikaelian et al., 2001; Murakami et al., 2002; Nolan et al., 2004; Nunoya et al., 1995; Welchman et al., 2002; Wellehan et al., 2001).

DNA G+C content (mol%): 31.8 (T_m), 31 (strain R complete genome sequence).

Type strain: PG31, X95, ATCC 19610, NCTC 10115.

Sequence accession nos.: M22441 (16S rRNA gene of strain A5969), NC_004829 (strain R complete genome sequence).

Further comment: previously known as avian serotype A (Kleckner, 1960).

54. ***Mycoplasma gallopavonis*** Jordan, Ernø, Cottew, Hinz and Stipkovits 1982, 114^{VP}

gal.lo.pa.vo'nis. N.L. n. *gallopavo*, -onis a turkey (*Meleagris gallopavo*); N.L. gen. n. *gallopavonis* of a turkey.

Cells are coccoid to coccobacillary. Motility has not been assessed for this species. Colonies on solid medium have typical fried-egg morphology. Grows well in Frey's medium supplemented with glucose at 37°C.

Opportunistic pathogen; occasionally associated with airsacculitis in turkeys, but is also isolated from clinically normal turkeys. Mode of transmission has not been assessed definitively.

Source: isolated from the choanae, trachea, and air sacs of domestic and wild turkeys (Benčina et al., 1987; Cobb et al., 1992; Hoffman et al., 1997; Luttrell et al., 1992).

DNA G+C content (mol%): 27 (Bd).

Type strain: WR1, ATCC 33551, NCTC 10186.

Sequence accession no. (16S rRNA gene): AF412980.

Further comment: previously known as avian serotype F (Kleckner, 1960).

55. ***Mycoplasma gateae*** Cole, Golightly and Ward 1967, 1456^{AL}

ga.te'ae. N.L. gen. n. *gateae* (probably from Spanish *gato*, a cat) of a cat.

Morphology is poorly defined. Motility for this species has not been assessed. Colonies on solid medium are vacuolated and lack a well-defined central spot. Grows well in SP-4 medium at 37°C.

Opportunistic pathogen; can cause polyarthritis in domestic cats (Moise et al., 1983), but appears to be primarily a commensal species of the oral cavity. *Mycoplasma gateae* also appears to be a commensal species of domestic dogs and cattle. Mode of transmission has not been assessed definitively.

Source: isolated from the synovial membrane, oropharynx, saliva, and urogenital tract of domestic cats; from the lungs, oropharynx, trachea, and urogenital tract of domestic dogs; and from the urogenital tract of cattle (Chalker, 2005; Gourlay and Howard, 1979; Røsendal, 1979).

DNA G+C content (mol%): 28.5 (T_m).

Type strain: CS, ATCC 23392, NCTC 10161.

Sequence accession no. (16S rRNA gene): U15796.

Further comment: the original specific epithet “*gateae*”, which has been perpetuated in lists of bacterial names approved by the International Committee on Systematics of Prokaryotes, the American Type Culture Collection's *Catalog of Bacteria and Bacteriophages*, and in GenBank, is illegitimate because the genitive of the medieval Latin word *gata* (female cat) would have been *gatae* and there is no word for which *gateae* would have been a legitimate genitive (Brown et al., 1995).

56. ***Mycoplasma genitalium*** Tully, Taylor-Robinson, Rose, Cole and Bové 1983, 395^{VP}

ge.ni.ta'li.um. L. pl. n. *genitalia*, -ium the genitals; L. gen. pl. n. *genitalium* of the genitals.

Cells are predominantly flask-shaped with a terminal organelle protruding from the cell pole that is narrower than that of *Mycoplasma gallisepticum* and shorter than that of *Mycoplasma pneumoniae*. The leading end of the terminal structure is often curved. Cells exhibit gliding motility in circular patterns and glide in the direction of the terminal organelle's curvature (Hatchel and Balish, 2008). Colonies on solid media are round and possess a defined center that is somewhat less distinct than most mycoplasma species. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes urethritis, cervicitis, endometritis, and pelvic inflammatory disease. *Mycoplasma genitalium* is associated with infertility in humans. Mode of transmission is via sexual contact, congenitally, and possibly, in rare instances, via droplet aerosol.

Macrolides and fluoroquinolones are effective chemotherapeutic agents; however, reports indicate that treatment should be extensive, as clinical signs and detection

of *Mycoplasma genitalium* tend to recur following cessation. This is potentially due to sequestration within host cells. *Mycoplasma genitalium* shares numerous surface antigens with *Mycoplasma pneumoniae*, complicating serology-based diagnosis of infection. Numerous molecular diagnostics have been described, but few have been developed commercially (Jensen, 2004; Waites and Talkington, 2005).

Source: isolated or detected in the urogenital tract, urine, rectum, synovial fluid, conjunctiva, and nasopharynx of humans (Baseman et al., 1988; de Barbeyrac et al., 1993; Jensen, 2004; Waites and Talkington, 2005).

DNA G+C content (mol%): 32.4 (Bd), 31 (strain G-37^T complete genome sequence).

Type strain: G-37, ATCC 33530, CIP 103767, NCTC 10195.

Sequence accession nos: X77334 (16S rRNA gene), NC_000908 (strain G-37^T complete genome sequence), CP000925 (strain JCVI-1.0 complete genome sequence).

57. ***Mycoplasma glyophilum*** Forrest and Bradbury 1984, 355^{VP} (Effective publication: Forrest and Bradbury 1984, 602)

gly.co.phi'lum. Gr. adj. *glykys* sweet (this adjective was used to coin the noun glucose); N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *glycophilum* sweet-loving, intended to mean glucose-loving.

Cells are spherical or elliptical with an extracellular layer. Nonmotile. Growth on solid medium shows colonies with typical fried-egg appearance. Grows well in Hayflick medium supplemented with glucose at 37°C.

Pathogenicity has not been established, although there may be an association with a slight decrease in hatchability. Mode of transmission has not been assessed definitively.

Source: isolated from the respiratory tract and cloaca of chickens; and from the respiratory tract of turkeys, pheasants, partridges, ducks, and geese (Forrest and Bradbury, 1984).

DNA G+C content (mol%): 27.5 (Bd).

Type strain: 486, ATCC 35277, NCTC 10194.

Sequence accession no. (16S rRNA gene): AF412981.

58. ***Mycoplasma gypis*** Poveda, Giebel, Flossdorf, Meier and Kirchhoff 1994, 98^{VP}

gy'pis. Gr. n. *gyps*, *gypos* vulture; N.L. gen. n. *gypis* of the vulture, the host from which the organism was first isolated.

Cells are coccoid or round. Motility for this species has not been assessed. Colonies on solid medium have a fried-egg appearance. Grows in Frey's medium supplemented with arginine at 37°C. Produces a "film and spots" reaction.

Pathogenicity has not been established. Associated with respiratory tract disease of griffon vultures, but has also been isolated from healthy birds of prey. Mode of transmission has not been assessed definitively.

Source: isolated from the trachea of griffon vultures (*Griffon fulvus*), and from the trachea and air sacs of Eurasian buzzards, red kites, and Western marsh harriers (Lierz et al., 2008a, 2000; Poveda et al., 1994).

DNA G+C content (mol%): 27.1 (Bd).

Type strain: B1/T1, ATCC 51370.

Sequence accession no. (16S rRNA gene): AF125589.

59. ***Mycoplasma haemocanis*** (Kikuth 1928) Messick, Walker, Raphael, Berent and Shi 2002, 697^{VP} [*Bartonella canis* Kikuth 1928, 1730; *Haemobartonella* (*Bartonella*) *canis* (Kikuth 1928) Tyzzer and Weinman 1939, 151; Kreier and Ristic 1984, 726] ha.e.mo.ca'nis Gr. neut. n. *haema* blood; L. fem. gen. n. *canis* of the dog; N.L. gen. n. *haemocanis* of dog blood.

Cells are coccoid to pleomorphic. Motility for this species has not been assessed. The morphology of infected erythrocytes is altered, demonstrating a marked depression at the site of *Mycoplasma haemocanis* attachment. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes hemolytic anemia in domestic dogs. Transmission is vector-borne and mediated by the brown dog tick (*Rhipicephalus sanguineus*).

Source: observed in association with erythrocytes of domestic dogs (Hoskins, 1991).

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF197337.

60. ***Mycoplasma haemofelis*** (Clark 1942) Neimark, Johansson, Rikihisa and Tully 2002b, 683^{VP} [*Eperythrozoon felis* Clark 1942, 16; *Haemobartonella felis* (Clark 1942) Flint and McKelvie 1956, 240 and Kreier and Ristic 1984, 725]

ha.e.mo.fe'lis. Gr. neut. n. *haema* blood; L. fem. gen. n. *felis* of the cat; N.L. gen. n. *haemofelis* of cat blood.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes hemolytic anemia in cats. The mode of transmission is percutaneous or oral; an insect vector has not been identified, although fleas have been implicated (Woods et al., 2005).

Tetracyclines and fluoroquinolones are effective therapeutic agents (Dowers et al., 2002; Tasker et al., 2006).

Source: observed in association with erythrocytes of domestic cats.

DNA G+C content (mol%): 38.5–38.8 (genome sequence survey of strain OH; Berent and Messick, 2003; J.B. Messick et al., unpublished).

Type strain: not established

Sequence accession no. (16S rRNA gene): U88563.

61. ***Mycoplasma haemomuris*** (Mayer 1921) Neimark, Johansson, Rikihisa and Tully 2002b, 683^{VP} (*Bartonella muris* Mayer 1921, 151; *Bartonella muris ratti* Regendanz and Kikuth 1928, 1578; *Haemobartonella muris* Tyzzer and Weinman 1939, 143)

ha.e.mo.mu'ris. Gr. neut. n. *haema* blood; L. masc. gen. n. *muris* of the mouse; N.L. gen. n. *haemomuris* of mouse blood.

Cells are coccoid and some display dense inclusion particles. Motility for this species has not been assessed. The morphology of infected erythrocytes is altered, demonstrating a marked depression at the site of *Mycoplasma haemomuris* attachment. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Opportunistic pathogen; causes anemia in splenectomized or otherwise immunosuppressed mice. Transmission is vector-borne and mediated by the rat louse (*Polyfax spinulosa*).

Source: observed in association with erythrocytes of wild and captive mice, and hamsters.

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): U82963.

62. ***Mycoplasma hominis*** (Freundt 1953) Edward 1955, 90^{AL} (*Micromyces hominis* Freundt 1953, 471)

ho'mi.nis. L. n. *homo*, -inis man; L. gen. n. *hominis* of man.

Cells are coccoid to filamentous. Motility for this species has not been assessed. Colonies on solid media have a typical fried-egg appearance. Grows well in SP-4 medium supplemented with arginine at 37°C.

Pathogenic; causes pyelonephritis, pelvic inflammatory disease, chorioamnionitis, and postpartum fevers in women; congenital pneumonia, meningitis, and abscesses in newborns; and rarely extragenital pathologies including bacteremia, arthritis, osteomyelitis, abscesses and wound infections, mediastinitis, pneumonia, peritonitis, prosthetic- and catheter-associated infections, and infection of hematomas. Extragenital manifestations of *Mycoplasma hominis* infection are more commonly seen in immunosuppressed individuals, but can be seen in immunocompetent patients as well. Synergism between *Mycoplasma hominis* and *Trichomonas vaginalis* infections has been reported and a recent report documents the intraprotazoal location and transmission of *Mycoplasma hominis* with *Trichomonas vaginalis* (Dessi et al., 2006; Germain et al., 1994; Vancini and Benchimol, 2008). Mode of transmission is via sexual contact, congenitally, or by artificial introduction on foreign objects (e.g., catheters) or transplanted tissues.

Macrolides and fluoroquinolones are effective chemotherapeutic agents. Combination therapy with metronidazole is required for complex infections involving *Trichomonas vaginalis*. Many commercial diagnostics are available for routine clinical use.

Source: isolated from the urogenital tract, amniotic fluid, placenta, umbilical cord blood, urine, semen, bloodstream, cerebrospinal fluid, synovial fluid, bronchoalveolar lavage fluid, peritoneal aspirates, conjunctivae, bone abscesses, and hematoma aspirates of humans; and from several species of nonhuman primates (Somerson and Cole, 1979; Taylor-Robinson and McCormack, 1979; Waites and Talkington, 2005).

DNA G+C content (mol%): 33.7 (T_m)

Type strain: PG21, ATCC 23114, NCTC 10111, CIP 103715, NBRC 14850.

Sequence accession no. (16S rRNA gene): M24473.

63. ***Mycoplasma hyopharyngis*** Erickson, Ross, Rose, Tully and Bové 1986, 58^{VP}

hy.o.pha.ryn'gis. Gr. n. *hys*, *hyos* a swine; N.L. n. *pharynx-yngis* (from Gr. n. *pharugx*, *pharuggos* throat) throat; N.L. gen. n. *hyopharyngis* of a hog's throat.

Cells are pleomorphic. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows in medium D-TS or Hayflick

medium supplemented with arginine at 37°C and produces a "film and spots" reaction.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the nasopharynx of pigs (Erickson et al., 1986).

DNA G+C content (mol%): 24 (Bd, T_m).

Type strain: H3-6B F, ATCC 51909, NCTC 11705.

Sequence accession no. (16S rRNA gene): U58997.

64. ***Mycoplasma hyopneumoniae*** (Goodwin, Pomeroy and Whittlestone 1965) Maré and Switzer 1965, 841^{AL} (*Mycoplasma suis pneumoniae* Goodwin, Pomeroy and Whittlestone 1965, 1249)

hy.o.pneu.mo'ni.ae. Gr. n. *hys*, *hyos* a swine; Gr. n. *pneumonia* pneumonia; N.L. gen. n. *hyopneumoniae* of swine pneumonia.

Cells are coccoid to coccobacillary. Nonmotile. Colonies on solid medium are very small, lack a defined central region, and are usually convex with a granular surface. Grows very slowly in modified Friis medium, medium A26, and modified SP-4 medium supplemented with glucose at 37°C. Produces a "film and spots" reaction.

Pathogenic; causes a very characteristic chronic pneumonia associated with ciliostasis and marked sloughing of the epithelial lining in pigs. This collection of lesions in conjunction with *Mycoplasma hyopneumoniae* is referred to as enzootic pneumonia of pigs (EPP), and is associated with high morbidity and poor feed conversion (with proportional economic loss). The mechanism of transmission is via droplet aerosol.

Tetracyclines and tylosin do not typically eradicate *Mycoplasma hyopneumoniae* from infected animals, but are effective in limiting sequelae. Maintenance of pigs on antibiotics in conjunction with management practices involving adequate nutrition, air quality, and stress reduction are commonly employed to control the effects of disease in endemic herds. Many molecular diagnostics have been described (Dubosson et al., 2004). Serological diagnostic techniques utilizing monoclonal antibodies have proven successful at distinguishing *Mycoplasma hyopneumoniae* from *Mycoplasma flocculare*, though the two share surface antigens (Armstrong et al., 1987). Numerous experimental vaccines have been described and several commercial vaccines are available. The latter appear to reduce or eliminate clinical signs rather than prevent infection (Browning et al., 2005).

Source: isolated from the lungs, nasopharynx, tonsils, trachea, and bronchiolar lavage fluid of pigs (Marois et al., 2007; Whittlestone, 1979).

DNA G+C content (mol%): 27.5 (Bd), 28 (strain J^T and strain 7448 complete genome sequence), 28.6 (strain 232 complete genome sequence).

Type strain: J, ATCC 25934, NCTC 10110.

Sequence accession nos.: AY737012 (16S rRNA gene), AE017243 (strain J^T complete genome sequence), AE017244 (strain 7448 complete genome sequence), AE017332 (strain 232 complete genome sequence).

65. ***Mycoplasma hyorhinis*** Switzer 1955, 544^{AL}

hy.o.rhi'nis. Gr. n. *hys*, *hyos* a swine; Gr. n. *rhis*, *rhinos* nose; N.L. gen. n. *hyorhinis* of a hog's nose.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid media display typical fried-egg morphology. Grows well on S-4 supplemented with glucose at 37°C.

Mycoplasma hyorhinis is associated with contamination of eukaryotic cell culture and can be removed by treatment of cells with antibiotics and/or maintenance of cell lines in antibiotic-containing medium. The noted effects of *Mycoplasma hyorhinis* on cell-cycle regulation make the detection and elimination of this organism particularly pertinent (Goodison et al., 2007; Schmidhauser et al., 1990). The most effective classes of antibiotics for cell culture eradication are tetracyclines and fluoroquinolones (Borup-Christensen et al., 1988; Schmitt et al., 1988).

Pathogenic; associated with arthritis, polyserositis, and otitis media in pigs. *Mycoplasma hyorhinis* is also regarded as a commensal of the nasopharynx that can occasionally cause pneumonia, often in association with other pathogens (most notably *Mycoplasma hyopneumoniae* and *Bordetella bronchiseptica*). Mode of transmission is via droplet aerosol.

Source: isolated from the nasopharynx, lungs, ear canal, synovial fluid, serous cavity, and pericardium of pigs (Friis and Szancer, 1994; Ross, 1992; Whittlestone, 1979).

DNA G+C content (mol%): 27.8 (T_m).

Type strain: BTS-7, ATCC 17981, NCTC 10130, CIP 104968, NBRC 14858.

Sequence accession no. (16S rRNA gene): M24658.

66. ***Mycoplasma hyosynoviae*** Ross and Karmon 1970, 710^{AL}

hy.o.sy.no.vi'ae. Gr. n. *hys*, *hyos* a swine; N.L. n. *synovia* fluid in the joints; N.L. gen. n. *hyosynoviae* of joint fluid of swine.

Cells are coccoid to filamentous. Motility of this species has not been assessed. Colonies display a typical fried-egg appearance at 37°C. Grows well in SP-4 medium supplemented with glucose at 37°C. A granular deposit and a waxy surface pellicle are produced during growth in broth.

Pathogenic; causes infectious synovitis, arthritis, and rarely pericarditis in pigs. Transmission occurs from sows to piglets or between adults via aerosol.

Lincosamides, fluoroquinolones, and macrolides have been used effectively for treatment in conjunction with improved disinfection and quarantine during husbandry.

Source: isolated from the synovial fluid, nasopharynx, tonsils, lymph nodes, and pericardium of pigs (Whittlestone, 1979).

DNA G+C content (mol%): 28.0 (Bd).

Type strain: S16, ATCC 25591, NCTC 10167.

Sequence accession no. (16S rRNA gene): U26730.

67. ***Mycoplasma iguanae*** Brown, Demcovitz, Plourdé, Potter, Hunt, Jones and Rotstein 2006, 763^{VP}

i.gua'nae. N.L. gen. n. *iguanae* of the iguana lizard.

Cells are predominantly coccoid. Nonmotile. Colonies on solid medium exhibit variable (convex to umbonate) forms; mature colonies display sectorized centers. Grows well in SP-4 medium supplemented with glucose between 25 and 42°C.

Associated with pathologic lesions, but unable to reproduce disease following experimental inoculation (Brown et al., 2007). Mechanism of transmission has not been established.

Source: isolated from vertebral abscesses of green iguanas.

DNA G+C content (mol%): not determined.

Type strain: 2327, ATCC BAA-1050, NCTC 11745.

Sequence accession no. (partial 16S rRNA gene sequence): AY714305.

68. ***Mycoplasma imitans*** Bradbury, Abdul-Wahab, Yavari, Dupiellet and Bové 1993, 726^{VP}

i'mi.tans. L. part. adj. *imitans* imitating, mimicking, referring to the organism's phenotypic resemblance to *Mycoplasma gallisepticum*.

Cells are oval and flask-shaped with a short, wide attachment organelle. Cells are motile and exhibit gliding motility in the direction of the attachment organelle (Hatchel and Balish, 2008). Colonies have typical fried-egg morphology on solid medium. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes sinusitis in ducks, geese, and partridges. Disease has been reproduced experimentally. Mode of transmission has not been assessed definitively.

Diagnosis of infection is potentially complicated by numerous factors. Serological cross-reactions occur with *Mycoplasma gallisepticum* due to known epitopes including PvpA, the VlhA hemagglutinins, pyruvate dehydrogenase, lactate dehydrogenase, and elongation factor Tu (Jan et al., 2001; Lavrič et al., 2005; Markham et al., 1999; Rosengarten et al., 1995). In addition, the 16S rRNA genes share 99.9% identity, despite whole genome hybridization showing a relatedness of only 40–46%, potentially complicating molecular diagnostics based on the 16S rRNA gene. Two molecular methods for distinguishing these two species have been described (Harasawa et al., 2004; Marois et al., 2001).

Source: isolated from the nasal turbinates and sinuses of ducks, geese, and partridges (Dupiellet, 1984; Ganapathy and Bradbury, 1998; Kleven, 2003).

DNA G+C content (mol%): 31.9 (Bd).

Type strain: 4229, NCTC 11733, ATCC 51306.

Sequence accession no. (16S rRNA gene): L24103.

69. ***Mycoplasma indiense*** Hill 1993, 39^{VP}

in.di.en'se. N.L. neut. adj. *indiense* pertaining to India (source of the infected primates).

Cells are pleomorphic. Nonmotile. Colonies on agar have a characteristic fried-egg appearance. Grows well in SP-4 medium supplemented with arginine at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established.

Source: isolated from the throats of a rhesus monkey and a baboon (Hill, 1993).

DNA G+C content (mol%): 32 (Bd).

Type strain: 3T, NCTC 11728, ATCC 51125.

Sequence accession no. (16S rRNA gene): AF125593.

70. ***Mycoplasma iners*** Edward and Kanarek 1960, 699^{AL}

i'ners. L. neut. adj. *iners* inactive, inert.

The cell morphology is poorly defined. Motility for this species has not been assessed. Colonies on solid medium are relatively small and of a typical fried-egg appearance. Grows in Frey's medium supplemented with arginine at 37°C.

No evidence of pathogenicity. Mode of transmission has not been assessed definitively.

Source: isolated from the respiratory tract of chickens, turkeys, geese pigeons, pheasants, and partridges; and from tissues of swine (Benčina et al., 1987; Bradbury et al., 2001; Taylor-Robinson and Dinter, 1968).

DNA G+C content (mol%): 29.1 (T_m), 29.6 (Bd).

Type strain: PG30, ATCC 19705, NCTC 10165.

Sequence accession no. (16S rRNA gene): AF221114.

Further comment: previously known as avian serotype E (Kleckner, 1960).

71. ***Mycoplasma iowae*** Jordan, Ernø, Cottew, Hinz and Stipkovits 1982, 114^{VP}

i.o'wa.e. N.L. gen. n. *iowae* of Iowa.

Cells are pleomorphic and some display a terminal protrusion with possible attachment properties (Gallagher and Rhoades, 1983; Mirsalimi et al., 1989). Motile. Colonies on agar show typical fried-egg appearance. Grows well in SP-4 medium supplemented with either glucose or arginine at 41–43°C (Grau et al., 1991; Yoder and Hofstad, 1964).

Pathogenic; causes airsacculitis and embryo lethality resulting in reduced hatchability in turkeys. Transmission occurs vertically and by direct contact.

Tetracyclines, macrolides, and fluoroquinolones are effective chemotherapeutic agents; however, medicating a commercial flock is not considered an effective control strategy. Management tactics are more commonly utilized. Molecular diagnostic methods have been described (Ramírez et al., 2008; Raviv and Kleven, 2009). *Mycoplasma iowae* strains show considerable intra-species antigenic heterogeneity and a cross-reactive epitope with both *Mycoplasma gallisepticum* and *Mycoplasma imitans* potentially complicating serology-based diagnosis of infection (Al-Ankari and Bradbury, 1996; Dierks et al., 1967; Rosengarten et al., 1995).

Source: isolated from the air sacs, intestinal tract, and eggs of turkeys, and from the seed of an apple tree with apple proliferation disease (Bradbury and Kleven, 2008; Grau et al., 1991; Mirsalimi et al., 1989).

DNA G+C content (mol%): 25 (Bd).

Type strain: 695, ATCC 33552, NCTC 10185.

Sequence accession no. (16S rRNA gene): M24293.

Further comment: previously known as avian serotype I (Yoder and Hofstad, 1964).

72. ***Mycoplasma lagogenitalium*** Kobayashi, Runge, Schmidt, Kubo, Yamamoto and Kirchhoff 1997, 1211^{VP}

la.go.ge.ni.ta'li.um. Gr. masc. n. *lagos* hare; L. neut. pl. gen. n. *genitalium* of genitals; N.L. gen. pl. n. *lagogenitalium* of hare's genitals.

Cells are primarily coccoid. Nonmotile. Colonies on agar have a characteristic fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

No evidence of pathogenicity. Mechanism of transmission has not been established.

Source: isolated from the preputial smegma of Afghan pikas (*Ochotona rufescens*; Kobayashi et al., 1997).

DNA G+C content (mol%): 23 (T_m).

Type strain: 12MS, ATCC 700289, CIP 105489, DSM 22062.

Sequence accession no. (16S rRNA gene): AF412983.

73. ***Mycoplasma leachii*** Manso-Silván, Vilei, Sachse, Djordjevic, Thiaucourt and Frey 2009, 1356^{VP}

le.a.chi'i. N.L. masc. gen. n. *leachii* of Leach, named in honor of Dr R.H. Leach, who first characterized this taxon.

Cells are pleomorphic. Nonmotile. Colonies on solid agar have a characteristic fried-egg appearance. Grows in modified Hayflick medium supplemented with glucose at 37°C.

Pathogenic; causes polyarthritis, mastitis, abortion, and pneumonia in cattle. Mode of transmission has not been established definitively.

Tetracyclines appear to control infection during acute outbreaks (Hum et al., 2000). *Mycoplasma leachii* shares surface antigens with *Mycoplasma mycoides* subsp. *mycoides*, *Mycoplasma capricolum* subsp. *capripneumoniae*, and *Mycoplasma capricolum* subsp. *capricolum*, potentially complicating serology-based diagnosis of infection.

Source: isolated from the synovial fluid, udders, expelled milk, lungs, lymph nodes, pericardium, cervix, vagina, prepuce, semen, and aborted calves of cattle (Alexander et al., 1985; Gourlay and Howard, 1979; Hum et al., 2000).

DNA G+C content (mol%): not determined.

Type strain: PG50, NCTC 10133, DSM 21131.

Sequence accession no. (16S rRNA gene): AF261730.

Further comment: the assignment of strains formerly called "Mycoplasma species bovine group 7 of Leach" to the species *Mycoplasma leachii* came in response to a request from the Subcommittee on the Taxonomy of Mollicutes of the International Committee on Systematics of Prokaryotes for a proposal for an emended taxonomy for the members of the *Mycoplasma mycoides* phylogenetic cluster (Manso-Silván et al., 2009).

74. ***Mycoplasma leonicaptivi*** corrig. Hill 1992, 521^{VP}

le.o.ni.cap'ti.vi. L. n. *leo*, -onis the lion; L. adj. *captivus* captive; N.L. gen. n. *leonicaptivi* of the captive lion.

Cells are pleomorphic (primarily coccoid). Nonmotile. Colonies on solid medium have a typical fried-egg appearance. Growth in SP-4 broth supplemented with glucose occurs between 35 and 37°C.

No evidence of pathogenicity. Mode of transmission has not been established.

Source: isolated from the throat and respiratory tract of captive lions and leopards (Hill, 1992).

DNA G+C content (mol%): 27 (Bd).

Type strain: 3L2, NCTC 11726, ATCC 49890.

Sequence accession no. (16S rRNA gene): U16759.

Further comment: the original spelling of the specific epithet, *leocaptivus* (*sic*), has been corrected by Trüper and De'Clari (1998).

75. ***Mycoplasma leopharyngis*** Hill 1992, 521^{VP}

le.o.pha.ryn'gis. L. masc. n. *leo*, -onis lion; N.L. n. *pharynx*, -yngis (from Gr. n. *pharugx*, *pharuggos* throat) throat; N.L. gen. n. *leopharyngis* (*sic*) of the throat of a lion.

Cells are coccoid to pleomorphic. Nonmotile. Colonies on solid medium have a typical fried-egg appearance under

anaerobic conditions. Grows in SP-4 broth supplemented with glucose at optimum temperatures of 35–37°C. Grows well under both aerobic and anaerobic conditions.

No evidence of pathogenicity. Mechanism of transmission has not been established.

Source: isolated from the throat of lions (Hill, 1992).

DNA G+C content (mol%): 28 (Bd).

Type strain: LL2, NCTC 11725, ATCC 49889.

Sequence accession no. (16S rRNA gene): U16760.

77. **Mycoplasma lipofaciens** Bradbury, Forrest and Williams 1983, 334^{VP}

li.po.fa'ci.ens. Gr. n. *lipos* animal fat, lard, tallow; L. v. *facio* to make; N.L. part. adj. *lipofaciens* fat-making, intended to refer to the production of a lipid film on solid media.

Cells are mainly spherical and elliptical. Nonmotile. Colonies on solid medium have typical fried-egg appearance. Grows in Hayflick medium supplemented with glucose or arginine at 37°C. Produces a strong “film and spots” reaction.

Commensal of birds; little evidence exists for naturally occurring pathogenicity of the isolates, although experimental inoculation of chicken or turkey eggs can result in embryo mortality. Inadvertent transmission to an investigator during experimental inoculation studies resulted in clinical signs including rhinitis and pharyngitis. Aerosol transmission has been documented in turkeys.

Source: isolated from the infraorbital sinuses of chickens; from tissues or eggs of turkeys and ducks; and from eggs of Northern goshawks (Benčina et al., 1987; Bradbury et al., 1983; Lierz et al., 2007a, b, c, 2008b).

DNA G+C content (mol%): 24.5 (Bd).

Type strain: R171, ATCC 35015, NCTC 10191.

Sequence accession no. (16S rRNA gene): AF221115.

78. **Mycoplasma lipophilum** Del Giudice, Purcell, Carski and Chanock 1974, 152^{AL}

li.po.phi'lum. Gr. n. *lipos* animal fat; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *lipophilum* fat-loving.

Cells are pleomorphic and granular. Motility for this species has not been assessed. Colonies display typical fried-egg morphology. Growth on solid medium is associated with heavy production of film that spreads over the surface of the agar, with the development of numerous internal particles in the colonies. A film similar to that produced on agar medium develops on the surface of broth-grown cultures (Del Giudice et al., 1974). Grows in SP-4 or Hayflick medium supplemented with arginine at 37°C.

Pathogenicity for this species is unclear. This species was first isolated from a human patient with primary atypical pneumonia; however, subsequent isolations from similarly symptomatic patients have not been achieved. Mode of transmission has not been formally assessed.

Source: isolated from the upper and lower respiratory tract of a human with primary atypical pneumonia and the lower respiratory tract of rhesus monkeys (Hill, 1977).

DNA G+C content (mol%): 29.7 (Bd).

Type strain: MaBy, ATCC 27104, NCTC 10173, NBRC 14895.

Sequence accession no. (16S rRNA gene): M24581.

79. **Mycoplasma maculosum** Edward 1955, 90^{AL}

ma.cu.lo'sum. L. neut. adj. *maculosum* spotted, alluding to a crinkled film covering the colonies and spreading between them, and spots appearing in the medium beneath and around the colonies.

Cells are short and filamentous, with occasional branching. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick or SP-4 medium supplemented with arginine at 37°C.

Opportunistic pathogen. Cause of pneumonia in domestic dogs and rarely of meningitis in immunocompromised humans. The route of transmission is via droplet aerosol.

Source: isolated from the nasopharynx, lungs, conjunctivae, and urogenital tract of domestic dogs and the cerebrospinal fluid of an immunocompromised human (Chalker, 2005).

DNA G+C content (mol%): 26.7 (T_m), 29.6 (Bd).

Type strain: PG15, ATCC 19327, NCTC 10168, NBRC 14848.

Sequence accession no. (16S rRNA gene): AF221116.

80. **Mycoplasma meleagridis** Yamamoto, Bigland and Ortmayer 1965, 47^{AL}

me.le.a'gri.dis. L. n. *meleagris*, -idis a turkey; L. gen. n. *meleagridis* of a turkey.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. An extracellular capsule can be visualized by electron microscopy following staining with ruthenium red (Green III and Hanson, 1973). Colonies on solid medium are not necessarily of typical fried-egg appearance. Grows in Frey's medium supplemented with arginine at 37–38°C (Yamamoto et al., 1965).

Pathogenic; causes airsacculitis, pneumonia, sinusitis, perosis, chondrodystrophy, bursitis, synovitis, and reduced hatchability due to embryo lethality in turkeys. Transmission is primarily vertical, but can also occur through droplet aerosol or sexual contact.

Tetracyclines, macrolides, and fluoroquinolones are effective chemotherapeutic agents; however, medicating a commercial flock is not considered an effective control strategy. The temporary use of *in ovo* antimicrobial therapy can be used to eradicate *Mycoplasma meleagridis* from a flock. Management tactics (e.g., single age “all in/all out” systems and culling of endemic flocks) are more commonly utilized (Kleven, 2008). Serological and molecular diagnostic methods have been described (Ben Abdelmoumen Mardassi et al., 2007; Ramírez et al., 2008; Raviv and Kleven, 2009).

Source: isolated from the air sacs, trachea, infraorbital sinuses, oviduct, cloaca, phallus, and eggs of turkeys, and the air sacs of buzzards, kites, and kestrels (Chin et al., 2008; Jordan, 1979; Lam et al., 2004; Lierz et al., 2000).

DNA G+C content (mol%): 27.0 (T_m), 28.6 (Bd).

Type strain: 17529, ATCC 25294, NCTC 10153.

Sequence accession no. (16S rRNA gene): L24106.

Further comment: previously known as avian serotype H (Kleckner, 1960).

81. **Mycoplasma microti** (Dillehay, Sander, Talkington, Thacker and Brown 1995) Brown, Talkington, Thacker, Brown,

Dillehay and Tully 2001b, 412^{VP} (*Mycoplasma volis* Dillehay, Sander, Talkington, Thacker and Brown 1995, 633) mi.cro'ti. N.L. n. *Microtus* a genus of field vole; N.L. gen. n. *microti* of *Microtus*.

Cells are predominantly coccoid in shape. Nonmotile. Colonies on solid medium exhibit a typical fried-egg appearance. Grows well in SP-4 supplemented with glucose in temperatures ranging from 35 to 37°C.

Opportunistic pathogen. No evidence exists for pathogenicity in the natural host; however, pneumonitis was experimentally induced in mice and rats (Evans-Davis et al., 1998).

Source: isolated from the nasopharynx and lung of prairie voles (Dillehay et al., 1995).

DNA G+C content (mol%): not determined.

Type strain: IL371, ATCC 700935.

Sequence accession no. (16S rRNA gene): AF212859.

82. ***Mycoplasma moatsii*** Madden, Moats, London, Matthew and Sever 1974, 464^{AL}

mo.at'si.i. N.L. gen. masc. n. *moatsii* of Moats, named after Kenneth E. Moats, whose primary interest has been in the mycoplasmas of nonhuman primates.

Cells are spheroidal and some exhibit protrusions from the membrane. Motility for this species has not been assessed. Colonies exhibit typical fried-egg morphology. Grows readily in SP-4 or Hayflick broth supplemented with either arginine or glucose at an optimum temperature of 37°C.

No evidence of pathogenicity.

Source: isolated from the respiratory and reproductive tracts of grivet monkeys and from the cecum, jejunum, and colon of wild Norway rats (Giebel et al., 1990).

DNA G+C content (mol%): 25.7 (Bd).

Type strain: MK 405, ATCC 27625, NCTC 10158.

Sequence accession no. (16S rRNA gene): AF412984.

83. ***Mycoplasma mobile*** Kirchhoff, Beyene, Fischer, Flossdorf, Heitmann, Khattab, Lopatta, Rosengarten, Seidel and Yousef 1987, 197^{VP}

mo'bi.le. L. neut. adj. *mobile* motile.

Cells are conical or flask-shaped and have a distinct terminal protrusion referred to as the "head-like structure". Cells demonstrate rapid gliding motility when adhering to charged surfaces and move in the directional of the head-like structure (Miyata et al., 2002, 2000). Colonies on solid medium have a typically fried-egg appearance. Grows well in Aluotto's medium supplemented with glucose or arginine. The temperature range for growth is 17–30°C, with optimum growth at 30°C.

Pathogenic; causes necrotic erythrodermatitis in tench. The mode of transmission has not been established.

Source: isolated from the gills of a freshwater fish (*Tinca tinca*) with "red disease" (Kirchhoff et al., 1987).

DNA G+C content (mol%): 23.5 (Bd), 24.9.

Type strain: 163K, ATCC 43663, NCTC 11711.

Sequence accession nos: M24480 (16S rRNA gene), NC_006908 (complete genome sequence of strain 163K).

84. ***Mycoplasma molare*** Røsendal 1974, 130^{AL}

mo.la're. L. neut. adj. *molare* of or belonging to a mill, here millstone-like, referring to the heavy film reaction, which resembles the pattern on the surface of a millstone.

Cells are coccoid to pleomorphic. Nonmotile. Colonies have a typical fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C. A lipid film of characteristic appearance develops on the surface and along the circumference of colonies grown on egg-yolk agar.

Opportunistic pathogen. Associated with pharyngitis and mild inflammatory lesions of the lower respiratory tract and may be associated with infertility, vaginitis, and posthitis of domestic dogs. No clear evidence for primary pathogenicity of the species. Mode of transmission has not been established definitively.

Source: isolated from the oral cavity, pharynx, cervix, vagina, and prepuce of domestic dogs (Røsendal, 1979; (Chalker, 2005).

DNA G+C content (mol%): 26.0 (Bd).

Type strain: H 542, ATCC 27746, NCTC 10144.

Sequence accession no. (16S rRNA gene): AF412985.

85. **"*Mycoplasma mucosicanis*"** Spergser, Langer, Muck, Macher, Szostak, Rosengarten and Busse 2010

mu.co.si.ca'nis. N.L. n. *mucosa* mucous membrane; L. n. *canis* a dog; N.L. gen. n. *mucosicanis* of mucous membranes of a dog.

Cells are pleomorphic, but primarily coccoid. Nonmotile. Colonies on solid media have a typical fried-egg morphology. Grows wells in modified Hayflick medium at 37°C and produces a "film and spots" reaction.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the prepuce, semen, vagina, cervix, and oral cavity of domestic dogs (Spergser et al., 2010).

DNA G+C content (mol%): not determined.

Type strain: 1642, ATCC BAA-1895, DSM 22457.

Sequence accession no. (16S rRNA gene): AM774638.

86. ***Mycoplasma muris*** McGarrity, Rose, Kwiatkowski, Dion, Phillips and Tully 1983, 355^{VP}

mu'ris. L. n. *mus*, *muris* mouse; L. gen. n. *muris* of a mouse.

Cells are primarily coccoid or coccobacillary, but exhibit a few other pleomorphic forms. Motility for this species has not been assessed. Colonies usually have a granular appearance and few colonies demonstrate the typical fried-egg appearance. Grow well in SP-4 broth supplemented with arginine at 37°C and produces a "film and spots" reaction.

No evidence of pathogenicity.

Source: isolated from the vagina of a pregnant mouse (laboratory strain RIII; McGarrity et al., 1983).

DNA G+C content (mol%): 24.9 (TLC).

Type strain: RIII-4, ATCC 33757, NCTC 10196.

Sequence accession no. (16S rRNA gene): M23939.

87. ***Mycoplasma mustelae*** Salih, Friis, Arseculeratne, Freundt and Christiansen 1983, 478^{VP}

mu.ste'lae. N.L. n. *Mustela* (from L. n. *mustela* a weasel) the generic name of the mink *Mustela vison*; N.L. gen. n. *mustelae* of *Mustela*.

Cells are highly pleomorphic; most common morphologies include pleomorphic rings, short filamentous forms, and coccoid elements. Nonmotile. Colonies on solid medium show a typical fried-egg appearance. Growth in Hayflick medium supplemented with glucose occurs at 37°C.

No evidence of pathogenicity.

Source: isolated from the trachea and lungs of juvenile minks (*Mustela vison*; Salih et al., 1983).

DNA G+C content (mol%): 28.2 (Bd).

Type strain: MX9, ATCC 35214, NCTC 10193, AMRC-C 1486.

Sequence accession no. (16S rRNA gene): AF412986.

88. ***Mycoplasma neurolyticum*** (Sabin 1941) Freundt 1955, 73^{AL} (*Musculomyces neurolyticus* Sabin 1941, 57)

neu.ro.ly'ti.cum. Gr. n. *neuron* nerve; N.L. adj. *lyticus* -a -um (from Gr. adj. *lutikos* -ê -on) able to loosen, able to dissolve; N.L. neut. adj. *neurolyticum* nerve-destroying.

Cells are filamentous and highly variable length. Nonmotile (Nelson and Lyons, 1965). Colonies show a typical fried-egg appearance after incubation at 37°C. Grows in Hayflick medium supplemented with glucose at 37°C (Naot et al., 1977).

Pathogenicity is currently uncertain. Potentially associated with spongiform encephalopathy and ischemic necrosis of the brain resulting in a clinical state referred to as "rolling disease" in mice and rats. Pathology may be exacerbated in the presence of additional neurotropic organisms (i.e., *Toxoplasma gondii*, *Chlamydia* spp., *Plasmodium* spp., and yellow fever virus) or during leukemic syndromes. Transmission to suckling rodents occurs shortly after birth. Treatment of *Mycoplasma neurolyticum* infections is uncommon, as pathology is typically not resolvable after the onset of clinical signs.

Source: isolated from the brain, conjunctivae, nasopharynx, and middle ear of captive mice and rats.

DNA G+C content (mol%): 22.8 (Bd), 26.2 (T_m).

Type strain: Type A, ATCC 19988, NCTC 10166, CIP 103926, NBRC 14799.

Sequence accession no. (16S rRNA gene): M23944.

Further comment: a putative exotoxin with neurological effects on rodents was formerly thought to be produced by most freshly isolated strains, although a few non-toxic strains were described (Tully and Ruchman, 1964). The findings were not substantiated by later work (Tryon and Baseman, 1992).

89. ***Mycoplasma opalescens*** Røsendal 1975, 469^{AL}

o.pa.les'cens. L. n. *opalus* precious stone; N.L. neut. adj. *opalescens* opalescent, referring to the opalescent film produced on solid medium.

Morphology by light microscopy or ultrastructural examination is not defined. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance and possess an iridescent quality. Grows well in SP-4 medium supplemented with arginine at 37°C.

No evidence of pathogenicity.

Source: isolated from the oral cavity, prepuce, and prostate gland of domestic dogs (Røsendal, 1975).

DNA G+C content (mol%): 29.2 (Bd).

Type strain: MH5408, ATCC 27921, NCTC 10149.

Sequence accession no. (16S rRNA gene): AF538961.

90. ***Mycoplasma orale*** Taylor-Robinson, Canchola, Fox and Chanock 1964, 141^{AL}

o.ra'le. L. n. *os*, *oris* the mouth; L. neut. suff. *-ale* suffix denoting pertaining to; N.L. neut. adj. *orale* pertaining to the mouth.

Cells can be either coccoid or filamentous. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in Hayflick or SP-4 medium supplemented with arginine at 37°C.

Mycoplasma orale is most commonly associated with contamination of eukaryotic cell culture and is frequently removed by treatment of cells with antibiotics and/or maintenance of cell lines in antibiotic-containing medium. The most effective classes of antibiotics for cell culture eradication are tetracyclines, macrolides, and fluoroquinolones. Additionally, passage of eukaryotic cells in hyperimmune serum raised against *Mycoplasma orale* has been shown to be an effective method of eradication (Vogelzang and Compeer-Dekker, 1969).

Commensal/opportunistic pathogen. Commonly found as a commensal of the human oral cavity; can cause respiratory tract infections, osteomyelitis, infectious synovitis, and abscesses in immunocompromised individuals (Paessler et al., 2002; Roifman et al., 1986).

Source: isolated from the oral cavity of subclinical humans, the sputum of an immunocompromised human with acute respiratory illness, and from synovial fluid, bone, and splenic abscesses of another immunocompromised individual.

DNA G+C content (mol%): 24.0–28.2 (T_m , Bd).

Type strain: CH19299, ATCC 23714, NCTC 10112, CIP 104969, NBRC 14477.

Sequence accession no. (16S rRNA gene): M24659.

91. ***Mycoplasma ovipneumoniae*** Carmichael, St George, Sullivan and Horsfall 1972, 677^{AL}

o.vi.pneu.mo.ní'ae. L. fem. n. *ovis* a sheep; Gr. n. *pneumonia* pneumonia; N.L. gen. n. *ovipneumoniae* of sheep pneumonia.

Morphology and motility are poorly described. The organism produces a polysaccharide capsule with variable thickness that is dependent upon culture conditions and strain (Niang et al., 1998). Colonies grown on standard agar are convex and have a lacy or vacuolated appearance. Grows well in Friis medium or SP-4 broth supplemented with glucose at 37°C.

Pathogenic; causes chronic proliferative interstitial pneumonia, pulmonary adenomatosis, conjunctivitis (Jones et al., 1976), and mastitis under experimental conditions (Jones, 1985) of sheep and goats. Transmission occurs via droplet aerosol and can occur via intravenous inoculation in experimental infection studies.

Source: isolated from the lungs, trachea, nose, and conjunctivae of sheep and goats.

DNA G+C content (mol%): 25.7 (Bd).

Type strain: Y98, NCTC 10151, ATCC 29419.

Sequence accession no. (16S rRNA gene): U44771.

92. **Mycoplasma ovis** (Neitz, Alexander and du Toit 1934) Neimark, Hoff and Ganter 2004, 369^{VP} (*Eperythrozoon ovis* Neitz, Alexander and du Toit 1934, 267)
o'vis. L. fem. n. *ovis*, -is a sheep; L. gen. n. *ovis* of a sheep.
Cells are coccoid and motility for this species has not been assessed. The morphology of infected erythrocytes is altered demonstrating a marked depression at the site of *Mycoplasma ovis* attachment. This species has not been grown on artificial medium; therefore, notable biochemical parameters are not known.
Neoarsphenamine is an effective therapeutic agent. *Mycoplasma ovis* is reported to share antigens with *Mycoplasma wenyonii* (Kreier and Ristic, 1963), potentially complicating serology-based diagnosis of infection.
Pathogenic; causes mild to severe anemia in sheep and goats that often results in poor feed conversion. Transmission occurs via blood-feeding arthropods, e.g., *Haemophysalis plumbeum*, *Rhipicephalus bursa*, *Aedes camptorhynchus*, and *Culex annulirostris* (Daddow, 1980; Howard, 1975; Nikol'skii and Slipchenko, 1969), and likely via fomites such as reused needles, shearing tools, and ear-tagging equipment (Brun-Hansen et al., 1997; Mason and Statham, 1991).
Source: observed in association with erythrocytes or unattached in suspension in the blood of sheep, goats, and rarely in eland and splenectomized deer.
DNA G+C content (mol%): not determined.
Type strain: not established.
Sequence accession no. (16S rRNA gene): AF338268.
93. **Mycoplasma oxoniensis** Hill 1991b, 24^{VP}
oxo.ni.en'sis. N.L. adj. *oxoniensis* (*sic*) pertaining to Oxon, an abbreviation of Oxfordshire, where the mycoplasma was first isolated.
Cells are primarily coccoid. Nonmotile. Colonies on agar have a typical fried-egg appearance. Growth in SP-4 broth supplemented with glucose occurs at 35–37°C.
No evidence of pathogenicity. Mode of transmission is unknown.
Source: isolated from the conjunctivae of the Chinese hamster (*Cricetulus griseus*; Hill, 1991b).
DNA G+C content (mol%): 29 (Bd).
Type strain: 128, NCTC 11712, ATCC 49694.
Sequence accession no. (16S rRNA gene): AF412987.
94. **Mycoplasma penetrans** Lo, Hayes, Tully, Wang, Kotani, Pierce, Rose and Shih 1992, 363^{VP}
pe.ne'trans. L. part. adj. *penetrans* penetrating, referring to the ability of the organism to penetrate into mammalian cells.
Cells are flask-shaped, with a distinct terminal structure reminiscent of the *Mycoplasma pneumoniae* attachment organelle. Cells demonstrate gliding motility when adhering to charged surfaces and move in the direction of the terminal structure. Colonies on agar plates display a typical fried-egg appearance. Grows well in SP-4 broth supplemented with either glucose or arginine at 37°C.
Opportunistic pathogen; found in the urogenital tract of immunocompromised humans, most notably HIV-positive individuals (serological detection in HIV-negative individuals is rare). Speculation regarding the ability of *Mycoplasma penetrans* to act as a cofactor in the progression of AIDS by modulation of the immune system remains intriguing, but in need of further substantiation (Blanchard, 1997). Transmission is presumed to be via sexual contact.
Source: isolated from the urine of HIV-positive humans, and from the blood, respiratory secretions, and trachea of an HIV-negative patient with multiple autoimmune syndromes (Yanez et al., 1999).
DNA G+C content (mol%): 30.5 (T_m), 25.7 (HF-2 genome sequence; Sasaki et al., 2002).
Type strain: GTU-54-6A1, ATCC 55252.
Sequence accession nos: L10839 (16S rRNA gene), NC_004432 (HF-2 complete genome sequence).
95. **Mycoplasma phocicerebrale** corrig. Giebel, Meier, Binder, Flossdorf, Poveda, Schmidt and Kirchhoff 1991, 43^{VP}
pho.ci.ce.re.bra'le. L. n. *phoca* seal; N.L. neut. adj. *cerebrale* of or pertaining to the brain; N.L. neut. adj. *phocicerebrale* pertaining to the brain of a seal.
Cells are coccoid or exhibit a dumbbell shape. Motility for this species has not been assessed. Colonies on solid medium typically show a fried-egg appearance. Grows well in SP-4 medium supplemented with arginine at 37°C.
Pathogenic; associated with respiratory disease and conjunctivitis in harbor seals (Kirchhoff et al., 1989) and a distinctive ulcerative keratitis subsequent to seal bites (known as “seal finger”) and secondary arthritis in humans (Baker et al., 1998; Ståby, 2004). Mode of transmission between harbor seals has not been established definitively; transmission to humans appears to be zoonotic following seal bites.
Source: isolated from the brains, noses, throats, lungs, and hearts of seals (*Phoca vitulina*) during an outbreak of respiratory disease (Kirchhoff et al., 1989), and from cutaneous lesions of humans with seal finger (Baker et al., 1998).
DNA G+C content (mol%): 25.9 (Bd).
Type strain: 1049, ATCC 49640, NCTC 11721.
Sequence accession no. (16S rRNA gene): AF304323.
Further comment: the original spelling of the specific epithet, *phocacerebrale* (*sic*), has been corrected by Königsson et al. (2001).
96. **Mycoplasma phocidae** Ruhnke and Madoff 1992, 213^{VP}
pho.ci'da.e. L. n. *phoca* seal; N.L. gen. n. *phocidae* (*sic*) of a seal.
Cells are primarily coccoid. Motility for this species has not been assessed. Colonies on solid medium have a typical fried-egg appearance. Grows well in SP-4 or Hayflick medium supplemented with arginine at 37°C. Produces “film and spots” reaction.
Opportunistic pathogen; associated with secondary pneumonia of harbor seals subsequent to influenza infection. Attempts to produce disease in gray or harp seals with *Mycoplasma phocidae* in pure culture were not successful (Geraci et al., 1982). Mode of transmission has not been established definitively.
Source: isolated from the lungs, tracheae, and heart of harbor seals.
DNA G+C content (mol%): 27.8 (Bd).
Type strain: 105, ATCC 33657.
Sequence accession no. (16S rRNA gene): AF304325.

Further comment: the species designation “*Mycoplasma phocae*” was suggested by Königsson et al. (2001), but the original epithet “*phocidae*” should be retained. The suggested change is forbidden by Rule 61 (Note) of the Bacteriological Code because it would change the first syllable of the original epithet without correcting any orthographic or typographical error.

97. ***Mycoplasma phocirhinis*** corrig. Giebel, Meier, Binder, Flossdorf, Poveda, Schmidt and Kirchhoff 1991, 43^{VP}
 pho.ci.rhi'nis. L. n. *phoca* seal; Gr. n. *rhis*, *rhinos* nose; N.L. gen. n. *phocirhinis* of the nose of a seal.

Cells are coccoid; motility for this species has not been assessed. Colonies on solid medium usually have a fried-egg appearance. Grows well in Friis or Hayflick medium at 37°C. Produces “film and spots” reaction.

Pathogenic; associated with respiratory disease and conjunctivitis of harbor seals (Kirchhoff et al., 1989). Mode of transmission has not been established definitively.

Source: isolated from the nose, pharynx, trachea, lungs, and heart of seals (*Phoca vitulina*; Kirchhoff et al., 1989).

DNA G+C content (mol%): 26.5 (Bd).

Type strain: 852, ATCC 49639, NCTC 11722.

Sequence accession no. (16S rRNA gene): AF304324.

Further comment: the original spelling of the specific epithet, *phocarhinis* (*sic*), has been corrected by Königsson et al. (2001)

98. ***Mycoplasma pirum*** Del Giudice, Tully, Rose and Cole 1985, 290^{VP}

pi'rum. L. neut. n. *pirum* (nominative in apposition) pear, referring to the pear-shaped morphology of the cells.

Cells are predominantly flask or pear-shaped and possess an organized terminal structure, with an outer, finely particulate nap covering the entire surface of the cell. Cells exhibit low-speed gliding motility and move in the direction of the terminal organelle (Hatchel and Balish, 2008). Colonies display a typical fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

No evidence of pathogenicity.

Source: isolated from the rectum of immunocompetent humans and whole blood and circulating lymphocytes of HIV-positive humans (Montagnier et al., 1990). Originally isolated from cultured eukaryotic cells that were of human origin (Del Giudice et al., 1985).

DNA G+C content (mol%): 25.5 (Bd).

Type strain: HRC 70-159, ATCC 25960, NCTC 11702.

Sequence accession no. (16S rRNA gene): M23940.

99. ***Mycoplasma pneumoniae*** Somerson, Taylor-Robinson and Chanock 1963, 122^{AL}

pneu.mo.ni'ae. Gr. n. *pneumonia* pneumonia; N.L. gen. n. *pneumoniae* of pneumonia.

Cells are highly pleomorphic; the predominant shape includes a long, thin terminal structure at one cell pole, with or without a trailing filament at the opposite pole. Cells are motile and glide in the direction of the terminal organelle when attached to cell surfaces, plastic, or glass. Colonies on solid medium usually lack the light peripheral zone, appearing rather as circular dome-shaped, granular

structures. Growth is best achieved in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes interstitial pneumonitis, tracheobronchitis, desquamative bronchitis, and pharyngitis [collectively referred to as primary atypical pneumonia (PAP); Krause and Taylor-Robinson (1992)]. Less commonly, *Mycoplasma pneumoniae* causes meningoenzephalitis, otitis media, bullous myringitis, infectious synovitis, glomerulonephritis, pancreatitis, hepatitis, myocarditis, pericarditis, hemolytic anemia, and rhabdomyolysis (Waites and Talkington, 2005). The preceding can be primary lesions, but are often secondary to respiratory disease. Dysfunction of the immune system by inappropriate cytokine responses or possibly molecular mimicry following infection are associated with long-term sequelae including the development or exacerbation of asthma and chronic obstructive pulmonary disease; Stevens-Johnson syndrome and other exanthemas; and Guillain-Barre syndrome, Bell's palsy, and demyelinating neuropathies (Atkinson et al., 2008). Mode of transmission is via droplet aerosols (PAP) or sexual contact (urogenital colonization).

Clinical manifestations are successfully treated with tetracyclines, fluoroquinolones, macrolides, and lincosamides (Waites and Talkington, 2005). Signs can be treated with inhaled or injected steroids. Experimental vaccinations aimed at preventing infection have been unsuccessful due to failure to elicit immune responses, retention of virulence, or invocation of immune responses that exacerbated clinical signs (Barile, 1984; Jacobs et al., 1988). *Mycoplasma pneumoniae* is reported to share antigens with *Mycoplasma genitalium* (Taylor-Robinson, 1983a), potentially complicating serology-based diagnosis of infection.

Source: isolated from the upper and lower respiratory tract, cerebrospinal fluid, synovial fluid, and urogenital tract of humans.

DNA G+C content (mol%): 38.6 (T_m), 40.0 (strain M129 genome sequence).

Type strain: FH, ATCC 15531, NCTC 10119, CIP 103766, NBRC 14401.

Sequence accession nos: M29061 (16S rRNA gene), U00089 (strain M129 genome sequence).

100. ***Mycoplasma primatum*** Del Giudice, Carski, Barile, Lemcke and Tully 1971, 442^{AL}

pri.ma'tum. L. n. *primas*, *primatis* chief, from which *primates*, the highest order of mammals originates; L. pl. gen. n. *primatum* of chiefs, of primates.

Cells are both spherical and coccobacillary. Motility for this species has not been assessed. Colony morphology has a fried-egg appearance. Grows well in SP-4 or Hayflick medium supplemented with arginine at 37°C.

Opportunistic pathogen; rarely associated with keratitis in humans (Ruiter and Wentholt, 1955). Mode of transmission has not been established.

Source: isolated from the oral cavity and/or urogenital tract of baboons, African green monkeys, rhesus macaques, squirrel monkeys, and humans (Hill, 1977; Somerson and Cole, 1979; Thomsen, 1974).

DNA G+C content (mol%): 28.6 (T_m).

Type strain: HRC292, ATCC 25948, NCTC 10163.

Sequence accession no. (16S rRNA gene): AF221118.

101. **Mycoplasma pullorum** Jordan, Ernø, Cottew, Hinz and Stipkovits 1982, 114^{VP}

pu.llo'rum. L. n. *pullus* a young animal, especially chicken; L. gen. pl. n. *pullorum* of young chickens.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colonies on solid medium display typical fried-egg appearance. Grows in Frey's or Hayflick medium supplemented with glucose at 37°C.

Pathogenicity not fully established, but has been associated with tracheitis and airsacculitis in chickens, and embryo lethality resulting in reduced hatchability in chickens and turkeys. Mode of transmission has not been assessed definitively.

Source: isolated from the trachea, air sacs, and eggs of chickens; from the eggs of turkeys; and from tissues of pheasants, partridges, pigeons, and quail (Benčina et al., 1987; Bradbury et al., 2001; Kempf et al., 1991; Kleven, 2003; Lobo et al., 2004; Moalic et al., 1997; Poveda et al., 1990).

DNA G+C content (mol%): 29 (Bd).

Type strain: CKK, ATCC 33553, NCTC 10187.

Sequence accession no. (16S rRNA gene): U58504.

Further comment: previously known as avian serotype C (Adler et al., 1958).

102. **Mycoplasma pulmonis** (Sabin 1941) Freundt 1955, 73^{AL} (*Murimycetes pulmonis* Sabin 1941, 57)

pu.lmo'nis. L. n. *pulmo*, -*onis* the lung; L. gen. n. *pulmonis* of the lung.

Cells are predominantly coccoid with a well-organized terminal structure. Cells are motile and glide in the direction of the terminal structure. An extracellular capsular matrix can be demonstrated by staining with ruthenium red and formation of biofilms has been demonstrated. Colonies on solid medium have a coarsely granulated and vacuolated appearance, with a lesser tendency to grow into the agar, and the central spot is consistently less well defined than in most other *Mycoplasma* species. Grows in SP-4 or modified Hayflick broth supplemented with glucose at an optimum temperature of 37°C.

Pathogenic; causes rhinitis, laryngotracheitis, bronchopneumonia (collectively described as murine respiratory mycoplasmosis in mice), otitis media, conjunctivitis, acute and chronic arthritis, oophoritis, salpingitis, epididymitis, and urethritis of rodents (chiefly mice, rats, guinea pigs, and hamsters). Transmission occurs via aerosol, fomites, sexual contact, or vertically during gestation.

Macrolides, fluoroquinolones, and tetracyclines are effective against *Mycoplasma pulmonis in vitro*; however, control measures such as decontamination of fomites, culling of infected colonies, and treatment of clinical signs with steroids are more commonly employed in clinical settings. Several candidate vaccines have been described.

Source: isolated from the respiratory and urogenital tracts, eyes, synovial fluid, and synovial membranes of (principally captive) rodents, and rarely from the nasopharynx of rabbits and horses (Allam and Lemcke, 1975; Cassell and Hill, 1979; Deeb and Kenny, 1967; Simecka et al., 1992).

DNA G+C content (mol%): 27.5–29.2 (Bd), 26.6 (strain UAB CTIP genome sequence).

Type strain: Ash, PG34, ATCC 19612, NCTC 10139, CIP 75.26, NBRC 14896.

Sequence accession nos: M23941 (16S rRNA gene sequence), NC_002771 (strain UAB CTIP genome sequence).

103. **Mycoplasma putrefaciens** Tully, Barile, Edward, Theodore and Ernø 1974, 116^{AL}

pu.tre.fa'ci.ens. L. v. *putrefacio* to make rotten; L. part. adj. *putrefaciens* making rotten or putrefying, connoting the production of a putrid odor in broth and agar cultures.

Cells are predominantly coccobacillary to pleomorphic. Nonmotile. Formation of biofilms has been demonstrated (McAuliffe et al., 2006). Colony morphology has a typical fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C.

Pathogenic; causes polyarthritis, mastitis, conjunctivitis (a syndrome collectively termed contagious agalactia) (Bergonier et al., 1997), abortion, salpingitis, metritis, and testicular atrophy (Gil et al., 2003) in goats.

Macrolides, fluoroquinolones, lincosamides, and tetracyclines are effective against *Mycoplasma putrefaciens*; however, control measures such as decontamination of fomites and culling of infected herds are typically recommended to discourage the development of antimicrobial-resistant strains in carrier animals (Antunes et al., 2007; Bergonier et al., 1997).

Source: isolated from the synovial fluid, udders, expelled milk, conjunctivae, ear canal, uterus, and testes of goats.

DNA G+C content (mol%): 28.9 (T_m).

Type strain: KS1, ATCC 15718, NCTC 10155.

Sequence accession no. (16S rRNA gene): M23938.

104. **Mycoplasma salivarium** Edward 1955, 90^{AL}

sa.li.va'ri.um. L. neut. adj. *salivarium* slimy, saliva-like, intended to denote of saliva.

Cells are coccoid to coccobacillary. Nonmotile. Colonies are large with a typical fried-egg appearance. Grows well in Hayflick medium supplemented with arginine at 37°C and produces a "film and spots" reaction.

Mycoplasma salivarium is most frequently associated with contamination of eukaryotic cell culture and is frequently removed by treatment of cells with antibiotics and/or maintenance of cell lines in antibiotic-containing medium. The most effective classes of antibiotics for cell culture eradication are tetracyclines, macrolides, and fluoroquinolones.

Opportunistic pathogen; primarily found as a commensal of the human oral cavity, and rarely associated with arthritis, submasseteric abscesses, gingivitis, and periodontitis in immunocompromised patients (Grisold et al., 2008; Lamster et al., 1997; So et al., 1983). Mode of transmission is via direct contact with human saliva.

Source: isolated from the oral cavity, synovial fluid, dental plaque, and abscessed mandibles of humans, and the nasopharynx of pigs (Erickson et al., 1988).

DNA G+C content (mol%): 27.3 (Bd).

Type strain: PG20, H110, ATCC 23064, NCTC 10113, NBRC 14478.

Sequence accession no. (16S rRNA gene): M24661.

105. *Mycoplasma simbae* Hill 1992, 520^{VP}

sim'bae. Swahili n. *simba* lion; N.L. gen. n. *simbae* of a lion.

Cells are pleomorphic and nonmotile. Colonies on solid medium have a typical fried-egg appearance. Film is produced by cultivation on egg yolk agar. Grows well in SP-4 medium at 37°C.

No evidence of pathogenicity. Mode of transmission has not been established.

Source: isolated from the throats of lions (Hill, 1992).

DNA G+C content (mol%): 37 (Bd).

Type strain: LX, NCTC 11724, ATCC 49888.

Sequence accession no. (16S rRNA gene): U16323.

106. *Mycoplasma spermatophilum* Hill 1991a, 232^{VP}

sper.ma.to.phi'lum. Gr. n. *sperma*, -atos sperm or seed; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *spermatophilum* sperm-loving.

Cells are primarily coccoid. Nonmotile. Colonies are convex to fried-egg shaped and are of below-average size. Grows well in SP-4 medium supplemented with added arginine under anaerobic conditions at 37°C.

Pathogenic; potentially associated with infertility, as infected spermatozoa do not fertilize ova and infected fertilized ova were unable to implant following *in vitro* fertilization (Hill et al., 1987; Hill, 1991a). Mode of transmission is via sexual contact.

Source: isolated from the semen and cervix of humans with impaired fertility.

DNA G+C content (mol%): 32 (Bd).

Type strain: AH159, NCTC 11720, ATCC 49695, CIP 105549.

Sequence accession no. (16S rRNA gene): AF221119.

107. *Mycoplasma spumans* Edward 1955, 90^{AL}

spu'mans. L. part. adj. *spumans* foaming, presumably alluding to thick dark markings that suggest the presence of globules inside the coarsely reticulated colonies.

Cells are coccoid to filamentous. Motility for this species has not been assessed. Colonies in early subcultures have a coarsely reticulated and vacuolated appearance. A typical fried-egg appearance of the colonies develops on repeated subculturing. Grows well in SP-4 or modified Hayflick medium supplemented with arginine.

Opportunistic pathogen; primarily found as a commensal of the nasopharynx, but has also been associated with pneumonia and arthritis of domestic dogs. Mode of transmission has not been established definitively.

Source: isolated from the lungs, nasopharynx, synovial fluid, cerebrospinal fluid, trachea, prepuce, prostate, bladder, cervix, vagina, and urine of domestic dogs (Chalker, 2005).

DNA G+C content (mol%): 28.4 (T_m).

Type strain: PG13, ATCC 19526, NCTC 10169, NBRC 14849.

Sequence accession no. (16S rRNA gene): AF125587.

108. *Mycoplasma sturni* Forsyth, Tully, Gorton, Hinckley, Frasca, van Kruiningen and Geary 1996, 719^{VP}

stur'ni. N.L. n. *Sturnus* (from L. n. *sturnus* a starling or stare) a genus of birds, N.L. gen. n. *sturni* of the genus *Sturnus*, the genus of the bird from which the organism was isolated.

Cells are primarily coccoid with some irregular flask-shaped and filamentous forms seen. Motility for this species has not been assessed. Colonies on agar usually have a fried-egg appearance when grown at 37°C. Grows well in SP-4 medium supplemented with glucose at 34–37°C.

Pathogenicity has not been fully established, but it is associated with conjunctivitis in the European starling, mockingbirds, blue jays, and American crows. The organism is also found in clinically normal birds. Mode of transmission has not been established definitively.

Source: isolated from the conjunctivae of European starlings, mockingbirds, blue jays, American crows, American robins, blackbirds, rooks, carrion crows, and magpies (Frasca et al., 1997; Ley et al., 1998; Pennycott et al., 2005; Wellehan et al., 2001).

DNA G+C content (mol%): 31 (Bd).

Type strain: UCMF, ATCC 51945.

Sequence accession no. (16S rRNA gene): U22013.

109. *Mycoplasma sualvi* Gourlay, Wyld and Leach 1978, 292^{AL}

su.al'vi. L. n. *sus*, *suis* swine; L. n. *alvus* bowel, womb, stomach; N.L. gen. n. *sualvi* of the bowel of swine.

Cells are coccobacillary and many possess organized terminal structures. Nonmotile. Colonies have a typical fried-egg appearance. Grows well in SP-4 medium supplemented with either arginine or glucose at 37°C.

No evidence of pathogenicity.

Source: isolated from the rectum, colon, small intestines, and vagina of pigs (Gourlay et al., 1978).

DNA G+C content (mol%): 23.7 (Bd).

Type strain: Mayfield B, NCTC 10170, ATCC 33004.

Sequence accession no. (16S rRNA gene): AF412988.

110. *Mycoplasma subdolum* Lemcke and Kirchhoff 1979, 49^{AL}

sub.do'lum. L. neut. adj. *subdolum* somewhat deceptive, alludes to the deceptive color change that led to the original erroneous description of the strains as urea-hydrolyzing.

Cells are coccoid to coccobacillary. Motility for this species has not been assessed. Colony growth on solid medium exhibits the typical fried-egg appearance. Grows well in SP-4, Frey's, or Hayflick medium supplemented with arginine at 37°C.

Opportunistic pathogen; equivocal evidence for virulence may represent variation among strains. Associated with impaired fecundity and abortion in horses; however, is highly prevalent in clinically normal horses (Spersger et al., 2002). Mode of transmission is via sexual contact.

Source: isolated from the cervix, semen, and aborted foals of horses (Lemcke and Kirchhoff, 1979).

DNA G+C content (mol%): 28.8 (Bd).

Type strain: TB, ATCC 29870, NCTC 10175.

Sequence accession no. (16S rRNA gene): AF125588.

111. *Mycoplasma suis* corrig. (Splitter 1950) Neimark, Johansson, Rikihisa and Tully 2002b, 683^{VP} (*Eperythrozoon suis* Splitter 1950, 513)

su'is. L. gen. n. *suis* of the pig.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on any artificial

medium; therefore, notable biochemical parameters are not known.

Neotarsphenamine and tetracyclines are effective therapeutic agents. An enzyme-linked immunosorbant assay (ELISA) and PCR-based detection assays to enable diagnosis of infection have been described (Groebel et al., 2009; Gwaltney and Oberst, 1994; Hoelzle, 2008; Hsu et al., 1992).

Pathogenic; causes febrile icterohemia in pigs. Transmission occurs via insect vectors including *Stomoxys calcitrans* and *Aedes aegypti* (Prullage et al., 1993).

Source: observed in association with the erythrocytes of pigs.

DNA G+C content (mol%): 31.1 (complete genome sequence of strain Illinois; J.B. Messick et al., unpublished).

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF029394.

Further comment: the original spelling of the specific epithet, *haemosuis* (*sic*), has been corrected by the List Editor.

112. ***Mycoplasma synoviae*** Olson, Kerr and Campbell 1964, 209^{AL}

synovi'ae. N.L. n. *synovia* the joint fluid; N.L. gen. n. *synoviae* of joint fluid.

Cells are coccoid and pleomorphic. Nonmotile. An amorphous extracellular layer is described. Colony appearance on solid medium is variable with some showing typical fried-egg type colonies. Grows well in Frey's medium supplemented with glucose, L-cysteine, and nicotinamide adenine dinucleotide at 37°C. Produces a "film and spots" reaction (Ajufo and Whithear, 1980; Frey et al., 1968).

Pathogenic; causes infectious synovitis, osteoarthritis, and upper respiratory disease which is often subclinical in chickens and turkeys. Also associated with a reduction in egg quality in chickens. *Mycoplasma synoviae* is often found in association with additional avian pathogens including *Mycoplasma gallisepticum*, avian strains of *Escherichia coli*, Newcastle disease virus, and infectious bronchitis virus. Direct contact with fomites and droplet aerosols are the primary mechanisms of transmission.

Tetracyclines and fluoroquinolones are effective chemotherapeutic agents; however, treatment is typically only sought for individual birds, as medicating a commercial flock is not considered an effective control strategy. Vaccination and management strategies (i.e., single age "all in/all out" systems and culling of endemic flocks) are more commonly utilized. A live vaccine is commercially available. *Mycoplasma synoviae* shares surface antigens with *Mycoplasma gallisepticum*, potentially complicating serology-based diagnosis of infection. Numerous molecular diagnostics have been described. This organism is listed in the Terrestrial Animal Health Code of the Office International des Epizooties (<http://oie.int>; Yogev et al., 1989; Browning et al., 2005; Kleven, 2008; Hammond et al., 2009; Raviv and Kleven, 2009)

Source: isolated from the synovial fluid, synovial membranes, and respiratory tract tissues of chickens and turkeys, and from ducks, geese, pigeons, Japanese quail, pheasants, red-legged partridges, wild turkeys, and house sparrows (Bradbury and Morrow, 2008; Feberwee et al., 2009; Jordan, 1979; Kleven, 1998).

DNA G+C content (mol%): 34.2 (Bd).

Type strain: WVU 1853, ATCC 25204, NCTC 10124.

Sequence accession nos.: X52083 (16S rRNA gene), NC_007294 (strain 53 complete genome sequence).

113. ***Mycoplasma testudineum*** Brown, Merritt, Jacobson, Klein, Tully and Brown 2004, 1529^{VP}

tes.tu.di'ne.um. L. neut. adj. *testudineum* of or pertaining to a tortoise.

Cells are predominantly coccoid in shape, though some exhibit a terminal protrusion. Cells exhibit gliding motility. Colonies on solid medium exhibit typical fried-egg forms. Grows well in SP-4 medium supplemented with glucose at 22–30°C.

Pathogenic; causes rhinitis and conjunctivitis in desert and gopher tortoises. Mode of transmission appears to be intranasal inhalation (Brown et al., 2004).

Source: isolated from the nares of desert tortoises (*Gopherus agassizii*) and gopher tortoises (*Gopherus polyphemus*).

DNA G+C content (mol%): not determined.

Type strain: BH29, ATCC 700618, MCCM 03231.

Sequence accession no. (16S rRNA gene): AY366210.

114. ***Mycoplasma testudinis*** Hill 1985, 491^{VP}

tes.tu'di.nis. L. n. *testudo*, *-inis* tortoise; L. gen. n. *testudinis* of a tortoise.

Cells are pleomorphic, with many possessing a terminal organelle similar to those of *Mycoplasma gallisepticum* and *Mycoplasma amphoriforme* that periodically exhibits curvature (Hatchel et al., 2006). A subset of cells are motile and glide at high speed in the direction of the terminal structure. Colonies on solid medium have a typical fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 25–37°C, with optimum growth at 30°C.

No evidence of pathogenicity. Mode of transmission has not been established definitively.

Source: isolated from the cloaca of a Greek tortoise (Hill, 1985).

DNA G+C content (mol%): 35 (T_m).

Type strain: 01008, NCTC 11701, ATCC 43263.

Sequence accession no. (16S rRNA gene): U09788.

115. ***Mycoplasma verecundum*** Gourlay, Leach and Howard 1974, 483^{AL}

ve.re'cun.dum. L. neut. adj. *verecundum* shy, unobtrusive, free from extravagance, alluding to the lack of obvious biochemical characteristics of the species.

Cells are highly pleomorphic, exhibiting coccoid bodies, ring forms, and branched filaments. Motility for this species has not been assessed. Growth on solid medium produces colonies with the typical fried-egg appearance. Grows well in SP-4 or Hayflick medium at 37°C.

Probable commensal; attempts to produce disease experimentally have been unsuccessful (Gourlay and Howard, 1979). Mode of transmission has not been established.

Source: isolated from the eyes of calves with conjunctivitis, the prepuce of clinically normal bulls, and from in-market kale (Gourlay and Howard, 1979; Gourlay et al., 1974; Somerson et al., 1982).

DNA G+C content (mol%): 27 (T_m).

Type strain: 107, ATCC 27862, NCTC 10145.

Sequence accession no. (16S rRNA gene): AF412989.

116. **Mycoplasma wenyonii** (Adler and Ellenbogen 1934) Neimark, Johansson, Rikihisa and Tully 2002b, 683^{VP} (*Eperythrozoon wenyonii* Adler and Ellenbogen 1934, 220)

we.ny.o'ni.i. N.L. masc. gen. n. *wenyonii* of Wenyon, named after Charles Morley Wenyon (1878–1948), an investigator of these organisms.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes anemia and subsequent lameness and/or infertility in cattle. Transmission is primarily vector-mediated by *Dermacentor andersoni* and reportedly can also occur vertically during gestation. Oxytetracycline is an effective therapeutic agent (Montes et al., 1994). *Mycoplasma wenyonii* is reported to share antigens with *Mycoplasma ovis* (Kreier and Ristic, 1963), potentially complicating serology-based diagnosis of infection.

Source: observed in association with the erythrocytes of cattle; Kreier and Ristic (1968) reported in addition to erythrocytes an association with platelets.

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF016546.

117. **Mycoplasma yeatsii** DaMassa, Tully, Rose, Pitcher, Leach and Cottew 1994, 483^{VP}

ye.at'si.i. N.L. masc. gen. n. *yeatsii* of Yeats, named after F.R. Yeats, an Australian veterinarian who was a co-isolator of the organism.

Cells are coccoid and nonmotile. Colonies on agar have a fried-egg appearance. Grows well in SP-4 medium supplemented with glucose at 37°C. Formation of biofilms has been demonstrated (McAuliffe et al., 2006).

Opportunistic pathogen; commensal of the ear canal of goats that has rarely been found in association with mastitis and arthritis (DaMassa et al., 1991). The mode of transmission has not been established.

Source: isolated from the external ear canals, retropharyngeal lymph node, nasal cavity, udders, and milk of goats.

DNA G+C content (mol%): 26.6 (T_m).

Type strain: GIH, ATCC 51346, NCTC 11730, CIP 105675.

Sequence accession no. (16S rRNA gene): U67946.

Species *incertae sedis*

1. **Mycoplasma coccoides** (Schilling 1928) Neimark, Peters, Robinson and Stewart 2005, 1389^{VP} (*Eperythrozoon coccoides* Schilling 1928, 1854)

coc.co'ides. N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; L. suff. *-oides* (from Gr. suff. *eides*, from Gr. n. *eidos* that which is seen, form, shape, figure), resembling, similar; N.L. neut. adj. *coccoides* coccus-shaped.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes anemia in wild and captive mice, and captive rats, hamsters, and rabbits. Transmission is believed

to be vector-borne and mediated by the rat louse *Polyplex spinulosa* and the mouse louse *Polyplex serrata*.

Neosarsphenamine and oxophenarsine were thought to be effective chemotherapeutic agents for treatment of *Mycoplasma coccoides* infection in captive rodents, whereas tetracyclines are effective only at keeping infection at subclinical levels (Thurston, 1953).

Source: observed in association with the erythrocytes of wild and captive rodents.

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AY171918.

Species *Candidatus*

1. “**Candidatus Mycoplasma haematoparvum**” Sykes, Ball, Bailiff and Fry 2005, 29

ha.e.ma.to.par'vum. Gr. neut. n. *haema*, *-atos* blood; L. neut. adj. *parvum* small; N.L. neut. adj. *haemoatoparvum* small (mycoplasma) from blood.

Source: blood of infected canines (Sykes et al., 2005).

Host habitat: circulation of infected canines.

Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of *Mollicutes* (Foley and Pedersen, 2001).

Cell morphology: wall-less; coccoid in shape.

Optimum growth temperature: not applicable.

Cultivation status: non-culturable.

Sequence accession no. (16S rRNA gene): AY854037.

2. “**Candidatus Mycoplasma haemobos**” Tagawa, Matsumoto and Inokuma 2008, 179

ha.e.mo'bos. Gr. neut. n. *haema* blood; L. n. *bos* an ox, a bull, a cow; N.L. n. *haemobos* (*sic*) intended to mean of cattle blood.

Source: blood of infected cattle.

Host habitat: blood of cattle.

Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of the genus *Mycoplasma*.

Cultivation status: non-culturable.

Cell morphology: wall-less; coccoid in shape.

Optimum growth temperature: not applicable.

Sequence accession no. (16S rRNA gene): EF460765.

Further comment: this organism is synonymous with “*Candidatus Mycoplasma haemobovis*” (sequence accession no. EF616468).

3. “*Candidatus Mycoplasma haemodidelphidis*” Messick, Walker, Raphael, Berent and Shi 2002, 697
 ha.e.mo.di.del’phi.dis. Gr. neut n. *haema* blood; N.L. fem. gen. n. *didelphidis* of the opossum; N.L. gen. n. *haemodidelphidis* of opossum blood.
Source: blood of an infected opossum.
Host habitat: circulation of an infected opossum.
Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of mollicutes (Messick et al., 2002).
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): AF178676.
4. “*Candidatus Mycoplasma haemolamae*” Messick, Walker, Raphael, Berent and Shi 2002, 697
 ha.e.mo.la’ma.e. Gr. neut n. *haema* blood; N.L. gen. n. *lamae* of the alpaca; N.L. fem. gen. n. *haemolamae* of alpaca blood.
Source: blood of infected llamas.
Host habitat: circulation of infected llamas (McLaughlin et al., 1991).
Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of mollicutes (Messick et al., 2002).
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): AF306346.
5. “*Candidatus Mycoplasma haemominutum*” Foley and Pedersen 2001, 817
 ha.e.mo.mi’nu.tum. Gr. neut n. *haema* blood; L. neut. part. adj. *minutum* small in size; N.L. neut. adj. *haemominutum* small (mycoplasma) from blood.
Source: blood of infected felines (George et al., 2002; Tasker et al., 2003).
Host habitat: circulation of infected felines.
Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of mollicutes (Foley and Pedersen, 2001).
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape; 300–600 nm in diameter.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): U88564.
6. “*Candidatus Mycoplasma kahaneii*” Neimark, Barnaud, Gounon, Michel and Contamin 2002a, 697
 ka.ha.ne’i.i. N.L. masc. gen. n. *kahaneii* of Kahane, named for I. Kahane.
Source: blood of infected monkeys (*Saimiri sciureus*) (Michel et al., 2000).
Host habitat: circulation of infected monkeys.
Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of mycoplasmas (Neimark et al., 2002a).
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): AF338269.
7. “*Candidatus Mycoplasma ravipulmonis*” Neimark, Mitchellmore and Leach 1998, 393
 ra.vi.pul.mo’nis. L. adj. *ravus* grayish; L. n. *pulmo*, *-onis* the lung; N.L. gen. n. *ravipulmonis* of a gray lung.
Source: lung tissue of mouse with respiratory infection (gray lung disease).
Host habitat: respiratory tissue of mice with pneumonia.
Phylogeny: forms a single species line in the hominis group of mollicutes (Neimark et al., 1998; Pettersson et al., 2000).
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape; 650 nm in diameter.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): AF001173.
8. “*Candidatus Mycoplasma turicensis*” Willi, Boretti, Baumgartner, Tasker, Wenger, Cattori, Meli, Reusch, Lutz and Hofmann-Lehmann 2006, 4430
 tu.ri.cen’sis. L. masc. (*sic*) adj. *turicensis* pertaining to Turicum, the Latin name of Zurich, the site of the organism’s initial detection.
Source: blood of infected domestic cats.
Host habitat: blood of domestic cats.
Phylogeny: assignment to the hemoplasma cluster of the pneumoniae group of the genus *Mycoplasma*.
Cultivation status: non-culturable.
Cell morphology: wall-less; coccoid in shape.
Optimum growth temperature: not applicable.
Sequence accession no. (16S rRNA gene): DQ157150.
- The following proposed species has been incidentally cited, but the putative organism remains to be established definitively and the name has no standing in nomenclature.
1. “*Candidatus Mycoplasma haemotarandirangiferis*” Stoffregen, Alt, Palmer, Olsen, Waters and Stasko 2006, 254
 ha.e.mo.ta.ran.di.ran.gi’fe.ris. Gr. neut n. *haema* blood; *Rangifer tarandus* scientific name of the reindeer; N.L. gen. n. *haemotarandirangiferis* epithet intended to indicate occurrence in blood of reindeer.
Source: blood of reindeer.
Host habitat: blood of reindeer.
Phylogeny: partial 16S rRNA gene sequences suggest possible relationships to *Mycoplasma ovis* and *Mycoplasma wenyonii* (suis cluster), and/or to *Mycoplasma haemofelis* (haemofelis cluster).
Cultivation status: non-culturable.
Cell morphology: single punctate, chaining punctate, clustering punctate, single bacillary, chaining bacillary, single rings, chaining rings, and clustering rings.
Optimum growth temperature: not applicable.
Sequence accession nos (16S rRNA gene): DQ524812–DQ524818.
Further comment: sequence accession no. DQ524819, representing clone 107LSIA (Stoffregen et al., 2006), does not support assignment of that clone to the genus *Mycoplasma* because it is most similar to 16S rRNA genes of *Fusobacterium* spp. Several different partial 16S rRNA gene sequences obtained from other clones are too variable to establish their coherence as a species.

Other organisms

1. “**Mycoplasma insons**” May, Ortiz, Wendland, Rotstein, Relich, Balish and Brown 2007, 298
in'sons. L. neut. adj. *insons* guiltless, innocent.
Source: trachea and choanae of a healthy green iguana (*Iguana iguana*).
Host habitat: respiratory tract and blood of green iguanas (*Iguana iguana*).
Phylogeny: assignment to the *Mycoplasma fastidiosum* cluster of the pneumoniae group of the genus *Mycoplasma*.
Cultivation status: cells are culturable in SP-4 medium supplemented with glucose.
Cell morphology: pleomorphic, but many have a highly atypical shape for a mycoplasma, often resembling a twisted rod.
Optimum growth temperature: 30°C.
Sequence accession no. (16S rRNA gene): DQ522159.
2. “**Mycoplasma sphenisci**” Frasca, Weber, Urquhart, Liao, Gladd, Cecchini, Hudson, May, Gast, Gorton and Geary 2005, 2979
sphe.nis'ci. N.L. gen. n. *sphenisci* of *Spheniscus*, the genus of penguin that includes the jackass penguin (*Spheniscus demersus*) from which this mycoplasma was isolated.
Source: choanae of a jackass penguin (*Spheniscus demersus*) with choanal discharge and halitosis.
Host habitat: upper respiratory tract of the jackass penguin.
Phylogeny: assignment to the *Mycoplasma lipophilum* cluster of the hominis group of the genus *Mycoplasma*.
Cultivation status: cells are culturable in Frey's medium supplemented with glucose.
Cell morphology: pleomorphic; some cells exhibit terminal structures.
Optimum growth temperature: 37°C.
Sequence accession no. (16S rRNA gene): AY756171.
3. “**Mycoplasma vulturis**” corrig. Oaks, Donahoe, Rurangirwa, Rideout, Gilbert and Virani 2004, 5911
vul.tu'ri.i. L. gen. n. *vulturis* of a vultures, named for the host animal (Oriental white-backed vulture).
Source: lung and spleen tissue of an Oriental white-backed vulture.
Host habitat: upper and lower respiratory tract of Oriental white-backed vulture, where it replicates intracellularly.
Phylogeny: assignment to the *Mycoplasma neurolyticum* cluster of the hominis group of the genus *Mycoplasma*.
Cultivation status: cells can be grown in co-culture with chicken embryo fibroblasts, but have not been grown in pure *in vitro* culture.
Cell morphology: coccoid; cells display intracellular vacuoles and intracellular granules of electron-dense material.
Optimum growth temperature: 37°C.
Sequence accession no. (16S rRNA gene): AY191226.
4. “**Mycoplasma zalophi**” Haulena, Gulland, Lawrence, Fauquier, Jang, Aldridge, Spraker, Thomas, Brown, Wendland and Davidson 2006, 43
za.lo'phi. N.L. gen. n. *zalophi* of *Zalophus*, the genus of sea lion that includes the California sea lion (*Zalophus californianus*) from which this mycoplasma was isolated.
Source: subdermal abscesses of captive sea lions.
Host habitat: subdermal and intramuscular abscesses, joints, lungs, and lymph nodes of captive sea lions.
Phylogeny: assignment to the *Mycoplasma hominis* cluster of the hominis group of the genus *Mycoplasma*.
Cultivation status: cells are culturable in SP-4 medium supplemented with glucose.
Cell morphology: not yet described.
Optimum growth temperature: 37°C.
Sequence accession no. (16S rRNA gene): AF493543.

Genus II. **Ureaplasma** Shepard, Lunceford, Ford, Purcell, Taylor-Robinson, Razin and Black 1974, 167^{AL}

JANET A. ROBERTSON AND DAVID TAYLOR-ROBINSON

U.re.a.plas'ma. N.L. fem. n. *urea* urea; Gr. neut. n. *plasma* anything formed or moulded, image, figure; N.L. neut. n. *Ureaplasma urea* form.

Coccioid cells about 500 nm in diameter; may appear as coccobacillary forms in exponential growth phase; filaments are rare. Nonmotile. Facultative anaerobes. Form **exceptionally small colonies** on solid media that are described either as **tiny (T) “fried-egg” colonies** or as **“cauliflower head” colonies** having a lobed periphery. **Unusual pH required for growth (about 6.0–6.5)**. Optimal incubation temperature for examined species is 35–37°C. Chemo-organotrophic. Like *Mycoplasma*, species of *Ureaplasma* **lack oxygen-dependent, NADH oxidase activity**. Unlike *Mycoplasma*, species of *Ureaplasma* **lack hexokinase or arginine deiminase activities** but have a **unique and obligate requirement for urea** and produce **potent ureases** that hydrolyze urea to CO₂ and NH₃ **for energy generation and growth**. **Genome sizes** range from 760 to 1170 kbp (PFGE). **Commensals or opportunistic pathogens** in vertebrate hosts, primarily birds and mammals (mainly primates, ungulates, and carnivores).

DNA G+C content (mol%): 25–32 (Bd, *T_m*).

Type species: **Ureaplasma urealyticum** Shepard, Lunceford, Ford, Purcell, Taylor-Robinson, Razin and Black 1974, 167 emend. Robertson, Stemke, Davis, Harasawa, Thirkell, Kong, Shepard and Ford 2002, 593.

Further descriptive information

Although cellular diameters as small as 100 nm and as large as 1000 nm, and minimal reproductive units of about 330 nm in diameter have been reported (Taylor-Robinson and Gourlay, 1984), published thin sections of these organisms (trivial name, ureaplasmas) show diameters only as large as 450–500 nm. The exceptions are feline ureaplasmas with thin section diameters of up to 800 nm (Harasawa et al., 1990a). Morphometric analysis of cells of the type strain of *Ureaplasma urealyticum* fixed in the exponential phase of growth showed coccoid cells with

diameters of about 500 nm (Robertson et al., 1983). Similar cellular diameters have been seen in hemadsorption studies in which cells were pre-fixed during incubation before usual fixation for electron microscopy. Reports of budding and filamentous forms probably reflect the effect of cultural and handling conditions on these highly plastic cells. Although the sequence of the *Ureaplasma parvum* genome lacks any recognizable *FtsZ* genes (Glass et al., 2000), ureaplasmas appear to reproduce by binary fission. Because of their minute size, ureaplasma cells are rarely seen by light microscopy. Although they are of the Gram-stain-positive lineage, the lack of cell wall results in the organisms appearing Gram-stain-negative. They are more easily detected if stained with crystal violet alone. Electron micrographs have indicated hair-like structures, possibly pili, 5–8 nm long, radiating from the membrane (Whitescarver and Furness, 1975). An extramembranous capsule was expected from light microscopic studies. In cytochemical studies, a carbohydrate-containing, capsular structure has been demonstrated in a strain of *Ureaplasma urealyticum* (Robertson and Smook, 1976; Figure 110). The structure is a lipoglycan that has also been demonstrated on the type strain T960^T of *Ureaplasma urealyticum* and on a serovar 3 strain of *Ureaplasma parvum*; the lipoglycan composition was strain-variable (Smith, 1986). No viruses have been seen nor has viral or plasmid nucleic acid been reported in any ureaplasma.

Ureaplasma colonies are significantly smaller in diameter (≤10–175 nm) than those of *Mycoplasma* species (300–800 nm; Figure 110). For this reason, they were first described as “tiny (T) form PPLO (pleuropneumonia-like organisms) colonies” (Shepard, 1954) and later called T-mycoplasmas (Meloni et al., 1980; Shepard et al., 1974). Cultures on solid media may grow in air, but more numerous and larger colonies result in 5–15% CO₂ in N₂ or H₂ (Robertson, 1982). Colonies of many strains are detectable after overnight incubation and reach maximum dimensions within 2 d. Isolates from ungulates may require

longer incubation. Temperatures of 20–40°C are permissive for growth of examined strains, but their optimal incubation temperatures are 35–37°C (Black, 1973). Ureaplasma cultures in liquid media are incubated aerobically with growth occurring in the bottom of the tube, as revealed by changes in the pH indicator. Mean generation times of 10 isolates from humans ranged from 50 to 105 min (Furness, 1975). Maximum titers of ≤10⁸ organisms per ml of culture produce insufficient cell mass for detectable turbidity, precluding growth measurement by turbidometric or spectrophotometric methods. Growth is best measured by broth dilution methods (Ford, 1972; Rodwell and Whitcomb, 1983; Stemke and Robertson, 1982). When immediate estimation of populations is required, ATP luminescence (Stemler et al., 1987) may be useful. An indicator system enhances colony detection and ureaplasma identification. Ammonia from urea degradation causes a rise in pH and certain cations to form a golden to deep brown precipitate on the colorless colonies, making them visible when viewed by directly transmitted light. Initially, the urease spot test used a solution of urea and 1 mM Mn²⁺ (as MnCl₂ or MnSO₄) dropped onto agar (Shepard and Howard, 1970); later, Mn²⁺ was incorporated into the agar itself to create a differential solid medium (e.g., Shepard, 1983). However, Mn²⁺ is toxic for ureaplasmas (Robertson and Chen, 1984). Equimolar CaCl₂ (Shepard and Robertson, 1986) gave a similar response, but allowed the recovery of live cells. Manganese susceptibility has taxonomic value (Table 138); animal isolates show differing responses (Stemke et al., 1984; Stemler et al., 1987).

Ureaplasma urealyticum has some elements of the glycolytic cycle and pentose shunt (Cocks et al., 1985), but cannot degrade glucose and lacks arginine deiminase (Woodson et al., 1965). Instead, ureaplasmas have a unique and absolute requirement for urea (0.4–1.0 mM) and a slightly acidic environment (pH 6.0–7.0); pH values outside this range can be associated with growth inhibition. The essential cytoplasmic

FIGURE 110. *Ureaplasma* colonial size and cellular morphology. (a) Many isolated *Ureaplasma urealyticum* colonies, accentuated by a urease spot test, surround a single large *Mycoplasma hominis* colony on a solid genital mycoplasma (GM) agar surface. Colonies of *Ureaplasma urealyticum* commonly have diameters of 15–125 μm; the diameter of the *Mycoplasma hominis* colony shown is approximately 0.9 mm. (Reproduced with permission from Robertson et al., 1983. Sexually Transmitted Diseases 10 (October-December Suppl.): 232–239 © Lippincott Williams & Wilkins.) (b) Transmission electron micrograph of *Ureaplasma urealyticum*, serovar 4, strain 381/74 cells, showing coccoid morphology, extramembranous capsule stained with ruthenium red, lack of a cell wall, the single limiting membrane, and apparently simple cytoplasmic contents in which only ribosomes are clearly evident. Cell diameters were 485–585 nm. (Reproduced with permission from Robertson and Smook, 1976. Journal of Bacteriology 128: 658–660.)

TABLE 138. Phenotypic characteristics that partition the human serovar-standard strains of ureaplasmas to *Ureaplasma* species^a

Characteristic	<i>U. urealyticum</i> serovar	<i>U. parvum</i> serovar	Reference

^aT, Type strain of species.

^b1-D, One-dimensional; 2-D, two-dimensional.

^cSerovar 13 gave an intermediate response and was excluded from the initial partition scheme.

^dHyperimmune rabbit sera and acute and convalescent sera from women with postpartum fever.

urease, comprising three subunits (Blanchard, 1990), produces a transmembrane potential, which leads to ATP synthesis (Romano et al., 1980; Smith et al., 1993). Ureaplasma dependence upon catalysis of urea for energy is the basis of growth inhibition by the urease inhibitor hydroxamic acid and its derivatives (Ford, 1972) and by fluorofamide (Kenny, 1983). The proton pump inhibitor lansoprazole and its metabolites interfere with ATP synthesis at micromolar concentrations (Nagata et al., 1995). Their small genomes make ureaplasmas dependent upon the host for amino acids, amino acid precursors, lipids, and other growth components. Ureaplasmas from humans exhibit minimal levels of acetate kinase activity (Muhlrad et al., 1981). Like other *Mycoplasmataceae*, ureaplasmas make superoxide dismutase (O'Brien et al., 1983), but, unlike the rest of this family, oxygen-dependent NADH oxidase has not been detected (Masover et al., 1977). The *Ureaplasma parvum* genome sequence includes genes for six hemin and/or Fe³⁺ transporters which are believed to be related to respiration (Glass et al., 2000). For information

on additional physiological traits, see: Black (1973); Shepard et al., (1974); Shepard and Masover (1979); Taylor-Robinson and Gourlay (1984); and Pollack (1986).

Except for the obligatory requirements for supplementary urea and lower pH, ureaplasma growth requirements are similar to those of members of the genus *Mycoplasma*. The sterol requirement is met by horse, bovine, or fetal bovine serum. Because heat-sensitive pantothenic acid is a growth factor supplied by serum (Shepard and Lunceford, cited by Shepard and Masover, 1979), the serum supplement should not be "inactivated" by heating to reduce complement activity. The effect of yeast extract is variable, perhaps depending upon the particular strain requirements or the batch of extract. Other defined additives have been reported to enhance growth but, in the absence of a defined medium, evaluation is difficult. Dependence on sterols for the integrity of the cell membrane renders ureaplasmas susceptible to digitonin and certain antifungal agents, but most strains tolerate the polyene nystatin (50 U/ml) that prevents overgrowth by yeasts.

Information about ureaplasma genetics is now abundant. The genomes of 26 strains of *Ureaplasma*, including six of the seven named species and six unnamed strains, range in size from 760 to 1170 kbp (Kakulphimp et al., 1991; Robertson et al., 1990). The largest genome belongs to *Ureaplasma felinum*. The G+C content of ureaplasma DNA is in the range 25.5–31.6 mol%, which is lower than that for other *Mollicutes* and for all other prokaryotes, greatly limiting the degeneracy in the genetic code of ureaplasmas. For the type strain of *Ureaplasma urealyticum*, UGA is a codon for tryptophan (Blanchard, 1990). The entire sequences of the genomes of two strains of *Ureaplasma parvum* serovar 3 (formerly known as *Ureaplasma urealyticum* biovar 1; Glass et al., 2000) have been determined. At 752 kbp, the organisms share with other obligate symbions, such as *Mycoplasma genitalium* (580 kbp) and *Buchnera aphidicola* (641 kbp), greatly reduced genomes. Of 641–653 total genes, 32–39 code for structural RNAs and about 610 code for proteins, about 47% of which have been classified as hypothetical genes of unknown function. Some (19%) resemble genes present in other genomes, but many (28%) appear unique. Unexpectedly absent in the *Ureaplasma parvum* genome are recognizable genes for FtsZ, for the GroEL and GroES chaperones, and for ribonucleoside-diphosphate reductase. Attempts have been made to reconcile the anomalies of gene functions assigned to this serovar of *Ureaplasma parvum* with the activities and pathways found in various ureaplasmas of humans (Glass et al., 2000; Pollack, 2001). One limitation to such analysis is that most of the physiological data that has been accumulated pertain not to *Ureaplasma parvum* but instead to the type species, *Ureaplasma urealyticum* strain T960^T, possessing a 7% larger genome. The entire sequences of the genomes of *Ureaplasma urealyticum* serovars 8 and 10 (Glass et al., 2000, 2008) have also been determined and the genomes of the type strains of all remaining *Ureaplasma urealyticum* and *Ureaplasma parvum* serovars are nearly completely annotated (Glass et al., 2008). Preliminary comparisons found that in addition to “core” and “dispensable” genomes for each species, *Ureaplasma urealyticum* had partly duplicated multiple-banded antigen (*mba*) genes (Kong et al., 1999a, 2000), and up to twice the number of genes that *Ureaplasma parvum* has for lipoproteins. Such comparisons are expected to substantially improve understanding of ureaplasma pathogenicity and differential strain virulence.

Clinical studies based entirely on qualitative assessments of ureaplasmas are often difficult to interpret and only a few investigators have presented quantitative data (Bowie et al., 1977; De Francesco et al., 2009; Heggie et al., 2001; Taylor-Robinson et al., 1977). Factors such as hormonal levels, specific genetic attributes, and even socio-economic conditions may encourage urogenital colonization and proliferation. Nevertheless, it is clear that ureaplasmas are commensals that, on occasion, contribute to disease in susceptible human hosts. Infections attributed to ureaplasmas are often associated with an immunological component (Bowie et al., 1977), including the subset of the human population with common variable hypogammaglobulinemia (Cordtz and Jensen, 2006; Furr et al., 1994; Lehmer et al., 1991; Webster et al., 1978), in which ureaplasma-induced septic arthritis and occasionally persistent ureaplasma urethritis is seen (Taylor-Robinson, 1985). Sexually acquired, reactive arthritis is usually linked to *Chlamydia trachomatis*, but immunological evidence of ureaplasma involvement exists (Horowitz et al., 1994). Through urea metabolism, ureaplasmas can induce crystallization of struvite and calcium phosphates

in urine *in vitro* and produce urinary calculi in animal models (Reyes et al., 2009). They are found in patients with infection stones more often than in those with metabolic stones (Grenabo et al., 1988). A statistical association with infection stones has been made (Kaya et al., 2003).

Evidence for the association of ureaplasmas with acute nongonococcal urethritis in men has been controversial, but a significant association of *Ureaplasma urealyticum* (but not *Ureaplasma parvum*) with this disease in two of three recent studies suggests a way forward to resolving this issue. Evidence for a role for ureaplasmas in acute epididymitis is, at the most, meager and it is very unlikely that they have a role in chronic prostatitis. Ureaplasmas have been associated with bacterial vaginosis and pelvic inflammatory disease, but are unlikely to be causal in either condition. It follows, therefore, that there is no convincing evidence to implicate ureaplasmas as an important cause of infertility in men or in couples. The most convincing data relating ureaplasmas to poor pregnancy outcomes have been seen when the organisms have been detected in amniotic fluid prior to membrane rupture, but there are conflicting opinions about the role of *Ureaplasma urealyticum* vs *Ureaplasma parvum*. Data since the 1980s have supported the association of neonatal ureaplasma infection with chronic lung disease and sometimes death in very low birth-weight infants. The ability of *Ureaplasma parvum* to induce chorioamnionitis and to contribute to pre-term labor and fetal lung injury is supported by experimental studies in rhesus monkeys (Novy et al., 2009).

Information on the range of animal species infected with ureaplasmas and their geographic distribution is patchy, possibly because ureaplasmas are largely avirulent or, at least, not an economic threat. Isolations have been reported from squirrel, talapoin, patas, macaque and green monkeys; as well as marmosets and chimpanzees (Taylor-Robinson and Gourlay, 1984). Also, there are reports of isolation from domestic dogs, raccoon dogs, cats and mink; cattle, sheep, goats, and camels; chickens and other fowl; and swine (the latter needing confirmation). Baboons, rats and mice are susceptible to experimental infection with ureaplasmas. While *Ureaplasma diversum* can inhabit all mucosal membranes of cattle, the two natural diseases it causes are subclinical respiratory infections in young calves, which occasionally develop into bronchopneumonia, and the economically important urogenital infections transmitted by bulls or their semen. The latter present as vulvovaginitis or ascend to cause infertility or abortion (Ruhnke et al., 1984; ter Laak et al., 1993). A species-specific PCR assay (Vasconcellos Cardoso et al., 2000) can circumvent culture insensitivity. As in humans, ureaplasma diseases in animals may be influenced by the particular ureaplasma strain or many other factors. Although ureaplasmas may be present initially in certain organ and primary cell cultures, the lack of urea and higher pH in most eukaryotic cell culture systems would discourage persistence.

Although the spectrum of diseases of primary ureaplasma etiology remains controversial, many potential virulence factors have been identified. Structural elements include a capsule, pilus-like fibrils, and the antigens of the outer membrane that constitute the serovar determinants. Erythrocytes from several animal species adhere firmly to colonies of certain strains of *Ureaplasma parvum* (Shepard and Masover, 1979), but most human isolates exhibit transient or no binding (Robertson and Sherburne, 1991). Strains of both *Ureaplasma urealyticum* and *Ureaplasma parvum* adhere to HeLa cells (Manchee and

Taylor-Robinson, 1969) and to spermatozoa (Knox et al., 2003). Demonstration of beta-hemolysis of erythrocytes by ureaplasmas depends upon several variables; hemolysis of guinea pig erythrocytes has been most consistently observed (Black, 1973; Manchee and Taylor-Robinson, 1970; Shepard, 1967). Manchee and Taylor-Robinson (1970) described hemolysis of homologous erythrocytes by a canine ureaplasma as peroxide-associated and blocked lysis by adding catalase, except in the presence of a catalase inhibitor. Genome sequencing has revealed genes resembling those for the hemolysins HlyA and HlyC of enterohemorrhagic *Escherichia coli* (Glass et al., 2000). Ammonia and ammonium ions generated by urea hydrolysis and the alkaline environment that they create are inhibitory to the ureaplasmas (Ford and MacDonald, 1967; Shepard and Lunceford, 1967). They have well-established deleterious effects on eukaryotic cell and mammalian tissue cultures and may be the "toxin" described but never substantiated (Furness, 1973). An IgA1 protease activity has been demonstrated by ureaplasmas from both humans and canines. Human IgA1-specific protease activity, apparently similar to the type 2 serine protease of certain bacterial pathogens of humans (Spooner et al., 1992), is produced by both *Ureaplasma parvum* and *Ureaplasma urealyticum* (Kilian et al., 1984; Robertson et al., 1984), but a gene responsible for the activity has not yet been identified. Putative phospholipase A₁, A₂, and C activities (De Silva and Quinn, 1986) could not be confirmed, nor could such gene sequences be identified (J. Glass, unpublished). Biofilm production has been described recently (García-Castillo et al., 2008). Ureaplasmas have been seen intracellularly during studies in cell cultures (Mazzali and Taylor-Robinson, 1971), but may be there transiently after phagocytosis. Cells in culture (Li et al., 2000), in either experimental infection models (Moss et al., 2008) or epidemiological study subjects (Buss et al., 2003; Dammann et al., 2003; Jacobsen et al., 2003; Shobokshi and Shaarawy, 2002), have exhibited proinflammatory responses. While assessment of clinical studies is sometimes difficult because of inherent reporting bias (Klassen et al., 2002; Schelonka et al., 2005), it is anticipated that the application of bioarray technologies will lead to improved understanding of ureaplasma mechanisms of pathogenesis.

Reviews of *in vitro* methodologies used for antimicrobial susceptibility testing for both human (Bébéar and Robertson, 1996; Waites et al., 2001) and animal (Hannan, 2000) isolates are available. Antimicrobial susceptibility patterns of *Ureaplasma urealyticum* and *Ureaplasma parvum* appear to be similar (Matlow et al., 1998). The choice of therapeutic agents active against them is limited. Tetracyclines or the macrolides (excluding lincomycin and clindamycin) are the bacteriostatic agents usually employed. Ureaplasmas from human, simian, bovine, caprine, feline, and avian sources (Koshimizu et al., 1983) withstand relatively high levels of lincomycin (10 µg/ml), to which most mycoplasmas are susceptible. Ureaplasmas also show *in vitro* resistance to rifampin and sulfonamides. Clinical resistance of ureaplasmas to tetracyclines has been long known (Ford and Smith, 1974). This high-level resistance is determined by the presence of the *tetM* determinant (Roberts and Kenny, 1986), which is now readily identified by PCR (Blanchard et al., 1997). Tetracycline-resistant strains exposed to a variety of antibiotics demonstrate a broad range of responses (Robertson et al., 1988). Clinical resistance to macrolides has also been reported (e.g., Taylor-Robinson and Furr, 1986). Certain aminoglyco-

sides, chloramphenicol, and newer fluoroquinolones inhibit ureaplasmas, but are inappropriate for broad clinical use. Fluoroquinolone resistance is increasing (Xie and Zhang, 2006) and has been found in a previously susceptible strain (Duffy et al., 2006). Ureaplasma strains exhibiting resistance to multiple antibiotics have been found in immunocompromised hosts. In one case, the isolates were of the same serovar, but exhibited different susceptibility patterns at different anatomical sites (Lehmer et al., 1991). Because of ongoing changes in antimicrobial susceptibility patterns, the recent literature should be consulted (e.g., Beeton et al., 2009). To treat natural *Ureaplasma diversum* infections, tiamulin hydrogen fumarate, a diterpene agent in common use in veterinary medicine, may be at least as effective as the macrolide tylosin (Stipkovits et al., 1984). Others have examined the efficacy of single or combinations of antibiotics in eradicating ureaplasmas from various sites in cattle as well as from semen used for artificial insemination (ter Laak et al., 1993). The urease inhibitor, fluorofamide, has been used with varying success in eliminating ureaplasmas from animals.

When establishing antibiograms for ureaplasmas, the requirements established for common bacterial pathogens do not suffice. First, medium components may affect antibiotic activity. For instance, serum-binding reduces tetracycline activity, while the initial acidic culture reduces macrolide activity against ureaplasmas (Robertson et al., 1981). Conventional bacteria of established, low-level susceptibility can be used to measure the effect of the ureaplasma medium on a particular antimicrobial agent. Second, the relatively slow growth of ureaplasmas as compared with many pathogenic bacteria requires that the half-life of the antibiotic be considered when test inoculum and incubation period are established. Lastly, the end points of the sensitivity tests on agar are about four-fold lower than for tests in broth (Waites et al., 1991). On consideration of the *in vivo* environment in which these organisms naturally occur, interpretation of susceptibility test end points continues to present a challenge. An international subcommittee under the aegis of the National Committee for Clinical Laboratory Standards Institute (USA) is currently finalizing a "Final Report for Development of Quality Control Reference Standards and Methods for Antimicrobial Susceptibility Testing" for *Ureaplasma* and *Mycoplasma* species infecting humans that have demonstrated variability in response to antimicrobial agents.

Enrichment and isolation procedures

Media formulations in current use for the cultivation of ureaplasmas from human sources include, in order of decreasing supplementation: the 10B broth of Shepard and Lunceford (Shepard, 1983); Taylor-Robinson's broth (Taylor-Robinson, 1983a), made without thallium acetate; and bromothymol blue broth (Robertson, 1978). Ureaplasmas are exquisitely sensitive to thallium acetate and it should not be used to inhibit other bacteria. The U4 formulation for ungulate isolates was developed by Howard et al. (1978). Consult Waites et al. (1991) for additional media formulations for isolation from humans, and Shepard (1983), Livingston and Gauer (1974), or Hannan (2000) for isolation from animals. The quality of medium components may be as important as the medium formulation. Serum supplements should be tested for their ability to support growth of the ureaplasmas of interest. Liquid medium may be stored at -20°C until required. Transport medium (e.g., 2SP) should be free of antibi-

otics inhibitory to ureaplasmas. Broth cultures should be diluted to $\geq 1:100$ to reduce effects of any growth inhibitors present in the specimen. In general, *Ureaplasma parvum* is less demanding nutritionally than *Ureaplasma urealyticum* and isolates from human and other animal sources together are less demanding than those from ungulate hosts. Agar surfaces are examined at $\geq 40\times$ magnification. The less fastidious strains (e.g., *Ureaplasma parvum* type strain) are more likely to produce recognizable “fried-egg” colonies than are the more fastidious strains (e.g., *Ureaplasma urealyticum* type strain), which are more likely to produce “cauliflower head” or core colonies. Cultures may be thrice cloned and the resultant culture used to initiate stocks.

Maintenance procedures

Broth cultures of ureaplasmas commonly become sterile within 12–24 h incubation at 35–37°C. “Red is dead” was the mantra of Shepard in regard to his phenol red-containing broth medium. One way to lessen this problem is to change to an indicator that changes color at a lower pH (Robertson, 1978). To Shepard’s mantra we might add, “the higher the urea concentration, the steeper the death phase”, an effect not countered by buffer. Incubation of diluted cultures at 30–34°C slows growth and maintains viability for up to 1 week, reducing the frequency of culture transfer and helping in transport. Short exposure of broth cultures to refrigeration reduces viability. Cells within colonies on solid medium may be recovered for approximately 1 week if the cultures are removed from incubation when growth is detectable and stored under cool, humidified conditions. For long-term storage, ultra-low temperatures (–80°C or liquid nitrogen) with a cryoprotectant [e.g., 10–20% (v/v) sterile glycerol] can maintain viability for well over a decade. For lyophilization, the pellets from broth cultures centrifuged at high speed are resuspended in a minimal volume of liquid medium or the serum used for its supplementation before processing; on reconstitution, urease activity occasionally is not immediately evident.

Differentiation of the genus *Ureaplasma* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. Aerobic or facultatively anaerobic growth in artificial media and the necessity for sterols for growth exclude assignment to the genera *Anaeroplasm*, *Asteroleplasma*, *Acholeplasma*, and “*Candidatus* Phytolasma”. Non-spiral cellular morphology and regular association with a vertebrate host or fluids of vertebrate origin support exclusion from the genera *Spiroplasma*, *Entomoplasma*, and *Mesoplasma*. The ability to hydrolyze urea, with the inability to metabolize either glucose or arginine, excludes assignment to the genus *Mycoplasma*. For routine purposes, the colonial morphology characteristic of ureaplasmas and demonstration of the isolate’s ability to catabolize urea, using the urease spot test or indicator agar, suffice for preliminary differentiation from other mollicutes. Other methods for urease detection have been largely replaced by PCRs that detect urease genes.

Taxonomic comments

The hypothetical evolutionary relationships of the *Mollicutes* have been based primarily upon 16S rRNA gene sequences (Weisburg et al., 1989). The nucleotide sequence for the 16S rRNA genes (Kong et al., 1999b; Robertson et al., 1993;

Robertson et al., 1994) and the 16S–23S rRNA intergenic spacer regions of all named species plus the 14 serovars associated with humans (*Ureaplasma urealyticum* and *Ureaplasma parvum*) have been determined (Harasawa and Kanamoto, 1999; Kong et al., 1999b). The genus *Ureaplasma* comprises two subclusters within the highly diverse pneumoniae group of the family *Mycoplasmataceae* (Johansson, 2002). One subcluster contains the human, avian, and mink isolates and the other contains feline, canine, and bovine strains (see genus *Mycoplasma* Figure 109, pneumonia group) Although the three serovars A, B, and C of *Ureaplasma diversum* are antigenically heterogeneous, the strains examined meet the 70% DNA–DNA hybridization benchmark used as an arbitrary species criterion. However, the available DNA–DNA hybridization values suggest that *Ureaplasma gallorale* and *Ureaplasma canigenitalium* might each represent more than a single species. The 16S rRNA gene sequences of ureaplasmas isolated from nonhuman primates and some less-studied vertebrates are unknown. The range of G+C contents of ureaplasma DNA is too narrow to have much taxonomic utility. Nevertheless, the values for isolates from cattle, sheep, and goats are between 28.7 and 31.6 mol% (Howard et al., 1978), at the higher end of the range for the genus.

It is generally assumed that all ureaplasmas from avian sources belong to the species *Ureaplasma gallorale*. The seven avian isolates examined were similar to each other serologically and in SDS-PAGE, immunoblot, and RFLP profiles, and they were distinct from *Ureaplasma urealyticum* and *Ureaplasma diversum*, although resemblances between *Ureaplasma gallorale* and *Ureaplasma urealyticum* based upon one- and two-dimensional PAGE analyses have been reported (Mouches et al., 1981). However, the DNA–DNA hybridization values among *Ureaplasma gallorale* strains fall into two clusters. Homology was 70–100% for the five strains within cluster A and 96–100% for the two strains within cluster B that were studied. Between strains of cluster A and B, homology was only 51–59% and, *vice versa*, 52–69% (Harasawa et al., 1985). The taxonomic status of avian ureaplasmas, therefore, might benefit from examination of additional strains and reconsideration. The clusters appear to be more closely related than *Ureaplasma urealyticum* and *Ureaplasma parvum* (Table 139).

The taxonomy of ureaplasmas of canines is also problematic. The first report indicated G+C contents of 27.2–27.8 mol% (Bd; Howard et al., 1978). Later, the representatives of four serogroups (SI to SIV for strains DIM-C, D29M, D11N-A, and D6P-C^T, respectively) were reported to have G+C contents of 28.3–29.4 mol% (HPLC). However, the published data regarding their DNA reassociation values are confusing. Initially, Barile (1986) and Harasawa et al. (1990b) reported that the serogroup SI representative, DIM-C, had 73% homology with the serotype 2 SII representative, D29M, indicating that these two strains likely belong to the same species. However, perhaps because of the borderline value, further work was undertaken, also using [³H]DNA–DNA hybridization procedures (Harasawa et al., 1993). The values obtained ranged from 41 to 63% homology among the four serogroups, i.e., each serogroup seemed to represent a distinct species. At present, the only named canine ureaplasma species is *Ureaplasma canigenitalium*; the SIV representative D6P-C^T is the type strain (Harasawa et al., 1993). Its degree of distinctiveness from the other serogroups is not emphasized in the literature.

TABLE 139. Genotypic characteristics that partition the serovar-standard strains of ureaplasmas isolated from humans to the level of species^a

Characteristic	<i>U. urealyticum</i> serovars	<i>U. parvum</i> serovars	Reference(s)
DNA–DNA relatedness with strain 27 ^T DNA: 91–102%		1, 3 ^T , 6	Christiansen et al. (1981)
38–60%	2, 4, 5, 7, 8 ^T		
DNA–DNA relatedness with strain T960 ^T DNA: 49–52%		1, 3 ^T , 6	Christiansen et al. (1981)
69–100%	2, 4, 5, 7, 8 ^T		
DNA–DNA relatedness with strain 27 ^T DNA: 75–100%		1, 3 ^T , 6, 14	Harasawa et al. (1991)
38–57%	2, 4, 5, 7, 8 ^T , 9–13		
DNA–DNA relatedness with strain T960 ^T DNA: 48–59%		1, 3 ^T , 6, 14	Harasawa et al. (1991)

^aT, Type strain of species.^bSerovar 13 response to *Eco*RI was anomalous.^cThis anomalous pattern resulted from cultures being misidentified as serovars 10 and 12; the error was corrected by Teng et al. (1994). Kong et al. (1999b) have confirmed the efficacy of the Blanchard (1990) primers.^dPrimers used for biovar-defining PCR(s).^eThe multiple band (MB) antigens seen by PAGE are putative virulence markers. See text for details.

While DNA–DNA hybridization has been key to species level identification for the genus *Ureaplasma*, serology led to our knowledge of intra-species relationships (Robertson et al., 2002) and still figures importantly. Much interest has been focused specifically on the multiple-banded antigens (MBA) of the ureaplasma cell surface. Watson et al. (1990), studying the type strain (serovar 3) of *Ureaplasma parvum*, identified the predominant ureaplasma antigens recognized by the host during human infection. The MBA were first seen as unusual, ladder-like bands in immunoblots. These lipoproteins exhibited epitopes for both serovar specificity and cross-reactivity, and showed *in vitro* size variation (Teng et al., 1994; Zheng et al., 1995). Monecke et al. (2003) added evidence that the MBA are involved in a phase-switching process similar to that identified in several *Mycoplasma* species. The *mba* gene sequences have since been used to further define ureaplasma phylogeny (Knox et al., 1998; Kong et al., 1999b), as well as to characterize isolates (Knox et al., 1998; Knox and Timms, 1998; Kong et al., 1999a; Pitcher et al., 2001). The sequences of the 5' ends of the *mba* genes of all 14 serovars have been defined (Kong et al., 1999a, 2000). Kong et al. (2000) found that for *Ureaplasma parvum*, a specific site on the gene determines serovar identity, whereas for *Ureaplasma urealyticum* at least the sequence of the 3' end is required and, for certain other serovars, the entire sequence is involved.

The genes for the three urease subunits, *ureA*, *ureB*, and *ureC*, and adjoining regions from many isolates have been sequenced (Blanchard, 1990; Kong et al., 1999b; Neyrolles et al., 1996; Ruifu et al., 1997). Rocha and Blanchard (2002) applied bioinformatics to predict how certain gene products (e.g., the MBA, restriction and modification systems, transcription anti-termination elements, and GTP-binding proteins) might exhibit species specificity. PCRs based upon the 16S rRNA genes are the most highly conserved, followed by the 16S–23S intergenic region, the urease-associated genes, the *mba* genes, and the region upstream of them.

Acknowledgements

We thank J. Glass and collaborators at the J. Craig Venter Institute and the University of Alabama - Birmingham for the gift of the genome sequences of *Ureaplasma parvum* and *Ureaplasma urealyticum*, and J.G. Tully, K.E. Johansson, and C. Williams for their suggestions regarding the initial chapter.

Differentiation of the species of the genus *Ureaplasma*

The first paper on ureaplasma taxonomy stated that “An advantage of forming a new genus is that it confers freedom to classify new species within the genus without adhering to the principles formulated for the other genera. A numbered serovar of a *Ureaplasma* from humans is broadly equivalent to a named species within the genera *Mycoplasma* or *Acholeplasma*” (Shepard et al., 1974). The serological diversity within the type strain, *Ureaplasma urealyticum*, was regarded as no more than antigenic heterogeneity, possibly reflecting minor differences within a single epitope. To ensure that taxonomy would develop rationally, official recognition of *Ureaplasma* subspecies was avoided. Thirty-five years later, this taxonomic restraint can be appreciated.

When the first genus and species, *Ureaplasma urealyticum*, was named, it had eight known antigenic specificities (Shepard et al., 1974); 6 years later, the number had reached 14 (Robertson and Stemke, 1982) where, surprisingly, it has remained. It is surprising because the serotypes were isolated over a 20-year

period representing antigens in Vancouver, BC, Canada (Ford, 1967), Camp Lejeune, NC (Shepard, 1954), and Boston, MA, USA (Lin et al., 1972), i.e., on the west and east coasts of North America. While putative untypable strains are occasionally encountered, after cloning, these have usually turned out to be serovar 3, probably the most likely to dominate in a mixed culture. However, additional serovars/genovars can be expected to emerge, especially from other parts of the world.

The named species were identified primarily by DNA–DNA hybridization and by serological tests. For taxonomic studies, the metabolism inhibition test (Purcell et al., 1966; Robertson and Stemke, 1979; Taylor-Robinson, 1983b) and either a direct or indirect immunofluorescence test (Black and Krosggaard-Jensen, 1974; Piot, 1977; Stemke and Robertson, 1981) have been most useful. However, serological tests sometimes gave confusing cross-reactivity patterns and were not ideal for differentiating strains within a single species (Stemke and Robertson, 1985). In an attempt to circumvent problems of cross-reactions obtained with polyclonal antisera, monoclonal antibodies (mAbs) to all 14 serovars of human isolates were developed (e.g., Echahidi et al., 2001). The use of mAbs coincided with and has been largely overshadowed by the genomic revolution.

In the 1980s, the same pattern of partitioning of the serovars of human isolates was demonstrated by other phenotypic traits, traits primarily related to protein structures and functions (Table 138). When phenotypy failed to deliver a clear and convenient means of discrimination, genotypy did. The initial DNA–DNA relatedness studies of ureaplasmas from humans (Christiansen et al., 1981) confirmed the two, distinct clusters; however, the large cell biomass, special equipment, and (then) rare expertise required resulted in few strains being tested. New techniques, especially PCR, became more easily performed and less expensive so that more strains were examined and non-ambiguous results were obtained (Table 139). Supported by these strong data, the taxonomy of *Ureaplasma urealyticum* was emended and extended (Robertson et al., 2002). The ten antigenic specificities of the larger cluster (known as group 2 or as the T960 biovar) retained the *Ureaplasma urealyticum* designation with strain T960^T as the type strain. The remaining four antigenic specificities (known as group 1 or the parvo biovar) were renamed *Ureaplasma parvum* in recognition of that cluster's considerably smaller genome size; strain 27^T, the serovar 3 standard, was designated the type strain. Many PCR primers to identify species and strains of ureaplasmas have been published; commercial PCR-based kits are currently available for all named *Ureaplasma* species.

In summary, current ureaplasma taxonomy is based upon pragmatic, polyphasic criteria, i.e., a synthesis of phylogeny, phenotypy, and genotypy. For the specific requirements for taxonomic studies of *Mollicutes*, consult the most recent minimal standards document (Brown et al., 2007). Some serological testing is mandatory. Rabbit antisera to the 14 serovars of ureaplasmas of humans and certain animal species are currently available from Jerry K. Davis, Curator of the *Mollicutes* Collection, School of Veterinary Medicine, Purdue University, West Lafayette, IN, USA. Expertise in determining phenotypic traits specific to ureaplasmas may be accessible through collaboration with the appropriate working team of the International Research Programme for Comparative Mycoplasmology (IRPCM) of the International Organization for Mycoplasmology (IOM) at www.the-iom.org.

List of species of the genus *Ureaplasma*

1. ***Ureaplasma urealyticum*** Shepard, Lunceford, Ford, Purcell, Taylor-Robinson, Razin and Black 1974, 167^{AL} emend. Robertson, Stemke, Davis, Harasawa, Thirkell, Kong, Shepard and Ford 2002, 593
 u.re.a.ly'ti.cum. N.L. fem. n. *urea* urea; N.L. adj. *lyticus-a-um* (from Gr. adj. *lutikos -ê-on*) able to loosen, able to dissolve; N.L. neut. adj. *urealyticum* urea-dissolving or urea-digesting.
 Cells are coccoid and approximately 500 nm in diameter. Coccobacillary forms are seen in exponential phase cultures. One strain has been shown to have a carbohydrate-containing capsule; it and others contain lipoglycans. Grows at temperatures between 20 and 40°C, grows better at 30–35°C and best at 36–37°C. Colonies are ≤20–50 µm in diameter with complete or partial fried-egg morphology.
 Serologically distinct from all other named species in the genus, but serologically heterogeneous. Ten specific antigenic determinants are known: 2, 4, 5, and 7–13. Multiple-banded antigens are serovar-related and recognized by the host. Like *Ureaplasma parvum*, it has human IgA-specific protease activity that specifically cleaves human IgA1, but not human IgA2. Has distinctive PAGE and RFLP patterns. DNA is not restricted by endonuclease Uur9601. Genome size of the type strain is 890 kbp, whereas the sizes of the 10 known serovar standard strains range from 840 to 1140 kbp (PFGE). DNA reassociation values: within the species (serovars 2, 4, 5, and 7), 69–100%; with *Ureaplasma parvum* (serovars 1, 3, and 6), 49–52%. Opportunistic pathogen of humans; causes some cases of nongonococcal urethritis, infectious kidney stones, systemic infection in immunologically compromised hosts. Associated with a broad variety of urogenital infections for which causality remains to be established.
Source: primarily found in the genitourinary tract of female and male humans; occasionally in the oral cavity and rectum.
DNA G+C content (mol%): 25.5–27.8 (T_m ; type strain) and 27.7–28.5 (Bd; serovars 2, 4, 5, and 7).
Type strain: T960, (CX8), ATCC 27618, NCTC 10177.
Sequence accession nos: M23935 and AF073450 (type strain 16S rRNA gene), AB028088 and AF059330 (type strain 16S–23S rRNA intergenic region). Complete and near-complete (>99%) genomes: serovar 2 strain ATCC 27814, NZ_ABF000000000; serovar 4 strain ATCC 27816, NZ_AAYO000000000; serovar 5 strain ATCC 27817, NZ_AAZR000000000; serovar 7 strain ATCC 27819, NZ_AAYP000000000; serovar 8 strain ATCC 27618, NZ_AAYN000000000; serovar 9 strain ATCC 33175, NZ_AAYQ000000000; serovar 10 strain ATCC 33699, NC_011374; serovar 11 strain ATCC 33695, NZ_AAZS000000000; serovar 12 strain ATCC 33696, NZ_AAZT000000000; serovar 13 strain ATCC 33698, NZ_ABEV000000000.
2. ***Ureaplasma canigenitalium*** Harasawa, Imada, Kotani, Koshimizu and Barile 1993, 644^{VP}
 ca.ni.ge.ni.ta'li.um. L. n. *canis* dog; L. pl. n. *genitalia* the genitals; N.L. pl. gen. n. *canigenitalium* of canine genitals.
 Cells are coccoid and about 500 nm in diameter; coccobacillary forms are seen. Colonies are ≤20–140 µm diameter with fried-egg morphology. Serogroup I strains represented by D6P-C^T are serologically distinct from all other established species in the genus and from the other three serogroups of ureaplasmas isolated from dogs (represented by the strains DIM-C, D29M, and D11N-A). The species designation refers only to serogroup I strains, although strain D11N-A shows a one-way, serological cross-reaction with D6P-C^T. It produces an IgA protease which specifically cleaves canine myeloma IgA, but not human or murine IgA. Genome size is 860 kbp (PFGE). DNA reassociation values: between D6P-C^T and the other three canine strains (DIM-C, D29M, and D11N-A) are 41–63% versus 33% with *Ureaplasma urealyticum* (strain T960^T).
Source: habitat is the prepuce, vagina, and oral and nasal cavities of canines.
DNA G+C content (mol%): 29.4 (HPLC).
Type strain: D6P-C, ATCC 51252, CIP 106087.
Sequence accession no. (16S rRNA gene): D78648 (type strain).
3. ***Ureaplasma cati*** Harasawa, Imada, Ito, Koshimizu, Cassell and Barile 1990a, 50^{VP}
 ca'ti. L. gen. n. *cati* of a cat.
 Cells are coccoid and ≥675 nm diameter, exceeding the 450–550 nm range of most named *Ureaplasma* species. Coccobacillary forms are seen and occasionally filaments. Colonies are ≤15–140 µm in diameter with diffuse, granular appearance; some fried-egg colonies may appear after passaging. Distinct from other established species in the genus, including *Ureaplasma felinum*, antigenically and in PAGE (Harasawa et al., 1990a) and RFLP patterns (Harasawa et al., 1984). Genome size has not been determined. DNA reassociation values: 83–100% within feline serogroup SII strains (*Ureaplasma cati*) versus <10% with serogroup SI strains (*Ureaplasma felinum*).
Source: found in the oral cavity of healthy domestic cats (*Felis domestica*).
DNA G+C content (mol%): 27.9 (Bd), 28.1 (HPLC) for strain F2^T.
Type strain: F2, ATCC 49228, NCTC 11710, CIP 106088.
Sequence accession nos: D78649 (type strain 16S rRNA gene), D63685 (type strain 16S–23S rRNA intergenic spacer region).
4. ***Ureaplasma diversum*** Howard and Gourlay 1982, 450^{VP}
 di.ver'sum. L. neut. part. adj. *diversum* different, distinct, heterogeneous, referring to the difference in polypeptides and G+C content as compared to *Ureaplasma urealyticum* and to the heterogeneous antigenic structure of the species.
 Cells are coccoid or coccobacillary and appear to be within the size range of other named *Ureaplasma* species although no measurements have been published. Colonies are ≤100–175 µm in diameter based on photomicrographs.
 Serologically distinct from other named species but antigenically heterogeneous, comprising serogroups A, B, and C, and represented by strains A417^T, D48, and T44. These show three distinctive PAGE patterns (Howard and Gourlay, 1982), but only one RFLP pattern (Harasawa et al., 1984), and, based upon the latter criterion, were considered homogeneous.
 Genome size range is 1100–1160 kbp for strains 95 TX, 1763, and 2065-B202 (PFGE). No DNA reassociation values are available.
Source: the type strain originated from a pneumonic calf lung.

DNA G+C content (mol%): 29.0 and 28.7–30.2 (Bd) for the type strain and 10 bovine isolates, respectively; thus, higher than and not overlapping the values for *Ureaplasma urealyticum* and *Ureaplasma parvum*.

Type strain: A417, ATCC 43321, NCTC 10182, CIP 106089.

Sequence accession nos: D78650 (type strain 16S rRNA gene), D63686 (type strain 16S–23S rRNA intergenic spacer region).

5. **Ureaplasma felinum** Harasawa, Imada, Ito, Koshimizu, Cassell and Barile 1990a, 50^{VP}
fe.li'num. L. neut. adj. *felinum* of or belonging to a cat.

Coccioid cells of ≥ 800 nm diameter exceed the 450–500 nm range of most *Ureaplasma* species. Coccobacillary forms and occasional filaments are seen. Colonies are ≤ 15 –140 μ m diameter with diffuse, granular appearance; some fried-egg colonies may appear after passaging. Distinct antigenically and by PAGE and RFLP patterns (Harasawa et al., 1984) from other established species in the genus, including *Ureaplasma cati*. The genome size is 1170 kbp (PFGE). It is the largest of any ureaplasma strain examined. DNA reassociation values: 89–100% within feline serogroup SI strains (*Ureaplasma felinum*) versus $< 10\%$ with serogroup II strains (*Ureaplasma cati*).

Source: found in the oral cavity of healthy domestic cats (*Felis domestica*).

DNA G+C content (mol%): 27.9 (HPLC).

Type strain: FT2-B, ATCC 49229, NCTC 11709, CIP 106090.

Sequence accession nos: D78651 (type strain 16S rRNA gene), D63687 (type strain 16S–23S rRNA intergenic spacer region).

6. **Ureaplasma gallorale** Koshimizu, Harasawa, Pan, Kotani, Ogata, Stephens and Barile 1987, 337^{VP}

gal.lo.ra'le. L. n. *gallus* a barnyard fowl; L. n. *os, oris* the mouth; L. neut. suff. *-ale* suffix used with the sense of pertaining to; N.L. neut. adj. *gallorale* relating to the mouth of barnyard fowl.

Cells are coccioid and about 500 nm in diameter; coccobacillary forms are seen. Colonies are ≤ 15 –60 μ m in diameter with fried-egg morphology. Serologically distinct from all other established species in the genus. Isolates have similar SDS-PAGE, immunoblot, and RFLP patterns, but demonstrate some species heterogeneity based on reassociation values (cluster A strains D6-1^T and T9-1; cluster B strain Y8-1). Genome size is 760 kbp (PFGE). DNA reassociation values fall into two clusters: within cluster A (strains D6-1^T, D23, F2, F5, and T9-1), values are 70–100%; within cluster B (strains Y8-1 and Y4-2), values are 96–100%; between these clusters, values are 51–69%. Although these values are below expectations for a single species status, they exceed the 19–27% reassociation values with *Ureaplasma urealyticum* and *Ureaplasma diversum*.

Source: found only in oropharynx of healthy red jungle fowl (*Gallus gallus*) and chickens (*Gallus gallus* var. *domesticus*) kept as laboratory or zoo animals in Japan and in chickens and turkeys with pneumonia or airsacculitis in Hungary.

DNA G+C content (mol%): 27.6 (HPLC).

Type strain: D6-1, ATCC 43346, NCTC 11707.

Sequence accession nos: U62937 (type strain 16S rRNA gene), D63688 (type strain 16S–23S rRNA intergenic spacer region).

7. **Ureaplasma parvum** Robertson, Stemke, Davis, Harasawa, Thirkell, Kong, Shepard and Ford 2002, 593^{VP}

par'vum. L. neut. adj. *parvum* small, referring to its significantly smaller genome sizes compared to *Ureaplasma urealyticum*, the other species from humans.

Cells are coccioid and about 500 nm in diameter. Coccobacillary forms are present in exponential phase cultures. Lipoglycans have been identified in a serovar 3 strain. Colonies are ≤ 20 –140 μ m in diameter with complete or partial fried-egg morphology.

Serologically distinct from all other named species in the genus, but serological heterogeneity is exhibited within the species. Four specific antigenic determinants are known: 1, 3, 6, and 14. Serovar specificities are related to the multiple-banded antigens recognized by the host. Like *Ureaplasma urealyticum*, *Ureaplasma parvum* has an IgA protease activity that specifically cleaves human IgA1, but not human IgA2. Distinctive PAGE and RFLP patterns. DNA restricted by endonuclease Uur9601. Genome size: 751,719 kbp for the type strain. Complete genomic sequence of the organism has been reported (Glass et al., 2000). DNA reassociation values: within the species (serovars 1, 3, and 6), 91–102%; with *Ureaplasma urealyticum* (serovars 2, 4, 5, 7–13), 38–60%.

Source: primary habitat is the genitourinary tract of female and male humans; occasionally found in the oral cavity and rectum. As yet, unclear whether an opportunistic pathogen in non-gonococcal urethritis, but likely to be so in systemic infection in immunologically compromised hosts. Associated with a broad variety of urogenital infections for which causality remains to be established.

DNA G+C content (mol%): 25.5 (from genome sequence) and 27.8–28.2 (T_m) for serovars 1 and 6.

Type strain: 27, ATCC 27815, NCTC 11736.

Sequence accession nos: L08642 and AF073456 (type strain 16S rRNA gene), AB028083 and AF059323 (type strain 16S–23S rRNA intergenic spacer region). Complete and near-complete (>99%) genomes: serovar 1 strain ATCC 27813, NZ_ABES000000000; serovar 3 strain ATCC 27815, NC_010503; serovar 3 strain ATCC 700970, NC_002162; serovar 6 strain ATCC 27818, NZ_AAZQ000000000; serovar 14 strain ATCC 33697, NZ_ABER000000000.

Family II. Incertae sedis

DANIEL R. BROWN, SEVERINE TASKER, JOANNE B. MESSICK AND HAROLD NEIMARK

This family accommodates the genera *Eperythrozoon* and *Haemobartonella*. These wall-less hemotropic bacteria were once placed in the family *Anaplasmataceae*, order *Rickettsiales*, because they are obligate blood parasites. None have been cultivated on artificial media, so no type strains have been established. Motility and biochemical parameters have not been definitively established for

any species. These organisms are now known to be unambiguously affiliated with the order *Mycoplasmatales* on the basis of 16S rRNA similarities, plus morphology, DNA G+C contents, and evidence that they use the codon UGA to encode tryptophan (Berent and Messick, 2003), but their nomenclature remains a matter of controversy (Neimark et al., 2005; Uilenberg et al., 2006).

Genus I. **Eperythrozoon** Schilling 1928, 293^{AL}

DANIEL R. BROWN, SÉVERINE TASKER, JOANNE B. MESSICK AND HAROLD NEIMARK

E.pe.ry.thro.zo'on. Gr. pref. *epi* on; Gr. adj. *erythros* red; Gr. neut. n. *zoon* living being, animal; N.L. neut. n. *Eperythrozoon* (presumably intended to mean) animals on red (blood cells).

Cells adherent to host erythrocyte surfaces are coccoid and about 350 nm in diameter, but may arrange to appear as chains or deform to appear rod- or ring-shaped in stained blood smears.

Type species: Eperythrozoon coccoides Schilling 1928, 1854.

Further descriptive information

Hemotropic mollicutes such as the species formerly called *Eperythrozoon coccoides* (trivial name, hemoplasmas; Neimark et al., 2005) infect a variety of mammals occasionally including humans. Transmission can be through ingestion of infected blood, percutaneous inoculation, or by arthropod vectors (Sykes et al., 2007; Willi et al., 2006). The pathogenicity of different hemoplasma species is variable, and strain virulence and host immunocompetence likely play roles in the development of disease. Clinical syndromes range from acute fatal hemolytic anemia to chronic insidious anemia. Signs may include anemia, pyrexia, anorexia, dehydration, weight loss, and infertility. The presence of erythrocyte-bound antibodies has been demonstrated in some hemoplasma-infected animals and may contribute to anemia. Animals can remain chronic asymptomatic carriers of hemoplasmas after acute infection. PCR is the diagnostic test of choice for hemoplasmosis. Tetracycline treatment reduces the number of organisms in peripheral blood, but probably does not eradicate the organisms from infected animals.

Enrichment and isolation procedures

Hemoplasmas have not yet been successfully grown in continuous culture *in vitro*, although recent work (Li et al., 2008) suggests that *in vitro* maintenance of the species *Mycoplasma suis* may be possible.

Maintenance procedures

Hemoplasmas can be frozen in heparin- or EDTA-anticoagulated blood cryopreserved with dimethylsulfoxide.

Differentiation of the genus *Eperythrozoon* from other genera

A distinctive characteristic of these organisms is that they are found only in the blood of vertebrate hosts or transiently in arthropod vectors of transmission. The tenuous distinction between species of *Eperythrozoon* and those of *Haemobartonella* was based on the relatively more common visualization of eperythrozoon as ring forms (now known to be artifactual) in stained blood smears and the perception that eperythrozoon were observed with about equal frequency on erythrocytes and free in plasma, while haemobartonellae were thought to occur less often free in plasma. Properties that partially fulfill criteria for assignment of this genus to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. Presumptive use of the codon UGA to encode tryptophan (Berent and Messick, 2003) supports exclusion from the genera *Anaeroplasma*, *Asteroleplasma*, *Acholeplasma*, and "*Candidatus* Phytoplasma". Non-spiral cellular

morphology and regular association with vertebrate hosts support exclusion from the genera *Spiroplasma*, *Entomoplasma*, and *Mesoplasma*, but sterol requirement, the degree of aerobiosis, and the capacity to hydrolyze arginine, characteristics that would help to confirm their provisional 16S rRNA-based placement in the genus *Mycoplasma*, remain unknown.

Taxonomic comments

The taxonomy and nomenclature of the uncultivated hemotropic bacteria originally assigned to the genus *Eperythrozoon* remain matters of current controversy. It is now undisputed that, on the basis of their lack of a cell wall, small cell size, low G+C content, use of the codon UGA to encode tryptophan, regular association with vertebrate hosts, and 16S rRNA gene sequences that are most similar (80–84%) to species in the pneumoniae group of genus *Mycoplasma*, these organisms are properly affiliated with the *Mycoplasmatales*. However, the proposed transfers of *Eperythrozoon* and *Haemobartonella* species to the genus *Mycoplasma* (Neimark et al., 2001, 2005) were opposed on the grounds that the degree of 16S rRNA gene sequence similarity is insufficient (Uilenberg et al., 2004, 2006). The alternative of situating the hemoplasmas in a new genus in the *Mycoplasmataceae* (Uilenberg et al., 2006) would regrettably compound the 16S rRNA gene-based polyphyly within *Mycoplasma* on no other basis than a capacity to adhere to the surface of erythrocytes *in vivo*.

The proposed transfer of the type species *Eperythrozoon coccoides* to the genus *Mycoplasma* (Neimark et al., 2005) is complicated by priority because *Eperythrozoon* predates *Mycoplasma*. However, the alternative of uniting the genera by transferring all mycoplasmas to the genus *Eperythrozoon* is completely unjustifiable considering the biological characteristics of the non-hemotropic majority of *Mycoplasma* species. The Judicial Commission of the International Committee on Systematics of Prokaryotes declined to rule on a request for an opinion in this matter during their 2008 meeting, but a provisional placement of the former *Eperythrozoon* species in the genus *Mycoplasma* has otherwise been embraced by specialists in the molecular biology and clinical pathogenicity of these and similar hemotropic organisms. At present, the designation "*Candidatus* Mycoplasma" must still be used for new types.

Kreier, J.P. and M. Ristic. 1974. Genus IV. *Haemobartonella* Tyzzer and Weinman 1939, 143^{AL}; Genus V. *Eperythrozoon* Schilling 1928, 1854^{AL}. In Bergey's Manual of Determinative Bacteriology, 8th edn (edited by Buchanan and Gibbons). Williams & Wilkins, Baltimore, pp. 910–914.

Differentiation of the species of the genus *Eperythrozoon*

Species differentiation relies principally on 16S rRNA gene sequencing. Some species exhibit a degree of host specificity, although cross-infection of related hosts has been reported.

List of species of the genus *Eperythrozoon*

1. ***Mycoplasma coccoides*** (Schilling 1928) Neimark, Peters, Robinson and Stewart 2005, 1389^{VP} (*Eperythrozoon coccoides* Schilling 1928, 1854)

coc.co'ides. N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; L. suff. *-oides* (from Gr. suff. *eides* from Gr. n. *eidos* that which is seen, form, shape, figure), resembling, similar; N.L. neut. adj. *coccoides* coccus-shaped.

Pathogenic; causes anemia in wild and captive mice, and captive rats, hamsters, and rabbits. Transmission is believed to be vector-borne and mediated by the rat louse *Polyplex spinulosa* and the mouse louse *Polyplex serrata*. Neoarsphenamine and oxophenarsine were thought to be effective chemotherapeutic agents for treatment of *Mycoplasma coccoides* infection in captive rodents, whereas tetracyclines are effective only at keeping infection at subclinical levels (Thurston, 1953).

Source: observed in association with the erythrocytes of wild and captive rodents.

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AY171918.
2. ***Eperythrozoon parvum*** Splitter 1950, 513^{AL}

par'vum. L. neut. adj. *parvum* small.

A nonpathogenic epierythrocytic parasite of pigs. Organic arsenicals are effective; tetracyclines suppress infection. Transmissible by parenteral inoculation and sometimes by massive oral inoculation. This is the only remaining species of *Eperythrozoon* whose name has standing in nomenclature that has not yet been examined by molecular genetic methods. It seems likely that, if a specimen of this organism can be found, it will prove to be a mycoplasma.
3. ***Mycoplasma ovis*** (Neitz, Alexander and de Toit 1934) Neimark, Hoff and Ganter 2004, 369^{VP} (*Eperythrozoon ovis* Neitz, Alexander and de Toit 1934, 267)

o'vis. L. fem. gen. n. *ovis* of a sheep.

Cells are coccoid and motility for this species has not been assessed. The morphology of infected erythrocytes is altered demonstrating a marked depression at the site of *Myplasma ovis* attachment. This species has not been grown on artificial medium; therefore, notable biochemical parameters are not known.

Neoarsphenamine is an effective therapeutic agent. *Mycoplasma ovis* is reported to share antigens with *Mycoplasma wenyonii* (Kreier and Ristic, 1963), potentially complicating serology-based diagnosis of infection.

Pathogenic; causes mild to severe anemia in sheep and goats that often results in poor feed conversion. Transmission occurs via blood-feeding arthropods, e.g., *Haemophysalis plumbeum*, *Rhipicephalus bursa*, *Aedes camptorhynchus*, and *Culex annulirostris* (Daddow, 1980; Howard, 1975; Nikol'skii and Slipchenko, 1969), and likely via fomites such as reused needles, shearing tools, and ear-tagging equipment (Brun-Hansen et al., 1997; Mason and Statham, 1991).
4. ***Mycoplasma suis*** corrig. (Splitter 1950) Neimark, Johansson, Rikihisa and Tully 2002, 683^{VP} (*Eperythrozoon suis* Splitter 1950, 513)

su'is. L. gen. n. *suis* of the pig.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Neoarsphenamine and tetracyclines are effective therapeutic agents. An enzyme-linked immunosorbant assay (ELISA) and PCR-based detection assays to enable diagnosis of infection have been described (Groebel et al., 2009; Gwaltney and Oberst, 1994; Hoelzle, 2008; Hsu et al., 1992).

Pathogenic; causes febrile icteroaemia in pigs. Transmission occurs via insect vectors including *Stomoxys calcitrans* and *Aedes aegypti* (Prullage et al., 1993).

Source: observed in association with the erythrocytes of pigs.

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF029394.

Further comment: the original spelling of the specific epithet, *haemosuis* (*sic*), has been corrected by the List Editor.
5. ***Mycoplasma wenyonii*** (Adler and Ellenbogen 1934) Neimark, Johansson, Rikihisa and Tully 2002, 683^{VP} (*Eperythrozoon wenyonii* Adler and Ellenbogen 1934, 220)

we.ny.o'ni.i. N.L. masc. gen. n. *wenyonii* of Wenyon, named after Charles Morley Wenyon (1878–1948), an investigator of these organisms.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes anemia and subsequent lameness and/or infertility in cattle. Transmission is primarily vector-mediated by *Dermacentor andersoni* and reportedly can also occur vertically during gestation. Oxytetracycline is an effective therapeutic agent (Montes et al., 1994). *Mycoplasma wenyonii* is reported to share antigens with *Mycoplasma ovis* (Kreier and Ristic, 1963), potentially complicating serology-based diagnosis of infection.

Source: observed in association with the erythrocytes and platelets of cattle (Kreier and Ristic, 1968).

DNA G+C content (mol%): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF016546.

Species of unknown phylogenetic affiliation

The phylogenetic affiliations of the following proposed organisms are unknown and their names do not have standing in nomenclature. They are listed here merely because they have been incidentally cited as species of *Eperythrozoon*.

1. “*Eperythrozoon mariboi*” Ewers 1971

The name given to uncultivated polymorphic structures observed on or in erythrocytes from flying foxes (*Pteropus macrotis*) following splenectomy (Ewers, 1971). The structures, described as fine lines, lines with rings, and rows of rings that span the diameter of the erythrocytes, differ from those of hemotropic mycoplasmas.

2. “*Eperythrozoon teganodes*” Hoyte 1962

The name given to uncultivated serially transmissible bodies observed in Giemsa-stained blood smears from cattle. The bodies only occur free in the blood plasma and do not

attach to erythrocytes (Hoyte, 1962). The bodies differ from *Mycoplasma wenyonii* in morphology and include “frying-pan” shaped structures.

3. “*Eperythrozoon tuomii*” Tuomi and Von Bonsdorff 1967

Uncultivated transmissible cell wall-less bodies observed in Giemsa-stained blood smears and electron micrographs of blood from splenectomized calves. The bodies appeared in blood smears predominantly as delicate rings that did not attach to erythrocytes but were associated exclusively with thrombocytes (Tuomi and Von Bonsdorff, 1967; Uilenberg, 1967; Zwart et al., 1969).

Genus II. *Haemobartonella* Tyzzer and Weinman 1939, 305^{AL}

DANIEL R. BROWN, SÉVERINE TASKER, JOANNE B. MESSICK AND HAROLD NEIMARK

Ha.e.mo.bar.to.nel'la. Gr. n. *haima* (L. transliteration *haema*) blood; N.L. fem. n. *Bartonella* a bacterial genus; N.L. fem. n. *Haemobartonella* the blood (-inhabiting) *Bartonella*.

Cells adherent to host erythrocyte surfaces are coccoid and about 350 nm in diameter, but may occur as chains or deform to appear rod- or ring-shaped in stained blood smears.

Type species: Haemobartonella muris (Mayer 1921) Tyzzer and Weinman 1939^{AL} (*Bartonella muris* Mayer 1921, 151; *Bartonella muris ratti* Regendanz and Kikuth 1928, 1578; *Haemobartonella muris* Tyzzer and Weinman 1939, 143).

Further descriptive information

Those organisms originally assigned to the genus *Haemobartonella* are properly affiliated with the *Mycoplasmatales*, but their transfer to the order has not yet been formalized. Any distinction between *Haemobartonella* and *Eperythrozoon* is tenuous and possibly arbitrary (Kreier and Ristic, 1974; Uilenberg et al., 2004). Enrichment, isolation and maintenance procedures, and methods of differentiation are essentially the same as those for genus *Eperythrozoon*.

List of species of the genus *Haemobartonella*1. *Mycoplasma haemomuris* (Mayer 1921) Neimark, Johansson, Rikihisa and Tully 2002, 683^{VP} [*Bartonella muris* Mayer 1921, 151; *Bartonella muris ratti* Regendanz and Kikuth 1928, 1578; *Haemobartonella muris* Tyzzer and Weinman 1939, 143]

ha.e.mo.mu'ris. Gr. neut. n. *haema* blood; L. masc. gen. n. *muris* of the mouse; N.L. gen. n. *haemomuris* of mouse blood.

Cells are coccoid and some display dense inclusion particles. Motility for this species has not been assessed. The morphology of infected erythrocytes is altered, demonstrating a marked depression at the site of *Mycoplasma haemomuris* attachment. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Opportunistic pathogen; causes anemia in splenectomized or otherwise immunosuppressed mice. Transmission is vector-borne and mediated by the rat louse (*Polydax spinulosa*).

Source: observed in association with erythrocytes of wild and captive mice, and hamsters.

DNA G+C content (mol %): not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): U82963.

2. *Mycoplasma haemocanis* (Kikuth 1928) Messick, Walker, Raphael, Berent and Shi 2002, 697^{VP} [*Bartonella canis* Kikuth 1928, 1730; *Haemobartonella (Bartonella) canis* (Kikuth 1928) Tyzzer and Weinman 1939, 151; Kreier and Ristic 1984, 726]

ha.e.mo.ca'nis Gr. neut. n. *haema* blood; L. fem. gen. n. *canis* of the dog; N.L. gen. n. *haemocanis* of dog blood.

Cells are coccoid to pleomorphic. Motility for this species has not been assessed. The morphology of infected erythrocytes is altered, demonstrating a marked depression at the site of *Mycoplasma haemocanis* attachment. This species has not been grown on any artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes hemolytic anemia in domestic dogs. Transmission is vector-borne and mediated by the brown dog tick (*Rhipicephalus sanguineus*).

Source: observed in association with erythrocytes of domestic dogs (Hoskins, 1991).

DNA G+C content (mol %): Not determined.

Type strain: not established.

Sequence accession no. (16S rRNA gene): AF197337.

3. *Mycoplasma haemofelis* (Clark 1942) Neimark, Johansson, Rikihisa and Tully 2002, 683^{VP} [*Eperythrozoon felis* Clark 1942, 16; *Haemobartonella felis* (Clark 1942) Flint and McKelvie 1956, 240 and Kreier and Ristic 1984, 725]

ha.e.mo.fe'lis. Gr. neut. n. *haema* blood; L. fem. gen. n. *felis* of the cat; N.L. gen. n. *haemofelis* of cat blood.

Cells are coccoid. Motility for this species has not been assessed. This species has not been grown on artificial medium; therefore, notable biochemical parameters are not known.

Pathogenic; causes hemolytic anemia in cats. The mode of transmission is percutaneous or oral; an insect vector has not been identified although fleas have been implicated (Woods et al., 2005).

Tetracyclines and fluoroquinolones are effective therapeutic agents (Dowers et al., 2002; Tasker et al., 2006).

Source: observed in association with erythrocytes of domestic cats.

DNA G+C content (mol%): 38.5 (genome sequence survey of strain OH; Berent and Messick, 2003).

Type strain: not established.

Sequence accession no. (16S rRNA gene): U88563.

The phylogenetic affiliations of the following proposed organism are unknown and its name does not have standing

in nomenclature. It is listed here merely because it has been incidentally cited as a species of *Haemobartonella*.

1. “*Haemobartonella procyoni*” Frerichs and Holbrook 1971

Electron microscopy shows this epierythrocytic organism from a raccoon (*Procyon lotor*) is wall-less and its description indicates it probably will prove to be a hemotropic mycoplasma (Frerichs and Holbrook, 1971).

Order II. Entomoplasmatales Tully, Bové, Laigret and Whitcomb 1993, 381^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND ROBERT F. WHITCOMB*

En.to.mo.plas.ma.ta'les. N.L. neut. n. *Entomoplasma* type genus of the order; -ales ending to denote an order: N.L. fem. pl. n. *Entomoplasmatales* the *Entomoplasma* order.

This order in the class *Mollicutes* has been assigned to a group of nonhelical and helical mollicutes that are regularly associated with arthropod or plant hosts. The description of organisms in the order is essentially the same as for the class. Two families are designated, *Entomoplasmataceae* for nonhelical mollicutes and *Spiroplasmataceae* for helical ones. The order consists of four major phylogenetic clades: the paraphyletic entomoplasmataceae clade, which consists of the genera *Entomoplasma* and *Mesoplasma*; and the Apis, Citri–Chrysopicola–Mirum, and Ixodetis clades of the genus *Spiroplasma*. All cells are chemo-organotrophic, usually fermenting glucose through the phosphoenolpyruvate-dependent sugar transferase system. Arginine may be hydrolyzed, but urea is not. Cells may require sterol for growth. Nonhelical strains that grow in serum-free media supplemented with polyoxyethylene sorbitan (PES) are currently assigned to the genus *Mesoplasma*. Temperature optimum for growth is usually 30–32°C, with a few species able to grow at 37°C. Genome sizes range from 780 to 2220 kbp by pulsed-field gel electrophoresis (PFGE), with DNA G+C contents ranging from 25 to 34 mol%. Like members of the *Mycoplasmatales*, all organisms in this order are thought to utilize the UGA codon to encode tryptophan.

Type genus: **Entomoplasma** Tully, Bové, Laigret and Whitcomb 1993, 379^{VP}.

Further descriptive information

The basis for the proposal for the order *Entomoplasmatales* (Tully et al., 1993) was the distinctive phylogenetic and phenotypic characteristics of culturable mollicutes regularly associated with arthropods or plants. Members of the family *Entomoplasmataceae* are nonhelical mollicutes that differ in their cholesterol or serum requirements for growth. Nonhelical organisms with a strict requirement for cholesterol were placed in the genus *Entomoplasma* (trivial name, entomoplasmas), whereas nonhelical strains able to grow in a sterol-free medium supplemented with PES were assigned to the genus *Mesoplasma* (trivial name, mesoplasmas). The proposal also included the transfer of the family *Spiroplasmataceae* from the family *Mycoplasmatales* to the family *Entomoplasmatales*. The helical organisms assigned to the genus *Spiroplasma* were within the *Spiroplasmataceae*, and genus and family descriptions of these organisms remained as proposed previously (Skripal, 1983; Whitcomb and Tully, 1984). The order *Entomoplasmatales* is a phylogenetic sister to the order *Mycoplasmatales*. These two orders together form a lineage with several unique properties, including the use of UGA as a tryptophan codon rather than a stop codon.

Taxonomic comments

The genera *Entomoplasma* and *Mesoplasma* constitute a polyphyletic sister lineage of the mycoides cluster of mycoplasmas that are eccentrically situated in the paraphyletic family *Entomoplasmataceae* (Gasparich et al., 2004). There is no current

*Deceased 21 December 2007.

phylogenetic support for separation of *Entomoplasma* and *Mesoplasma* species based on neighbor-joining or maximum-parsimony methods of 16S rRNA gene sequence similarity analysis because they do not form coherent clusters, but are instead intermixed in one paraphyletic group (Johansson and Pettersson, 2002; Tully et al., 1998). No DNA–DNA reassociation experiments have been performed nor is there any other polyphasic taxonomic basis to support the separation. In particular, the growth requirement for sterols is not as profound a character as was initially believed and fails to justify these two species (Gasparich et al., 2004; Rose et al., 1993). For these reasons, and because *Entomoplasma* has priority

(Tully et al., 1993), the species currently assigned to the genus *Mesoplasma* should most likely be transferred to the genus *Entomoplasma*. Because the transfer would include its type species, the genus *Mesoplasma* would then become illegitimate. Moreover, Knight (2004) showed that the species formerly called *Mesoplasma plecicae* (Tully et al., 1994) is properly affiliated with the genus *Acholeplasma* on undisputed grounds of 16S rRNA gene sequence similarity and preferred use of UGG rather than UGA as the codon for tryptophan. Therefore, transfer of the currently remaining members of genus *Mesoplasma* cannot be endorsed until similar analyses have been completed for all of those organisms (D.V. Volokhov, unpublished).

Family I. Entomoplasmataceae Tully, Bové, Laigret and Whitcomb 1993, 380^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND ROBERT F. WHITCOMB*

En.to.mo.plas.ma.ta.ce'ae. N.L. neut. n. *Entomoplasma*, -atos type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Entomoplasmataceae* the *Entomoplasma* family.

Cells are **usually coccoid** or occur as short, branched or unbranched, pleomorphic, nonhelical filaments. Filterable through membranes with a mean pore diameter of 220–450 nm. **Cells lack a cell wall** and are bounded only by a plasma membrane. **Nonmotile. Facultatively anaerobic.** The temperature range for growth varies from 10 to 37°C, with the optimum usually at 30°C. The typical colony has a “fried-egg” appearance. **Chemo-organotrophic**; acid is produced from glucose, with evidence of a phosphoenolpyruvate-dependent sugar transport system(s) in some members. Arginine and urea are not hydrolyzed. The organisms **may require serum or cholesterol for growth** or may grow in serum-free media plus 0.04% PES. The genome sizes range from 790 to 1140 kbp.

DNA G+C content (mol%): 26–34.

Type genus: **Entomoplasma** Tully, Bové, Laigret and Whitcomb 1993, 379^{VP}.

Further descriptive information

All members of this paraphyletic family are nonhelical and are regularly associated with arthropod or plant hosts. They may require cholesterol or serum for growth, and most have an optimal growth temperature near 30°C. Separation of members of the genera *Entomoplasma* and *Mesoplasma* within the *Entomoplasmataceae* is based on the capacity of the *Mesoplasma* species to grow in a serum-free or cholesterol-free medium supplemented with PES (Rose et al., 1993; Tully et al., 1995), whereas *Entomoplasma* species have a growth requirement for cholesterol. The family is derived from the *Spiroplasma* lineage and is most closely related to the *Apis* cluster of that group. The *mycoides* cluster of species in the genus *Mycoplasma* is related to this family and seems to have evolved from it.

*Deceased 21 December 2007.

Genus I. *Entomoplasma* Tully, Bové, Laigret and Whitcomb 1993, 379^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND ROBERT F. WHITCOMB*

En.to.mo.plas'ma. Gr. n. *entomon* insect; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Entomoplasma* name intended to show association with insects.

Cells are **nonhelical** and **nonmotile**, frequently pleomorphic and range in size from 200 to 1200 nm in diameter. Some cells exhibit short filamentous forms. Most species ferment glucose. Species possess the phosphoenolpyruvate-dependent sugar-phosphotransferase system. Organisms **require serum or cholesterol** for growth. The temperature range for growth ranges from 10 to 32°C, with the optimum usually at 30–32°C. The genome sizes range from 870 to 900 kbp (PFGE). All currently assigned species were isolated from insects or from plant surfaces where they were presumably deposited by insects.

DNA G+C content (mol%): 27–34.

Type species: *Entomoplasma ellychniae* Tully, Rose, Hackett, Whitcomb, Carle, Bové, Colflesh and Williamson (Tully et al., 1989) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma ellychniae* Tully, Rose, Hackett, Whitcomb, Carle, Bové, Colflesh and Williamson 1989, 288).

Further descriptive information

Cells of these organisms vary from coccoid to pleomorphic forms exhibiting short, branching, nonhelical filaments. Round cells are usually in the size range of 200–300 nm, but may be larger. Most strains were initially isolated in either MID or SP-4 medium and all entomoplasmas grow well in SP-4 broth containing a supplement of 17% fetal bovine serum. Some strains are able to grow on media with reduced serum content. Most established species have an optimal growth temperature of 30°C, but some species grow better in broth medium maintained at 23–25°C or at 32°C. Colony growth on solid medium is best obtained on SP-4 medium incubated under anaerobic conditions at about 30°C. Under these conditions, most species produce colonies with a classic fried-egg appearance, although *Entomoplasma freundtii* is notable for its granular colony morphology.

All species show strong fermentation of glucose with production of acid and a reduction in medium pH (Table 140). Actively growing cultures in broth medium containing glucose may rapidly acidify the medium, causing partial or complete loss of

viability after 7–10 d. Arginine hydrolysis and “film and spot” lipase reactions are rare among species described to date. Entomoplasmas were shown to lack some key metabolic activities found in other mollicutes, especially PP_i-dependent phosphofructokinase and dUTPase, and to possess uracil DNA glycosylase activity. Although the latter pyrimidine enzymic activity distinguished *Entomoplasma* from *Mesoplasma* species, only two *Entomoplasma* species and three *Mesoplasma* species have been tested so far for these activities (Pollack et al., 1996).

Antisera to whole cell antigens of entomoplasmas have been used extensively to provide specific identification to the species level with a variety of serologic techniques, including growth inhibition, metabolism inhibition, and agar plate immunofluorescence (Tully et al., 1989, 1990, 1998). There is no evidence for the pathogenicity of entomoplasmas to either plant or insect hosts. Like other mollicutes, the entomoplasmas are resistant to 500 U/ml penicillin G.

Enrichment and isolation procedures

Flowers and other plant material should be cut in the field and placed in plastic bags without touching by hand. In the laboratory, plant materials are rinsed briefly in either SP-4 or MID media (May et al., 2008). In both of these media, fetal bovine serum is a critical component for successful growth of these organisms (Hackett and Whitcomb, 1995; Tully, 1995). The rinse medium is immediately decanted and passed through a sterile membrane filter, usually of 450 nm porosity. The filtrate is then passed through at least several tenfold dilutions in the selected culture medium. The retentate may be frozen at –70°C for later use or for retesting. The cultures are incubated at 27–30°C and monitored by dark-field microscopy and/or by observing acidification of the medium. It is important to note that several non-sterol-requiring *Acholeplasma* species have also been isolated from plant and insect material (Tully et al., 1994b).

Insect material, primarily from gut contents or hemolymph obtained by dissection or by fine-pointed glass pipettes, should be added to small volumes of SP-4 or MID medium and filtered through a 450 nm membrane filter. Serial tenfold dilutions of the filtrate should be incubated at 27–30°C and observed for a decrease in pH of the medium. After two to three serial passages, the organisms should be purified by conventional filter-cloning techniques (Tully, 1983) and stocks of various clones and early passage isolates frozen for further identification procedures (Whitcomb and Hackett, 1996).

Maintenance procedures

Stock cultures of entomoplasmas can be maintained well in SP-4 and/or MID broth medium containing about 17% fetal bovine serum. Most strains in the group can be adapted to grow in a broth medium containing bovine serum. Stock cultures in broth medium can be stored at –70°C for indefinite periods. For optimum preservation, the organisms should be lyophilized as broth cultures in the early exponential phase of growth and the dried cultures should be sealed under vacuum and stored at 4°C.

Differentiation of the genus *Entomoplasma* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. Aerobic or facultative anaerobic growth in artificial media and the necessity for sterols for growth exclude assignment to the genera *Anaeroplasma*, *Asteroleplasma*, *Acholeplasma*, *Mesoplasma*, or “*Candidatus* Phytoplasma”. Non-helical cellular morphology and regular association with arthropod or plant hosts support exclusion from the genera *Spiroplasma* or *Mycoplasma*. The inability to hydrolyze urea excludes assignment to the genus *Ureaplasma*. However, the difficulty in assigning novel species to this genus is well demonstrated by the earlier difficulties in establishing accurately the taxonomic status of these organisms (Tully et al., 1993). The availability of 16S rRNA gene sequence analyses was critical to the differentiation of these organisms from other mollicutes. Although isolates from vertebrates are very unlikely to be entomoplasmas, two bona fide *Mycoplasma* species, *Mycoplasma iowae* and *Mycoplasma equigenitalium*, have been isolated from plants [Grau et al., 1991; J.C. Vignault, J.M. Bové and J.G. Tully, unpublished (see ATCC 49192)].

Taxonomic comments

The landmark studies of Weisburg et al. (1989), using 16S rRNA gene sequences of about 50 species of mollicutes, were critical in the resolution of certain taxonomic conflicts regarding the species that became *Entomoplasma*. The first entomoplasmas to be recognized were serologically related isolates from the flowers of *Melaleuca* and *Grevillea* trees (McCoy et al., 1979). Others, found in a wide range of insect species (Tully et al., 1987), included strain ELCN-1^T from the hemolymph of the firefly beetle *Ellychnia corrusca* (Tully et al., 1989) and three serologically distinct strains isolated from gut contents of *Pyroctomena* and *Photinus* beetles (Williamson et al., 1990). Although these nonhelical, sterol-requiring mollicutes were initially placed in the genus *Mycoplasma*, 16S rRNA gene sequence analysis clearly indicated that strain MI^T, previously designated *Mycoplasma melaleucae*, and strain ELCN-1^T, previously designated *Mycoplasma ellychniae*, were most closely affiliated with the *Spiroplasma* lineage of helical organisms isolated primarily from arthropods. These findings prompted a proposal to reclassify the nonhelical mollicutes from arthropods and plants in a new order, *Entomoplasmatales*, and new family, *Entomoplasmataceae*, with the genus *Entomoplasma* reserved for sterol-requiring species (Tully et al., 1993). Strains MI^T and ELCN-1^T were renamed as *Entomoplasma melaleucae* and *Entomoplasma ellychniae*, respectively. Subsequent phylogenetic analysis of *Mycoplasma freundtii*, later renamed *Entomoplasma freundtii*, confirmed the placement (Tully et al., 1998).

The paraphyletic relationship between the genera *Entomoplasma* and *Mesoplasma* is currently an unresolved problem in the systematics of this genus. It is possible that these genera, separated by the single criterion of sterol requirement, should be combined into the single genus *Entomoplasma*. However, Knight (2004) showed that *Mesoplasma pleciae* (Tully et al., 1994b) should belong to the genus *Acholeplasma* based on 16S rRNA gene sequence similarity and the preferred use of UGG rather than UGA as the codon for tryptophan. Therefore, transfer of the currently remaining members of genus *Mesoplasma* to other genera cannot be endorsed until similar analyses have been completed for all of those species (D.V. Volokhov, unpublished).

Acknowledgements

We thank Karl-Erik Johansson for helpful comments and suggestions and Gail E. Gasparich for her landmark contributions regarding the phylogenetics of the *Entomoplasmatales*. The major contributions to the foundation of this material by Joseph G. Tully are gratefully acknowledged.

Differentiation of the species of the genus *Entomoplasma*

The primary technique for differentiation of *Entomoplasma* species is 16S rRNA gene sequence comparisons, confirmed by serology (Brown et al., 2007). Nonhelical mollicutes that belong to a known species isolated from arthropods or plants can be readily identified serologically provided that a battery of potent antisera for classified species is available. Growth inhibition tests, performed by placing paper discs saturated with type-specific antisera on agar plates inoculated with the organism, are perhaps the most convenient and rapid serological technique to differentiate species (Clyde, 1983). The agar plate immunofluorescence test is also a convenient and rapid means of mollicute species identification. In the absence of specific conjugated antiserum, an indirect immunofluorescence test can be performed with type-specific antiserum and a fluorescein-conjugated secondary antibody. The metabolism inhibition test (Taylor-Robinson, 1983) has also been applied to differentiation of *Entomoplasma* species (Tully et al., 1998).

List of species of the genus *Entomoplasma*

1. ***Entomoplasma ellychniae*** (Tully, Rose, Hackett, Whitcomb, Carle, Bové, Colflesh and Williamson 1989) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma ellychniae* Tully, Rose, Hackett, Whitcomb, Carle, Bové, Colflesh and Williamson 1989, 288)

el.lych.ni'ae. N.L. n. *Ellychnia* a genus of firefly beetles; N.L. gen. n. *ellychniae* of *Ellychnia*, from which the organism was first isolated.

This is the type species of the genus *Entomoplasma*. Cells are nonhelical, pleomorphic filaments, with some branching;

small coccoid forms, ranging in diameter from 200 to 300 nm, also occur. Passage of broth cultures through 450 and 300 nm porosity membrane filters does not reduce viable cell numbers, whereas passage through 220 nm porosity reduces cell populations by about 10%. Grows well in SP-4 medium with fetal bovine serum supplements. Does not grow well in horse serum-supplemented broth or agar media. Optimum temperature for broth growth is 30°C; can grow at 18–32°C. Colonies incubated at 30°C under anaerobic conditions have a fried-egg appearance. Does not hemadsorb guinea pig erythrocytes.

No evidence for pathogenicity for insects.

Source: isolated from the hemolymph of the firefly beetle *Ellychnia corrusca*.

DNA G+C content (mol%): 27.5 (Bd).

Type strain: ELCN-1, ATCC 43707, NCTC 11714.

Sequence accession no. (16S rRNA gene): M24292.

2. **Entomoplasma freundtii** Tully, Whitcomb, Hackett, Williamson, Laigret, Carle, Bové, Henegar, Ellis, Dodge and Adams 1998, 1203^{VP}

freund'ti.i. N.L. masc. gen. n. *freundtii* of Freundt, named after Eyvind Freundt, a Danish pioneer in the taxonomy and classification of mollicutes.

Cells are predominantly coccoid in shape, ranging from 300 to 1200 nm in diameter. Organisms are readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm; more than 90% of viable cells in broth culture are able to pass 220 nm porosity membranes. The temperature range for growth is 10–32°C, with an optimum at 30°C. Colonies under anaerobic conditions are granular and frequently exhibit multiple satellite forms although the organism is considered nonmotile. The organism grows well in SP-4 broth medium or other media containing horse serum supplements.

No evidence for pathogenicity for insects.

Source: isolated from the gut contents of a green tiger beetle (Coleoptera: Cicindelidae).

DNA G+C content (mol%): 34.1 (Bd).

Type strain: BARC 318, ATCC 51999.

Sequence accession no. (16S rRNA gene): AF036954.

3. **Entomoplasma lucivorax** (Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma lucivorax* Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990, 164)

lu.ci.vo'rax. L. fem. n. *lux lucis* light; L. neut. adj. *vorax* glutinous, devouring; N.L. neut. adj. *lucivorax* light devouring, referring to the predacious habit of the host insect, which preys on other luminescent firefly species.

Cells are either pleomorphic coccoid or subcoccoid, with a diameter of 200–300 nm, or are short, branched or unbranched filaments. Cells are readily filterable through membrane filters with mean pore diameters of 450, 300, and 220 nm, but do not pass 100 nm porosity membranes. Optimum temperature for growth is 30°C; can grow at 10–32°C. Nonmotile. Colonies under anaerobic conditions usually have a fried-egg appearance. Grows well in SP-4 broth medium or other media containing horse serum supplements. Colonies do not hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects or plants.

Source: first isolated from the gut of a firefly beetle (*Photinus pyralis*); also isolated from a flower (*Spirea ulmaria*; C. Chastel, unpublished).

DNA G+C content (mol%): 27.4 (Bd).

Type strain: PIPN-2, ATCC 49196, NCTC 11716.

Sequence accession no. (16S rRNA gene): AF547212.

4. **Entomoplasma luminosum** (Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma luminosum* Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990, 163)

lu.mi.no'sum. L. neut. adj. *luminosum* luminous, emitting light, referring to the luminescence of the adult host from which the organism was isolated.

Cells are pleomorphic and coccoid or subcoccoid with a diameter of 200–300 nm. Cells also occur as short, branched or unbranched filaments. The organisms are readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm, but do not pass 100 nm porosity membranes. The temperature range for growth is 10–32°C, with an optimum at 32°C. Nonmotile. Colonies under anaerobic conditions have a fried-egg appearance. The organism grows well in SP-4 broth medium or other media containing horse serum supplements. Colonies hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects.

Source: isolated from the gut of the firefly beetle (*Photinus marginata*).

DNA G+C content (mol%): 28.8 (Bd).

Type strain: PIMN-1, ATCC 49195, NCTC 11717.

Sequence accession no. (16S rRNA gene): AY155670.

5. **Entomoplasma melaleuca** (Tully, Rose, McCoy, Carle, Bové, Whitcomb and Weisburg 1990) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma melaleuca* Tully, Rose, McCoy, Carle, Bové, Whitcomb and Weisburg 1990, 146)

me la.leu'cae. N.L. n. *Melaleuca* a genus of tropical trees having white flowers with sweet fragrance; N.L. gen. n. *melaleuca* of *Melaleuca*, the plant from which the type strain was isolated.

Cells are pleomorphic and coccoid or subcoccoid, with few filamentous forms. Coccoid forms have mean diameters of 250–300 nm. Cells are readily filterable through 450 and 300 nm porosity membrane filters, with few cells passing 220 nm porosity membranes. The temperature range for growth is 10–30°C, with an optimum at about 23°C. Nonmotile. Colonies under anaerobic conditions at 23–30°C display a fried-egg appearance. Grows well in SP-4 broth or in modified Edward medium containing fetal bovine serum. The organism does not grow well in horse serum-based broth medium. Agar colonies do not adsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects or plants.

Source: isolated from flower surfaces of a subtropical plant, *Melaleuca quinquenervia*, in south Florida. Related strains have been isolated from flowers of other subtropical trees in Florida, *Melaleuca decora* and *Grevillea robusta* (silk oak), and from an anthophorine bee (*Xylocopa micans*) in the same geographic area.

DNA G+C content (mol%): 27.0 (Bd).

Type strain: M1, ATCC 49191, NCTC 11715.

Sequence accession nos (16S rRNA gene): M24478, AY345990.

Further comment: the 16S rRNA gene sequence is more similar to that of members of genus *Mesoplasma* than to others in the genus *Entomoplasma*.

6. **Entomoplasma somnilux** (Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma somnilux* Williamson, Tully, Rose, Hackett, Henegar, Carle, Bové, Colflesh and Whitcomb 1990, 163)

som.ni'lux. L. masc. n. *somnus* sleep; L. fem. n. *lux* light; N.L. n. *somnilux* intended to mean sleeping light, referring to the quiescent pupal stage of the host from which the organism was isolated, which precedes the luminescent adult stage.

Cells are pleomorphic and coccoidal or subcoccoidal, with a diameter of 200–300 nm; also occur as short, branched or unbranched filaments. Readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm. The temperature range for growth is 10–32°C, with optimum growth at 30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C have a fried-egg appearance. The organism grows well in SP-4 broth medium or other media containing horse serum supplements. Colonies do not adsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects.

Source: isolated from a pupal gut of the firefly beetle (*Pyraetomena angulata*).

DNA G+C content (mol%): 27.4 (Bd).

Type strain: PYAN-1, ATCC 49194, NCTC 11719.

Sequence accession no. (16S rRNA gene): AY157871.

Genus II. *Mesoplasma* Tully, Bové, Laigret and Whitcomb 1993, 380^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND ROBERT F. WHITCOMB*

Me.so.plas'ma. Gr. adj. *mesos* middle; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Mesoplasma* middle form, name intended to denote a middle position with respect to sterol or cholesterol requirement.

Cells are **nonhelical** and **nonmotile**, generally **coccoid or short filamentous forms**. Coccoid cells are usually 220–300 nm in diameter, but some cells in some species can be as large as 400–500 nm. Most strains ferment glucose and most, but not all, lack the ability to hydrolyze arginine. Species possess the phosphoenolpyruvate-dependent sugar-phosphotransferase system. Neither serum nor cholesterol is required for growth, but strains show **sustained growth in a serum-free or cholesterol-free medium when the medium is supplemented with 0.04% PES**. The optimum temperature for growth is usually near 28–32°C, with some strains able to grow well at temperatures as low as 23°C or as high as 37°C. Genome sizes range from 825 to 930 kbp (PFGE).

DNA G+C content (mol%): 26–32.

Type species: ***Mesoplasma florum*** (McCoy, Basham, Tully, Rose, Carle and Bové 1984) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Acholeplasma florum* McCoy, Basham, Tully, Rose, Carle and Bové 1984, 14).

Further descriptive information

Cells are predominantly coccoid in the exponential phase of growth when examined by dark-field microscopy. Cells from broth cultures examined by transmission electron microscopy are also coccoid, with individual cells usually 220–500 nm in diameter and clearly defined by a single cytoplasmic membrane. Colony growth is best obtained on SP-4 agar medium. Plates incubated under anaerobic conditions at about 30°C usually display characteristic fried-egg type colonies after 5–7 d incubation.

Several mesoplasmas lack certain key metabolic activities found in other mollicutes, especially PP_i-dependent phosphofructokinase, dUTPase, and uracil DNA glycosylase activity (Pollack et al., 1996). Most mesoplasmas were isolated in MID medium containing 15% fetal bovine serum (Whitcomb, 1983), but adapt well to growth in SP-4 broth containing 15–17% fetal

bovine serum, or in broth medium containing a 1% bovine serum fraction supplement (Tully, 1984; Tully et al., 1994a). All species show strong fermentation of glucose with acid production (Table 141), with a rapid decline in pH of the medium and loss of viability. Arginine hydrolysis has been observed only with the type strain (PUPA-2^T) of *Mesoplasma photuris*.

Antisera directed against whole-cell antigens of filter-cloned mesoplasmas have been used extensively to establish species and to provide species identifications. There is no evidence of pathogenicity of any currently established species in the genus for either an insect or plant host. Mesoplasmas are resistant to 500 U/ml penicillin.

Enrichment, isolation, and maintenance procedures

The culture media and procedures for isolation and maintenance of entomoplasmas from plant and insect sources can also be effectively applied for mesoplasmas.

Differentiation of the genus *Mesoplasma* from other genera

Properties that fulfill criteria for assignment to this genus are the same as those for the genus *Entomoplasma*, with the exception that the genus *Mesoplasma* is currently reserved for species that are able to grow in serum-free medium supplemented with PES (Tully et al., 1993).

Taxonomic comments

The existence of a flora of nonhelical, wall-less prokaryotes associated with arthropod or plant hosts was first documented by T.B. Clark, S. Eden-Green, and R.E. McCoy and colleagues. Some of the plant isolates were clearly related to previously described *Acholeplasma* species, such as *Acholeplasma oculi* (Eden-Green and Tully, 1979), whereas others were established as novel *Acholeplasma* species, able to grow well in broth media without any cholesterol, serum, or fatty acid supplements. However, a significant group of other similarly derived strains were able to

*Deceased 21 December 2007.

TABLE 141. Differential characteristics of species of the genus *Mesoplasma*^a

Characteristic	<i>M. florum</i>	<i>M. chauiocola</i>	<i>M. coleopterae</i>	<i>M. corruscae</i>	<i>M. entomophilum</i>	<i>M. grammopterae</i>	<i>M. lactucae</i>	<i>M. pholuris</i>	<i>M. seiffertii</i>	<i>M. sypthidae</i>	<i>M. tabanidae</i>
Glucose fermentation	+	+	+	+	+	+	+	+	+	+	+
Arginine hydrolysis	-	-	-	-	-	-	-	+	-	-	-
Hemadsorption of guinea pig red blood cells	-	+	-	+	+	-	+	-	+	+	-
DNA G+C content (mol%)	27.3	28.3	27.7	26.4	30	29.1	30	28.8	30	27.6	28.3

^aSymbols: +, >85% positive; -, 0–15% positive.

grow in serum-free or cholesterol-free media only when small amounts of PES were added to the medium. Because these strains grew in the absence of cholesterol or serum, several of them were initially described as *Acholeplasma* species, including *Acholeplasma florum* (McCoy et al., 1984), *Acholeplasma entomophilum* (Tully et al., 1988), and *Acholeplasma seiffertii* (Bonnet et al., 1991). Although the growth response to PES in serum-free or cholesterol-free media suggested that there were fundamental differences between such mollicutes and classic acholeplasmas, conclusive taxonomic evidence was lacking. The subsequent analysis of 16S rRNA gene sequences by Weisburg et al. (1989) showed that the PES-requiring organisms were closely related to the spiroplasma group of mollicutes and were phylogenetically distant from acholeplasmas. On the basis of these findings and additional phylogenetic data, a proposal was made that the plant- and insect-derived mollicutes with growth responses to PES in serum-free or cholesterol-free media would be assigned to a new family, *Entomoplasmataceae*, and a new genus, *Mesoplasma* (Tully et al., 1993). Three of the plant-derived strains previously described as *Acholeplasma* species (*Acholeplasma florum*, *Acholeplasma entomophilum*, and *Acholeplasma seiffertii*) were transferred to the genus *Mesoplasma*, with retention of their species epithets. A single plant-derived strain that had previously been described as *Mycoplasma lactucae*, and later found to grow in serum-free or cholesterol-free media supplemented with PES, was renamed *Mesoplasma lactucae*. Later, eight novel *Mesoplasma* species were described (Tully et al., 1994a).

The paraphyletic relationship between the genera *Entomoplasma* and *Mesoplasma* is a currently unresolved problem in the systematics of this genus. It is possible that these genera,

separated by the single criterion of sterol requirement, should be combined into the single genus *Entomoplasma*. However, Knight (2004) showed that *Mesoplasma plecica* (Tully et al., 1994a) should belong to the genus *Acholeplasma* based on 16S rRNA gene sequence similarity and the preferred use of UGG rather than UGA as the codon for tryptophan. Therefore, transfer of the currently remaining members of the genus *Mesoplasma* to other genera cannot be endorsed until similar analyses have been completed for all of those species (D.V. Volokhov, unpublished).

Differentiation of the species of the genus *Mesoplasma*

The techniques for differentiation of *Mesoplasma* species are the same as those for genus *Entomoplasma*.

List of species of the genus *Mesoplasma*

1. ***Mesoplasma florum*** (McCoy, Basham, Tully, Rose, Carle and Bové 1984) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Acholeplasma florum* McCoy, Basham, Tully, Rose, Carle and Bové 1984, 14)

flo'rum. L. gen. pl. n. *florum* of flowers, indicating the recovery site of the organism.

This is the type species of the genus. Cells are oval or coccoid. The organism is readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm, but does not pass a membrane with 100 nm porosity. Temperature range for growth is 18–37°C, with an optimum at 28–30°C. Colonies on agar medium containing horse serum supplements have a typical fried-egg appearance after anaerobic

incubation at 37°C. Colonies on agar do not hemadsorb guinea pig erythrocytes.

The 16S rRNA gene sequence is identical to that of *Mesoplasma entomophilum* (GenBank accession no. AF305693), but antiserum against *Mesoplasma florum* did not inhibit growth of *Mesoplasma entomophilum* or label the surfaces of *Mesoplasma entomophilum* colonies on agar (Tully et al., 1988). There are additional phenotypic distinctions between the two species.

No evidence of pathogenicity for plants or insects.

Source: first isolated from surface of flowers on a lemon tree (*Citrus limon*) in Florida, with subsequent isolations from floral surfaces of grapefruit (*Citrus*

paradisii) and powderpuff trees (*Albizia julibrissin*) in Florida (McCoy et al., 1979). Also isolated from a variety of plants and from the gut tissues of numerous species of insects (Clark et al., 1986; Tully et al., 1990; Whitcomb et al., 1982).

DNA G+C content (mol%): 27.3 (Bd, whole genome sequence).

Type strain: L1, ATCC 33453, NCTC 11704.

Sequence accession nos: AF300327 (16S rRNA gene), NC_006055 (strain L1^T genome sequence).

2. **Mesoplasma chauliocola** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 691^{VP}

chau.li.o'co.la. N.L. n. *chaulio* first part of the genus name of goldenrod beetle (*Chauliognathus*); L. suff. *-cola* (from L. masc. or fem. n. *incola*) inhabitant; N.L. masc. n. *chauliocola* inhabitant of the goldenrod beetle.

Cells are primarily coccoid, ranging in size from 300 to 500 nm in diameter. Cells are readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm, with a small number of cells able to pass through 100 nm porosity filters. Temperature range for growth is 10–37°C, with an optimum of 32–37°C. Nonmotile. Colonies incubated anaerobically at 32–37°C show fried-egg morphology. Colonies hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: originally isolated from gut fluid of an adult goldenrod soldier beetle (*Chauliognathus pennsylvanicus*).

DNA G+C content (mol%): 28.3 (Bd, T_m, HPLC).

Type strain: CHPA-2, ATCC 49578.

Sequence accession no. (16S rRNA gene): AY166704.

3. **Mesoplasma coleopterae** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 692^{VP}

co.le.op.te'rae. N.L. fem. gen. n. *coleopterae* of *Coleoptera*, referring to the order of insects (Coleoptera) from which the organism was first isolated.

Cells are primarily coccoid, ranging in diameter from 300 to 500 nm. Organisms are readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm. Temperature range for growth is 10–37°C, with an optimum of 30–37°C. Nonmotile. Colonies incubated anaerobically at 30°C usually have a fried-egg appearance. Agar colonies do not hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from the gut of an adult soldier beetle (*Chauliognathus* sp.).

DNA G+C content (mol%): 27.7 (Bd, T_m, HPLC).

Type strain: BARC 779, ATCC 49583.

Sequence accession no. (16S rRNA gene): DQ514605 (partial sequence).

4. **Mesoplasma corruscae** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 691^{VP}

cor.rus'cae. N.L. fem. gen. n. *corruscae* of *corrusca*, referring to the species of firefly beetle (*Ellychnia corrusca*) from which the organism was first isolated.

Cells are primarily coccoid, ranging in diameter from 300 to 500 nm. Cells are readily filterable through membranes with mean pore diameters of 450, 300, and 220 nm.

Temperature range for growth is 10–32°C, with an optimum of 30°C. Nonmotile. Colonies incubated anaerobically at 30°C usually have a fried-egg appearance. Colonies hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from the gut of an adult firefly (*Ellychnia corrusca*).

DNA G+C content (mol%): 26.4 (Bd, T_m, HPLC).

Type strain: ELCA-2, ATCC 49579.

Sequence accession no. (16S rRNA gene): AY168929.

5. **Mesoplasma entomophilum** (Tully, Rose, Carle, Bové, Hackett and Whitcomb 1988) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Acholeplasma entomophilum* Tully, Rose, Carle, Bové, Hackett and Whitcomb 1988, 166)

en.to.mo.phi'lum. Gr. n. *entomon* insect; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *entomophilum* insect-loving.

Cells are pleomorphic, but primarily coccoid, ranging from 300 to 500 nm in diameter. Cells are readily filterable through 220 nm porosity membrane filters. The temperature range for growth is 23–32°C, with an optimum at 30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C usually have a fried-egg appearance. Colonies hemadsorb guinea pig erythrocytes.

The 16S rRNA gene sequence is identical to that of *Mesoplasma florum* (GenBank accession no. AF300327), but antiserum against *Mesoplasma florum* did not inhibit growth of *Mesoplasma entomophilum* or label the surfaces of *Mesoplasma entomophilum* colonies on agar (Tully et al., 1988). There are additional phenotypic distinctions between the two species.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from the gut contents of a tabanid fly (*Tabanus catenatus*). Also isolated from a variety of other species of insects.

DNA G+C content (mol%): 30 (Bd).

Type strain: TAC, ATCC 43706, NCTC 11713.

Sequence accession no. (16S rRNA gene): AF305693.

6. **Mesoplasma grammopterae** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 691^{VP}

gram.mop.te'rae. N.L. fem. gen. n. *grammopterae* of *Grammoptera*, referring to the genus of beetle (*Grammoptera*) from which the organism was first isolated.

Cells are primarily coccoid, ranging in diameter from 300 to 500 nm. Cells are readily filterable through membrane filters with mean pore diameters of 450, 300, and 220 nm. Temperature range for growth is 10–37°C, with an optimum at 30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C have a fried-egg appearance. Colonies do not hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from the gut contents of an adult long-horned beetle (*Grammoptera* sp.). Other isolations were made from adult soldier beetle (*Cantharidae* sp.) and from an adult mining bee (*Andrena* sp.).

DNA G+C content (mol%): 29.1 (Bd, T_m, HPLC).

Type strain: GRUA-1, ATCC 49580.

Sequence accession no. (16S rRNA gene): AY174170.

7. **Mesoplasma lactucae** (Rose, Kocka, Somerson, Tully, Whitcomb, Carle, Bové, Colflesh and Williamson 1990) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Mycoplasma lactucae* Rose, Kocka, Somerson, Tully, Whitcomb, Carle, Bové, Colflesh and Williamson 1990, 141)

lac.tu'cae. L. fem. n. *lactucae* lettuce; L. gen. n. *lactucae* of lettuce, referring to the plant from which the organism was first isolated.

Cells are primarily coccoid, ranging in size from 300 to 500 nm in diameter, with only occasional short, nonhelical, pleomorphic filaments. Cells are readily filterable through membrane filters with mean pore diameters of 450, 300, and 220 nm, and a few cells are able to pass 100 nm porosity membranes. Temperature range for growth is 18–37°C, with optimal growth at 30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C have a fried-egg appearance. Colonies hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from lettuce (*Lactuca sativa*).

DNA G+C content (mol%): 30 (Bd).

Type strain: 831-C4, ATCC 49193, NCTC 11718.

Sequence accession no. (16S rRNA gene): AF303132. Has been reported to possess three rRNA operons (Grau, 1991).

8. **Mesoplasma photuris** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 691^{VP} pho.tu'ris. N.L. gen. n. *photuris* of *Photuris*, referring to the genus of firefly beetle (*Photuris* sp.) from which the organism was first isolated.

Cells are primarily coccoid, ranging in diameter from 300 to 500 nm. Readily filterable through membrane filters with mean pore diameters of 450, 300, and 220 nm. Temperature range for growth is 10–32°C, with optimum at 30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C have a fried-egg appearance. Colonies do not hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for plants or insects.

Source: original isolation was from gut fluids of larval and adult fireflies (*Photuris lucicrescens* and other *Photuris* spp.). One isolate (BARC 1976) was obtained by F.E. French from the gut of a horse fly (*Tabanus americanus*).

DNA G+C content (mol%): 28.8 (Bd, T_m , HPLC).

Type strain: PUPA-2, ATCC 49581.

Sequence accession no. (16S rRNA gene): AY177627.

9. **Mesoplasma seiffertii** (Bonnet, Saillard, Vignault, Garnier, Carle, Bové, Rose, Tully and Whitcomb 1991) Tully, Bové, Laigret and Whitcomb 1993, 380^{VP} (*Acholeplasma seiffertii* Bonnet, Saillard, Vignault, Garnier, Carle, Bové, Rose, Tully and Whitcomb 1991, 48)

seif.fer'ti.i. N.L. masc. gen. n. *seiffertii* of Seiffert, in honor of Gustav Seiffert, a German microbiologist who performed pioneering studies on mollicutes that occur in soil and compost and do not require sterols for growth.

Cells are primarily coccoid, ranging in diameter from 300 to 500 nm. Cells are readily filterable through membranes with mean pore diameters of 450, 300, and

220 nm. Temperature range for growth is 20–35°C, with optimum at about 28–30°C. Nonmotile. Colonies incubated under anaerobic conditions at 30°C have a fried-egg appearance. Colonies hemadsorb guinea pig erythrocytes.

Three insect isolates of *Mesoplasma seiffertii*, two from mosquitoes and one from a horse fly, were compared to strain F7^T of plant origin. High relatedness values of 78–98% DNA–DNA reassociation under high stringency conditions were obtained (Gros et al., 1996).

No evidence of pathogenicity for plants or insects.

Source: first isolated from floral surfaces of a sweet orange tree (*Citrus sinensis*) and from wild angelica (*Angelica sylvestris*). Also isolated from insects.

DNA G+C content (mol%): 30 (Bd).

Type strain: F7, ATCC 49495.

Sequence accession no. (16S rRNA gene): L12056.

10. **Mesoplasma syrphidae** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 691^{VP}

syr.phi'dae. N.L. fem. gen. n. *syrphidae* of a syrphid, referring to the syrphid fly family (Syrphidae), from which the organism was first isolated.

Cells are primarily coccoid, ranging in size from 300 to 500 nm in diameter. Cells readily pass membrane filters with mean pore diameters of 450, 300, and 220 nm. Temperature range for growth is 10–32°C, with optimum at 23–25°C. Nonmotile. Colonies incubated under anaerobic conditions at 23–25°C have a fried-egg appearance. Colonies hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects.

Source: original isolation was from the gut of an adult syrphid fly (Diptera: Syrphidae). Similar strains have been isolated from a bumblebee (*Bombus* sp.) and a skipper (Lepidoptera: Hesperidae).

DNA G+C content (mol%): 27.6 (Bd, T_m , HPLC).

Type strain: YJS, ATCC 51578.

Sequence accession no. (16S rRNA gene): AY231458.

11. **Mesoplasma tabanidae** Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 692^{VP}

ta.ba.ni.dae. N.L. fem. gen. n. *tabanidae* of a tabanid, referring to the horse fly family (Tabanidae), the host from which the organism was first isolated.

Cells are primarily coccoid, ranging in size from 300 to 500 nm in diameter. Cells readily pass membrane filters with mean pore diameters of 450, 300, and 220 nm. Temperature range for growth is 10–37°C, with optimum at 37°C. Nonmotile. Colonies incubated under anaerobic conditions at 37°C display a fried-egg appearance. Colonies do not hemadsorb guinea pig erythrocytes.

No evidence of pathogenicity for insects.

Source: original isolation was from the gut of an adult horse fly (*Tabanus abactor*).

DNA G+C content (mol%): 28.3 (Bd, T_m , HPLC).

Type strain: BARC 857, ATCC 49584.

Sequence accession no. (16S rRNA gene): AY187288.

Family II. Spiroplasmataceae Skripal 1983, 408^{VP}

DAVID L. WILLIAMSON, GAIL E. GASPARICH, LAURA B. REGASSA, COLLETTE SAILLARD, JOËL RENAUDIN, JOSEPH M. BOVÉ AND ROBERT F. WHITCOMB*

Spi.ro.plas.ma.ta.ce'ae. N.L. neut. n. *Spiroplasma*, -atos type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Spiroplasmataceae* the *Spiroplasma* family.

Cells are helical during exponential growth, with rotatory, flexional, and translational motility. Genome size is variable: 780–2220 kbp. Variable sterol requirement for growth. Procedures for determining sterol requirement are as described for Family I (*Entomoplasmataceae*). Possess a phosphoenolpyruvate phosphotransferase system for glucose uptake. Reduced

nicotinamide adenine dinucleotide (NADH) oxidase activity is located only in the cytoplasm. Unable to synthesize fatty acids from acetate. Other characteristics are as described for the class and order.

Type genus: **Spiroplasma** Saglio, L'Hospital, Lafèche, Dupont, Bové, Tully and Freundt 1973, 201^{AL}.

Genus I. Spiroplasma Saglio, L'Hospital, Lafèche, Dupont, Bové, Tully and Freundt 1973, 201^{AL}

DAVID L. WILLIAMSON, GAIL E. GASPARICH, LAURA B. REGASSA, COLLETTE SAILLARD, JOËL RENAUDIN, JOSEPH M. BOVÉ AND ROBERT F. WHITCOMB*

Spi.ro.plas'ma. Gr. n. *speira* (L. transliteration *spira*) a coil, spiral; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Spiroplasma* spiral form.

Cells are pleomorphic, varying in size and shape from **helical** and branched nonhelical filaments to spherical or ovoid. The helical forms, usually 100–200 nm in diameter and 3–5 µm in length, generally occur during the exponential phase of growth and in some species persist during stationary phase. The cells of some species are short (1–2 µm). In certain cases, helical cells may be very tightly coiled, or the coils may show continuous variation in amplitude. Spherical cells ~300 nm in diameter and nonhelical filaments are frequently seen in the stationary phase, where they may not be viable, and in all growth phases in suboptimal growth media, where they may or may not be viable. In some species during certain phases, spherical forms may be the replicating form. **Helical filaments are motile, with flexional and twitching movements, and often show an apparent rotatory motility. Fibrils are associated with the membrane, but flagellae, periplasmic fibrils, or other organelles of locomotion are absent.** Fimbriae and pili observed on the cell surface of insect- and plant-pathogenic spiroplasmas are believed to be involved in host-cell attachment and conjugation (Ammar et al., 2004; Özbek et al., 2003), but not in locomotion. Cells divide by binary fission, with doubling times of 0.7–37 h. Facultatively anaerobic. The temperature growth range varies among species, from 5 to 41°C. **Colonies on solid media are frequently diffuse**, with irregular shapes and borders, a condition that reflects the motility of the cells during active growth (Figure 111). Colony type is strongly dependent on the agar concentration. Colony sizes vary from 0.1 to 4.0 mm in diameter. Colonies formed by nonmotile variants or mutants, or by cultures growing on inadequate media are typically umbonate with diameters of 200 µm or less. Some species, such as *Spiroplasma platyhelix*, have barely visible helicity along most of their length and display little rotatory or flexing motility. Colonies of motile, fast-growing spiroplasmas are diffuse, often with satellite colonies developing from foci adjacent to the initial site of colony development. Light turbidity may be produced in liquid cultures. Chemo-organotrophic. Acid is produced from glucose. Hydrolysis of arginine is variable. Urea, arbutin, and

FIGURE 111. Colonial morphology of *Spiroplasma lamphyridicola* strain PUP-1^T grown on SP-4 agar under anaerobic conditions for 4 d at 30°C. The diffuse appearance and indistinct margins reflect the motility of spiroplasmas during active growth. Bar = 50 µm. (Reprinted with permission from Stevens et al., 1997. *Int. J. Syst. Bacteriol.* 47: 709–712.)

esculin are not hydrolyzed. Sterol requirements are variable. An optimum osmolality, usually in the range of 300–800 mOsm, has been demonstrated for some spiroplasmas. Media containing mycoplasma broth base, serum, and other supplements are required for primary growth, but after adaptation, growth often occurs in less complex media. Defined or semi-defined media are available for some species. Resistant to 10,000 U/ml penicillin. Insensitive to rifampicin, sensitive to erythromycin and tetracycline. **Isolated from the surfaces of flowers and other plant parts, from the guts and hemolymph of various insects and crustaceans, and from tick triturates. Also isolated from vascular plant fluids (phloem sap) and insects that feed on the fluids.** Specific host associations are common. The type species, *Spiroplasma citri*, is pathogenic for citrus (e.g., orange and

*Deceased 21 December 2007.

grapefruit), producing “stubborn” disease. Experimental or natural infections also occur in horseradish, periwinkle, radish, broad bean, carrot, and other plant species. *Spiroplasma kunkelii* is a maize pathogen. Some species are pathogenic for insects. Certain species are pathogenic, under experimental conditions, for a variety of suckling rodents (rats, mice, hamsters and rabbits) and/or chicken embryos. Genome sizes vary from 780 to 2220 kbp (PFGE).

DNA G+C content (mol%): 24–31 (T_m , Bd).

Type species: *Spiroplasma citri* Saglio, L’Hospital, Laflèche, Dupont, Bové, Tully and Freundt 1973, 202^{AL}.

Further descriptive information

Morphology. The morphology of spiroplasmas is most easily observed in suspensions with the light microscope under dark-field illumination (Williamson and Poulson, 1979). In the exponential phase in liquid media, most spiroplasma cells are helical filaments 90–250 nm in diameter and of variable length (Figure 112). Fixed and negatively stained cells usually show a blunt and a tapered end (Williamson, 1969; Williamson and Whitcomb, 1974). The tapered ends of the cells are a consequence of the constriction process preceding division (Garnier et al., 1981, 1984). However, they are adapted as attachment sites in some species (Ammar et al., 2004).

Motility. Helical spiroplasma cells exhibit flexing, twitching, and apparent rotation about the longitudinal axis (Cole et al., 1973; Davis and Worley, 1973). Spiroplasmas exhibit temperature-dependent chemotactic movement toward higher concentrations of nutrients, such as carbohydrates and amino acids

FIGURE 112. Electron micrograph of *Drosophila willistoni* strain B3SR sex-ratio spiroplasmas. Hemolymph suspension in phosphate buffered saline, glutaraldehyde vapor-fixed, and negatively stained with 1% phosphotungstic acid, pH 7.2. (Reprinted with permission from Whitcomb et al., 2007. *Biodiversity and Conservation* 16: 3877–3894.)

(Daniels and Longland, 1984, 1980); but motility is random in the absence of attractants (Daniels and Longland, 1984). Both natural (Townsend et al., 1980b, 1977) and engineered (Cohen et al., 1989; Duret et al., 1999; Jacob et al., 1997) motility mutants have been described. These mutants form perfectly umbonate colonies on solid medium. Mutational analysis has highlighted the involvement of the *smc1* gene in motility. Jacob et al. (1997) demonstrated that a Tn4001 insertion mutant with reduced flexional motility and no rotational motility could be complemented with the wild-type *smc1* gene. The *smc1* gene encodes a 409 amino acid polypeptide having ten transmembrane domains but no significant homology with known proteins. In another study, the *smc1* gene was inactivated through homologous recombination, abolishing motility (Duret et al., 1999). The disrupted *smc1* mutant was injected into the leafhopper vector (*Circulifer haematoceps*); it multiplied actively in the insect vector and was then transmitted to periwinkle plants. The mutant induced symptoms that were indistinguishable from those caused by the motile wild-type strain showing that spiroplasma motility is not essential for phytopathogenicity and transmission to the plant host (Duret et al., 1999).

Fibrils and motility. Microfibrils 3.6 nm in width have been envisioned in the membranes of some spiroplasmas. These structures have repeat intervals of 9 nm along their lengths (Williamson, 1974) and form a ribbon that extends the entire length of the helix (Charbonneau and Ghiorse, 1984; Williamson et al., 1984). The sequence of the fibril protein gene has been determined (Williamson et al., 1991) and the calculated mass of the fibril protein is 59 kDa. The flat, monolayered, membrane-bound ribbon composed of several well-ordered fibrils represents the internal spiroplasmal cytoskeleton. The spiroplasmal cytoskeletal ribbon follows the shortest helical line on the cellular coil. Recent studies have focused on the detailed cellular and molecular organization of the cytoskeleton in *Spiroplasma melliferum* and *Spiroplasma citri* (Gilad et al., 2003; Trachtenberg, 2004; Trachtenberg et al., 2003a, b; Trachtenberg and Gilad, 2001). Each cytoskeletal ribbon contains seven fibril pairs (or 14 fibrils) and the functional unit is a pair of aligned fibrils (Trachtenberg et al., 2003a). Paired fibrils can be viewed as chains of tetramers composed of 59 kDa monomers. Cryo-electron tomography has been used to elucidate the native state, cytoskeletal structure of *Spiroplasma melliferum* and suggested the presence of three parallel ribbons under the membrane: two appear to be composed of the fibril protein and the third is composed of the actin-like MreB protein (Kürner et al., 2005). Subsequent studies suggest the presence of a single ribbon structure (Trachtenberg et al., 2008). The subunits in the fibrils undergo conformational changes from circular to elliptical, which results in shortening of the fibrils and helix contraction, or from elliptical to circular, leading to a length increase of the fibrils and cell helix. The cytoskeleton, which is bound to the spiroplasmal membrane over its entire length, acts as a scaffold and controls the helical shape of the cell. The cell shape is therefore dynamic. Movement appears to be driven by the propagation of a pair of kinks that travel down the length of the cell along the fibril ribbons (Shaevitz et al., 2005; Wada and Netz, 2007; Wolgemuth and Charon, 2005). The contractile cytoskeleton can thus be seen as a “linear motor” in contrast to the common “rotary motor” that is part of the flagellar apparatus in bacteria (Trachtenberg, 2006).

There are several adherent proteins that copurify with the cytoskeleton, ranging in size from 26 to 170 kDa (Townsend et al., 1980a; Trachtenberg, 2006; Trachtenberg and Gilad, 2001). These proteins are apparently membrane-associated and may function as anchor proteins (Trachtenberg and Gilad, 2001). The structural organization of the cytoskeleton-associated proteins of *Spiroplasma melliferum* is beginning to be elucidated (Trachtenberg et al., 2008). The 59 kDa polypeptide is the cytoskeletal fibril protein. The 26 kDa polypeptide is probably spiralin, the major spiroplasmal membrane protein. However, the involvement of spiralin in helicity and motility is unlikely (see "Spiralin" section below), especially since spiralin is anchored on the outside surface of the cell (Béven et al., 1996; Bové, 1993; Brenner et al., 1995; Foissac et al., 1996) and spiralin-deficient mutants maintain helicity and motility (Duret et al., 2003). The 45 kDa protein may correspond to the product of the *scm1* gene, shown to be essential for motility (Jacob et al., 1997), and the 34 kDa protein may be the product of the *mreB1* gene (W. Maccheroni and J. Renaudin, unpublished).

MreB is the bacterial homolog to eukaryotic actin (Jones et al., 2001; Van den Ent et al., 2001). Early work provided evidence for the presence of actin-like proteins in spiroplasmas. Antisera prepared against SDS-denatured invertebrate actin coupled to horseradish peroxidase specifically stained cells of *Spiroplasma citri* (Williamson et al., 1979a). Also, a protein with a molecular mass similar to that of actin (protein P25) was isolated from *Spiroplasma citri* and reacted with IgG directed against rabbit actin (Mouches et al., 1982b, c, 1983b). Monospecific antibodies raised against the P25 protein recognized not only P25 of *Spiroplasma citri*, but also a homologous protein from *Mycoplasma mycoides* PG50 and *Ureaplasma urealyticum* serotype V (Mouches et al., 1983b). More recent work has focused on the molecular organization of the genes. *mreB* genes are present in rod-shaped, filamentous, and helical bacteria, but not in coccoid, spherical bacteria, regardless of whether or not they are Gram-stain-positive or Gram-stain-negative. *mreB* genes are also absent from the pleomorphic mycoplasmas. However, *Spiroplasma citri* contains five homologs of *Bacillus subtilis* *mreB* genes (Maccheroni et al., 2002). Four of these (*mreB2*, 3, 4, and 5) form a cluster on the genome and are transcribed in two separate operons. Gene *mreB1* is transcribed as a monocistronic operon and at a much higher level.

Growth characteristics. Spiroplasma cells increase in length and divide by constriction. Pulse labeling of the membrane with tritiated amino acids revealed a polar growth of the helix. Polarity was also observed by tellurium-labeling of oxido-reduction sites (Garnier et al., 1984). In the stationary or death phase, the cells are usually distorted, often forming either subovoid bodies or nonhelical filaments. Within cultured insect cells, all the spiroplasma cells were subovoid, but presumably viable (Waydande and Fletcher, 1998). Thus, the ability of cells to grow and divide is not linked inextricably to helicity.

Growth rate. Enumerated microscopically (Rodwell and Whitcomb, 1983), spiroplasmas reach titers of 10^8 – 10^{11} cells/ml in medium containing horse or fetal bovine serum. Growth rates of related strains tend to be similar. Konai et al. (1996a) calculated doubling times from the time required for medium acidification. In general, spiroplasmas adapted to complex cycles or single hosts had slower growth rates than spiroplasmas known or suspected to be transmitted on plant surfaces.

Temperature. Konai et al. (1996a) determined temperature ranges and optima for a large number of spiroplasma strains. The ranges of some strains (e.g., *Spiroplasma apis*) were very wide (5–41°C), but some group I strains from leafhoppers and plants grew only at 25° and 30°C. Although some spiroplasmas grew well at 41°C, none grew at 43°C.

Biochemical reactions. All tested spiroplasmas ferment glucose with concomitant acid production, although the utilization rates may vary. Some strains of group I (e.g., members of subgroups I-4 and I-6) and all strains of *Spiroplasma mirum* ferment glucose slowly. With *Spiroplasma citri*, all strains tested grew actively on fructose and strain GII3 grew on fructose, glucose, or trehalose. The ability of spiroplasmas to utilize arginine varies (Hackett et al., 1996a). Arginine hydrolysis by some spiroplasmas can be observed only if glucose is also present in the medium. In other cases, aggressive glucose metabolism interferes with detection of arginine hydrolysis (Hackett et al., 1996a).

Regulation of the fructose and trehalose operons of *Spiroplasma citri*. The fructose operon of *Spiroplasma citri* (Gaurivaud et al., 2000a) became of special interest when fructose utilization was implicated in *Spiroplasma citri* phytopathogenicity (see "Mechanism of *Spiroplasma citri* phytopathogenicity" below). In particular, the role of the first gene of the operon, *fruR*, was investigated. *In vivo* transcription of the operon is greatly enhanced by the presence of fructose in the growth medium, whereas glucose has no effect. When *fruR* is not expressed (*fruR* mutants), transcription of the operon is not stimulated by fructose and the rate of fructose fermentation is decreased, indicating that FruR is an activator of the fructose operon (Gaurivaud et al., 2001). Trehalose is the major sugar in leafhoppers and other insects. The trehalose operon of *Spiroplasma citri* has a gene organization very similar to that of the fructose operon and the first gene of the trehalose operon, *treR*, also encodes a transcriptional activator of the operon (André et al., 2003).

Sterol utilization. It was originally thought that all spiroplasmas require sterol for growth. Subsequent screening by Rose et al. (1993) showed that a minority of the spiroplasmas tested were able to sustain growth in mycoplasma broth base medium without sterols. The discovery that the sterol requirement in *Mollicutes* is polyphyletic greatly diminished the significance of sterol requirements in mollicute taxonomy (Tully et al., 1993).

Metabolic pathways and enzymes. The intermediary metabolism of *Mollicutes* has been reviewed (Miles, 1992; Pollack, 2002a, b; Pollack et al., 1997). Like all mollicutes, *Spiroplasma* species apparently lack both cytochromes and, except for malate dehydrogenase, the enzymes of the tricarboxylic acid cycle. They do not have an electron-transport system and their respiration is characterized as being flavin-terminated. McElwain et al. (1988) studied *Spiroplasma citri* and Pollack et al. (1989) screened ten spiroplasma species for 67 enzyme activities. All spiroplasmas were fermentative; their 6-phosphofructokinases (6-PFKs) required ATP for substrate phosphorylation during glycolysis. This enzymic requirement is common to all mollicutes except *Acholeplasma* and *Anaeroplasm* spp. The 6-PFKs of the species in these genera require pyrophosphate and cannot use ATP. Additionally, except for *Spiroplasma floridcola*, all *Spiroplasma* species have dUTPase activity. Pollack et al. (1989) also

reported that all spiroplasmas except *Spiroplasma floricola* have deoxyguanosine kinase activity. They found that deoxyguanosine, but no other nucleoside, could be phosphorylated to GMP with ATP.

Spiroplasmal proteins with multiple functions have been described. The CpG-specific methylase from *Spiroplasma monobiae* appears to also have topoisomerase activity (Matsuo et al., 1994). Protein P46 of *Spiroplasma citri* is a bifunctional protein in which the N-terminal domain represents ribosomal protein L29, whereas the C-terminal domain is capable of binding a specific inverted repeat sequence. It could be involved in regulation (Le Dantec et al., 1998). Such protein multifunctionality may reflect genomic economy in the small mollicute genome (Pollack, 2002b). However, functional redundancy has also been reported; *Spiroplasma citri* apparently has two distinct membrane ATPases (Simoneau and Labarère, 1991).

Genome size, genomic maps, and chromosomal rearrangements. PFGE revealed that the genome size range for spiroplasmas varied continuously (Pyle and Finch, 1988) from 780 kbp for *Spiroplasma platyhelix* to 2220 kbp for *Spiroplasma ixodetis* (Carle et al., 1995, 1990). There is a general trend for genomic simplification in *Spiroplasma* lineages. This trend culminated in loss of helicity and motility in the *Entomoplasmataceae* and eventually to the host transfer events forming the mycooides group of mycoplasmas (Gasparich et al., 2004).

The genome size of *Spiroplasma citri* varies among strains from 1650 to 1910 kbp (Ye et al., 1995). It was found that the relative positions of mapped loci were conserved in most of the strains, but that differences in the sizes of certain fragments permitted genome size variation. Genome size can fluctuate rapidly in spiroplasma cultures after a relatively short number of *in vitro* passages (Melcher and Fletcher, 1999; Ye et al., 1996). The genome of *Spiroplasma melliferum* is 360 kbp shorter than that of *Spiroplasma citri* strain R8-A2^T, but DNA hybridization has shown that the two spiroplasmas share extensive DNA hybridization (65%). Comparison of their genomic maps revealed that the genome region, which is shorter in *Spiroplasma melliferum*, corresponds to a variable region in the genomes of *Spiroplasma citri* strains and that a large region of the *Spiroplasma melliferum* genome is inverted in comparison with *Spiroplasma citri*. Therefore, chromosomal rearrangements and deletions were probably major events during evolution of the genomes of *Spiroplasma citri* and *Spiroplasma melliferum*. In addition, a large amount of noncoding DNA is present as repeat sequences (McIntosh et al., 1992; Nur et al., 1986, 1987) and integrated viral DNA (Bébéar et al., 1996) may also account for differences in genome sizes of closely related species.

Base composition. The DNA G+C content for most spiroplasma groups and subgroups has been determined (Carle et al., 1995, 1990; Williamson et al., 1998). Most group I spiroplasmas and *Spiroplasma poulsonii* have a G+C content of 25–27 mol%. However, the G+C content of subgroup I-6 *Spiroplasma insolitum* is significantly higher, indicating that the base composition of spiroplasmal DNA may shift over relatively short evolutionary periods. The range of G+C content of 25–27 mol% is modal for *Spiroplasma* and is also common in the Apis clade. However, *Spiroplasma mirum* (group V), strains of *Spiroplasma apis* (group IV), and group VIII strains have a G+C content of about 29–31 mol%. Restriction sites containing only G and C

nucleotides are not uniformly distributed over the genome (Ye et al., 1992).

Methylated bases. Methylated bases have been detected in spiroplasmal DNA (Nur et al., 1985). The gene encoding the CpG methylase in *Spiroplasma monobiae* has been cloned (Renbaum et al., 1990) and its mode of action studied (Renbaum and Razin, 1992).

DNA restriction patterns. Restriction patterns of spiroplasmal DNA, as determined by polyacrylamide gel electrophoresis, may be highly similar among strains of a given species (Bové et al., 1989). Variations in restriction fragment length patterns among strains of *Spiroplasma corruscae* correlated imperfectly with serological variation, so their significance was uncertain (Gasparich et al., 1998).

RNA genes. Some spiroplasmas, such as *Spiroplasma citri*, have only one rRNA operon, whereas others, such as *Spiroplasma apis*, have two (Amikam et al., 1984, 1982; Bové, 1993; Grau et al., 1988; Razin, 1985). The three rRNA genes are linked in the classical order found in bacteria: 5'-16S-23S-5S-3'. The sequence of the 16S rRNA gene (rDNA) of most spiroplasma species has been determined for phylogenetic studies (Gasparich et al., 2004; Weisburg et al., 1989). A gene cluster of ten tRNAs (Cys, Arg, Pro, Ala, Met, Ile, Ser, fMet, Asp, Phe) was identified in *Spiroplasma melliferum* (Rogers et al., 1987). Similar tRNA gene clusters have been cloned and sequenced from *Spiroplasma citri* (Citti et al., 1992).

Codon usage. In spiroplasmas, UGA is not a stop codon but encodes tryptophan. The universal tryptophan codon, UGG, is also used (Citti et al., 1992; Renaudin et al., 1986). Codon usage also reflects the A+T richness of spiroplasmal DNA (usually about 74 mol% A+T). For example, in *Spiroplasma citri*, UGA is used to code for tryptophan eight times more frequently than the universal tryptophan codon UGG (Bové, 1993; Citti et al., 1992; Navas-Castillo et al., 1992). Also, synonymous codons with U or A at the 5' or 3' ends are preferentially used over those with a C or G in that position.

RNA polymerase and spiroplasmal insensitivity to rifampicin. Spiroplasmas are insensitive to rifampicin. DNA-dependent RNA polymerases from *Spiroplasma melliferum* and *Spiroplasma apis* were at least 1000 times less sensitive to rifampicin than the corresponding *Escherichia coli* enzyme (Gadeau et al., 1986). Rifampicin insensitivity of *Spiroplasma citri* and all other mollicutes tested was found to be associated with the presence of an asparagine residue at position 526 in RpoB. The importance of the asparagine residue was confirmed by site-directed mutagenesis of the histidine codon (CAC) to an asparagine codon (AAC) at position 526 of *Escherichia coli* RpoB, resulting in a rifampicin-resistant mutant (Gaurivaud et al., 1996). The genetic organization surrounding the *rpoB* gene in spiroplasmas is also atypical. In many bacteria, *rpoB* is part of the β operon in which the four genes *rplK*, *rplA*, *rplJ*, and *rplL*, encoding ribosomal proteins L11, L1, L10, and L12, respectively, are located immediately upstream of *rpoB*; *rpoC* is immediately downstream of *rpoB*. In *Spiroplasma citri*, the gene organization is different in that the *hdsS* gene, encoding a component of a type I restriction-modification system, is upstream of *rpoB*. Sequences showing similarities with insertion elements are found between *hdsS* and *rpoB* (Laigret et al., 1996).

DNA polymerases and other proteins involved in DNA replication and repair. From genomic studies, it appears that *Mycoplasma* species carry the essential, multimeric enzyme for genomic DNA replication, DNA polymerase III. The subunit responsible for actual DNA biosynthesis is subunit α , encoded by *polC* (*dnaE*). The *polC* gene has been identified in all sequenced mollicute genomes, including *Spiroplasma citri*. The genes encoding the other subunits, *dnaN* (subunit β) and *dnaX* (subunits τ and γ), are also shared by the *Spiroplasma* and *Mycoplasma* species studied to date. So, it seems that spiroplasmas, like other mollicutes, possess DNA polymerase III and that it is probably the major DNA replication enzyme. However, there is also evidence for two additional DNA polymerases. A second gene for a DNA polymerase (enzyme B) was found in the *Spiroplasma citri* genome and there is evidence that the *Spiroplasma kunkelii* *polA* gene may encode a full-length DNA polymerase I protein (Bai and Hogenhout, 2002). DNA polymerase I is a single polypeptide that has, in addition to DNA synthesis activity, two exonuclease activities: exo-3' to 5' as well as exo-5' to 3'. At this stage, it is not possible to determine the equivalence between the three spiroplasmal DNA polymerases identified by sequencing (Pol III, enzyme B, and Pol I) and those originally detected biochemically (ScA, ScB, ScC) (Charron et al., 1979, 1982). As the *Spiroplasma citri* genome sequencing project has progressed, the following *Spiroplasma citri* genes involved in DNA replication have been detected: *dnaA*, *dnaB*, *polA*, *dnaE*, *polC*, *dnaN*, *dnaX*, *holB*, *dinB* (truncated), *dnaJ*, *dnaK*, *gyrA*, *gyrB*, *parC*, *parE*, *topA*, *rnhB*, *rnhC*, *rnpA*, *rnr*, *rnc*, *yrre*, *xseA*, *xseB*, and *ssb* (Carle et al., 2010; accession numbers AM285301–AM285339). Genes encoding DNA replication proteins have also been identified in *Spiroplasma kunkelii* (Bai and Hogenhout, 2002). *Spiroplasma citri* is highly sensitive to UV irradiation (Labarère and Barroso, 1989) and the organism has no functional *recA* gene, since a significant portion of the C-terminal part of the gene is lacking (Marais et al., 1996).

Origin of DNA replication. Even before the *Spiroplasma citri* genome project was initiated, some fragments with multiple open reading frames had been completely sequenced. For example, Ye et al. (1994b) sequenced a 5.6 kbp fragment containing genes for the replication initiation protein (*dnaA*), the beta subunit of DNA polymerase III (*dnaN*), and the DNA gyrase subunits A and B (*gyrA* and *gyrB*). Several *dnaA*-box consensus sequences were found upstream and downstream of the *dnaA* gene. From these data, it was established that the *dnaA* region was the origin of replication in *Spiroplasma citri* (Ye et al., 1994b). Zhao et al. (2004a) cloned a cell division gene cluster from *Spiroplasma kunkelii* and functionally characterized the key division gene, *ftsZ_{sk}*, and showed that it encodes a cell division protein similar to FtsZ proteins from other bacteria.

Spiralin. Spiralin, encoded by the *spi* gene, is the major membrane protein of *Spiroplasma citri* (Wróblewski et al., 1977, 1989). The deduced amino acid sequence of the protein (Bové et al., 1993; Chevalier et al., 1990; Saillard et al., 1990) corresponds well with the experimentally determined amino acid composition (Wróblewski et al., 1984). In particular, spiralin lacks tryptophan and, thus, has no UGG and/or UGA codons, which facilitates gene expression in *Escherichia coli*. Detailed analyses showed that all *Spiroplasma citri* spiralin genes were 241–242 amino acids long (Foissac et al., 1996). A conserved central

region and an amino acid sequence repetition, including a VTKXE consensus sequence, are present in all spiralin genes analyzed (Foissac et al., 1997a). Spiralin confers a significant amount of the antigenic activity in group I spiroplasmas (Whitcomb et al., 1983) and has a high degree of species specificity, although minor cross-reactions have been detected (Zaaria et al., 1990). The spiralin genes of *Spiroplasma citri* and *Spiroplasma melliferum* species, which have about 65% overall DNA–DNA hybridization, shared 89% nucleotide sequence identity and 75% deduced amino acid sequence similarity (Bové et al., 1993).

Spiralin mutants were constructed through homologous recombination in *Spiroplasma citri* to examine the role of spiralin *in vivo* (Duret et al., 2003). Phenotypic characterization of mutant 9a2 showed that, in spite of a total lack of spiralin, it maintained helicity and motility similar to the wild-type strain GII3 (Duret et al., 2003). When injected into the leafhopper vector, *Circulifer haematocaps*, the mutant multiplied to a high titer, but transmission efficiency to periwinkle plants was very low compared to the wild-type strain. In the infected plants, however, the spiralin-deficient mutant multiplied well and produced the typical symptoms of the disease. In addition, preliminary results indicated that the mutant could not be acquired by insects feeding on 9a2-infected plants, suggesting that spiralin may mediate spiroplasma invasion of insect tissues (Duret et al., 2003). In order to test this possibility, *Circulifer haematocaps* leafhopper proteins were screened as putative *Spiroplasma citri*-binding molecules using Far-Western analysis (Killiny et al., 2005). These experiments showed that spiralin is a lectin capable of binding to insect 50 and 60 kDa mannose glycoproteins. Hence, spiralin could play a key role in insect transmission of *Spiroplasma citri* by mediating spiroplasma adherence to epithelial cells of the insect vector gut or salivary gland (Killiny et al., 2005). This would also explain why the spiralin-negative mutant 9a2 is poorly transmitted by the vector and is not acquired by insects feeding on 9a2-infected plants.

Viruses. Four different virus types have been found in *Spiroplasma*, SpV1–SpV4. Use of SpV1 viruses for recombinant DNA studies in *Spiroplasma citri* is described later in the section on “Tools for molecular genetics of *Spiroplasma citri*”.

Cells of many spiroplasma species contain filamentous/rod-shaped viruses (SVCl = SpV1) that are associated with nonlytic infections (Bové et al., 1989; Ranhand et al., 1980; Renaudin and Bové, 1994). They belong to the *Plectrovirus* group within the *Inoviridae*. SpV1 viruses have circular, single-stranded DNA genomes (7.5 to 8.5 kbp), some of which have been sequenced (Renaudin and Bové, 1994). SpV1 sequences also occur as prophages in the genome of the majority of *Spiroplasma citri* strains studied (Renaudin and Bové, 1994). These insertions take place at numerous sites in the chromosomes of *Spiroplasma citri* (Ye et al., 1992) and *Spiroplasma melliferum* (Ye et al., 1994a). The SpV1-ORF3 and the repeat sequences could be part of an IS-like element of chromosomal origin. Resistance of spiroplasmas to virus infection may be associated with integration of viral DNA sequences in the chromosome or extrachromosomal elements (Sha et al., 1995). The evolutionary history of these viruses is unclear, but there is some evidence for virus and plasmid co-evolution in the group I *Spiroplasma* species (Gasparich et al., 1993a) and indications of potentially widespread horizontal transmission (Vaughn and de Vos, 1995). Virus infection of spiroplasma cells can pose problems in cultures. For example,

lyophilized early passages of *Spiroplasma citri* R8-A2^T proved difficult to grow and electron microscopy revealed that these cells carried large numbers of virions of virus SpV1-R8A2 (Cole et al., 1974). Likewise, SpV1 viruses have been found in *Spiroplasma poulsonii* (Cohen et al., 1987) and *Spiroplasma melliferum* (Liss and Cole., 1981); the *Spiroplasma melliferum* SpV1-KC3 virus forms plaques on various strains of *Spiroplasma melliferum*, including the type strain BC-3^T.

A second virus, reminiscent of a type B tailed bacterial virus, occurs in a small number of *Spiroplasma citri* strains (Cole et al., 1973). This SCV2 (= SpV2) virus is a polyhedron with a long, noncontractile tail. It may be associated with lytic infection. Infections in which large numbers of virions of SpV2 viruses are produced tend to be irregular and difficult to maintain under experimental conditions, so this is the least studied of the spiroplasma viruses.

A third virus (SpV3) forms polyhedral virions with short tails and has been found in many strains of *Spiroplasma citri* (Cole, 1979, 1977, 1974). The SpV3 genome is a linear double-stranded DNA molecule of 16 kbp, which can circularize to form a covalently closed molecule with single-stranded gaps, indicating that the linear molecule has cohesive ends. There is significant diversity among SpV3 viruses, extending even to major differences in genome sizes. Virus SpV3-AV9/3 was isolated from *Spiroplasma citri* strain ASP-9 (Stephens, 1980). Dickinson and Townsend (1984) isolated the SpV3 virus from plants infected with *Spiroplasma citri*. This virus, when plated on cells of *Spiroplasma citri*, had a plaque morphology typical of temperate phages. In spiroplasma cells that have been lysogenized, complete virus genomes may be integrated into the spiroplasma chromosome. These cells are then immune to superinfection by the lysogenizing virus, but susceptible to other SpV3 viruses. It is possible that lysogenization of *Spiroplasma citri* by SpV3-ai affects spiroplasma pathogenicity, particularly with respect to attenuation. *Drosophila* spiroplasmas, male-lethal or nonlethal, usually carry SpV3 viruses. Each strain of *Drosophila* spiroplasma carries an associated virus that is lytic to certain other strains (Oishi et al., 1984).

A fourth virus (SpV4), with a naked, icosahedral nucleocapsid 25 nm in diameter, was discovered (Ricard et al., 1982) in the B63 strain of *Spiroplasma melliferum*. SpV4 has a circular, single-stranded DNA genome (Renaudin and Bové, 1994; Renaudin et al., 1984a, b) and is a lytic *Spiromicrovirus* within the *Microviridae* (Chipman et al., 1998). Infection with this virus results in very clear plaques, indicating a lytic process. Host range studies (Renaudin et al., 1984a, b) have shown that only *Spiroplasma melliferum* is susceptible to SpV4. Two strains of *Spiroplasma melliferum*, including the type strain BC-3^T and B63, are not susceptible, as no plaques were formed on lawns of these spiroplasmas. These strains could be infected by transfection suggesting that resistance to the whole virus occurred at the level of adsorption or penetration of the virus (Renaudin and Bové, 1994; Renaudin et al., 1984b).

Genome sequencing. Genomic DNA sequencing efforts for two *Spiroplasma* species are in progress. For *Spiroplasma citri* GII3 (Carle et al., 2010; Saillard et al., 2008), assembly of 20,000 sequencing reads obtained from shotgun and chromosome specific libraries yielded: (1) 39 chromosomal contigs totalling 1525 kbp of the 1820 kbp *Spiroplasma citri* GII3 chromosome as well as (2) 8 circular contigs, which proved to represent seven

plasmids: pSciA (7.8 kbp), pSci1 to pSci6 (12.9 to 35.3 kbp), and one viral RF DNA (SVTS2). The chromosomal contigs contained 1905 putative genes or coding sequences (CDS). Of the CDS-encoded proteins, 29% are involved in cellular processes, cell metabolism, or cell structure. CDS for viral proteins and mobile elements represented 24% of the total, whereas 47% of the CDS were for hypothetical proteins with no known function; 21% of the total CDS appeared truncated as compared to their bacterial orthologs. Families of paralogs were mainly clustered in a large region of the chromosome opposite the origin of replication. Eighty-four CDS were assigned to transport functions, including phosphoenolpyruvate phosphotransferase systems (PTS), ATP binding cassette (ABC) transporters, and ferritin. In addition to the general enzymes EI and HPr, glucose- fructose- and trehalose-specific PTS permeases, and glycolytic and ATP synthesis pathways, *Spiroplasma citri* possesses a Sec-dependent protein export system and a nearly complete pathway for terpenoid biosynthesis. The sequencing of the *Spiroplasma kunkelii* CR2-3x genome (1.55 Mb) is also nearing completion (<http://www.genome.ou.edu/spiro.html>); the physical and genetic maps have been published (Dally et al., 2006). Several studies have begun to focus on gene content and genomic organization (Zhao et al., 2003, 2004a, b). Results show that, in addition to virus SpV1 DNA insertions, the *Spiroplasma kunkelii* genome harbors more purine and amino acid biosynthesis, transcriptional regulation, cell envelope, and DNA transport/binding genes than *Mycoplasmataceae* (e.g., *Mycoplasma genitalium* and *Mycoplasma pneumoniae*) genomes (Bai and Hogenhout, 2002).

Plasmids. Several plasmids have been discovered in spiroplasmas (Archer et al., 1981; Gasparich and Hackett, 1994; Gasparich et al., 1993a; Mouches et al., 1984a; Ranhand et al., 1980). They are especially common in spiroplasmas of group I. Eight extrachromosomal elements, including seven plasmids, were discovered during the *Spiroplasma citri* GII3 genome sequencing project. The six largest plasmids, pSci1 to pSci6, range from 12.9 to 35.3 kb (Saillard et al., 2008). *In silico* analyses of plasmid sequences revealed that they share extensive regions of homology and display a mosaic gene organization. Genes encoding proteins of the TraD-TraG, TrsE-TraE, and Soj-ParA protein families, were predicted in most of the pSci sequences. The presence of such genes, usually involved in chromosome integration, cell to cell DNA transfer, or DNA element partitioning; suggests that these molecules could be inherited vertically as well as horizontally. The largest plasmid, pSci6, encodes P32 (Killiny et al., 2006), a membrane-associated protein interestingly absent in all insect non-transmissible strains tested so far. The five remaining plasmids (pSci1 to pSci5) encode eight different *Spiroplasma citri* adhesion-related proteins. The complete sequences of plasmids pSKU146 from *Spiroplasma kunkelii* CR2-3x and pBJS-O from *Spiroplasma citri* BR3 have been reported (Davis et al., 2005; Joshi et al., 2005). These large plasmids, like the above *Spiroplasma citri* plasmids, encode an adhesin and components of a type IV translocation-related conjugation system. Characterizing the replication and stability regions of *Spiroplasma citri* plasmids resulted in the identification of a novel replication protein, suggesting that *Spiroplasma citri* plasmids belong to a new plasmid family and that the *soj* gene is involved in segregational stability of these plasmids (Breton et al., 2008a). Similar replicons were detected in various spiroplasmas of group I, such as *Spiroplasma melliferum*,

Spiroplasma kunkelii, *Spiroplasma* sp. 277F, and *Spiroplasma phoeniceum*, showing that they are not restricted to plant pathogenic spiroplasmas.

Tools for molecular genetics of *Spiroplasma citri*. Recent recombinant DNA tools are described in this section.

Several reports have been published concerning the use of SpV1 viruses as tools to introduce recombinant DNA into spiroplasmas, including optimization of transfection conditions (Gasparich et al., 1993b). The replicative form of SpV1 was used to clone and express the *Escherichia coli*-derived chloramphenicol acetyltransferase (*cat*) gene in *Spiroplasma citri*. Both the replicative form (RF) and the virion DNA produced by the transfected cells contained the *cat* gene sequences (Stamburski et al., 1991). The G fragment of the *Mycoplasma pneumoniae* cytoadhesin P1 gene could also be expressed in *Spiroplasma citri* (Marais et al., 1993) using a similar method. However, the recombinant RF proved unstable, resulting in the loss of the DNA insert (Marais et al., 1996).

Recombinant plasmids have also been developed to introduce genes into *Spiroplasma citri* cells. The introduced genes include antibiotic resistance markers and wild-type genes to complement auxotrophic mutants. Most recombinant plasmids contain the origin of DNA replication (*oriC*) of the *Spiroplasma citri* chromosome (Ye et al., 1994b). One such plasmid is pBOT1 (Renaudin, 2002; Renaudin et al., 1995). This plasmid contains a 2 kbp *oriC* region, a tetracycline resistance gene (*tetM*) from Tn916, and the linearized *Escherichia coli* plasmid pBS with a *colE1* origin of replication. Because of its two origins of replication, *oriC* and *colE1*, pBOT1 is able to shuttle between *Spiroplasma citri* and *Escherichia coli*. When introduced into *Spiroplasma citri*, pBOT1 replicates first as a free extrachromosomal element, but later integrates into the chromosome via homologous recombination involving a single crossover event in the *oriC* region. Once integrated into the host chromosome, the whole plasmid is stably maintained. Recent studies suggest that the broad host range *Spiroplasma citri* GII3 plasmids and their shuttle derivatives may have significant advantages over *oriC* plasmids for gene transfer and expression in spiroplasmas (Breton et al., 2008a). They transform *Spiroplasma citri* (as well as *Spiroplasma kunkelii* and *Spiroplasma phoeniceum*) strains at relatively high efficiencies, the growth of the transformants is not significantly affected, they do not integrate into the chromosome, and their stability/loss can be modulated depending upon the presence/absence of the *soj* gene.

Spiroplasma citri mutants have been produced by random and targeted approaches. The transposon Tn4001 has been used successfully for random mutagenesis of *Spiroplasma citri* (Foissac et al., 1997c). For targeted gene inactivation, plasmids derived from pBOT1 have been used to disrupt genes (e.g., fructose operon, motility gene *scmI*) through homologous recombination involving a single crossover event (Duret et al., 1999; Gaurivaud et al., 2000c). More recently, Lartigue et al. (2002) developed vector pC2, in which the *oriC* fragment was reduced to the minimal sequence needed to promote plasmid replication; this vector increases recombination frequency at the target gene. To avoid the extensive passaging that was required for recombination prior to transformant screening, vector pC55 was designed using a selective tetracycline resistance marker that is only expressed after the plasmid has integrated into the chromosome at the target gene. This approach was used to inactivate the spiralin gene (*spi*) and the gene encoding the

IICB component of the glucose phosphotransferase system permease (*ptsG*) (André et al., 2005; Duret et al., 2003; Lartigue et al., 2002). Another series of recombinant plasmids, the pGOT vectors, allow for selection of rare recombination events by using two distinct selective markers. First, transformants are screened for their resistance to gentamicin and next, site-specific recombinants are selected for based on their resistance to tetracycline, which can only be expressed through recombination at the target gene. In this way, inactivation of the *crr* gene, encoding the glucose phosphotransferase permease IIA component, was obtained (Duret et al., 2005). The use of the transposon $\gamma\delta$ TnpR/res recombination system to produce unmarked mutations (i.e., without insertion of antibiotic markers) in *Spiroplasma citri* was demonstrated by the production of a disrupted *arcA* mutant (Duret et al., 2005); *arcA* encodes arginine deiminase. In this system, the target gene is disrupted by integration of a plasmid containing target gene sequences along with the *tetM* gene flanked by binding-specific recombination (*res*) sites. After integration of the plasmid, a second plasmid is introduced that encodes the resolvase TnpR. TnpR mediates the resolution of the cointegrate at the *res* sites, thereby removing *tetM* but leaving behind a mutated version of the target gene. The TnpR-encoding plasmid is lost spontaneously when selective pressure is removed.

Antigenic structure. Growth inhibition tests (Whitcomb et al., 1982) were used in the early years to identify spiroplasma species or groups, but metabolism inhibition (Williamson et al., 1979b; Williamson and Whitcomb, 1983) and deformation tests (Williamson et al., 1978) are now used almost exclusively (see below).

Antigenic variability, which has been described for some *Mycoplasma* species (Rosengarten and Wise, 1990; Yogev et al., 1991), has not been demonstrated in spiroplasmas (R. Rosengarten, personal communication).

Group classification. The classification of spiroplasmas was first proposed by Junca et al. (1980) and has been revised periodically (Tully et al., 1987; Williamson et al., 1998). These classifications are based on serological reactions of the organisms in growth inhibition, deformation and metabolism inhibition tests and/or characteristics of their genomes. Development of a classification scheme has resulted in the delineation of spiroplasma groups and subgroups (Table 142). In the scheme, "groups" have been defined as clusters of similar organisms, all of which possess negligible DNA–DNA hybridization with representatives of other groups, but moderate to high levels of hybridization (20–100%) with each other. Groups are, therefore, putative species. This level of genomic differentiation correlates well with substantial differences in serology. Thirty-four groups were presented in a revised classification of spiroplasmas in 1998 (Williamson et al., 1998). Four additional groups (XXXV–XXXVIII) were proposed recently as the result of a global spiroplasma environmental survey (Whitcomb et al., 2007) and more are anticipated (Jandhyam et al., 2008). Subgroups have been defined by the International Committee on Systematics of Bacteria (ICSB) Subcommittee on the Taxonomy of *Mollicutes* (ICSB, 1984) as clusters of spiroplasma strains showing intermediate levels of intragroup DNA–DNA hybridization (10–70%) and possessing corollary serological relationships. Three spiroplasma groups [group I (Junca et al., 1980; Saillard et al., 1987), group VIII (Gasparich et al., 1993c), and

group XVI (Abalain-Colloc et al., 1993)] have been divided into a total of 15 subgroups. "Serovars" have been defined as genotypic clusters varying substantially in metabolism inhibition and deformation serology, but that are insufficiently differentiated from members of existing groups or subgroups to warrant separation. However, with the discovery of a large number of strains for some groups (e.g., group VIII), the serovar/subgroup picture has become very confused (Regassa et al., 2004; see *Phylogeny*, below).

Procedures for species descriptions and minimal standards. Species descriptions of spiroplasmas have been in accord with recommendations of minimum standards proposed by the ICSP (International Committee on Systematics of Prokaryotes) Subcommittee on the Taxonomy of *Mollicutes* (Brown et al., 2007).

Cloning. Production of spiroplasma lineages produced from a single cell or clonings are performed largely by serial dilution of filtered cultures using 96-well microtiter plates (Whitcomb et al., 1986; Whitcomb and Hackett, 1987). At a certain dilution, which varies from plating to plating, the mean number of cells per well decreases so that fewer than about 8 of the 96-wells support growth of a spiroplasma clone. Very probably, such clones arise from a single spiroplasmal cell.

Cellular morphology. Using dark-field microscopy, cultures should appear helical and motile during at least one growth phase (see "Morphology" and "Motility" above). However, morphological exceptions do occur (see "Differentiating characters" below and reviewed by Gasparich et al., 2004).

16S rRNA gene sequence analysis. Preliminary identification is performed by PCR amplification using universal 16S rRNA (Gasparich et al., 2004) or other described primers (e.g., Fukatsu and Nikoh, 1998; Jandhyam, 2008). DNA sequence analysis using a BLAST search provides preliminary placement within the genus *Spiroplasma*. Those strains showing close phylogenetic relationships based on 16S rRNA gene sequence analyses should then be screened using serological tests.

Serological tests. The deformation test (Williamson et al., 1978) is used routinely for serological analyses. Reciprocal titers of ≥ 320 are generally required for definitive group placement. Deformation is defined as entire or partial loss of helicity. At the end point, cells are often seen in which an unaffected part of the helical filament exhibits flexing motility despite the presence of a bleb on another part of the cell. The deformation titer is the reciprocal of the final antiserum dilution that exhibits deformation of $\geq 50\%$ of the cells. Antiserum should be produced for any strain thought to represent a novel serogroup and any positive test against characterized groups requires a reciprocal test using the newly prepared antiserum.

The high levels of specificity and sensitivity of the metabolism inhibition test make it especially useful for defining groups and subgroups (Williamson et al., 1979b; Williamson and Whitcomb, 1983). Other serological tests have also been employed for characterization of spiroplasmas. Growth inhibition tests were used for delineation of spiroplasma groups I through XI (Whitcomb et al., 1982), but were not used thereafter. Growth inhibition tests are problematic for spiroplasmas because they require development of procedures for obtaining colonies. The spiroplasma motility inhibition test (Hackett et al., 1997) has proved useful for determination of intraspecific variation in

Spiroplasma leptinotarsae. ELISA has been used for detection of *Spiroplasma kunkelii* (Gordon et al., 1985) and *Spiroplasma citri* (Saillard and Bové, 1983).

Optimum growth temperature. Optimal growth temperatures between 10 and 41°C have been determined (Konai et al., 1996a).

Substrate metabolism. The ability to ferment glucose and produce acid must be examined (Aluotto et al., 1970). The ability to hydrolyze arginine and produce ammonia should be assessed (Barile, 1983). See the section on "Biochemical reactions" above for more details.

Ecology. The species description must include ecological information such as isolation site within the host and cultivation conditions, common and binomial host name, geographical location of host (with GPS), any known interaction between the spiroplasma and its host, and, in the case of a pathogen, disease symptoms observed.

Antibiotic sensitivities. In early studies (Bowyer and Calavan, 1974; Liao and Chen, 1981b), spiroplasmas proved to be especially sensitive *in vitro* to tetracycline, erythromycin, tylosin, tobramycin, and lincomycin. Strains have been isolated that are permanently resistant to kanamycin, neomycin, gentamicin, erythromycin, and several tetracycline antibiotics (Liao and Chen, 1981b). Insensitivity to rifampicin has been studied in relation to its inhibition of transcription (see "RNA polymerase and spiroplasmal insensitivity to rifampicin" above) and penicillin insensitivity is seen for all spiroplasmas due to the lack of a cell wall. Natural amphipathic peptides such as Gramicidin S alter the membrane potential of spiroplasma cells and induce the loss of cell motility and helicity (Bévén and Wróblewski, 1997). The toxicity of the lipopeptide antibiotic globomycin was found to be correlated with an inhibition of spiralin processing (Bévén et al., 1996). As with Gramicidin S, the antibiotic was effective against spiroplasmas, but not *Mycoplasma mycoides*. Natural 18-residue peptaibols (trichorzins PA) are bacteriocidal to spiroplasmas (Bévén et al., 1998). The mode of action appears to be permeabilization of the host cell membrane.

Hosts, ecology, and pathogenicity

Hosts. Almost all spiroplasmas have been found to be associated with arthropods or an arthropod connection is strongly suspected. Hackett et al. (1990) searched for mollicutes in a wide variety of insect orders. Isolates were obtained from six orders and 14 insect families. Only one of these orders, Odonata (dragonflies), was primitive (heterometabolous) and it was speculated that the spiroplasma from a dragonfly host might have been acquired via predation. Hackett et al. (1990) suggested that the *Spiroplasma/Entomoplasma* clade may have arisen in a paraneopteran-holometabolous ancestor, coevolved with these orders, and never adapted to more primitive insect orders. Some insect families have an especially rich spiroplasma, entomoplasma, and mesoplasma flora.

Insect gut. The majority of spiroplasmas appear to be maintained in an insect gut/plant surface cycle. Clark (1984) hypothesized several types of gut infection in which persistence in the gut and the ability to invade hemolymph varied among spiroplasma species. It has been hypothesized (Hackett and Clark, 1989) that the gut cycle was primitive and that other cycles were derived from it. Spiroplasmas have been isolated from guts of

tabanids (Diptera: Tabanidae) worldwide (French et al., 1997, 1990, 1996; Jandhyam et al., 2008; Le Goff et al., 1991, 1993; Regassa and Gasparich, 2006; Vazeille-Falcoz et al., 1997; Whitcomb et al., 1997a). Examination of diversity trends among the tabanid isolates suggests that spiroplasma diversity increases with temperature, resulting in more diversity in southern climes in the Northern Hemisphere (Whitcomb et al., 2007). Although evidence points strongly to multiple cycles of horizontal transmission, the sites where such transmission occurs remain unknown. However, some tabanids utilize honeydew (excreta of sucking insects) deposited on leaf surfaces, suggesting a possible transmission mechanism. Mosquitoes (Chastel and Humphery-Smith, 1991) are also common spiroplasma hosts (Lindh et al., 2005). Additionally, spiroplasmas inhabit the gut of ground beetles (*Harpalus pensylvanicus* and *Anisodactylus sanctaerucis*) as evidenced by 16S rRNA gene sequence analysis of the digestive tract bacterial flora (Lundgren et al., 2007).

Plant surfaces. Flowers and other plant surfaces represent a major site where spiroplasmas and other microbes are transmitted from insect to insect (Clark, 1978; Davis, 1978; McCoy et al., 1979). Members of several spiroplasma groups have been isolated only from flowers and strains of several other spiroplasmas have been isolated from both insects and flowers. Biological evidence suggests that mosquito spiroplasmas are transmitted from insect to insect on flowers (Chastel et al., 1990; Le Goff et al., 1990). It is not known whether any of the so-called “flower spiroplasmas” can exist as true epiphytes. Isolations of spiroplasmas from a variety of insects (Clark, 1982; Hackett et al., 1990) suggest that it is likely that many or most of these flower isolates are deposited passively by visiting arthropods.

Plant phloem and sucking insects. Several spiroplasmas possess a life cycle that involves infection of plant phloem and homopterous insects (Bové, 1997; Fletcher et al., 1998; Garnier et al., 2001; Saglio and Whitcomb, 1979). In the course of passage through the insect, spiroplasmas pass through, accumulate, or multiply in gut epithelial cells and salivary cells. They also accumulate in the insect neurolemma. Large accumulations of spiroplasma cells occur frequently in the hemolymph, where they undoubtedly multiply (Whitcomb and Williamson, 1979). Spiroplasmas may multiply in a number of sucking insect species that have been exposed to diseased plants, but often only a single vector or several vector species transmit spiroplasma pathogens from plant to plant (summarized in Calavan and Bové, 1989; Whitcomb, 1989; Kersting and Sengonca, 1992).

Sex ratio organisms. Once thought to be a genetic factor, the sex ratio trait in *Drosophila* was shown by Poulson and Sakaguchi (1961) to be induced by a micro-organism, *Spiroplasma poulsonii* (Williamson et al., 1999). A number of other spiroplasmas in a variety of insect hosts have been identified that also cause sex ratio distortions, including isolates from the chrysomelid beetle *Adalia bipunctata* (Hurst and Jiggins, 2000; Hurst et al., 1999) and the butterfly *Danaus chrysippus* (Jiggins et al., 2000). In addition, 16S rRNA gene sequence analysis identified spiroplasmas as the causative agent for male-killing: in a population of *Harmonia axyridis* (ladybird beetle) in Japan (Nakamura et al., 2005); in populations of *Drosophila neocardini*, *Drosophila ornatifrons* and *Drosophila paraguayensis* from Brazil (Montenegro et al., 2006, 2005); in populations of *Anisosticta novemdecimpunctata* (ladybird beetle) in Britain (Tinsley and Majerus, 2006); in

a population of *Adalia bipunctata* (Sokolova et al., 2002); in several strains from the Tucson *Drosophila* stock culture collection (Mateos et al., 2006); and in *Drosophila melanogaster* populations from Uganda and Brazil (Pool et al., 2006). Other organisms closely associated with their insect hosts were discovered inferentially by PCR studies (Fukatsu and Nikoh, 2000, 2001) and also appear to be related to *Spiroplasma mirum*. They also cause preferential male killing in an infected *Drosophila* population (Anbutsu and Fukatsu, 2003). Natural infection rates of male-killing spiroplasmas in *Drosophila melanogaster* are about 2.3%, as determined for a Brazilian population (Montenegro et al., 2005), and vary between 0.1 and 3% for Japanese populations of *Drosophila hydei* (Kageyama et al., 2006). The male-killing spiroplasma strain isolated from *Adalia bipunctata* was used to artificially infect eight different coccinellid beetle species. The data suggest that host range could serve to limit horizontal transfer to closely related host species (Tinsley and Majerus, 2007). Supporting this hypothesis was the study that showed the interspecific lateral transmission of spiroplasmas from *Drosophila nebulosa* to *Drosophila willistoni* via ectoparasitic mites (Jaenike et al., 2007). A recent multilocus analysis by Haselkorn et al. (2009) showed that *Drosophila* species are infected with at least four distinct spiroplasma haplotypes.

Studies on *Drosophila* infections by the sex-ratio organism showed that it did not induce the innate immunity of the insect (Hurst et al., 2003). The sex-ratio spiroplasmas have been shown to be vertically transmitted through female hosts, with spiroplasmas present during oogenesis (Anbutsu and Fukatsu, 2003). Although the exact mechanism of male-killing has not been determined, studies have shown that male killing occurs shortly after formation of the host dosage compensation complex (Bentley et al., 2007) and that male *Drosophila melanogaster* mutants lacking any of the five genes involved in the dosage compensation complex are not killed (Veneti et al., 2005). In the Kenyan butterfly *Danaus chrysippus*, a correlation between male killing and a recessive allele for a gene controlling infection susceptibility has been reported. Moreover, infections seemed to have a negative effect on body size (Herren et al., 2007).

Ticks. Three *Spiroplasma* species have been isolated from ticks. Two of these, *Spiroplasma mirum* and *Spiroplasma* sp. 277F, are from the rabbit tick *Haemaphysalis leporispalustris* (Tully et al., 1982; Williamson et al., 1989). The third species was isolated from *Ixodes pacificus* ticks and named *Spiroplasma ixodetis* (Tully et al., 1995). 16S rRNA gene sequence analysis of spiroplasmas originally isolated from *Ixodes* ticks and growing in a Buffalo Green Monkey mammalian cell culture line showed a high degree of identity with the *Spiroplasma ixodetis* 16S rRNA gene (Henning et al., 2006). Analysis of the 16S rRNA gene sequence from DNA extracted from unfed *Ixodes ovatus* from Japan indicated the presence of spiroplasmas that were also closely related to *Spiroplasma ixodetis* (Taroura et al., 2005). The ability of tick spiroplasmas, including *Spiroplasma ixodetis*, to multiply at 37°C reflects the role of vertebrates as tick hosts. The ability of *Spiroplasma ixodetis* to grow at 32°C as well as 37°C (Tully et al., 1982) may reflect the ecology of some of the cold-blooded vertebrate hosts of these ticks. There is no evidence that any of these spiroplasmas are transmitted to vertebrate hosts of the ticks.

Crustaceans. *Spiroplasma* sp. have recently been isolated in both freshwater and salt-water crustaceans.

Spiroplasma penaei (strain SHRIMP^T) was isolated from the hemolymph of Pacific white shrimp (*Penaeus vannamei*) after high mortalities were observed in an aquaculture pond in Columbia, South America (Nunan et al., 2004). The pathogenic agent was the spiroplasma (Nunan et al., 2005). Although not cultivated, 16S rRNA gene sequence analysis also revealed the presence of spiroplasmas in the gut of the hydrothermal shrimp *Rimicaris exoculata* (Zbinden and Cambon-Bonavita, 2003). In another outbreak, Chinese mitten crab (*Eriocheir sinensis*) reared in aquaculture ponds in China became infected with tremor disease. The causative agent was determined to be a spiroplasma with 99% 16S rRNA gene sequence identity to *Spiroplasma mirum* (Wang et al., 2004a, b). However, recent studies suggest that the infective agent may be a species similar to, but distinct from, *Spiroplasma mirum* (Bi et al., 2008). The same organism also infects red swamp crayfish (*Procambarus clarkii*) that are co-reared with the Chinese mitten crab (Bi et al., 2008; Wang et al., 2005) as well as the shrimp *Penaeus vannamei* (Bi et al., 2008).

Other hosts. Spiroplasmas have been identified in a variety of other hosts, although not necessarily linked to the gut habitat. The first spiroplasma isolated from a lepidopteran came from the hemolymph of white satin moth larvae (*Leucoma salicis* L.) from Poland (designated strain SMA^T) and was serologically distinct from any previously described spiroplasma group (Oduori et al., 2005). Another novel spiroplasma (designated strain GNAT3597^T) was isolated from biting midges from the genus *Atrichopogon* (Koerber et al., 2005). Spiroplasmas that are closely related to the male-killing spiroplasmas in ladybird beetles (Majerus et al., 1999; Tinsley and Majerus, 2006) have also been identified in the predatory mite *Neoseiulus californicus* using 16S rRNA gene sequence analysis (Enigl and Schausberger, 2007). A broad survey of 16 spider families for the presence of endosymbionts using 16S rRNA gene sequence analysis revealed that six families contained spiroplasmas, including *Agelenidae*, *Araneidae*, *Gnaphosidae*, *Linyphiidae*, *Lycosidae*, and *Tetragnathidae* (Goodacre et al., 2006).

Biogeography. Spiroplasmas have been identified from hosts in Africa, Asia, Australia, Europe, South America, and North America. While they are worldwide in distribution, studies suggest that biodiversity may be greatest in warm climates (Whitcomb et al., 2007). Because spiroplasmas are host-associated, it seems reasonable that *Spiroplasma* species distribution would be limited by host biogeography. Early studies indicated that some spiroplasmas have discrete geographic distributions (Whitcomb et al., 1990). As the diversity of sampling sites increases, the view of spiroplasma biogeography is likely to shift (Regassa and Gasparich, 2006). Distinct distributions may exist, but probably on a larger geographic scale. While it is not clear what factors account for spiroplasma ranges, the level of host specificity and host overwintering ranges may contribute to the biogeography of *Spiroplasma* species (Whitcomb et al., 2007).

Pathogenicity. Symptoms of infection and confirmation of Koch's postulates have been reported for the etiologic roles of: *Spiroplasma citri* in "stubborn" disease of citrus (Calavan and Bové, 1989; Markham et al., 1974); corn stunt spiroplasma (Chen and Liao, 1975; Nault and Bradfute, 1979; Williamson and Whitcomb, 1975); *Spiroplasma phoeniceum* in aster, an experimental host (Saillard et al., 1987); *Spiroplasma poulsonii*

in *Drosophila pseudoobscura* (Williamson et al., 1989); *Spiroplasma penaei* in *Penaeus vannamei* (Nunan et al., 2005); and *Spiroplasma eriocheiris* (Wang et al., 2010) in the Chinese mitten crab, *Eriocheir sinensis* (Wang et al., 2004b). Recent studies have focused on spiroplasma infection and replication in the midgut and Malpighian tubules of leafhoppers (Özbek et al., 2003). The use of immunofluorescence confocal laser scanning microscopy has revealed the presence of *Spiroplasma kunkelii* in the midgut, filter chamber, Malpighian tubules, hindgut, fat tissues, hemocytes, muscle, trachea, and salivary glands of leafhopper hosts, but not in the nerve cells of the brain or nerve ganglia (Ammar and Hogenhout, 2005). Plant spiroplasmas may also be pathogenic for unusual vectors (Whitcomb and Williamson, 1979), but are much less so for their usual host (Madden and Nault, 1983; Nault et al., 1984). In fact, some spiroplasmas are beneficial to their leafhopper hosts (Ebbert and Nault, 1994) and it has been hypothesized that infection plays an important role in the host's overwintering strategies (Moya-Raygoza et al., 2007a, b; Summers et al., 2004).

Spiroplasma mirum is experimentally pathogenic for a variety of suckling animals, causing cataract and other ocular symptoms, neural pathology (Clark and Rorke, 1979), and malignant transformation in cultured cells (Kotani et al., 1990). *Spiroplasma melliferum* also persists and causes pathology in suckling mice (Chastel et al., 1990, 1991). *Spiroplasma eriocheiris* is neurotropic to brain tissue in experimentally injected chicken embryos (Wang et al., 2003). There are two recent reports of spiroplasmas in aquatic invertebrates. Nunan et al. (2005) characterized a spiroplasma in commercially raised shrimp that led to a lethal disease. *Spiroplasma melliferum* and *Spiroplasma apis* cause disease in honey bees (Clark, 1977; Mouches et al., 1982a, 1983a). Intrathoracic inoculation of *Spiroplasma taiwanense* reduced the survival and impaired the flight capacity of inoculated mosquitoes (Humphery-Smith et al., 1991a), and inoculation of *Spiroplasma taiwanense* per os decreased the survival of mosquito larvae in laboratory trials (Humphery-Smith et al., 1991b). *Spiroplasma poulsonii* causes sex ratio abnormalities (male-killing) in *Drosophila* (Williamson and Poulson, 1979). Male-killing spiroplasma strains related to *Spiroplasma poulsonii* cause necrosis in neuroblastic and fibroblastic cells (Kuroda et al., 1992). The significance of some biological properties of spiroplasmas is incompletely understood. For example, membranes of *Spiroplasma monobiae* are potent inducers of tumor necrosis factor alpha secretion and of blast transformation (Sher et al., 1990a, b) in insect cell culture.

Spiroplasmas are implicated by circumstantial evidence, in the view of some workers, to be associated with human disease. Bastian first claimed in 1979 that spiroplasmas were associated with Creutzfeldt-Jakob Disease (CJD), an extremely rare scrapie-like disease of humans (Bastian, 1979). Bastian and Foster (2001) reported finding spiroplasma 16S rRNA genes in CJD- and scrapie-infected brains that were not observed in controls. More recent studies (Bastian et al., 2004) presented evidence to show that spiroplasma 16S rRNA genes were found in brain tissue samples from scrapie-infected sheep, chronic wasting disease-infected cervids, and CJD-infected humans. All the brain tissues from non-infected controls were negative for spiroplasmal DNA. These authors further showed that the sequence of the PCR products from the infected brains was 96% identical to the *Spiroplasma mirum* 16S rRNA gene. However, these

results could not be replicated in an independent blind study of uninfected and Scrapie-infected hamster brains using the same primers (Alexeeva et al., 2006). A recent study to fulfill Koch's postulate reported the transfer of spiroplasma from transmissible spongiform encephalopathy (TSE) brains and *Spiroplasma mirum* to induce spongiform encephalopathy in ruminants (Bastian et al., 2007). The current status of the involvement of spiroplasmas in TSE is the subject of recent reviews (Bastian, 2005; Bastian and Fermin, 2005). Other proposed connections between mollicutes and human disease have been evaluated by Baseman and Tully (1997).

Mechanism of *Spiroplasma citri* phytopathogenicity. Transposon (Tn4001) mutants have been examined extensively to elucidate the molecular mechanisms associated with *Spiroplasma citri* phytopathogenicity. One of these mutants, GMT553, highlighted the involvement of selective carbohydrate utilization in *Spiroplasma citri* pathogenicity (see review by Bové et al., 2003). When introduced into periwinkle plants via injected leafhoppers (*Circulifer haematocaps*), GMT553 multiplied in the plants as actively as wild-type *Spiroplasma citri* strain GII3, but did not induce symptoms (Foissac et al., 1997b, c; Gaurivaud et al., 2000b). In this mutant, the transposon was found to be inserted in *fruR*, a transcriptional activator of the fructose operon (*fruRAK*; Gaurivaud et al., 2000a). The second gene of the operon, *fruA*, encodes fructose permease, which enables uptake of fructose; and the third gene, *fruK*, encodes 1-phosphofructokinase. In mutant GMT553, transcription of the fructose operon is abolished and, hence, the mutant cannot utilize fructose as a carbon or energy source (Gaurivaud et al., 2000a). Mutant GMT553 was functionally complemented for fructose utilization and phytopathogenicity in *trans* by a recombinant *fruR-fruA-fruK* operon, *fruA-fruK* partial operon, or *fruA* alone, but not *fruR* or *fruR-fruA* (Gaurivaud et al., 2000a, b). It should be pointed out that both fructose⁺ and fructose⁻ spiroplasmas are able to utilize glucose.

Further insight into *Spiroplasma citri* phytopathogenicity in relation to sugar metabolism comes from the production of a spiroplasma mutant unable to use glucose (André et al., 2005). The import of glucose into *Spiroplasma citri* cells involves a phosphotransferase (PTS) system composed of two distinct polypeptides encoded by (1) *crr* (glucose PTS permease IIA^{Glc} component) and (2) *ptsG* (glucose PTS permease IICB^{Glc} component). A *ptsG* mutant (GII3-glc1) proved unable to import glucose. When introduced into periwinkle (*Catharanthus roseus*) plants through leafhopper transmission, the mutant induced severe symptoms similar to those obtained with wild-type GII3, in strong contrast to the fructose operon mutant, GMT553, which was virtually non-pathogenic. These results indicated that fructose and glucose utilization were not equally involved in pathogenicity and are consistent with biochemical data showing that, in the presence of both sugars, *Spiroplasma citri* preferentially used fructose. NMR analyses of carbohydrates in plant extracts revealed the accumulation of soluble sugars, particularly glucose, in plants infected by wild-type *Spiroplasma citri* GII3 or GII3-glc1, but not in those infected by GMT553. In the infected plant, *Spiroplasma citri* cells are restricted to the sieve tubes. In the companion cell, sucrose is cleaved by invertase to fructose and glucose. In the sieve tube, wild-type *Spiroplasma citri* cells will use fructose preferentially over glucose leading to a decreased fructose concentration and, consequently, to an increase of invertase activity, which

in turn results in glucose accumulation. Glucose accumulation is known to induce stunting and repression of photosynthesis genes in *Arabidopsis thaliana*. Such symptoms are precisely those observed in periwinkle plants infected by wild-type *Spiroplasma citri* (André et al., 2005).

Genes that are up- or down-regulated in plants following infection with *Spiroplasma citri* have been studied by differential display analysis of mRNAs in healthy and symptomatic periwinkle plants (Jagoueix-Eveillard et al., 2001). Expression of the transketolase gene was inhibited in plants infected by the wild-type spiroplasma, but not by the non-phytopathogenic mutant GMT553, further indicating that sugar metabolism and transport are important factors in pathogenicity. Sugar PTS system permeases have been shown to be important in rapid adaptation to sugar differences between plant host and insect vector (André et al., 2003).

Leafhopper transmission of *Spiroplasma citri*. Spiroplasmas are acquired by leafhopper vectors that imbibe sap from the sieve tubes of infected plants. However, in order to be transmitted to a plant, the mollicutes need first to multiply in the insect vector after crossing the gut barrier (Wayadande and Fletcher, 1995). They multiply to high titers (10⁶-10⁷/ml) in the insect hemolymph, but only when they have reached the salivary glands can they be inoculated into a plant. One gene required for efficient transmission, *sc76*, was inactivated in a transposon mutant (G76) with reduced transmissibility (Boutareaud et al., 2004); *sc76* encodes a putative lipoprotein. Plants infected with the G76 mutant showed symptoms 4-5 weeks later than those infected with wild-type GII3, but when they appeared, the symptoms induced were severe. Mutant G76 multiplied in plants and leafhoppers as efficiently as the wild-type strain. However, leafhoppers injected with the wild-type spiroplasma transmitted the spiroplasma to 100% of exposed plants. In contrast, those injected with mutant G76 infected only 50% of the plants. This inefficiency was shown to be associated with a numerical decrease in spiroplasma cells in the salivary glands that correlated with reduced output from the stylets of transmitting leafhoppers; the number of mutant cells transmitted through Parafilm membranes was less than 5% of numbers of wild-type cells transmitted based on colony-forming units. Functional complementation of the G76 mutant with the *sc76* gene restored the wild-type phenotype. Because both wild-type and mutant cells multiplied to equally high titers in the hemolymph, the results suggest that the mutant is inefficiently passed from the hemolymph into the salivary glands or that it may multiply to a lower titer in the glands.

Transmission of *Spiroplasma citri* by leafhopper vectors must involve adherence to and invasion of insect host cells. Electron microscopic studies of leafhopper midgut by Ammar et al. (2004) have demonstrated the attachment of *Spiroplasma kunkelii* cells by a tip structure to the cell membrane between microvilli of epithelial cells. *Spiroplasma citri* surface protein P89 was shown to mediate adhesion of the spiroplasma to cells of the vector *Circulifer tenellus* and was designated SARP1 (Berg et al., 2001; Yu et al., 2000). The gene encoding SARP1, *arp1*, was cloned and characterized from *Spiroplasma citri* BR3-T. The putative gene product SARP1 contains a novel domain at the N terminus, called "sarpin" (Berg et al., 2001). The *arp1* gene is located on plasmid pBJS-O in *Spiroplasma citri* (Joshi et al., 2005). The *Spiroplasma kunkelii* plasmid pSKU146 encodes an

adhesin that is a homolog of SARP1 (Davis et al., 2005). Other spiroplasma plasmids encode additional adhesin-related proteins. As indicated above (see *Plasmids*), *Spiroplasma citri* GII3 contains six large plasmids, pSci1 to pSci6 (Saillard et al., 2008). Although plasmids pSci1 to pSci5 encode eight different *Spiroplasma citri* adhesin-related proteins (ScARPs), they are not required for insect transmission (Berho et al., 2006b). One of the ScARPs, protein P80, shared 63% similarity and 45% identity with SARP1. Protein P80 is carried by plasmid pSci4 and has been named ScARP4a. The ScARP-encoding genes could not be detected in DNA from non-transmissible strains (Berho et al., 2006b). Sequence alignments of ScARP proteins revealed that they share common features including a conserved signal peptide followed by six to eight repeats of 39–42 amino acids each, a central conserved region of 330 amino acids, and a transmembrane domain at the C terminus (Saillard et al., 2008).

Plasmid pSci6 carries the gene for protein P32, which is present in all *Spiroplasma citri* strains capable of being transmitted by the leafhopper vector *Circulifer haematocaps*, but absent from all non-transmissible strains (Killiny et al., 2006). Complementation studies with P32 alone did not restore transmissibility (Killiny et al., 2006). However, if the pSci6 plasmid was transferred to an insect-non-transmissible *Spiroplasma citri* strain, then the phenotype could be converted to insect-transmissible, indicating the likely presence of additional transmissibility factors on pSci6 (Berho et al., 2006a). Indeed, recent data indicates that factors essential for transmissibility are encoded by a 10 kbp fragment of pSci6 (Breton et al., 2010). The finding that the insect-transmissible strain *Spiroplasma citri* Alc254 contains only a single plasmid, pSci6 (S. Richard and J. Renaudin, unpublished) also reinforces the hypothesis that pSci6-encoded determinants play a key role in insect transmission of *Spiroplasma citri* by its leafhopper vector.

Enrichment and isolation procedures

Isolation. Success in the isolation of fastidious spiroplasmas is influenced strongly by the titer of the inoculum. Spiroplasmas have been isolated from salivary glands, gut, and nerve tissues of their insect hosts. Many spiroplasmas envisioned by dark-field microscopy have proved to be noncultivable (Hackett and Clark, 1989). Initial insect extracts in growth media are passed through a 0.45 μm filter. The filtrate is then observed daily for pH indicator change. An alternative to filtration involves the use of antibiotics or other inhibitors (Grulet et al., 1993; Markham et al., 1983; Whitcomb et al., 1973). Spiroplasma isolations from infected plants are best obtained from sap expressed from vascular bundles of hosts showing early disease symptoms. Plant sap often contains spiroplasmal substances (Liao et al., 1979) whose presence in primary cultures may necessitate blind passage or serial dilution.

Isolation media. MID medium (Whitcomb, 1983) has been used for primary isolations of the large proportion of spiroplasma species. SP-4 medium, a rich formulation derived from experiments with MID, is necessary for isolation of *Spiroplasma mirum* from fluids of the embryonated egg (Tully et al., 1982). SP-4 medium is also required for isolation of *Spiroplasma ixodetis* (Tully et al., 1981). Some very fastidious spiroplasmas such as *Spiroplasma poulsonii* (Hackett et al., 1986) and *Spiroplasma*

leptinotarsae (Hackett and Lynn, 1985) were isolated by co-cultivation with insect cells. However, the requirement for co-cultivation of *Spiroplasma leptinotarsae* can be circumvented by placing the primary cultures in BBL anaerobic GasPak jar systems with low redox potential and enhanced CO_2 atmosphere (Konai et al., 1996b). By lowering the pH of the growth medium from 7.4 to 6.2 and using bromocresol purple as a pH indicator (pH 5.2 yellow to pH 6.8 purple), it was possible to perform metabolism inhibition tests involving *Spiroplasma leptinotarsae* as the antigen. The same low-pH medium containing 2.0% Noble agar permitted the growth of colonies (Williamson, unpublished data). Cohen and Williamson (1988) reported that a fortuitous contamination of H-2 medium by a slow-growing, pink-colored yeast (*Rhodotorula rubra*) permitted primary isolation of the non-male-lethal variant of the *Dorsophila willistoni* spiroplasma. After 10–12 passages with yeast, the spiroplasmas were able to grow in yeast-free H-2 medium.

Maintenance procedures. Adaptation. Most spiroplasmas can be adapted to a wide variety of media formulations. Spiroplasmas commonly grow more slowly upon transfer to new media. Initial reduction in growth rate is probably related to a combination of differences in nutrients, pH, osmolality, etc. Isolates may grow at only slightly reduced rates during the first 1–5 passages in a new medium. However, if the new medium is markedly deficient, the growth rate may decrease precipitously after 5–10 passages. Continuous careful passaging may result in growth rate recovery to levels similar to that in the initial medium. For such adaptations, best results are achieved by starting with a 1:1 ratio of old and new media and gradually withdrawing the old formulation. *Spiroplasma clarkii*, after continuous passage for hundreds of generations, finally adapted to extremely simple media (Hackett et al., 1994). Adaptation may involve mutation and/or activation of adaptive enzymes, or, possibly, other mechanisms. Growth rates in such simple media were much slower than those in rich media.

Maintenance media. *Spiroplasma citri* can be cultivated in a relatively simple medium that utilizes sorbitol to maintain osmolality (Saglio et al., 1971). A modification of this medium (BSR) has been used extensively for *Spiroplasma citri* (Bové and Saillard, 1979), in which the horse serum content was lowered to 10% and the fresh yeast extract was omitted. Other simple media, such as C-3G (Liao and Chen, 1977), are suitable for maintenance or large-batch cultivation of fast-growing spiroplasmas. This medium is also adequate for primary isolation of *Spiroplasma kunkelii* (Alivizatos, 1988). However, cultivation of more fastidious spiroplasmas is best achieved in MID medium (Hackett and Whitcomb, 1995; Whitcomb, 1983; Williamson and Whitcomb, 1975) if they derive from plant or insect habitats. SP-4 medium (Tully et al., 1977) is very suitable if spiroplasmas derive from tick habitats. SM-1 medium (Clark, 1982) has also been successfully employed for many insect spiroplasmas.

Defined media. *Spiroplasma floricola* and some strains of *Spiroplasma apis* have been cultivated in chemically defined media (Chang, 1989, 1982).

Preservation. Spiroplasmas are routinely preserved by lyophilization (FAO/WHO, 1974). Most spiroplasmas can be maintained at -70°C indefinitely. Preservation success at -20°C is irregular and uncertain.

Differentiation of the genus *Spiroplasma* from other closely related taxa

Spiroplasmas can be clearly differentiated from all other microorganisms by their unique properties of helicity and motility, combined with the complete absence of periplasmic fibrils, cell walls, or cell wall precursors. However, spiroplasmas may be nonhelical under some environmental conditions or when cultures are in the stationary phase of growth. Morphological study of the organisms in the exponential phase of growth usually reveals characteristic helical forms. However, the existence of spiroplasmas that appear entirely or largely as nonhelical forms (e.g., *Spiroplasma ixodetis* and group XXIII strain TIUS-1) raises the theoretical possibility that an organism situated at an apomorphic (advanced) position on the spiroplasma phylogenetic tree could totally lack helicity or motility. In fact, the clade containing *Mycoplasma mycoides* and the *Entomoplasmataceae* has apparently done exactly that. *Spiroplasma floricola* produces nonhelical, but viable, cells early in stationary phase, which can begin within 24 h of medium inoculation. For reasons such as this, it is necessary to examine cultures throughout the growth cycle to ensure that an adequate search for helical cells has been made.

Taxonomic comments

Early history. The term “spiroplasma” was first coined as a trivial term to describe helical organisms shown to be associated with corn stunt disease (Davis et al., 1972a, b) that could not, at that time, be cultivated (Davis and Worley, 1973). Shortly thereafter, when similar organisms associated with citrus stubborn disease were characterized (Saglio et al., 1973), the trivial term was adopted as the generic name and the stubborn organism was named *Spiroplasma citri*. This species was the first cultured spiroplasma and the first cultured mollicute of plant origin. Shortly after the stubborn agent was named, the genus *Spiroplasma* was elevated to the status of a family (Skripal, 1974) and added to the Approved Lists of Bacterial Names (Skripal, 1983). The organism that was eventually named *Spiroplasma mirum* (Tully et al., 1982) was isolated by Clark (1964) in embryonated chicken eggs soon after the discovery of the organism later named *Spiroplasma poulsonii*. Because *Spiroplasma mirum* readily passed through filters, it was first mistaken for a virus. The subgroup I-4 277F spiroplasma was cultivated in 1968, but was mistaken for a spirochete (Pickens et al., 1968). The first organism to be initially recognized as a spiroplasma was *Spiroplasma kunkelii*, which was envisioned by dark-field and electron microscopy in 1971–1972 and cultivated in 1975 (Liao and Chen, 1977; Williamson and Whitcomb, 1975). More than a decade passed before Clark (1982) showed that spiroplasmas, many of them fast-growing, occurred principally in insects.

Species concept. The species concept in spiroplasmas, as in all bacteria, was based on DNA–DNA reassociation (ICSB Subcommittee on the Taxonomy of *Mollicutes*, 1995; Johnson, 1994; Rosselló-Mora and Amann, 2001; Stackebrandt et al., 2002; Wayne et al., 1987). In practice, DNA–DNA reassociation results with spiroplasmas have proven difficult to standardize. Estimates of reassociation between *Spiroplasma citri* (subgroup I-1) and *Spiroplasma kunkelii* (subgroup I-3) varied between 30 and 70%, depending on the method employed and the degree of stringency (Bové and Saillard, 1979; Christiansen et al., 1979; Lee

and Davis, 1980; Liao and Chen, 1981a; Rahimian and Gumpf, 1980). Given these challenges, an alternative method was identified in serology. Surface serology of spiroplasmas has proven to be a robust surrogate for DNA–DNA hybridization assays.

Phylogeny. Phylogenetic studies of *Spiroplasma* became possible when Carl Woese and colleagues, searching for a molecular chronometer by which microbial evolution could be reconstructed, found that rRNA met most or all of the desired criteria (reviewed by Woese, 1987). Today, sequencing of rRNA genes has become a universal tool for phylogenetic reconstruction. Early phylogenetic analyses involved distance estimates (DeSoete, 1983). Later, neighbor-joining (Saitou and Nei, 1987) was introduced into mollicute phylogeny (Maniloff, 1992) and several mollicute workers have used maximum-likelihood (Felsenstein, 1993). The extensive and classical studies of K.-E. Johansson’s group (Johansson et al., 1998; Pettersson et al., 2000) were completed using neighbor-joining, but selectively confirmed by maximum-likelihood and maximum-parsimony (Swofford, 1998). Gasparich et al. (2004) studied the phylogeny of *Spiroplasma* and its nonhelical descendants using parsimony, maximum-likelihood, distance, and neighbor-joining analyses, which generated 24 phylogenetic inferences that were common to all, or almost all, of the trees. More recently, Bayesian analysis [MrBayes (<http://mrbayes.csit.fsu.edu/index.php>)] was used to examine an expanded *Spiroplasma* Apis clade based on 16S rRNA and 16S–23S ITS sequences; the analyses showed congruency between Bayesian and maximum-parsimony trees (Jandhyam et al., 2008).

Woese et al. (1980) presented a 16S rRNA gene-based phylogenetic tree for *Mollicutes*, including *Spiroplasma*, indicating that these wall-less bacteria were related to members of the phylum *Firmicutes* such as *Lactobacillus* spp. and *Clostridium innocuum*. The tree suggested that *Mollicutes* might be monophyletic. However, a later study by Weisburg et al. (1989) with 40 additional species of *Mollicutes* including ten spiroplasmas, failed to confirm the monophyly of *Mollicutes* at the deepest branching orders. The Woese et al. (1980) model also suggested that the genus *Mycoplasma* might not be monophyletic, in that the type species, *Mycoplasma mycoides*, and two related species, *Mycoplasma capricolum* and *Mycoplasma putrefaciens*, appeared to be more closely related to the Apis clade of *Spiroplasma* than to the other *Mycoplasma* species. This conclusion was supported by analyses of the 5S rRNA genes (Rogers et al., 1985). All trees so far obtained indicate that the acholeplasma-anaeroplasmatales (*Acholeplasmatales–Anaeroplasmatales*) and spiroplasma-mycoplasma (*Mycoplasmatales–Entomoplasmatales*) lineages are monophyletic, but are separated by an ancient divergence.

In-depth analysis of characterized spiroplasmas and their nonhelical descendants indicates the existence of four major clades within the monophyletic spiroplasma-mycoplasma lineage (Gasparich et al., 2004; Figure 113). One of the four clades consists of the nonhelical species of the mycoides group (as defined by Johansson, 2002) as well as the six species of *Entomoplasma* and twelve species of *Mesoplasma* (the *Entomoplasmataceae*); this assemblage was designated the Mycoides-Entomoplasmataceae clade. The analyses indicated that the remaining three clades represented *Spiroplasma* species. One of these clades, the Apis clade, was found to be a sister to the Mycoides-Entomoplasmataceae clade. The Apis clade contains a large number of species from diverse insect hosts, many of which possess life cycles

Scale: 0.1 substitutions/site

FIGURE 113. Phylogenetic relationships of members of the class *Mollicutes* and selected members of the phylum *Firmicutes*. The phylogram was based on a Jukes-Cantor corrected distance matrix and weighted neighbor-joining analysis of the 16S rRNA gene sequences of the type strains, except where noted. *Escherichia coli* was the outgroup. Bootstrap values (100 replicates) <50% are indicated (*). The GenBank accession numbers for 16S rRNA gene sequences used are: *Mycoplasma mycoides* (U26039); *Mycoplasma pneumoniae* (M29061); *Entomoplasma freundtii* (AF036954); *Mesoplasma seiffertii* (AY351331); *Spiroplasma apis* (M23937); *Spiroplasma clarkii* (M 24474); *Spiroplasma gladiatoris* (M24475); *Spiroplasma taiwanense* (M24476); *Spiroplasma monobiae* (M24481); *Spiroplasma diabroticae* (M24482); *Spiroplasma melliferum* (AY325304); *Spiroplasma citri* (M23942); *Spiroplasma mirum* (M24662); *Spiroplasma ixodetis* (M24477); *Spiroplasma* sp. strain N525 (DQ186642); *Spiroplasma poulsonii* (M24483); *Spiroplasma penaei* (AY771927); *Spiroplasma phoeniceum* (AY772395); *Spiroplasma kunkelii* (DQ319068); *Spiroplasma cantharicola* (DQ861914); *Spiroplasma lineolae* (DQ860100); *Spiroplasma* sp. strain 277F (AY189312); *Spiroplasma* sp. strain LB-12 (AY189313); *Spiroplasma insolitum* (AY189133); *Spiroplasma floricola* (AY189131); *Spiroplasma syrphidicola* (AY189309); *Spiroplasma chrysopicola* (AY189127); *Spiroplasma* sp. strain TAAS-1 (AY189314); *Spiroplasma culicicola* (AY189129); *Spiroplasma velocicrescens* (AY189311); *Spiroplasma sabaudiense* (AY189308); *Spiroplasma corruscae* (AY189128); *Spiroplasma* sp. strain CB-1 (AY189315); *Spiroplasma* sp. strain Ar-1357 (AY189316); *Spiroplasma turonicum* (AY189310); *Spiroplasma litorale* (AY189306); *Spiroplasma lampyridicola* (AY189134); *Spiroplasma leptinotarsae* (AY189305); *Spiroplasma* sp. strain W115 (AY189317); *Spiroplasma chinense* (AY189126); *Spiroplasma diminutum* (AY189130); *Spiroplasma alleghenense* (AY189125); *Spiroplasma* sp. strain BIUS-1 (AY189319); *Spiroplasma montanense* (AY189307); *Spiroplasma helicoides* (AY189132); *Spiroplasma* sp. strain BARC 1901 (AY189320); *Ureaplasma urealyticum* (M23935); “*Candidatus Phytoplasma*” sp. Vigna II (AJ289195); *Acholeplasma laidlawii* (M23932); *Anaeroplasmatactoclasticum* (M25049); *Clostridium innocuum* (M23732); *Asteroleplasma anaerobium* (M22351); *Bacillus subtilis* (AF058766); *Escherichia coli* (J01859).

involving transmission between the guts of insects and plant surfaces. One of these species, *Spiroplasma* sp. TIUS-1 (group XXVIII) has very poor helicity and a genome size of 840 kbp, smaller than that of most other spiroplasmas. This species diverged from the spiroplasma lineage close to the node of entomoplasmal divergence and can be envisioned as a “missing link” in the evolutionary development of the Mycoides-Entomoplasmataceae clade. The other two *Spiroplasma* clades are the monospecific Ixodetis clade (group VI) and the Citri-Chrysopicola-Mirum clade (with representatives from groups I, II, V, and VIII). The Citri-Chrysopicola-Mirum clade contains *Spiroplasma mirum*, *Spiroplasma poulsonii*, the three subgroups of the Chrysopicola (group VIII) clade, and the nine subgroups of the Citri (group I) clade. Members of group I and group VIII show close intragroup relationships, as indicated by the similarities of their 16S rRNA gene sequences (Gasparich et al., 2004). DNA–DNA reassociation studies for group I (Bové et al., 1983, 1982; Junca et al., 1980) spiroplasmas supported the subgroup cluster. The Chrysopicola clade (group VIII) subgroups have met a different fate. Although their DNA–DNA similarities in reassociation procedures were slightly less than 70%, their 16S rRNA gene sequence similarities were >99% (Gasparich et al., 1993c). The strains of this group, including not only the subgroups, but a plethora of isolates from the same ecological context, appear to form a matrix of interrelated strains. Boundaries that seemed clear when the subgroups were initially described, eventually eroded beyond recognition. The 16S rRNA gene sequence similarities are too high to permit cladistic analysis and even 16S–23S rRNA spacer region sequence analysis failed to resolve the

existing subgroups (Regassa et al., 2004). Over time, the concept of the microbial species has undergone a subtle change. It is now recognized (Rosselló-Mora and Amann, 2001; Stackebrandt et al., 2002) that microbial species must at times consist of strain clusters that may contain species with <70% similarity as determined by DNA–DNA reassociation. Group VIII spiroplasmas may comprise such a cluster and efforts to subdivide this cluster may have been inadvisable.

Character mapping of non-genetic features has been completed in conjunction with phylogenetic analyses (Gasparich et al., 2004). Serological classifications of spiroplasmas are generally supported by the trees, but the resolution of genetic analyses appears to be much greater than that of serology. Genome size and G+C content were moderately conserved among closely related strains. Apparent conservation of slower growth rates in some clades was most likely attributable to host affiliation; spiroplasmas of all groups that were well adapted to a specific host had slower growth rates. Sterol requirements were polyphyletic, as was the ability to grow in the presence of PES, but not serum.

List of species of the genus *Spiroplasma*

1. ***Spiroplasma citri*** Saglio, L'Hospital, Lafèche, Dupont, Bové, Tully and Freundt 1973, 202^{AL}

cit'ri. L. masc. n. *citrus* the citrus; N.L. masc. n. *Citrus* generic name; N.L. gen. n. *citri* of *Citrus*, to denote the plant host.

Cells are helices that divide in mid-exponential phase when they have four turns. Helical filaments are usually 100–200 nm in diameter and 2–4 µm in length. Cells are longer in late exponential phase and early stationary phase. Nonviable cells in late exponential phase are non-helical.

Colonies on solid media containing 20% horse serum and 0.8% Noble agar (Difco) are umbonate, 60–150 µm in diameter. Moderate turbidity is produced in liquid cultures. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares some cross-reactivity with members of other group I subgroups. Has close phylogenetic affinities with other group I members, and with *Spiroplasma poulsonii* in trees constructed using 16S rRNA gene sequences.

Pathogenic for citrus plants and a variety of plant hosts (aster, periwinkle, broad bean) following transmission by infected insects (leafhoppers).

DNA–DNA renaturation experiments confirm serological data that indicate that the differences between the type strain (subgroup I-1) and other subgroups of group I are great enough to warrant its designation as a distinct species. The genome size is 1820 kbp (PFGE).

Source: isolated from leaves, seed coats, and fruits of citrus plants (orange and grapefruit) infected with stubborn disease, and from other naturally infected plants (e.g., periwinkle, horseradish or brassicaceous weeds) or insects. Known from Mediterranean and other warm climates of Europe, North Africa, Near and Middle East, and the Western United States (California and Arizona).

DNA G+C content (mol%): 25–27 (T_m , Bd).

Type strain: ATCC 27556, Morocco strain, R8-A2.

Sequence accession no. (16S rRNA gene): M23942.

2. ***Spiroplasma alleghenense*** Adams, Whitcomb, Tully, Clark, Rose, Carle, Konai, Bové, Henegar and Williamson 1997, 762^{VP}

al.le.ghen.en'se. N.L. neut. adj. *alleghenense* of the Allegheny Mountains, referring to the geographic origin of the type strain, the range of the Appalachian Mountains from which it was derived.

Cells are motile helical filaments, 100–300 nm in diameter. Under many growth conditions, cells in medium are deformed. Colonies on solid medium containing 3.0% Noble agar are small and granular and never have a fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. When tested as an antigen, cross-reacts broadly with many nonspecific sera (one-way reaction). Has close phylogenetic relationship to *Spiroplasma*

sabaudiense (group XIII) and strain TIUS-1 (group XXVIII) in trees constructed using 16S rRNA gene sequences. The genome size is 1,465 kbp (PFGE).

Source: isolated from the hemolymph of a common scorpion fly, *Panorpa helena* in West Virginia, USA.

DNA G+C content (mol%): 31 ± 1 (T_m , Bd).

Type strain: ATCC 51752, PLHS-1.

Sequence accession no. (16S rRNA gene): AY189125.

3. ***Spiroplasma apis*** Mouches, Bové, Tully, Rose, McCoy, Carle-Junca, Garnier and Saillard 1984b, 91^{VP} (Effective publication: Mouches, Bové, Tully, Rose, McCoy, Carle-Junca, Garnier and Saillard 1983a, 383.)

a'pis. L. fem. n. *apis*, -is a bee, and also the genus name of the honey bee, *Apis mellifera*; L. gen. n. *apis* of a bee, of *Apis mellifera*, the insect host for this species.

The morphology is as described for the genus. Helical filaments are usually 100–150 nm in diameter and 3–10 µm in length. Colonies on solid medium containing 20% fetal bovine serum and 0.8% Noble agar (Difco) are usually diffuse, rarely exhibiting central zones of growth into the agar. Colonies on solid medium with 2.25% Noble agar and 1–5% bovine serum fraction are smaller, but exhibit central zones of growth into the agar and some peripheral growth on the agar surface around the central zones. Marked turbidity is produced during growth in most spiroplasma media (BSR, MIA, SP-4). Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Many strains show partial cross-reactions when tested against sera to strain B31^T (Tully et al., 1980). These strains show more than 80% DNA–DNA reassociation with strain B31^T, but their exact taxonomic status is unclear. Some strains show a very low level reciprocal cross-reaction with *Spiroplasma montanense* in deformation serology. In accordance with serology, *Spiroplasma apis* and *Spiroplasma montanense* are sister species in phylogenetic trees constructed using 16S rRNA gene sequences. The genome size is 1300 kbp (PFGE).

Etiologic agent of May disease of honey bees in southwestern France. Various strains of the organism exhibit experimental pathogenicity for young honey bees in feeding experiments.

Source: isolated from honey bees (*Apis mellifera*) and from flower surfaces in widely separated geographic regions (France, Corsica, Morocco, USA).

DNA G+C content (mol%): 29–31 (T_m , Bd).

Type strain: ATCC 33834, B31.

Sequence accession no. (16S rRNA gene): AY736030.

4. ***Spiroplasma atrichopogonis*** Koerber, Gasparich, Frana and Grogan 2005, 291^{VP}

a.tri.cho.po.go'nis. N.L. gen. n. *atrichopogonis* of *Atrichopogon*, systematic genus name of a biting midge (Diptera: Ceratopogonidae).

The morphology is as described for the genus. Cells are helical and motile. Biological properties are listed in Table 142.

Serologically distinct from previously established *Spiroplasma* species, groups, and subgroups. The genome size has not been determined.

Source: isolated from a pooled sample of two nearly identical species of biting midges (*Atrichopogon geminus* and *Atrichopogon levis*).

DNA G+C content (mol%): 28.8 ± 1 (T_m).

Type strain: ATTC BAA-520, NBRC 100390, GNAT3597.

Sequence accession no. (16S rRNA gene): not available.

5. ***Spiroplasma cantharicola*** Whitcomb, Chastel, Abalain-Colloc, Stevens, Tully, Rose, Carle, Bové, Henegar, Hackett, Clark, Konai and Williamson 1993a, 423^{VP}

can.thar.i'co.la. Gr. *kantharos* scarab beetle; L. suff. -cola (from L. n. *incola*) inhabitant, dweller; N.L. n. *cantharicola* an inhabitant of a family of beetles.

The morphology is as described for the genus. Cells are helical and motile. Colonies on solid medium containing 0.8% Noble agar are diffuse, without fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares some reciprocal cross-reactivity with members of other group XVI subgroups.

Not yet classified phylogenetically, but no doubt closely related to subgroups XVI-2 and XVI-3, which are sisters forming a clade related to *Spiroplasma diminutum* in phylogenetic trees constructed using 16S rRNA gene sequences. Moreover, DNA–DNA renaturation experiments confirm that the differences between the type strain and other subgroups of group XVI are great enough to warrant its designation as a distinct species. The genome size is 1320 kbp (PFGE).

Source: isolated from the gut of an adult cantharid beetle (*Cantharis carolinus*) in Maryland, USA. Based on its residence in the gut of a flower-visiting insect, this species is thought to be transmitted on flowers.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 43207, CC-1.

Sequence accession no. (16S rRNA gene): DQ861914.

6. ***Spiroplasma chinense*** Guo, Chen, Whitcomb, Rose, Tully, Williamson, Ye and Chen 1990, 424^{VP}

chi.nen'se. N.L. neut. adj. *chinense* of China, the location where the organism was first isolated.

The morphology is as described for the genus. Cells are motile helical filaments ~160 nm in diameter. Colonies on solid medium containing 0.8–1.0% Noble agar are diffuse with many small satellite colonies; growth on 2.25% agar produces smaller rough or granular colonies and fewer satellite forms. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, this species is closely related to *Spiroplasma velovicrescens* in phylogenetic trees constructed using 16S rRNA gene sequences. The genome size is 1530 kbp (PFGE).

Source: isolated from flower surfaces of bindweed (*Calystegia hederacea*) in Jiangsu, People's Republic of China.

DNA G+C content (mol%): 29 ± 1 (T_m).

Type strain: ATCC 43960, CCH.

Sequence accession no. (16S rRNA gene): AY189126.

7. ***Spiroplasma chrysopicola*** Whitcomb, French, Tully, Gasparich, Rose, Carle, Bové, Henegar, Konai, Hackett, Adams, Clark and Williamson 1997b, 718^{VP}

chry.so.pi'co.la. N.L. n. *Chrysops* a genus of deer flies in the Tabanidae; L. suff. *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *chrysopicola* inhabiting *Chrysops* spp.

Helical motile filaments are short and thin, passing a 220 nm filter quantitatively. Grows to titers as high as 10^{11} /ml. Colonies on solid medium containing 2.25% Noble agar have dense centers and smooth edges (a fried-egg appearance) and do not have satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but exhibits some reciprocal or one-way cross-reactivity with members of other group VIII subgroups. Some strains of group VIII spiroplasmas may be difficult to identify to subgroup. Shares less than 70% DNA–DNA reassociation with *Spiroplasma syrphidicola* and strain TAAS-1 (subgroup VIII-3). Phylogenetically, this species is closely related to other group VIII strains in trees constructed using 16S rRNA gene sequences. The 16S rRNA gene similarity coefficients of group VIII spiroplasmas are >0.99, so this gene is insufficient for distinguishing species in group VIII. The genome size is 1270 kbp (PFGE). Pathogenicity for insects has not been determined.

Source: isolated from the gut of a deer fly (*Chrysops* sp.) in Maryland, USA. Other strains from deer flies have been collected from as far west as Wyoming, from New England, and very rarely, as far south as Georgia, USA.

DNA G+C content (mol%): 30 ± 1 (Bd).

Type strain: ATCC 43209, DF-1.

Sequence accession no. (16S rRNA gene): AY189127.

8. ***Spiroplasma clarkii*** Whitcomb, Vignault, Tully, Rose, Carle, Bové, Hackett, Henegar, Konai and Williamson 1993c, 264^{VP}

clar'ki.i. N.L. masc. gen. n. *clarkii* of Clark, in honor of Truman B. Clark, a pioneer spiroplasma ecologist.

The morphology is as described for the genus. The helical motile filaments remain stable throughout exponential growth. Colonies on solid medium containing 0.8% Noble agar are diffuse, without fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, this species is placed in the classical Apis cluster of spiroplasmas, but it does not have an especially close neighbor in trees constructed using 16S rRNA gene sequences. The genome size is 1720 kbp (PFGE). Pathogenicity for insects has not been determined.

Source: isolated from the gut of a larval scarabaeid beetle (*Cotinus nitida*) in Maryland, USA.

DNA G+C content (mol%): 29 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 33827, CN-5.

Sequence accession no. (16S rRNA gene): M24474.

9. ***Spiroplasma corruscae*** Hackett, Whitcomb, French, Tully, Gasparich, Rose, Carle, Bové, Henegar, Clark, Konai, Clark and Williamson 1996c, 949^{VP}

cor.rus'cae. N.L. gen. n. *corruscae* of *corrusca*, referring to the species of firefly beetle (*Ellychnia corrusca*) from which the organism was first isolated.

The morphology is as described for the genus. Cells are helical and motile. Colonies on solid medium containing

2.25% Noble agar are slightly diffuse to discrete and generally without the characteristic fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from previously established *Spiroplasma* species, groups, and subgroups. Phylogenetically, closely related to *Spiroplasma turonicum* and *Spiroplasma litoreale* in trees constructed using 16S rRNA gene sequences. The genome size has not been determined.

Source: isolated from the gut of an adult lampyrid beetle (*Ellychnia corrusca*) in Maryland in early spring, but found much more frequently in horse flies in summer months. Other strains have been collected from Canada and Georgia, Connecticut, South Dakota, and Texas, USA.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 43212, EC-1.

Sequence accession no. (16S rRNA gene): AY189128.

10. ***Spiroplasma culicicola*** Hung, Chen, Whitcomb, Tully and Chen 1987, 368^{VP}

cu.li.ci'co.la. L. n. *Culex*, *-icis* a gnat, midge, and also a genus of mosquitoes (*Culex*, family Culicidae); L. suffix *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *culicicola* intended to mean an inhabitant of the Culicidae.

Cells are pleomorphic, but are commonly very short motile helices, 1–2 μ m in length. Colonies on solid medium containing 1% Noble agar have a fried-egg appearance with satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, this species is placed in the classical Apis cluster of spiroplasmas, but does not have an especially close neighbor in trees constructed using 16S rRNA gene sequences. The genome size is 1350 kbp (PFGE).

Source: isolated from a triturate of a salt marsh mosquito (*Aedes sollicitans*) collected in New Jersey, USA.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 35112, AES-1.

Sequence accession no. (16S rRNA gene): AY189129.

11. ***Spiroplasma diabroticae*** Carle, Whitcomb, Hackett, Tully, Rose, Bové, Henegar, Konai and Williamson 1997, 80^{VP}

di.a.bro.ti'cae. N.L. gen. n. *diabroticae* of *Diabrotica*, referring to *Diabrotica undecimpunctata*, the chrysomelid beetle from which the organism was isolated.

The morphology is as described for the genus. Cells are helical, motile filaments, 200–300 nm in diameter. Colonies on solid medium containing 0.8% Noble agar are diffuse, without fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from other established *Spiroplasma* species, groups, and subgroups. Phylogenetically, closely related to *Spiroplasma floricola* in trees constructed using 16S rRNA gene sequences. The genome size is 1350 kbp (PFGE).

Source: isolated from the hemolymph of an adult chrysomelid beetle, *Diabroticae undecimpunctata howardi*.

DNA G+C content (mol%): 25 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 43210, DU-1.

Sequence accession no. (16S rRNA gene): M24482.

12. **Spiroplasma diminutum** Williamson, Tully, Rosen, Rose, Whitcomb, Abalain-Colloc, Carle, Bové and Smyth 1996, 232^{VP}

di.min.u'tum. L. v. *deminuere* to break into small pieces, make smaller; L. neut. part. adj. *diminutum* made smaller, reflecting a smaller size.

The morphology is as described for the genus. Cells are short (1–2 µm), helical filaments, 100–200 nm in diameter that appear to be rapidly moving, irregularly spherical bodies when exponential phase broth cultures are examined under dark-field illumination. Colonies on solid medium containing 1.6% Noble agar have dense centers, granular perimeters, and nondistinct edges with satellite colonies. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, closely related to group XVI spiroplasmas in trees constructed using 16S rRNA gene sequences. The genome size is 1080 kbp (PFGE).

Source: isolated from a frozen triturate of adult female *Culex annulus* mosquitoes collected in Taishan, Taiwan.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 49235, CUAS-1.

Sequence accession no. (16S rRNA gene): AY189130.

13. **Spiroplasma floricola** Davis, Lee and Worley 1981, 462^{VP}

flor.i'co.la. L. n. *flos*, -*oris* a flower; L. suff. -*cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *floricola* flower-dweller.

The morphology is as described for the genus. Helical cells are 150–200 nm in diameter and 2–5 µm in length. Colonies on solid media have granular central regions surrounded by satellite colonies that probably form after migration of cells from the central focus. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, closely related to *Spiroplasma diabroticae* and various flower spiroplasmas in trees constructed using 16S rRNA gene sequences. The genome size of strain OBMG is 1270 kbp. Experimentally pathogenic for insects and embryonated chicken eggs.

Source: isolated from flowers of tulip tree and magnolia trees in Maryland, USA. Other strains have been collected from coleopterous insects.

DNA G+C content (mol%): 25 (T_m).

Type strain: ATCC 29989, 23-6.

Sequence accession no. (16S rRNA gene): AY189131.

14. **Spiroplasma gladiatoris** Whitcomb, French, Tully, Gasparich, Rose, Carle, Bové, Henegar, Konai, Hackett, Adams, Clark and Williamson 1997b, 718^{VP}

gla.di.a'to.ris. L. gen. n. *gladiatoris* of a gladiator, reflecting the initial isolation of the organism from the horse fly *Tabanus gladiator*.

Morphology is as described for the genus. Cells are motile helical filaments. Colonies on solid medium containing 3% Noble agar are granular with dense centers and diffuse edges, do not have satellites, and never have a fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. This species has a specific antigen,

common to several spiroplasmal inhabitants of horse flies, that confers a high level of one way cross-reactivity when it is used as an antigen. Phylogenetically, closely related to two other tabanid spiroplasmas, *Spiroplasma helicoides* and group XXXIV strain B1901, in phylogenetic trees constructed using 16S rRNA gene sequences. The genome size has not been determined.

Source: isolated from the gut of a horse fly (*Tabanus gladiator*) in Maryland, USA. Other strains have been collected at various locations in the southeastern United States.

DNA G+C content (mol%): 26 ± 1 (Bd).

Type strain: ATCC 43525, TG-1.

Sequence accession no. (16S rRNA gene): M24475.

15. **Spiroplasma helicoides** Whitcomb, French, Tully, Gasparich, Rose, Carle, Bové, Henegar, Konai, Hackett, Adams, Clark and Williamson 1997b, 718^{VP}

he.li.co.i'des. Gr. n. *helix* spiral; Gr. suff. -*oides* like, resembling, similar; N.L. neut. adj. *helicoides* spiral-like.

The morphology is as described for the genus. Cells are motile helical filaments that lack a cell wall. Colonies on solid medium containing 2.25% Noble agar have dense centers and smooth edges, do not have satellites, and have a perfect fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. This species has a specific antigen, common to several spiroplasmal inhabitants of horse flies, that confers a high level one-way cross-reaction when it is used as antigen. Phylogenetically, closely related to two other tabanid spiroplasmas, *Spiroplasma gladiatoris* and *Spiroplasma* sp. BARC 1901, in trees constructed using 16S rRNA gene sequences. Genome size has not been determined.

Source: isolated from the gut of a horse fly *Tabanus abactor* collected in Oklahoma, USA. Other strains have been collected in Georgia, USA.

DNA G+C content (mol%): 26 ± 1 (Bd).

Type strain: ATCC 51746, TABS-2.

Sequence accession no. (16S rRNA gene): AY189132.

16. **Spiroplasma insolitum** Hackett, Whitcomb, Tully, Rose, Carle, Bové, Henegar, Clark, Clark, Konai, Adams and Williamson 1993, 276^{VP}

in.so'li.tum. L. neut. adj. *insolitum* unusual or uncommon, to denote unusual base composition.

Cells in exponential phase are long, motile, helical cells that lack true cell walls and periplasmic fibrils. Colonies on solid SP-4 medium containing 0.8 or 2.25% Noble agar are diffuse, with small central zones of growth surrounded by small satellite colonies. Colonies on solid SP-4 medium containing horse serum and 0.8% Noble agar show fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species and groups, but cross-reacts reciprocally in complex patterns of relatedness with group I subgroups and *Spiroplasma poulsonii*. DNA–DNA renaturation experiments confirm that the differences between the type strain and other subgroups of group I are great enough to warrant its designation as a distinct species. Has close phylogenetic affinities with other group I members and with *Spiroplasma poulsonii*

in trees constructed using 16S rRNA gene sequences. The genome size is 1850 kbp (PFGE). Pathogenicity for insects has not been determined.

Source: the type strain was isolated from a fall flower (Asteraceae: *Bidens* sp.) collected in Maryland, USA. Similar isolates have been found in the hemocoel of click beetles. Also isolated from other composite and onagracead flowers and from the guts of many insects visiting these flowers, including cantharid and meloid beetles; syrphid flies; andrenid and megachilid bees; and four families of butterflies.

DNA G+C content (mol%): 28 ± 1 (T_m , Bd).

Type strain: ATCC 33502, M55.

Sequence accession no. (16S rRNA gene): AY189133.

17. ***Spiroplasma ixodetis*** Tully, Rose, Yunker, Carle, Bové, Williamson and Whitcomb 1995, 27^{VP}

ix.o.de'tis. N.L. gen. n. *ixodetis* of *Ixodes*, the genus name of *Ixodes pacificus* ticks, from which the organism was first isolated.

Cells are coccoid forms, 300–500 nm in diameter, straight and branched filaments, or tightly coiled helical organisms. Motility is flexional, but not translational. Colonies on solid medium containing 2.25% Noble agar usually have the appearance of fried eggs. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically unique; occurs at base of spiroplasma lineage in trees constructed using 16S rRNA gene sequences. The genome size is 2220 kbp (PFGE).

Source: isolated from macerated tissue suspensions prepared from pooled adult *Ixodes pacificus* ticks (Ixodidae) collected in Oregon, USA.

DNA G+C content (mol%): 25 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 33835, Y32.

Sequence accession no. (16S rRNA gene): M24477.

18. ***Spiroplasma kunkelii*** Whitcomb, Chen, Williamson, Liao, Tully, Bové, Mouches, Rose, Coan and Clark 1986, 175^{VP}

kun.kel'i.i. N.L. masc. gen. n. *kunkelii* of Kunkel, named after Louis Otto Kunkel (1884–1960), to honor his major and fundamental contributions to the study of plant mollicutes.

Cells in exponential phase are helical, motile filaments, 100–150 nm in diameter and 3–10 μ m long to nonhelical filaments or spherical cells, 300–800 nm in diameter. Colonies on solid medium containing 0.8% Noble agar are usually diffuse, rarely exhibiting central zones of growth into agar. Colonies on solid C-3G medium containing 5% horse serum or on media containing 2.25% Noble agar frequently have a fried-egg morphology. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares complex patterns of reciprocal cross-reactivity with members of other group I subgroups and *Spiroplasma poulsonii*. DNA–DNA renaturation experiments confirm that the serological differences between the type strain and other subgroups of group I are great enough to warrant its designation as a distinct species. Has close phylogenetic affinities with other group I

members and with *Spiroplasma poulsonii* in trees constructed using 16S rRNA gene sequences. The genome size is 1610 kbp (PFGE). Pathogenicity for plants and insects has been experimentally verified.

Source: isolated from maize displaying symptoms of corn stunt disease and from leafhoppers associated with diseased maize, largely in the neotropics.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 29320, E275.

Sequence accession no. (16S rRNA gene): DQ319068 (strain CR2-3x).

19. ***Spiroplasma lampyridicola*** Stevens, Tang, Jenkins, Goins, Tully, Rose, Konai, Williamson, Carle, Bové, Hackett, French, Wedincamp, Henegar and Whitcomb 1997, 711^{VP}

lam.py.ri.di'co.la. N.L. n. *Lampyridae* the firefly beetle family; L. suff. *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *lampyridicola* an inhabitant of members of the Lampyridae.

The morphology is as described for the genus. Cells are motile helical filaments. Colonies on solid medium containing 3.0% Noble agar are small and granular with dense centers, but do not have a true fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. When tested as antigen, cross-reacts (one-way) with many specific spiroplasma antisera. Phylogenetically, a sister to *Spiroplasma leptinotarsae* in trees constructed using 16S rRNA gene sequences. The genome size is 1375 kbp (PFGE).

Source: isolated from the gut fluids of a firefly beetle (*Photuris pennsylvanicus*) collected in Maryland, USA. Also known from Georgia and New Jersey, USA.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 43206, PUP-1.

Sequence accession no. (16S rRNA gene): AY189134.

20. ***Spiroplasma leptinotarsae*** Hackett, Whitcomb, Clark, Henegar, Lynn, Wagner, Tully, Gasparich, Rose, Carle, Bové, Konai, Clark, Adams and Williamson 1996b, 910^{VP}

lep.ti.no.tar'sae. N.L. gen. n. *leptinotarsae* of *Leptinotarsa*, referring to *Leptinotarsa decemlineata*, the Colorado potato beetle.

Cells *in vivo* are usually seen in the resting stage, in which they consist of coin-like compressed coils. When placed in fresh medium, these bodies turn immediately into “spring”- or “funnel”-shaped spirals, which are capable of very rapid translational motility. After a relatively small number of passes *in vitro*, this spectacular morphology is lost and the cells return to the modal morphology as described for the genus. Colonies on solid medium containing 2.0% Noble agar are slightly diffuse to discrete and produce numerous satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. When tested as antigen, cross-reacts with many spiroplasma antisera (one-way). Phylogenetically, a sister to *Spiroplasma lampyridicola* in trees constructed using 16S rRNA gene sequences. The genome size is 1,085 kbp (PFGE).

Source: isolated from the gut of Colorado potato beetle (*Leptinotarsa decemlineata*) larvae in Maryland, USA. Also

isolated from beetles collected in Maryland, Michigan, New Mexico, North Carolina, Texas, Canada, and Poland.

DNA G+C content (mol%): 25 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 43213, LD-1.

Sequence accession no. (16S rRNA gene): AY189305.

21. ***Spiroplasma leucomae*** Oduori, Lipa and Gasparich 2005, 2449^{VP}

leu.co'mae. N.L. gen. n. *leucomae* of *Leucoma*, systematic genus name of the white satin moth (Lepidoptera: Lymantriidae), the source of the type strain.

Morphology is as described for the genus. Cells are filamentous, helical, motile, and approximately 150 nm in diameter. They freely pass through filters with pores of 450 and 220 nm, but do not pass through filters with 100 nm pores. Biological properties are listed in Table 142.

Serologically distinct from previously established *Spiroplasma* species, groups, and subgroups. The genome size has not been determined. Pathogenicity for the moth larvae is not known.

Source: isolated from fifth instar satin moth larvae (*Leucoma salicis*).

DNA G+C content (mol%): 24 ± 1 (T_m).

Type strain: ATCC BAA-521, NBRC 100392, SMA.

Sequence accession no. (16S rRNA gene): DQ101278.

22. ***Spiroplasma lineolae*** French, Whitcomb, Tully, Carle, Bové, Henegar, Adams, Gasparich and Williamson 1997, 1080^{VP}

lin.e.o'lae. N.L. n. *lineola* a species of tabanid fly; N.L. gen. n. *lineolae* of *Tabanus lineola*, from which the organism was isolated.

The morphology is as described for the genus. Cells are motile, helical filaments, 200–300 nm in diameter. Colonies on solid medium containing 3% Noble agar are small, granular, and never have a fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetic position has not been determined, but its other taxonomic properties suggest that it may be related to other tabanid spiroplasmas of the *Apis* cluster. The genome size is 1390 kbp (PFGE).

Source: type strain isolated from the viscera of the tabanid fly *Tabanus lineola* collected in coastal Georgia. A strain from *Tabanus lineola* has been collected in Costa Rica (Whitcomb et al., 2007).

DNA G+C content (mol%): 25 ± 1 (T_m , Bd).

Type strain: ATCC 51749, TALS-2.

Sequence accession no. (16S rRNA gene): DQ860100.

23. ***Spiroplasma litorale*** Konai, Whitcomb, French, Tully, Rose, Carle, Bové, Hackett, Henegar, Clark and Williamson 1997, 361^{VP}

li.to.ra'le. L. neut. adj. *litorale* of the shore or coastal area.

The morphology is as described for the genus. Cells are motile, helical filaments. Colonies on solid medium containing 2.25% Noble agar are granular with dense centers, uneven margins, and multiple satellites, and never have fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, closely related to

two other tabanid spiroplasmas, *Spiroplasma turoanicum* and *Spiroplasma litorale*, in trees constructed using 16S rRNA gene sequences. The genome size is 1370 kbp (PFGE).

Source: isolated from the gut of a female green-eyed horse fly (*Tabanus nigrovittatus*) from the Outer Banks of North Carolina. Also collected from coastal Georgia and both Atlantic and Pacific coasts of Costa Rica.

DNA G+C content (mol%): 25 ± 1 (Bd).

Type strain: ATCC 34211, TN-1.

Sequence accession no. (16S rRNA gene): AY189306.

24. ***Spiroplasma melliferum*** Clark, Whitcomb, Tully, Mouches, Saillard, Bové, Wróblewski, Carle, Rose, Henegar and Williamson 1985, 305^{VP}

mell.i'fe.rum. L. adj. *mellifer*, *-fera*, *-ferum* honey-bearing, honey-producing; L. neut. adj. *melliferum* intended to mean isolated from the honey bee (*Apis mellifera*).

Morphology is as described for the genus. Cells are pleomorphic, varying from helical filaments that are 100–150 nm in diameter and 3–10 μ m in length to nonhelical filaments or spherical cells that are 300–800 nm in diameter. The motile cells lack true cell walls and periplasmic fibrils. Colonies on solid medium supplemented with 0.8% Noble agar are usually diffuse, rarely exhibiting central zones of growth into agar. Colonies on solid medium containing 2.25% Noble agar are smaller, but frequently have a fried-egg morphology. Physiological and genomic properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares complex patterns of reciprocal cross-reactivity with members of other group I subgroups and *Spiroplasma poulsonii*. Has close phylogenetic affinities with other group I members and with *Spiroplasma poulsonii* in trees constructed using 16S rRNA gene sequences. DNA–DNA renaturation experiments confirm that the serological differences between the type strain and other subgroups of group I are great enough to warrant its designation as a distinct species. The genome size is 1460 kbp (PFGE). Pathogenic for honey bees in natural and experimental oral infections.

Source: isolated from hemolymph and gut of honey bees (*Apis mellifera*) in widely separated geographic regions. Also recovered from hemolymph of bumble bees, leafcutter bees, and a robber fly, and the intestinal contents of sweat bees, digger bees, bumble bees, and a butterfly. Also recovered from a variety of plant surfaces (flowers) in widely separated geographic regions.

DNA G+C content (mol%): 26–28 (T_m , Bd).

Type strain: ATCC 33219, BC-3.

Sequence accession no. (16S rRNA gene): AY325304.

25. ***Spiroplasma mirum*** Tully, Whitcomb, Rose and Bové 1982, 99^{VP}

mi'rum. L. neut. adj. *mirum* extraordinary.

The morphology is as described for the genus. Helical filaments measure 100–200 nm in diameter and 3–8 μ m in length. Colonies on solid media containing fetal bovine serum and 0.8–2.25% Noble agar (Difco) are diffuse and without central zones of growth into the agar. Solid media prepared with 1.25% agar and in which fetal bovine serum

has been replaced with bovine serum fraction yield colonies with central zones of growth into the agar and no peripheral growth on the surface of the medium. Moderate turbidity is produced during growth in liquid media. Biological properties are listed in Table 142. This species has been cultivated in a defined medium.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, in trees constructed using 16S rRNA gene sequences, this species is basal to group I and group VIII spiroplasmas on the one hand, and to the Apis cluster and *Entomoplasmataceae* on the other. It is the most primitive (plesiomorphic) spiroplasma with modal helicity. The genome size is 1300 kbp (PFGE). Produces experimental ocular and nervous system disease and death in intracerebrally inoculated suckling animals (rats, mice, hamsters, and rabbits). Pathogenic for chicken embryos via yolk sac inoculation. Experimentally pathogenic for the wax moth (*Galleria mellonella*).

Source: the type strain was isolated from rabbit ticks (*Haemaphysalis leporispalustris*) collected in Georgia, USA. Other strains have been collected in Georgia, Maryland, and New York, USA.

DNA G+C content (mol%): 30–31 (T_m).

Type strain: ATCC 29335, SMCA.

Sequence accession no. (16S rRNA gene): M24662.

26. ***Spiroplasma monobiae*** Whitcomb, Tully, Rose, Carle, Bové, Henegar, Hackett, Clark, Konai, Adams and Williamson 1993b, 259^{VP}

mo.no.bi'ae. N.L. n. *Monobia* a genus of vespidae wasps; N.L. gen. n. *monobiae* of the genus *Monobia*, from which the organism was isolated.

The morphology is as described for the genus, with motile helical filaments. Colonies on solid medium containing 2.25% Noble agar are diffuse and never have a fried-egg appearance. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, a member of the Apis clade, but with no especially close neighbors in trees constructed using 16S rRNA gene sequences. The genome size is 940 kbp (PFGE).

Source: isolated from the hemolymph of an adult vespidae wasp (*Monobia quadridens*) collected in Maryland, USA. Based on its residence in the gut of a flower-visiting insect, this species is thought to be transmitted on flowers.

DNA G+C content (mol%): 28 ± 1 (T_m , Bd, HPLC).

Type strain: ATCC 33825, MQ-1.

Sequence accession no. (16S rRNA gene): M24481.

27. ***Spiroplasma montanense*** Whitcomb, French, Tully, Rose, Carle, Bové, Clark, Henegar, Konai, Hackett, Adams and Williamson 1997c, 722^{VP}

mon.ta.nen'se. N.L. neut. adj. *montanense* pertaining to Montana, where the species was first isolated.

The morphology is as described for the genus. Cells are motile, helical filaments that lack a cell wall. Colonies on solid medium containing 2.25% Noble agar are granular and have dense centers, irregular margins, and numerous small satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Reacts reciprocally in deformation serology at very low levels in deformation tests with *Spiroplasma apis*. "Bridge strains" have been isolated in Georgia with substantial cross-reactivity with both *Spiroplasma montanense* and *Spiroplasma apis*. Sister to *Spiroplasma apis* in trees constructed using 16S rRNA gene sequences. The genome size is 1225 kbp (PFGE).

Source: isolated from the gut of the tabanid fly *Hybomitra opaca*, in southwestern Montana. Other isolates have been obtained from New England, Connecticut, and southeastern Canada.

DNA G+C content (mol%): 28 ± 1 (Bd).

Type strain: ATCC 51745, HYOS-1.

Sequence accession no. (16S rRNA gene): AY189307.

28. ***Spiroplasma penaei*** Nunan, Lightner, Oduori and Gasparich 2005, 2320^{VP}

pe.na'e.i. N.L. n. *Penaeus* a species of shrimp; N.L. gen. *penaei* of *Penaeus*, referring to *Penaeus vannamei*, from which the organism was isolated.

The morphology is as described for the genus. Cells are helical and motile. Biological properties are listed in Table 142.

Serologically distinct from previously characterized *Spiroplasma* species, groups, and subgroups, but shares some cross-reactivity with members of other group I subgroups. Has close phylogenetic affinities with other group I members and with *Spiroplasma poulsonii* in trees constructed using 16S rRNA gene sequences. The genome size has not been determined. Pathogenicity has been indicated by injection into *Penaeus vannamei*.

Source: isolated from the hemolymph of the Pacific white shrimp, *Penaeus vannamei*.

DNA G+C content (mol%): 29 ± 1 (T_m).

Type strain: CAIM 1252, SHRIMP, ATCC BAA-1082.

Sequence accession no. (16S rRNA gene): AY771927.

29. ***Spiroplasma phoeniceum*** Saillard, Vignault, Bové, Raie, Tully, Williamson, Fos, Garnier, Gadeau, Carle and Whitcomb 1987, 113^{VP}

phoe.ni'ce.um. N.L. neut. adj. *phoeniceum* (from L. neut. adj. *phonicium*) of Phoenice, an ancient country that was located on today's Syrian coast, referring to the geographical origin of the isolates.

Morphology is as described for the genus. Colonies on solid medium containing 0.8% Noble agar show fried-egg morphology. Physiological and genomic properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares some cross-reactivity with members of other group I subgroups and *Spiroplasma poulsonii*. Has close phylogenetic affinities with other group I members and with *Spiroplasma poulsonii* in trees constructed using 16S rRNA gene sequences. Has been shown to be transmissible to leafhoppers by injection and experimentally pathogenic to aster inoculated by the injected leafhoppers. DNA–DNA renaturation experiments confirm that the differences between the type strain and other subgroups of group I are great enough to warrant its designation as a distinct species. The genome size is 1860 kbp (PFGE).

Source: isolated from periwinkles that were naturally infected in various locations along the Syrian coastal area.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 43115, P40.

Sequence accession no. (16S rRNA gene): AY772395.

30. **Spiroplasma platyhelix** Williamson, Adams, Whitcomb, Tully, Carle, Konai, Bové and Henegar 1997, 766^{VP}

pla.ty.he'lix. Gr. adj. *platys* flat; Gr. fem. n. *helix* a coil or spiral; N.L. fem. n. *platyhelix* flat coil, referring to the flattened nature of the helical filament.

Cells are flattened, helical filaments, 200–300 nm in diameter. They show no rotatory or translational motility, but exhibit contractile movements in which tightness of coiling moves along the axis of the filament. Colonies on solid medium containing 2.25% Noble agar form perfect fried-egg colonies with dense centers, smooth edges, and without satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. The genome size is 780 kbp (PFGE).

Source: isolated from the gut of a dragonfly, *Pachydiplax longipennis*, collected in Maryland, USA.

DNA G+C content (mol%): 29 ± 1 (Bd).

Type strain: ATCC 51748, PALS-1.

Sequence accession no. (16S rRNA gene): AY800347.

31. **Spiroplasma poulsonii** Williamson, Sakaguchi, Hackett, Whitcomb, Tully, Carle, Bové, Adams, Konai and Henegar 1999, 616^{VP}

poul.so'ni.i. N.L. masc. gen. n. *poulsonii* of Poulson, named in memory of Donald F. Poulson, in whose laboratory at Yale University this spiroplasma was discovered and studied intensively.

Morphology is as described for the genus. Long, motile, helical filaments, 200–250 nm in diameter occur *in vivo* in *Drosophila* hemolymph and *in vitro*. Colonies on solid medium containing 1.8% Noble agar are small (60–70 µm in diameter), have dense centers and uneven edges, and are without satellites. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares some reciprocal cross-reactivity with members of group I subgroups. Phylogenetically related to group I spiroplasmas in trees constructed using 16S rRNA gene sequences. The genome size is 2040 kbp (PFGE). Spiroplasmas causing sex-ratio abnormalities occur naturally in *Drosophila* spp. collected in Brazil, Colombia, Dominican Republic, Haiti, Jamaica, and the West Indies. Non-male-lethal spiroplasmas also occur in natural populations of *Drosophila hydei* in Japan. Pathogenicity (lethality to male progeny) has been confirmed by injection into *Drosophila pseudoobscura* female flies. Vertical transmissibility is lost after cultivation and cloning.

Source: isolated from the hemolymph of *Drosophila pseudoobscura* females infected by hemolymph transfer of the Barbados-3 strain of *Drosophila willistoni* SR organism.

DNA G+C content (mol%): 26 ± 1 (T_m , Bd).

Type strain: ATCC 43153, DW-1.

Sequence accession no. (16S rRNA gene): M24483.

32. **Spiroplasma sabaudiense** Abalain-Colloc, Chastel, Tully, Bové, Whitcomb, Gilot and Williamson 1987, 264^{VP}

sa.bau.di.en'se. L. neut. adj. *sabaudiense* of *Sabaudia*, an ancient country of Gaul, corresponding to present day Savoy, referring to the geographic origin of the isolate.

The morphology is as described for the genus. Cells are helical filaments, 100–160 nm in diameter and 3.1–3.8 µm long. Motile. Colonies on solid medium containing 1.6% Noble agar are diffuse, rarely exhibiting fried-egg morphology, with numerous satellite colonies. Physiological and genomic properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, related to *Spiroplasma alleghenense* and *Spiroplasma* sp. TIUS-1 in trees constructed using 16S rRNA gene sequences. The genome size is 1175 kbp (PFGE).

Source: isolated from a triturate of female *Aedes* spp. mosquitoes in Savoy, France.

DNA G+C content (mol%): 30 ± 1 (T_m , Bd).

Type strain: ATCC 43303, Ar-1343.

Sequence accession no. (16S rRNA gene): AY189308.

33. **Spiroplasma syrphidicola** Whitcomb, Gasparich, French, Tully, Rose, Carle, Bové, Henegar, Konai, Hackett, Adams, Clark and Williamson 1996, 799^{VP}

syr.phi.di'co.la. N.L. pl. n. *Syrphidae* a family of flies; L. suff. *-cola* (from L. masc. or fem. n. *incola*) inhabitant, dweller; N.L. masc. n. *syrphidicola* inhabitant of syrphid flies, the insects from which the organism was isolated.

Helical motile filaments are short and thin, passing a 220 nm filter quantitatively. Grows to titers as high as 10¹¹/ml. These short, thin, abundant cells are provisionally diagnostic for group VIII. Colonies on solid medium containing 2.25% Noble agar are irregular with satellites, diffuse, and never have a fried-egg appearance. Growth on solid medium containing 1.6% Noble agar is diffuse. Biological properties are listed in Table 142.

Serologically distinct from other *Spiroplasma* species, groups, and subgroups, but shares some reciprocal cross-reactivity with members of other group VIII subgroups. Placement of group VIII strains into subgroups has become increasingly difficult as more strains have accumulated. Phylogenetically, this species is closely related to other group VIII strains in trees constructed using 16S rRNA gene sequences. The 16S rRNA gene sequence similarity coefficients of group VIII spiroplasmas are >0.99, so this gene is insufficient for species separations in group VIII. DNA–DNA renaturation experiments confirm that the differences between the type strain and other subgroups of group VIII are great enough to warrant its designation as a distinct species. Genome size is 1230 kbp (PFGE).

Source: isolated from the hemolymph of the syrphid fly *Eristalis arbustorum* in Maryland, USA. Strains that are provisionally identified as *Spiroplasma syrphidicola* have been obtained from horse flies collected from several locations in the southeastern United States.

DNA G+C content (mol%): 30 ± 1 (Bd).

Type strain: ATCC 33826, EA-1.

Sequence accession no. (16S rRNA gene): AY189309.

34. ***Spiroplasma tabanidicola*** Whitcomb, French, Tully, Gasparich, Rose, Carle, Bové, Henegar, Konai, Hackett, Adams, Clark and Williamson 1997b, 718^{VP}
 ta.ba.ni.di'co.la. N.L. n. *Tabanidae* family name for horse flies; L. suff. *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *tabanidicola* an inhabitant of horse flies.
 The morphology is as described for the genus. Cells are motile, helical filaments that lack a cell wall. Colonies on solid medium containing 3% Noble agar are uneven and granular with dense centers and irregular edges, do not have satellites, and never have a fried-egg appearance. Physiological and genomic properties are listed in Table 142.
 Serologically distinct from other *Spiroplasma* species, groups, and subgroups. However, some strains may show a very low level reciprocal serological cross-reaction in deformation serology with *Spiroplasma gladiatoris*. This species has a specific antigen, common to several spiroplasmal inhabitants of horse flies, that confers a high level one-way cross-reaction when it is used as antigen. The genome size is 1375 kbp (PFGE).
Source: isolated from the gut of a horse fly belonging to the *Tabanus abdominalis-limbatae* complex.
DNA G+C content (mol %): 26 ± 1 (Bd).
Type strain: ATCC 51747, TAUS-1.
Sequence accession no. (16S rRNA gene): DQ004931.
35. ***Spiroplasma taiwanense*** Abalain-Colloc, Rosen, Tully, Bové, Chastel and Williamson 1988, 105^{VP}
 tai.wan.en'se. N.L. neut. adj. *taiwanense* of or belonging to Taiwan, referring to the geographic origin of the isolate.
 The morphology is as described for the genus. Cells are motile, helical filaments, 100–160 nm in diameter and 3.1–3.8 µm long. Colonies on solid medium containing 1.6% Noble agar have fried-egg morphology. Biological properties are listed in Table 142.
 Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, this species is in the classical *Apis* cluster of spiroplasmas, but does not have an especially close neighbor in trees constructed using 16S rRNA gene sequences. The genome size is 1195 kbp (PFGE).
Source: isolated from a triturate of female mosquitoes (*Culex tritaeniorhynchus*) at Taishan, Taiwan, Republic of China.
DNA G+C content (mol %): 25 ± 1 (T_m , Bd).
Type strain: ATCC 43302, CT-1.
Sequence accession no. (16S rRNA gene): M24476.
36. ***Spiroplasma turonicum*** Hélias, Vazeille-Falcoz, Le Goff, Abalain-Colloc, Rodhain, Carle, Whitcomb, Williamson, Tully, Bové and Chastel 1998, 460^{VP}
 tu.ro'ni.cum. L. neut. adj. *turonicum* of Touraine, the province in France from which the organism was first isolated.
 The morphology is as described for the genus. Cells are motile, helical filaments. Colonies on solid medium containing 3% Noble agar exhibit a “cauliflower-like” appearance and do not have a fried-egg morphology. Biological properties are listed in Table 142.
 Serologically distinct from previously established *Spiroplasma* species. Phylogenetically, related to two other tabanid spiroplasmas, *Spiroplasma corruscae* and *Spiroplasma litorale*, in trees constructed using 16S rRNA gene sequences. The genome size is 1305 kbp (PFGE).
Source: isolated from a triturate of a single horse fly (*Haematopota pluvialis*) collected in France.
DNA G+C content (mol %): 25 ± 1 (Bd).
Type strain: ATCC 700271, Tab4c.
Sequence accession no. (16S rRNA gene): AY189310.
37. ***Spiroplasma velocicrescens*** Konai, Whitcomb, Tully, Rose, Carle, Bové, Henegar, Hackett, Clark and Williamson 1995, 205^{VP}
 ve.lo.ci.cres'cens. L. adj. *velox*, *-ocis* fast, quick; L. part. adj. *crescens* growing; N.L. n. part. adj. *velocicrescens* fast-growing.
 The morphology is as described for the genus. Cells are helical, motile filaments, 200–300 nm in diameter. Colonies on solid medium containing 0.8% Noble agar are diffuse and never have a fried-egg appearance. Biological properties are listed in Table 142.
 Serologically distinct from other *Spiroplasma* species, groups, and subgroups. Phylogenetically, this species is sister to *Spiroplasma chinense* in trees constructed using 16S rRNA gene sequences. The genome size is 1480 kbp (PFGE).
Source: isolated from the gut of a vespid wasp, *Monobia quadridens*, collected in Maryland, USA. Based on its residence in the gut of a flower-visiting insect, this species is thought to be transmitted on flowers.
DNA G+C content (mol %): 27 ± 1 (T_m , Bd, HPLC).
Type strain: ATCC 35262, MQ-4.
Sequence accession no. (16S rRNA gene): AY189311.

Order III. **Acholeplasmatales** Freundt, Whitcomb, Barile, Razin and Tully 1984, 348^{VP}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.cho.le.plas.ma.ta'les. N.L. neut. n. *Acholeplasma* type genus of the order; *-ales* ending to denote an order; N.L. fem. pl. n. *Acholeplasmatales* the *Acholeplasma* order.

This order in the class *Mollicutes* is assigned to a group of wall-less prokaryotes that do not require sterol for growth and occur in a wide variety of habitats, including many vertebrate hosts, insects, and plants. A single family, *Acholeplasmataceae*, and a single genus, *Acholeplasma*, recognize the prominent and distinct characteristics of the assigned organisms.

Type genus: Acholeplasma Edward and Freundt 1970, 1^{AL}.

Further descriptive information

The trivial name *acholeplasma*(s) is commonly used when reference is made to species of this order. The initial proposal for elevation of the *acholeplasmas* to ordinal rank (Freundt et al., 1984) was based primarily on the universal lack of a sterol requirement for growth of *Acholeplasma* species, in addition to other major genetic, nutritional, biochemical, and physiological characteristics that distinguish them from other members of the class *Mollicutes*. A subsequent proposal for an additional order, *Entomoplasmatales* (Tully et al., 1993), within the class to distinguish a group of mollicutes that are phylogenetically more closely related to the *Mycoplasmatales* than to *acholeplasmas* necessitated further revisions within the class.

Although most mollicutes require exogenous cholesterol or serum for growth, all species within the genus *Acholeplasma* and some assigned to the genera *Asteroleplasma*, *Spiroplasma*, and *Mesoplasma* do not have that requirement. The species that do not have a sterol requirement can easily be excluded from the sterol-requiring taxa by tests that measure growth responses to cholesterol or to a number of serum-free broth preparations (Edward, 1971; Razin and Tully, 1970; Rose et al., 1993; Tully, 1995). For instance, the *Acholeplasmatales* grow through end-point dilutions in serum-containing medium and in serum-free preparations, indicating the absence of a growth requirement for cholesterol.

Analyses of rRNA and other genes have shown that a large group of uncultured, plant-pathogenic organisms referred to by the trivial name phytoplasmas (Sears and Kirkpatrick, 1994) are closely related to *acholeplasmas* (Lim and Sears, 1992; Toth et al., 1994). The 16S rRNA gene sequences for members of the genus *Acholeplasma* that have been determined so far show that the *acholeplasmas* form two clades, one of which is a sister lineage to the phytoplasmas, although the formal taxonomic assignment of "*Candidatus* Phytoplasma" proposed gen. nov. (IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004) currently remains *incertae sedis*.

Family I. Acholeplasmataceae Edward and Freundt 1970, 1^{AL}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.cho.le.plas.ma.ta.ce'ae. N.L. neut. n. *Acholeplasma*, *-atos* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Acholeplasmataceae* the *Acholeplasma* family.

Further descriptive information

This family is monotypic, so its properties are essentially those of the genus *Acholeplasma*.

Type genus: Acholeplasma Edward and Freundt 1970, 1^{AL}.

Genus I. *Acholeplasma* Edward and Freundt 1970, 1^{AL}

DANIEL R. BROWN, JANET M. BRADBURY AND KARL-ERIK JOHANSSON

A.cho.le.plas'ma. Gr. pref. *a* not; Gr. n. *chole* bile; Gr. neut. n. *plasma* something formed or molded, a form; N.L. neut. n. *Acholeplasma* name intended to indicate that cholesterol, a constituent of bile, is not required.

Cells are **spherical**, with a diameter of about 300 nm, or **filamentous**, 2–5 µm long. **Nonmotile**. Colonies have a “fried-egg” appearance and may reach 2–3 mm in diameter. Facultatively anaerobic; most strains grow readily in simple media. All members **lack a sterol requirement for growth**. **Chemo-organotrophic**, most species utilizing glucose and other sugars as the major energy sources. Many strains are capable of fatty acid biosynthesis from acetate. Arginine and urea are not hydrolyzed. Pigmented carotenoids occur in some species. All species are resistant, or only slightly susceptible, to 1.5% digitonin. Saprophytes found in soil, compost, wastewaters, or commensals of vertebrates, insects, or plants. None are known to be a primary pathogen, but they may cause cytopathic effects in tissue cultures. The **genome sizes** range from about **1500 to 2100 kbp**. All species examined utilize the universal genetic code in which UGA is a stop codon.

DNA G+C content (mol%): 27–38.

Type species: *Acholeplasma laidlawii* (Sabin 1941) Edward and Freundt 1970, 1^{AL} (*Sapromyces laidlawii* Sabin 1941, 334).

Further descriptive information

Cells of acholeplasmas typically appear as pleomorphic coccoid, coccobacillary, or short filamentous forms when grown in mycoplasma broth containing 20% horse serum or 1% bovine serum fraction. Viable spherical cells usually have a minimum diameter of about 300 nm. Filaments may be as much as 500 nm in length, but some longer filaments and branching filaments occur in some strains. Filaments often show beading with eventual development of coccoid forms. Cellular morphology may also depend upon the ratio of unsaturated to saturated fatty acids in the medium. Adjustment of preparative materials to the osmolarity of the culture medium is necessary for proper morphological examination.

Most acholeplasmas exhibit heavy turbidity when grown aerobically in broth containing 5–20% serum, usually of horse or fetal bovine origin, or when grown in 1% bovine serum fraction broth at 37°C. Less turbidity is evident when most acholeplasmas are cultured in serum-free broth and some species may be inhibited in media containing 20% horse serum. Strains of some acholeplasmas (*Acholeplasma morum*, *Acholeplasma modicum*, and *Acholeplasma axanthum*) may not grow well in serum-free medium unless glucose and some fatty acids (Tween 80 and palmitic acid) are included. Colonies on solid medium containing serum or bovine serum fraction are usually large (100–200 nm in diameter) with the classical “fried-egg” appearance after 24–72 h at 37°C (Figure 114). Colonies of *Acholeplasma axanthum* and several other acholeplasmas may show only central zones of growth into the agar or other unusual colony forms, such as mulberry-like colonies. Most acholeplasmas display optimum growth at 37°C. Growth is much slower at 25–27°C and strains may require 7–10 d to reach the turbidity observed after 24 h at 37°C. Species of plant origin (*Acholeplasma brassicae* and *Acholeplasma palmae*) have an optimum growth temperature of 30°C.

FIGURE 114. Colonies of *Acholeplasma laidlawii* PG8^T (=NCTC 10116^T; diameter 0.15–0.25 mm) after 3 d growth on Mycoplasma Experience Solid Medium at 36°C in 95% nitrogen/5% carbon dioxide. Original magnification = 25×. Image provided by Helena Windsor and David Windsor.

Most species in the genus are strong fermenters and produce acid from glucose metabolism, although a few species such as *Acholeplasma parvum* may not ferment glucose or other carbohydrates (Table 143). Fermentation of mannose is usually negative, although several species do catabolize this carbohydrate. All *Acholeplasma* species examined possess a fructose 1,6-diphosphate-activated lactate dehydrogenase, which is a property shared with certain streptococci.

Gourlay (1970) found that a fresh isolate of *Acholeplasma laidlawii* from a bovine source was infected with a filamentous, single-stranded DNA virus designated L1 (Bruce et al., 1972; Maniloff, 1992). Later, L2 and L3 viruses were also isolated from *Acholeplasma laidlawii* (Gourlay, 1971, 1972, 1973; Gourlay et al., 1973). L2 virus is a quasi-spherical, double-stranded DNA virus (Maniloff et al., 1977), and L3 is a short-tailed phage with double-stranded DNA (Garwes et al., 1975; Gourlay, 1974; Haberer et al., 1979; Maniloff et al., 1977). Another virus isolated from *Acholeplasma laidlawii* is L172, a single-stranded DNA, quasi-spherical virus that is different from L1 (Liska, 1972). Two viruses have been isolated from other acholeplasmas, including one from *Acholeplasma modicum*, designated M1 (Congdon et al., 1979), and from *Acholeplasma oculi* strain PG49 (designated O1) (Ichimaru and Nakamura, 1983). The nucleic acid structure of the last two viruses has not been defined.

Antisera to filter-cloned whole-cell antigens are utilized in several serological techniques to assess the antigenic structure of acholeplasmas and to provide identification of the organism to the species level (Tully, 1979). The three most useful techniques are growth inhibition (Clyde, 1983), plate immunofluorescence

(Gardella et al., 1983; Tully, 1973), and metabolism inhibition (Taylor-Robinson, 1983).

Acholeplasmas may be the most common mollicutes in vertebrate animals and they are found frequently in the upper respiratory tract and urogenital tract of such hosts (Tully, 1979, 1996). Eukaryotic cells in continuous culture are frequently contaminated with acholeplasmas, primarily from the occurrence of acholeplasmas in animal serum used in tissue culture media. At least five *Acholeplasma* species have been identified on plant surfaces (*Acholeplasma axanthum*, *Acholeplasma brassicae*, *Acholeplasma laidlawii*, *Acholeplasma oculi*, and *Acholeplasma palmae*), possibly representing contamination from insects. However, with the exception of *Acholeplasma pleciae* (Knight, 2004), the only acholeplasmas identified from insects have been from mosquitoes. *Acholeplasma laidlawii* was identified in a pool of *Anopheles sinensis*, and a strain of *Acholeplasma morum* was present in a pool of *Armigeres subalbatus* (D.L. Williamson and J.G. Tully, unpublished).

Little evidence exists for a pathogenic role of acholeplasmas in natural diseases. The widespread distribution of acholeplasmas in both healthy and diseased animal tissues and of antibodies against acholeplasmas in most animal sera complicates experimental pathogenicity studies. However, *Acholeplasma axanthum* was pathogenic for goslings and young goose embryos (Kisary et al., 1975, 1976). Inoculation into leafhoppers, including those known to be vectors of plant mycoplasma diseases, shows multiplication and prolonged persistence of acholeplasmas in host tissues (Eden-Green and Markham, 1987; Whitcomb et al., 1973; Whitcomb and Williamson, 1975), but there is no evidence that the few *Acholeplasma* species found on plant surfaces play any role in plant or insect disease.

A few recent reports are available on the antibiotic sensitivity of acholeplasmas and whether the actions of these drugs are inhibitory to growth or kill cells. Acholeplasmas are sensitive to the following antibiotics (minimum inhibitory concentration range in µg/ml): tetracycline, 0.5–25.0; erythromycin, 0.03–1.0; lincomycin, 0.25–1.0; tylosin tartarate, 0.1–12.5; and kanamycin, 20–200 (Kato et al., 1972; Lewis and Poland, 1978; Ogata et al., 1971).

Enrichment and isolation procedures

Typical steps in isolation of all mollicutes were outlined in the recently revised minimal standards for descriptions of novel

species (Brown et al., 2007). Techniques for isolation of acholeplasmas from animal tissues and from cell cultures have been described (Tully, 1983). Although colonies are occasionally first detected on blood agar, complex undefined media such as American Type Culture Collection medium 988 (SP-4) are usually required for primary isolation and maintenance. Cell wall-targeting antibiotics are included to discourage growth of other bacteria. Phenol red facilitates detection of species that excrete acidic or alkaline metabolites. Commonly used alternatives such as Frey's, Hayflick's and Friis' media differ from SP-4 mainly in the proportions of inorganic salts, amino acids, serum sources, and types of antibiotics included. Broths are incubated aerobically at 37°C for 14 d and examined periodically for turbidity or pH changes, either to acid or alkaline levels. Tubes showing turbidity are plated to agar prepared from the same medium formulation, and the plates are incubated at 37°C in an atmosphere of 95% N₂, 5% CO₂, as in the GasPak system. Tubes without obvious turbidity should be plated at the end of the 14-d incubation period. Initial isolates may contain a mixture of species, so cloning by repeated filtration through membrane filters with a pore size of 450 or 220 nm is essential. The initial filtrate and dilutions of it are cultured on solid medium and an isolated colony is subsequently picked from a plate on which only a few colonies have developed. This colony is used to found a new cultural line, which is then expanded, filtered, plated, and picked two additional times. Identification is confirmed by additional biochemical and serological tests.

Maintenance procedures

Stock acholeplasma cultures can be maintained in either mycoplasma broth medium containing 5–20% serum or in the serum-fraction broth formulation at room temperature (25–30°C) with only weekly transfer (Tully, 1995). Maintenance is best in broth medium devoid of glucose, since excess acid production reduces viability. Stock cultures can also be maintained indefinitely when frozen at -70°C. Agar colonies can also be maintained for 1–2 weeks at 25°C if plates are sealed to prevent drying. For optimum preservation, acholeplasmas should be lyophilized directly in the culture medium when the broth cultures reach a mid-exponential phase, usually 1–2 d at 37°C. Lyophilized cultures should be sealed under vacuum and stored at 4°C (Leach, 1983).

Differentiation of the genus *Acholeplasma* from other genera

Properties that partially fulfill criteria for assignment to the class *Mollicutes* (Brown et al., 2007) include absence of a cell wall, filterability, and the presence of conserved 16S rRNA gene sequences. They usually possess two 16S rRNA operons. Aerobic or facultative anaerobic growth in artificial media and the absence of a requirement for sterols or cholesterol for growth exclude assignment to the genera *Anaeroplasma*, *Asteroleplasma*, “*Candidatus* *Phytoplasma*”, *Mycoplasma*, or *Ureaplasma*. Absence of a spiral cellular morphology, regular association with a vertebrate host or fluids of vertebrate origin, and regular use of the codon UGG to encode tryptophan (Knight, 2004) and UGA as a stop codon (Tanaka et al., 1989, 1991) support exclusion from the genera *Spiroplasma*, *Entomoplasma*, or *Mesoplasma*. Reduction of the redox indicator benzyl viologen has been reported to be fairly specific for differentiation of the genus *Acholeplasma* from other mollicutes (Pollack et al., 1996a). Only *Acholeplasma multilocale* failed to give a positive reaction, although several *Mesoplasma* and *Entomoplasma* species yielded variable responses to the test (Pollack et al., 1996a). Most acholeplasmas have membrane-localized NADH oxidase activity, in comparison to the NADH oxidase activity located in the cytoplasm of other genera within the class. Another special characteristic is the occurrence in most acholeplasmas of unique pyrimidine enzymic activities, especially a dUTPase enzyme, with the possible exception again of *Acholeplasma multilocale* (Pollack et al., 1996b). Acholeplasmas may possess a number of other biological characteristics that may distinguish them from other genera within the class *Mollicutes*, including polyterpenol synthesis (Smith and Langworthy, 1979), positional distribution of fatty acids (Rottem and Markowitz, 1979), the presence of superoxide dismutase (Kirby et al., 1980; Lee and Kenny, 1984; Lynch and Cole, 1980; O’Brien et al., 1981), and the presence of spacer tRNA (Nakagawa et al., 1992). However, most of these features have not been established for even a majority of *Acholeplasma* species.

Taxonomic comments

Acholeplasma genome sizes range from 1215 to 2095 kbp by pulsed-field gel electrophoresis or complete DNA sequencing, but most are in a more narrow range of 1215–1610 kbp (Carle et al., 1993; Neimark et al., 1992) that overlaps with genome sizes of many *Spiroplasma* species. Tests of eight *Acholeplasma* species showed less than 8% DNA–DNA hybridization between type strains and surprisingly extensive genomic heterogeneity within species (Aulakh et al., 1983; Stephens et al., 1983a, b). The highest level of relatedness, 21% DNA–DNA hybridization, was between the type strains of *Acholeplasma laidlawii* and *Acholeplasma granularum*. Some strain pairs, such as within *Acholeplasma laidlawii*, shared as little as 40% DNA–DNA hybridization, differences that in other genera would have justified subdivision of an apparently diverse strain complex into component species. However, no polyphasic taxonomic basis was found to support such designations. Restriction endonuclease digest patterns also reflect heterogeneity within some species (Razin et al., 1983). The DNA–DNA hybridization and restriction digest patterns of eight *Acholeplasma axanthum* strains isolated from a variety of hosts and habitats differed markedly

from each other and some heterogeneity occurred among six different *Acholeplasma oculi* strains.

Mesoplasma pleciae was first isolated from the hemolymph of a larva of a *Plecia* corn root maggot and assigned to the genus *Mesoplasma* because sustained growth occurred in serum-free mycoplasma broth only when the medium contained 0.04% Tween 80 fatty acid mixture (Tully et al., 1994a). However, 16S rRNA gene sequence similarities and its preferred use of UGG rather than UGA to encode tryptophan support proper reclassification as *Acholeplasma pleciae* comb. nov. (Knight, 2004); the type strain is PS-1^T (Tully et al., 1994a).

Mycoplasma feliminutum was first described during a time when the only named genus of mollicutes was *Mycoplasma*. Its publication coincided with the first proposal of the genus *Acholeplasma* (Edward and Freundt, 1969, 1970), with which *Mycoplasma feliminutum* is properly affiliated through established phenotypic (Heyward et al., 1969) and 16S rRNA gene sequence (Brown et al., 1995; Johansson and Pettersson, 2002) similarities. This explains the apparent inconsistencies with its assignment to the genus *Mycoplasma*. The name *Mycoplasma feliminutum* should therefore be revised to *Acholeplasma feliminutum* comb. nov.; the type strain is Ben^T (=ATCC 25749^T; Heyward et al., 1969).

The lack of signature enzymic activities cast serious doubt on the status of *Acholeplasma multilocale* PN525^T as an authentic member of the genus *Acholeplasma* (Pollack et al., 1996b). It may be affiliated with an unrecognized metabolic subgroup, but it seems more likely to be a strain of *Mycoplasma* or *Entomoplasma*.

Differentiation of the species of the genus *Acholeplasma*

Esculin hydrolysis by a β -D-glucosidase and arbutin hydrolysis are sometimes useful diagnostic tests for differentiation of some acholeplasmas (Bradbury, 1977; Rose and Tully, 1983). The production of carotenoid pigments, principally neurosporene, has been used to differentiate some acholeplasmas, especially *Acholeplasma axanthum* and *Acholeplasma modicum* (Mayberry et al., 1974; Smith and Langworthy, 1979; Tully and Razin, 1970). Carotenoids are also synthesized in some strains of *Acholeplasma laidlawii* under certain growth conditions (Johansson, 1974). The “film and spots” reaction, which occurs in a number of *Mycoplasma* and several *Acholeplasma* species, relates to the production of crystallized calcium soaps of fatty acids on the surface of agar plates (Edward, 1954; Fabricant and Freundt, 1967). Fatty acids are liberated from the serum or

supplemental egg yolk (Fabricant and Freundt, 1967; Thorns and Boughton, 1978) in the agar medium by the lipolytic activity of the organisms. Failure to cross-react with antisera against previously recognized species provides evidence for species novelty. For this reason, deposition of antiserum against a novel type strain into a recognized collection is still mandatory for new species descriptions (Brown et al., 2007). Prelimi-

nary differentiation can be by PCR and DNA sequencing using primers specific for bacterial 16S rRNA genes or the 16S–23S intergenic region. A similarity matrix relating the candidate strain to its closest neighbors, usually species with >0.94 16S rRNA gene sequence similarity, will suggest an assemblage of related species that should be examined for serological cross-reactivities.

List of species of the genus *Acholeplasma*

1. *Acholeplasma laidlawii* (Sabin 1941) Edward and Freundt 1970, 1^{AL} (*Sapromyces laidlawii* Sabin 1941, 334)

laid.law'i.i. N.L. gen. masc. n. *laidlawii* of Laidlaw, named after Patrick P. Laidlaw, one of the microbiologists who first isolated this species.

This is the type species of the genus *Acholeplasma*. Filaments, usually relatively short, although much longer branched filaments may develop in media with certain ratios of saturated to unsaturated fatty acids. Coccoid forms may predominate in certain cultures including co-culture with eukaryotic cells. Agar colonies are large for a mollicute and exhibit well-developed central zones and peripheral growth on horse serum agar. On serum-free agar, colonies are smaller and may show only the central zone of growth into the agar. Relatively strong turbidity is produced during growth in broth containing serum. Temperature range for growth is 20–41°C with optimum at 37°C, even for strains recovered from plant or non-animal sources. Usually produces large amounts of carotenoids when cultivated in the presence of PPLO serum fraction (Difco).

Serologically distinct from most established species in the genus, but partial cross-reactions may occur with *Acholeplasma granularum* strains. DNA–DNA hybridization between strains of this species range from 40 to >80%. *Acholeplasma granularum* strain BTS-39^T showed 20% hybridization with *Acholeplasma laidlawii* strain PG8^T. Pathogenicity has not been established.

Source: isolated from sewage, manure, humus, soil, and many animal hosts and their tissues, including some isolates from the human oral cavity, vagina, and wounds. Has been recovered from the surfaces of some plants, although few isolations have been reported from insect hosts. Frequent contaminant of eukaryotic cell cultures.

DNA G+C content (mol%): 31.7–35.7 (Bd, T_m).

Type strain: ATCC 23206, PG8, NCTC 10116, CIP 75.27, NBRC 14400.

Sequence accession no. (16S rRNA gene): U14905.

Further comment: on the Approved Lists of Bacterial Names and on the Approved Lists of Bacterial Names (Amended Edition), this taxon is incorrectly cited as *Acholeplasma laidlawii* [Freundt 1955 (*sic*)] Edward and Freundt (1970).

2. *Acholeplasma axanthum* Tully and Razin 1970, 754^{AL}

a.xan'thum. Gr. pref. *a* not, without; Gr. adj. *xanthos* -ê -on yellow; N.L. neut. adj. *axanthum* without yellow (pigment).

Predominantly coccobacillary and coccoid with a few short myceloid elements. Large colonies with clearly marked centers form on horse serum agar; colonies on serum-free agar are smaller and usually lack the peripheral

growth around their center. Agar colonies produce zones of β-hemolysis by the overlay technique. Growth in media devoid of serum or serum fraction is much poorer than for other acholeplasmas. Minimal nutritional requirements are poorly defined, but marked stimulation of growth with polyoxyethylene sorbitan (Tween 80) suggests a requirement for fatty acids. Temperature range for growth is 22–37°C with optimum growth at 37°C. Synthesis of carotenoid pigments can be demonstrated only when large volume cultures are tested. Produces sphingolipids. No evidence for pathogenicity.

Source: originally isolated from murine leukemia tissue culture cells, but numerous subsequent isolations of the organism from bovine serum and a variety of bovine tissue sites (nasal cavity, lymph nodes, kidney) suggest cell-culture contamination was of bovine serum origin. Also isolated from variety of other animals and surfaces of some plants.

DNA G+C content (mol%): 31 (Bd).

Type strain: S-743, ATCC 25176, NCTC 10138.

Sequence accession no. (16S rRNA gene): AF412968.

3. *Acholeplasma brassicae* Tully, Whitcomb, Rose, Bové, Carle, Somerson, Williamson and Eden-Green 1994b, 683^{VP}

bras.si'cae. L. fem. gen. n. *brassicae* of cabbage, referring to the plant origin of the organism.

Cells are primarily coccoid. Temperature range for growth is 18–37°C. Optimal growth occurs at 30°C. No evidence for pathogenicity.

Source: isolated as a surface contaminant from broccoli (*Brassica oleracea* var. *italica*).

DNA G+C content (mol%): 35.5 (Bd, T_m , HPLC).

Type strain: 0502, ATCC 49388.

Sequence accession no. (16S rRNA gene): AY538163.

4. *Acholeplasma cavigenitalium* Hill 1992, 591^{VP}

ca.vi.ge.ni.ta'li.um. N.L. n. *cavia* guinea pig (*Cavia cobaya*); L. pl. n. *genitalia-ium* the genitals; N.L. pl. gen. n. *cavigenitalium* of guinea pig genitals.

Pleomorphic cells, mostly coccoid. Grows on broth or agar medium under aerobic conditions, with optimum temperature between 35 and 37°C. Colonies on agar medium have typical fried-egg appearance. Originally described as a non-fermenter, but the type strain ferments glucose. Does not grow well on SP-4 broth or in horse serum broth, but grows well on simple base medium with additions of 10–15% fetal bovine serum. No evidence for pathogenicity.

Source: isolated from the vagina of guinea pigs.

DNA G+C content (mol%): 36 (Bd).

Type strain: GP3, NCTC 11727, ATCC 49901.

Sequence accession no. (16S rRNA gene): AY538164.

5. **Acholeplasma entomophilum** Tully, Rose, Carle, Bové, Hackett and Whitcomb 1988, 166^{VP}

en.to.mo.phi'lum. Gr. n. *entomon* insect; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *entomophilum* insect-loving.

Cells are pleomorphic, but primarily coccoid. Colonies on solid medium usually have a fried-egg appearance. Acid is produced from glucose, but not mannose. Carotenoids are not produced. "Film and spot" reaction is negative. Agar colonies hemadsorb guinea pig erythrocytes. Strains require 0.4% Tween 80 or fatty acid supplements for growth in serum-free media. Temperature range for growth is 23–32°C, with optimum growth at about 30°C. Pathogenicity has not been established.

Source: isolated from gut contents of tabanid flies, beetles, butterflies, honey bees, and moths, and from flowers.

DNA G+C content (mol %): 30 (Bd).

Type strain: TAC, ATCC 43706.

Sequence accession no. (16S rRNA gene): M23931.

Further comment: with the proposal of the order *Entomoplasmatales* (Tully et al., 1993), *Acholeplasma entomophilum* was transferred to the family *Entomoplasmataceae*. The name *Acholeplasma entomophilum* was therefore revised to *Mesoplasma entomophilum* comb. nov. The type strain is TAC^T (=ATCC 43706^T; Tully et al., 1988).

6. **Acholeplasma equifetale** Kirchoff 1978, 81^{AL}

eq.ui.fe.ta'le. L. n. *equus* horse; N.L. adj. *fetalis -is -e* pertaining to the fetus; N.L. neut. adj. *equifetale* pertaining to the horse fetus.

Cells are pleomorphic, but predominantly coccoid. Colonies on solid medium containing serum usually have a fried-egg appearance; on serum-free medium, colonies are similar, but usually smaller. Growth temperature range is 22–37°C. Pathogenicity has not been established.

Source: isolated from the lung and liver of aborted horse fetuses. Also recovered from the respiratory tract of apparently normal horses and the respiratory tract and cloacae of broiler chickens (Bradbury, 1978).

DNA G+C content (mol %): 30.5 (Bd).

Type strain: C112, ATCC 29724, NCTC 10171.

Sequence accession no. (16S rRNA gene): AY538165.

Further comment: Kirchoff is incorrectly cited as "Kirchoff" on the Approved Lists of Bacterial Names.

7. **Acholeplasma florum** McCoy, Basham, Tully, Rose, Carle and Bové 1984, 14^{VP}

flo'rum. L. gen. pl. n. *florum* of flowers, indicating the recovery site of the organism.

Cells are ovoid. Colonies on agar are umbonate. Films and spots are produced on serum-containing media. Glucose is utilized, but mannose is not. Carotenes are not produced, nor is β -D-glucosidase. Pathogenicity has not been established.

Source: the known strains were isolated from flower surfaces.

DNA G+C content (mol %): 27.3 (Bd).

Type strain: L1, ATCC 33453.

Sequence accession nos. AF300327 (16S rRNA gene), NC_006055 (strain L1^T complete genome).

Further comment: with the proposal of the order *Entomoplasmatales* (Tully et al., 1993), *Acholeplasma florum* was transferred to the family *Entomoplasmataceae*. The name *Acholeplasma florum* was therefore revised to *Mesoplasma florum* comb. nov. The type strain is L1^T (=ATCC 33453^T; McCoy et al., 1984).

8. **Acholeplasma granularum** (Switzer 1964) Edward and Freundt 1970, 2^{AL} (*Mycoplasma granularum* Switzer 1964, 504)

gra.nu.la'rum. N.L. fem. n. *granula* (from L. neut. n. *granulum*) a small grain, a granule; N.L. gen. pl. n. *granularum* of small grains, made up of granules, granular.

Cells are pleomorphic, with short filaments and coccoid cells. Colonies on solid medium are large with clearly marked central zones and a fried-egg appearance. Colonies on serum-free medium are smaller and may lack the peripheral zone of growth around central core. Temperature range for growth is 22–37°C, with optimum around 37°C. Agar colonies produce a zone of β -hemolysis by the overlay technique using sheep erythrocytes. DNA–DNA hybridization studies showed 20–22% hybridization with *Acholeplasma laidlawii*, but none with other acholeplasmas. Pathogenicity has not been established. Aerosol challenge of specific pathogen-free pigs did not induce clinical or histological evidence of disease.

Source: isolated frequently from the nasal cavity of swine, with occasional isolates from swine lung and feces. Also isolated from the conjunctivae and nasopharynx of horses, and the genital tract of guinea pigs. Occasional contaminant of eukaryotic cell cultures.

DNA G+C content (mol %): 30.5–32.4 (T_m , Bd).

Type strain: BTS-39, ATCC 19168, NCTC 10128.

Sequence accession no. (16S rRNA gene): AY538166.

9. **Acholeplasma hippikon** Kirchoff 1978, 81^{AL}

hip.pi'kon. Gr. neut. adj. *hippikon* pertaining to the horse.

Cells are pleomorphic with predominantly coccoid forms. Colonies on solid medium containing horse serum typically have a fried-egg appearance, with smaller colonies on serum-free agar medium. Growth occurs over a temperature range of 22–37°C, with optimal growth at 35–37°C. Agar colonies produce β -hemolysis with the overlay technique, using a variety of animal red blood cells. Pathogenicity has not been established.

Source: isolated from the lung of aborted horse fetuses.

DNA G+C content (mol %): 33.1 (Bd).

Type strain: C1, ATCC 29725, NCTC 10172.

Sequence accession no. (16S rRNA gene): AY538167.

Further comment: Kirchoff is incorrectly cited as "Kirchoff" on the Approved Lists of Bacterial Names.

10. **Acholeplasma modicum** Leach 1973, 147^{AL}

mo'di.cum. L. neut. adj. *modicum* moderate, referring to moderate growth.

Cells are pleomorphic, with spherical, ring-shaped, and coccobacillary forms. Colonies on solid medium are distinctly smaller than those of most other acholeplasmas. Very small colonies without peripheral zones of growth are noted on serum-free solid medium. Very light turbidity is observed in serum-free broth, but more turbidity is found

in broth containing serum. Growth temperature range is 22–37°C, with optimum growth around 35–37°C. Can be shown to produce carotenoids when large volumes of cells are examined. Agar colonies produce α - or β -hemolysis by the overlay technique using sheep, ox, or guinea pig red blood cells. Pathogenicity has not been established.

Source: isolated from various tissues of cattle, including blood, bronchial lymph nodes, thoracic fluids, lungs, and semen. Also isolated from nasal secretions of pigs, and occasionally from chickens, turkeys, and ducks.

DNA G+C content (mol%): 29.3 (T_m).

Type strain: PG49, ATCC 29102, NCTC 10134.

Sequence accession no. (16S rRNA gene): M23933.

11. **Acholeplasma morum** Rose, Tully and Del Giudice 1980, 653^{VP}

mor'um. L. n. *morum* a mulberry, denoting the mulberry-like appearance of agar colonies of the organism.

Cells are pleomorphic, predominantly coccoid or coccobacillary forms, but with some beaded filaments. Colonies on solid medium without serum supplements are very small in size and have only central zones without any peripheral growth. Optimal growth on solid medium occurs with a 10% serum concentration and colony growth appears to be suppressed in a medium with 20% serum. Optimal growth in broth is apparent when 5–10% serum is added or when 1% bovine serum fraction supplements are added, but poor growth occurs in broth containing 20% horse serum. Growth in serum-free broth usually requires some fatty acid supplements, such as palmitic acid or polyoxyethylene sorbitan (Tween 80). Temperature range for growth is 23–37°C, with optimum growth at about 35–37°C.

Pathogenicity has not been established. Calf kidney cell cultures containing the organism show cytopathogenic effects.

Source: originally recovered from commercial fetal bovine serum and from calf kidney cultures containing fetal bovine serum. One isolation, in broth containing horse serum, was from a pool of *Armigeres subalbatus* mosquitoes collected by Leon Rosen in Taiwan in 1978 (strain SP7; D.L. Williamson and J.G. Tully, unpublished).

DNA G+C content (mol%): 34.0 (T_m).

Type strain: 72-043, ATCC 33211, NCTC 10188.

Sequence accession no. (16S rRNA gene): AY538168.

12. **Acholeplasma multilocale** Hill, Polak-Vogelzang and Angulo 1992, 516^{VP}

mul.ti.lo.ca'le. L. adj. *multus* many, numerous; L. adj. *localis* -is-e of or belonging to a place, local; N.L. neut. adj. *multilocale* referring to more than one location.

Pleomorphic cells. Colonies on agar medium have a typical fried-egg appearance. Organisms grow well in broth medium at 35–37°C. No evidence for pathogenicity.

Source: isolated from the nasopharynx of a horse and the feces of a rabbit.

DNA G+C content (mol%): 31 (Bd).

Type strain: PN525, NCTC 11723, ATCC 49900.

Sequence accession no. (16S rRNA gene): AY538169.

13. **Acholeplasma oculi** corrig. al-Aubaidi, Dardiri, Muscoplatt and McCauley 1973, 126^{AL}

o'cu.li. L. n. *oculus* the eye; L. gen. n. *oculi* of the eye.

Cells are pleomorphic, including spherical, ring-shaped, and coccobacillary forms. Medium-sized colonies with typical fried-egg appearance are formed on horse serum agar. Colonies on serum-free agar are smaller and may lack the peripheral growth around the central core. Growth occurs at temperatures of 25–37°C. Agar colonies produce zones of hemolysis by the overlay technique using sheep red blood cells.

Pathogenicity is not well established. Intravenous inoculation of goats produced signs of pneumonia and death within 6 d. Conjunctival inoculation of goats produced mild conjunctivitis.

Source: isolated from the conjunctiva of goats with keratoconjunctivitis; porcine nasal secretions; equine nasopharynx, lung, spinal fluid, joint, and semen; the urogenital tract of cattle; and the external genitalia of guinea pigs. Present in amniotic fluid of pregnant women (Waites et al., 1987). Occasionally isolated from ducks and turkeys, with unreported isolations from an ostrich. Also several isolations from palm trees and other plants (Eden-Green and Tully, 1979; Somerson et al., 1982). Isolations from eukaryotic cell cultures may represent contamination of bovine origin.

DNA G+C content (mol%): 27 (T_m).

Type strain: 19-L, ATCC 27350, NCTC 10150.

Sequence accession no. (16S rRNA gene): U14904.

Further comment: originally named *Acholeplasma oculusi* by al-Aubaidi et al. (1973); the orthographic error was corrected by al-Aubaidi (1975).

14. **Acholeplasma palmae** Tully, Whitcomb, Rose, Bové, Carle, Somerson, Williamson and Eden-Green 1994b, 683^{VP}

pal'mae. L. fem. gen. n. *palmae* of a palm tree, referring to the plant from which the organism was isolated.

Cells are primarily coccoid. Colonies on solid medium usually have a fried-egg appearance. The temperature range for growth is 18–37°C, with optimal growth occurring at 30°C. No evidence for pathogenicity. It is one of the closest phylogenetic relatives of the phytoplasmas.

Source: isolated from the crown tissues of a palm tree (*Cocos nucifera*) with lethal yellowing disease.

DNA G+C content (mol%): 30 (Bd, T_m , HPLC).

Type strain: J233, ATCC 49389.

Sequence accession no. (16S rRNA gene): L33734.

15. **Acholeplasma parvum** Atobe, Watabe and Ogata 1983, 348^{VP}

par'vum. L. neut. adj. *parvum* small, intended to refer to the poor biochemical activities and tiny agar colonies of the organism.

Pleomorphic coccobacillary cells. Colonies on agar medium present a typical fried-egg appearance under both aerobic and anaerobic conditions. Initial reports of growth in the absence of cholesterol or serum have been made, but growth on serum-free medium is not well confirmed. The organism does not grow in most standard media for acholeplasmas or in most other medium formulations for sterol-requiring mycoplasmas. Needs special growth factor of 1% pytone or soytone peptone supplements; growth is sometimes better with the addition of 15% fetal bovine serum. Organisms grow on agar better than in broth; growth is

better under aerobic conditions than under anaerobic conditions and better at 22–30°C than at 37°C. No evidence of fermentation of any carbohydrate, including glucose, salicin, and esculin. No evidence for pathogenicity.

Source: isolated from the oral cavities and vagina of healthy horses.

DNA G+C content (mol%): 29.1 (T_m).

Type strain: H23M, ATCC 29892, NCTC 10198.

Sequence accession no. (16S rRNA gene): AY538170.

16. **Acholeplasma pleciae** (Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a) Knight 2004, 1952^{VP} (*Mesoplasma pleciae* Tully, Whitcomb, Hackett, Rose, Henegar, Bové, Carle, Williamson and Clark 1994a, 690)

ple.ci'ae. N.L. gen. n. *pleciae* of *Plecia*, referring to the genus of corn maggot (*Plecia* sp.) from which the organism was first isolated.

Cells are primarily coccoid. Colonies on solid media incubated under anaerobic conditions at 30°C have a fried-egg appearance. Supplements of 0.04% polyoxyethylene sorbitan (Tween 80) are required for growth in serum-free media. Temperature range for growth is 18–32°C, with optimal growth at 30°C. Agar colonies do not hemadsorb guinea pig erythrocytes. No evidence for pathogenicity.

Source: originally isolated from the hemolymph of a larva of the corn root maggot (*Plecia* sp.).

DNA G+C content (mol%): 31.6 (Bd, T_m , HPLC).

Type strain: PS-1, ATCC 49582.

Sequence accession no. (16S rRNA gene): AY257485.

17. **Acholeplasma seiffertii** Bonnet, Saillard, Vignault, Garnier, Carle, Bové, Rose, Tully and Whitcomb 1991, 48^{VP}

seif.fer'ti.i. N.L. gen. masc. n. *seiffertii* of Seiffert, in honor of Gustav Seiffert, a German microbiologist who performed

pioneering studies of sterol-nonrequiring mollicutes that occur in soil and compost.

Cells are primarily coccoid. Colonies on solid medium usually have the appearance of fried-eggs. Acid produced from glucose and mannose. Colonies on agar hemadsorb guinea pig erythrocytes. Temperature range for growth is 20–35°C; optimum growth occurs at 28°C. No evidence for pathogenicity.

Source: isolated from floral surfaces of a sweet orange (*Citrus sinensis*) and wild angelica (*Angelica sylvestris*).

DNA G+C content (mol%): 30 (Bd).

Type strain: F7, ATCC 49495.

Sequence accession no. (16S rRNA gene): AY351331.

Further comment: with the proposal of the order *Entomoplasmatales* (Tully et al., 1993), *Acholeplasma seiffertii* was transferred to the family *Entomoplasmataceae*. The name *Acholeplasma seiffertii* was therefore revised to *Mesoplasma seiffertii* comb. nov. The type strain is F7^T (=ATCC 49495^T; Bonnet et al., 1991).

18. **Acholeplasma vituli** Angulo, Reijgers, Brugman, Kroesen, Hekkens, Carle, Bové, Tully, Hill, Schouls, Schot, Roholl and Polak-Vogelzang 2000, 1130^{VP}

vi.tu'li. L. n. *vitulus* calf; L. gen. n. *vituli* of calf, referring to the provenance or occurrence of the organism in fetal calf serum.

Cells are predominantly coccoid in shape. Colonies on solid media demonstrate a fried-egg appearance under both aerobic and anaerobic conditions. Temperature range for growth is 25–37°C. No evidence for pathogenicity.

Source: isolated from fetal bovine serum or contaminated eukaryotic cell cultures containing serum.

DNA G+C content (mol%): 38.3 (Bd), 37.6 (T_m).

Type strain: FC 097-2, ATCC 700667, CIP 107001.

Sequence accession no. (16S rRNA gene): AF031479.

Family II. Incertae sedis

This family includes the phytoplasma strains of the order *Acholeplasmatales*. Although never cultured in cell-free media,

these plant pathogens and symbionts have been well studied by culture-independent methods.

Genus I. “*Candidatus Phytoplasma*” gen. nov. IRPCM Phytoplasma/Spiroplasma Working Team 2004, 1244

NIGEL A. HARRISON, DAWN GUNDERSEN-RINDAL AND ROBERT E. DAVIS

Phy.to.plas'ma. Gr. masc. n. *phytos* a plant; Gr. neut. n. *plasma* something formed or molded, a form.

Phytoplasmas (Sears and Kirkpatrick, 1994) are wall-less, nutritionally fastidious, phytopathogenic prokaryotes 0.2–0.8 µm in diameter that morphologically resemble members of the *Mollicutes*. Sequencing of nearly full-length PCR-amplified 16S rRNA genes (Gundersen et al., 1994; Namba et al., 1993; Seemüller et al., 1994), combined with earlier studies (Kuske and Kirkpatrick, 1992b; Lim and Sears, 1989), provided the first comprehensive phylogeny of the organisms and showed that they constitute a unique, monophyletic clade within the *Mollicutes*. These organisms are most closely related to members of the genus *Acholeplasma* within the *Anaeroplasmatales* clade as defined by Weisburg et al. (1989). Sustained culture in cell-free

media has not yet been demonstrated for any phytoplasma. Their genome sizes have been estimated to range from 530 to 1350 kb, and the G+C content of phytoplasma DNA is about 23–30 mol%. The presence of a characteristic oligonucleotide sequence in the 16S rRNA gene, CAA GAY BAT KAT GTK TAG CYG GDC T, and standard codon usage indicate that phytoplasmas represent a distinct taxon for which the name “*Candidatus Phytoplasma*” has been adopted by specialists in the molecular biology and pathogenicity of these and similar phytopathogenic organisms (IRPCM Phytoplasma/Spiroplasma Working Team – Phytoplasma Taxonomy Group, 2004). At present, the designation “*Candidatus*” must still be used for new types.

Further descriptive information

Phytoplasma cells typically have a diameter less than 1 μm and are polymorphic. Viewed in ultra-thin section by electron microscopy Figure 115, they appear ovoid, oblong, or filamentous in plant and insect hosts (Doi et al., 1967; Hearon et al., 1976). Transmission electron microscopy of semi-thick (0.3 μm) sections (Thomas, 1979) and serial sections (Chen and Hiruki, 1978; Florance and Cameron, 1978; Waters and P. Hunt., 1980), and scanning electron microscopy studies (Bertaccini et al., 1999; Haggis and Sinha, 1978; Marcone et al., 1996) have done much to clarify the gross cellular morphology of phytoplasmas. They range from spherical to filamentous, often with extensive branching reminiscent of that seen in *Mycoplasma mycoides*. Small dense rounded forms $\sim 0.1 \mu\text{m}$ in diameter, formerly considered to be "elementary bodies" when seen in thin section, were shown to represent constrictions in filamentous forms. Dumbbell-shaped forms once thought to be "dividing cells" are actually branch points of filamentous forms, whereas forms thought to have internal vesicles have been shown to have invaginated membranes oriented such that the plane of the sections cut through the cell membrane twice (McCoy, 1979). Phytoplasma cell membranes are resistant to digitonin and sensitive to hypotonic salt solutions, and, as such, are similar to those of non-sterol requiring mollicutes (Lim et al., 1992).

Phytoplasmas are consistently observed within phloem sieve elements (Christensen et al., 2004; McCoy et al., 1989; Oshima et al., 2001b; Webb et al., 1999) and occasionally have been reported in both companion cells (Rudzinska-Langwald and Kaminska., 1999; Sears and Klomparens, 1989) and parenchyma cells (Esau et al., 1976; Siller et al., 1987) of infected plants. Sieve elements are specialized living cells that lack nuclei when mature and transport photosynthate from leaves not only to growing tissues, but also to other tissues unable to photosynthesize (Oparka and Turgeon, 1999; Sjölund, 1997). This applies particularly to roots that require considerable energy

for the uptake of water and nutrients (Flores et al., 1999). Phloem sap is unique in that it contains from 12 to 30% sucrose and is under high hydrostatic (turgor) pressure (Evert, 1977). Sieve elements have pores in their end plates and lateral walls, allowing passage of photosynthate to adjacent sieve tube elements. The sieve pores, which have an average diameter of $\sim 0.2 \mu\text{m}$, are of sufficient size to allow passage of spherical and filamentous phytoplasma cells from one sieve element to another (McCoy, 1979). The chemical composition of sieve sap is complex, containing sugars, minerals, free amino acids, proteins, and ATP (Van Helden et al., 1994). This rich milieu, with its high osmotic and hydrostatic pressures, serves to support extensive multiplication of phytoplasmas *in planta*. Phytoplasmas also multiply in the internal tissues and organs of their insect vectors (Kirkpatrick et al., 1987; Lefol et al., 1994; Marzachi et al., 2004; Nasu et al., 1970), which are primarily leafhoppers, planthoppers, and psyllids (D'Arcy and Nault, 1982; Jones, 2002; Weintraub and Beanland, 2006). In many respects, the composition of insect hemolymph is similar to that of plant phloem sap, as both contain high levels of complex and simple organic compounds (Moriwaki et al., 2003; Saglio and Whitcomb, 1979).

Physical maps of several phytoplasma genomes have been constructed (Firrao et al., 1996; Lauer and Seemüller, 2000; Marcone and Seemüller, 2001; Padovan et al., 2000). The presence of extrachromosomal DNAs or plasmids in numerous phytoplasmas has also been reported (Davis et al., 1988; Denes and Sinha, 1991; Kuboyama et al., 1998; Kuske and Kirkpatrick, 1990; Liefing et al., 2004; Lin et al., 2009; Nakashima and Hayashi, 1997; Nishigawa et al., 2003; Oshima et al., 2001a; Tran-Nguyen and Gibb, 2006) and suggested as a potential means of intermolecular recombination (Nishigawa et al., 2002b). Phytoplasma-associated extrachromosomal DNAs have been shown to contain genes encoding a putative geminivirus-related replication (Rep) protein (Liefing et al., 2006; Nishigawa et al., 2001; Rekab et al., 1999) and a single-stranded DNA-binding

FIGURE 115. Electron micrographs of ultrathin sections of leaf petiole from a sunnhemp (*Crotalaria juncea* L.) plant displaying *Crotalaria* phyllody disease symptoms. (a) Polymorphic phytoplasma cells occluding the lumen of adjacent leaf phloem sieve tube elements. Bar = 2 μm . (b) Ultrastructural morphology indicates phytoplasma cells are bounded by a unit membrane and contain DNA fibrils and ribosomes. Bar = 200 nm. Images provided by Phil Jones.

protein (Nishigawa et al., 2002a), as well as a putative gene similar to DNA primase of other bacterial chromosomes (Liefing et al., 2004) and still other genes of as yet unknown identity. Moreover, heterogeneity in extrachromosomal DNAs has been associated with reduced pathogenicity and loss of insect vector transmissibility (Denes and Sinha, 1992; Nishigawa et al., 2002a, 2003).

Onion yellows mild strain (OY-M) was the first phytoplasma genome to be completely sequenced. The genome of this aster yellows group strain consists of a circular chromosome of 860,632 bp. It also contains two extrachromosomal DNAs, EcOYM (5025 bp) and plasmid pOYM (3932 bp) (Nishigawa et al., 2003; Oshima et al., 2002), representing two different classes based on the type of replication protein encoded. While EcOYM contains a *rep* gene homologous to that of the geminiviruses, pOYM has a *rep* gene that encodes a unique protein with characteristics of both viral-*rep* and plasmid-*rep* (Namba, 2002). The chromosome is a circular DNA molecule with a G+C content of 28 mol% and contains 754 open reading frames (ORFs), comprising 73% of the chromosome. Of these, 66% of ORFs exhibit significant homology to gene sequences currently archived in the GenBank database. Putative proteins encoded by ORFs could be assigned to one of six different functional categories: (1) information storage and processing (260 ORFs); (2) metabolism (107 ORFs); (3) cellular processes (77 ORFs); (4) poorly characterized, i.e., with homology to uncharacterized proteins of other organisms (50 ORFs); or (5) others, i.e., without homology to any known proteins (260 ORFs). Like mycoplasmal genomes, the OY-M phytoplasma genome lacks many genes related to amino acid and fatty acid biosynthesis, the tricarboxylic acid cycle, and oxidative phosphorylation. However, OY-M phytoplasma differs from mycoplasma in that it lacks genes for the phosphotransferase system and for metabolizing UDP-galactose to glucose 1-phosphate, suggesting that it possesses a unique sugar intake and metabolic system. Furthermore, OY-M phytoplasma lacks most of the genes needed to synthesize nucleotides and ATP suggesting that it probably assimilates these and other necessary metabolites from host cytoplasm. Many genes, such as those for glycolysis, are present as multiple redundant copies representing 18% of the total genome. Twenty-seven genes encoding transporter systems such as malate, metal-ion and amino acid transporters, some of which have multiple copies, were identified, suggesting that phytoplasmas aggressively import many metabolites from the host cell. Other than genes encoding glucanase and hemolysin-like proteins, no other genes presently known to be related to bacterial pathogenicity were evident in the OY-M phytoplasma genome, suggesting novel mechanisms for virulence.
