Menstrual blood loss is the most common cause of iron deficiency in women.[8,240,241,242] In healthy normal women, menstrual blood flow averages ~35 ml per menstrual period, and the upper limit of normal is ~80 ml per period. Although flow varies considerably among different women, it is remarkably constant from one period to the next in the same person. In Swedish women with a dietary intake of ~10 mg of iron per day, 67% of women with menstrual blood loss >80 ml per period were anemic.[240,241] In another study, British women with iron deficiency anemia lost an average of 85 ml per period.[242] In contrast, a Canadian population with flows >80 ml per period had no overt anemia or hypoferremia.[243]

Menstrual blood flow is increased by the use of certain intrauterine contraceptive devices[244] and is reduced by the use of oral contraceptives. Estimating menstrual blood loss from information obtained in interviews is difficult because few women have a basis for determining the normality of their flow. It is important to elicit a history including a detailed description of the events during each menstrual period. Any of the following findings are indications of excessive menstrual flow: (a) inability to control flow with tampons alone; (b) use of more than 12 pads per period or 4 per day, unless the patient is unusually fastidious; (c) passage of clots, especially if they are larger than ~2 cm in diameter or if they persist after the first day; and (d) period duration exceeding 7 days.

Blood Donation

There are 5 million regular blood donors in the United States,[245] and regular blood donation is an important source of iron loss. Each unit of blood donated contains 200 ml RBC[246] equaling ~200 mg of iron. In most blood centers, a hemoglobin concentration, which is an insensitive determination for iron status, is the only indicator for iron deficiency anemia. As assessed by serum ferritin concentration, iron stores were reduced in 8% of male and 23% of female blood donors.[245] The authors concluded that the use of iron supplements decreased the incidence of deficiency, and should be recommended to people who choose to donate more than once or twice a year. In a recent analysis of the RISE (Retrovirus Epidemiology Donor Iron Status Evaluation) study,[247] for frequent blood donors, two thirds of women and almost half the men were iron deficient: the true prevalence among regular donors is even higher, inasmuch as the RISE study enrolled only frequent donors who had been accepted for donation, and excluded those deferred because of anemia. The unavoidable conclusion is that presently, blood collection practices fail to protect committed blood donors from iron deficiency.[248] Re-examination of measures to prevent iron deficiency in women of child-bearing age by iron replacement after donation[249] may now be in order to protect donors better, including changes in evaluation of iron status, in the hemoglobin standard, and internally between donations.[250]

Alveolar Hemorrhage

Acute hemorrhage into the pulmonary alveoli may be severe enough to cause the blood hemoglobin level to fall 1.5 to 3.0 g/dl in 24 hours.[251] Reticulocytosis and hyperbilirubinemia often accompany such episodes, leading to an incorrect diagnosis of hemolytic anemia. Iron in the shed blood is converted to hemosiderin by pulmonary macrophages, but it cannot be used for hemoglobin synthesis. Thus, repeated hemorrhages can lead to iron deficiency despite a normal total amount of body iron. Hemoptysis and alveolar infiltrates are the other prominent manifestations. However, if the hemorrhages are small, the hemoptysis may be unnoticed, making the diagnosis difficult without a chest x-ray examination. Patients may swallow the blood-containing sputum, rendering the stools positive for occult blood and resulting in further diagnostic confusion.

Idiopathic pulmonary hemosiderosis, an illness of children and young adults, is characterized by alveolar hemorrhage that is not due to another form of lung disease.[252,253] Iron deficiency anemia almost invariably accompanies the disease and may be the initial and only symptom. Hemoptysis and alveolar infiltrates, however, are common manifestations. Interstitial fibrosis may develop after repeated episodes, with dyspnea, clubbing, and even cor pulmonale.

Anemia is also a common finding in antiglomerular basement membrane antibody disease (Goodpasture syndrome).[253,254] The presence of renal disease distinguishes this illness from other forms of pulmonary hemosiderosis, but kidney involvement may not be evident early in the course of the disease or the degree of proteinuria or microscopic hematuria may be modest. Eventually, however, most patients develop azotemia. Focal or diffuse glomerulonephritis is evident from renal biopsy, and linear deposits of immunoglobulins are characteristic of, although not completely specific for, the disease. Detection of antibasement membrane antibodies in serum is ~80% to 85% sensitive and 98% specific for the diagnosis.[251]

Other illnesses associated with pulmonary alveolar hemorrhage include rapidly progressive glomerulonephritis, systemic lupus erythematosus, and certain other collagen vascular diseases and systemic vasculitides. The presence of antineutrophil cytoplasm antibodies or other autoantibodies is considered a particularly poor prognostic sign in patients with pulmonary hemosiderosis.[252] Alveolar hemorrhage is also observed as a toxic reaction to trimellitic anhydride, d-penicillamine, or lymphangiography.

Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria can result in urinary iron losses averaging 1.8 to 7.8 mg/day.[255] Consequently, this rare disorder often is complicated by hypoferremia and hypochromic anemia.[256] Hemoglobinuria in other disorders, such as the erythrocyte fragmentation syndromes associated with prosthetic cardiac valves, also may be complicated by iron deficiency.[257,258]

Factitious Anemia

Self-induced blood-letting (autophlebotomy) is an unusual cause of iron deficiency.[259,260] In almost all reported instances, such anemia occurred in unmarried women in paramedical occupations. Blood was removed by venipuncture or injuring preexisting

hemorrhoids, by laceration of the gastrointestinal tract with such instruments as knitting needles, or by means that remained obscure. A single case was reported in which an infant apparently developed severe iron deficiency as a result of deliberate parental action in which all iron from the child's diet was removed.[261]

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia is an uncommon disorder characterized by recurrent hemorrhages from the nose, gastrointestinal tract, and other sites. Iron deficiency anemia, sometimes very difficult to control, is an important complication of the illness.[262]

Iatrogenic Blood Loss

Diagnostic phlebotomy can result in substantial iron losses in patients with chronic disorders, particularly in hospitalized patients.[263,264] In a study of 100 adult hospital inpatients in the 1980s, the average blood loss from diagnostic phlebotomy was 12.4 ml/day or 175.0 ml over the course of hospitalization on general wards.[263] Patients in intensive care units lost an average of 41.5 ml/day or 762.0 ml during their stay. Of the 100 patients, 36 required blood transfusions, in part because of the losses from phlebotomy. Phlebotomy can contribute to a negative iron balance, and in patients with marginal iron stores, may precipitate or aggravate iron deficiency anemia and prevent compensatory erythropoiesis.

Chronic Renal Failure Treated with Hemodialysis

Iron deficiency affects a significant fraction of patients treated with hemodialysis now that the anemia related to chronic kidney disease is treated with pharmacologic agents and blood transfusions are restricted.[265,266] Absolute iron deficiency results from the loss of blood associated with the dialysis process and diagnostic tests. Gastrointestinal blood losses may also be substantial, averaging 6.27 ml/day in one study.[267] Telangiectasias are among the most common bleeding gastrointestinal lesions in patients with renal failure. Other factors contributing to negative iron balance include reduced dietary iron intake and malabsorption of iron caused by the aluminum hydroxide used to control hypophosphatemia.

Administration of erythropoiesis stimulating agents (ESA) results in a "functional iron deficiency" even when body iron stores are replete.[268] The intense, periodic erythropoietic stimulus due to ESA therapy exceeds the mobilization of iron from macrophages, so that adequate transferrin-bound iron is not available to red blood cell precursors.[268–270] For this reason, parenteral iron supplementation is often provided as an adjunct to ESA therapy in patients with ESKD.[143,268]

Runner's Anemia

Iron deficiency anemia can occur in long-distance runners.[271] Over 50% of regular joggers and competitive runners become iron deficient.[272] Mild mechanical hemolysis accompanies strenuous exercise, resulting in hemoglobinemia and hemoglobinuria (also called march hemoglobinuria). Gastrointestinal bleeding contributes to blood loss and iron deficiency.[272–274] Fecal blood excretion increases substantially after a race or an intense training exercise and may reach 5 to 7 ml/day. Stress, intestinal ischemia, and the jarring effect of running have been advanced as possible explanations for the gastrointestinal blood loss.

Decreased Total Body Iron at Birth

Body iron concentration in normal neonates averages ~75 to 100 mg/kg weight. Similar concentrations are found throughout fetal development, resulting in a linear relationship between body iron and body weight. Newborn babies in the upper range of normal birth weights have more iron than those in the lower range. Premature infants are at higher risk of iron deficiency during the first year of life, because they have not had the full opportunity to accumulate iron stores during the third trimester of gestation.

Newborn iron levels can be influenced by the technique that the obstetrician uses to clamp the umbilical cord at delivery.[275] As much as 100 ml of fetal blood may remain in the placenta with early clamping of the cord. Cord clamping delayed for only 3 minutes can result in a 58% increase in red cell volume. If delayed clamping is impractical, as in cesarean section procedures, a similar effect can be achieved by clamping the cord at the placental end, raising the clamp, and allowing gravity to drain the cord.[276] Although the newborn has no immediate need for these erythrocytes, the iron they contain can be used later to meet the demands of growth.

The fetus is an effective scavenger of maternal iron, in which fetal hepcidin controls the placental transfer of iron from maternal plasma to the fetal circulation,[124] therefore, maternal iron stores have little or no effect on the body iron stores of the newborn.[277] No difference was found between the hemoglobin values in infants of anemic mothers and those in infants of nonanemic mothers either at birth or later.[278] Furthermore, iron supplementation during pregnancy has no effect on the subsequent development of iron deficiency in the infant, although it may be protective for the mother. Finally, as measured by serum ferritin levels, maternal iron stores bear no relation to fetal stores.[276] These observations are consistent with results of studies in animals that demonstrate iron transported across the placenta against a gradient, even at the expense of maternal iron stores.[279]

Growth

In the absence of disease, iron requirements of an adult man are relatively low and vary little. In contrast, in infancy, childhood, and adolescence, the requirements for iron are relatively great because of the increased needs of rapidly growing tissues. The most rapid relative growth rates in human development occur in the first year of life. Body weight and blood volume approximately triple, and the circulating hemoglobin mass nearly doubles. Still greater relative growth occurs in premature and low birth–weight infants. Premature infants weighing 1.5 kg may increase their weight and blood volume sixfold and may triple the circulating hemoglobin mass in 1 year. To meet the demands imposed by growth, the normal-term infant must acquire 135 to 200 mg of iron during the first year of life. A premature infant may require as much as 350 mg in the same period.[280]

The relatively slower rates of growth in children through the remainder of the first decade require a positive iron balance of ~0.2 to 0.3 mg/day. The growth spurt that occurs in the early teens requires a positive balance of ~0.5 mg/day in girls and 0.6 mg/day in boys.[196] Toward the end of this period, the onset of menstruation occurs in girls, and their requirements then equal those of adult women.

Diet in Infancy and Childhood

Iron stores in the infant are typically depleted by 4 to 6 months of age as a result of the demands of growth. During this critical period, a normal full-term infant must absorb ~0.4 to 0.6 mg of iron daily from the diet. To achieve this level of absorption, an iron intake of 1 mg/kg/day is recommended for full-term infants, 2 to 4 mg/kg/day for preterm infants, and at least 6 mg (to a maximum of 15 mg) for preterm infants receiving erythropoietin therapy.[281] These amounts may be difficult to achieve without supplementation.

Both human milk and cow's milk contain relatively small amounts of iron, but the infant more readily absorbs the iron in

human milk. In one study, 49% of the iron in human breast milk was absorbed, compared with 10% of the iron in cow's milk.[282] As a result, iron deficiency is relatively uncommon in the first 6 months of life in infants exclusively fed breast milk.

Formula-fed infants are likely to become iron deficient unless iron-supplemented formulas are used. In the United States, such formulas are often supplemented with iron (10 to 12 mg/L) as ferrous sulfate, of which a variable proportion is absorbed.[281] Approximately 7% to 12% of the iron in cow's milk–based formulas is absorbed, with the lower percentage seen when formulas with higher iron content are given.[283] Less iron is absorbed from soy-based formulas, but soy formulas containing 12 mg/L of iron appear to be adequate.[284] Fortified dry cereals for infants are another important source of iron in the diet of both breast-fed and formula-fed infants. Currently, infant cereals are fortified with small-particle elemental iron at a concentration of 0.45 mg/g, from which ~4% is absorbed.[285] Two servings per day will supply the needs of most infants.

Excessive intake of cow's milk is an important cause of iron deficiency in the first 2 years of life.[280,286] Not only is cow's milk a poor source of iron, it may cause gastrointestinal blood loss (see next section). In general, cow's milk should not be given to infants <1 year of age, although it may be tolerated if the remainder of the diet is iron-rich.[287] Some parents allow their toddler children to use the bottle as a pacifier and constant companion, and the children become addicted ("milkaholics"). In one study, inadequate diet was considered the only factor in the development of iron deficiency in 20 of 55 infants[288]; few patients in this series had iron deficiency resulting from defective stores at birth, unless the diet was also inadequate. A unique disorder termed Bahima disease, described in Uganda, was attributed to the practice of feeding children a diet of cow's milk almost exclusively.[289]

Blood Loss in Infancy

Occult hemorrhage, often without obvious anatomic lesions, may be observed in some iron-deficient infants.[285,290,291] The process is often accompanied by diffuse disease of the bowel with protein-losing enteropathy and impaired absorption of other nutrients.[292,293] It probably results from hypersensitivity to a heat-labile protein in cow's milk.[294,295] The daily loss of 1 to 4 ml of blood, along with increased serum albumin turnover, was observed while fresh cow's milk was consumed, and these abnormalities ceased abruptly with the substitution of heat-treated or soybean-protein feeding formulas.

Pregnancy and Lactation

Pregnancy is a major drain on the limited iron reserves of young women. Each pregnancy results in an average loss to the mother of 680 mg of iron, the equivalent of 1,300 ml of blood. An additional 450 mg of iron must be available to support the expanded blood volume during pregnancy. The latter amount of iron does not represent a net loss after delivery because the iron is returned to stores; it must be available. However, during the pregnancy or iron deficiency will supervene.

Prorated over the full term of pregnancy, the iron requirement amounts to ~2.5 mg/day (Table 23.6). Because most of the loss occurs during the third trimester, the requirement is small early in pregnancy and rises to as much as 3.0 to 7.5 mg/day in the third trimester. These amounts are greater than those that can be absorbed from even the best of diets, and stores may be insufficient to meet them. For this reason, iron supplementation is frequently recommended as a component of prenatal care. In the absence of supplements, maternal iron deficiency may occur, usually manifesting in the third trimester.

Lactation results in a daily iron loss of ~0.5 to 1.0 mg. The iron content of human breast milk is probably not affected by the maternal iron stores.[296] Because normal menstruation is usually inhibited while breastfeeding continues, iron requirements in the lactating mother approximate those of the menstruating woman.

TABLE 23.6

IRON BALANCE IN PREGNANCY

Iron Fate	Mean Amount (mg)	Range (mg)
Lost to fetus	270	200–370
Lost in placenta, cord	90	30–170
Lost with bleeding at delivery	150	90–310
Normal body iron loss	170	150–200
Added to expanded red blood cell mass	450	200–600
Total	1,130	670–1,650
Returned to stores when red blood cell mass contracts after delivery	450	200–600
Net loss (over 9 months)	680	470–1,050

Signs and Symptoms of Iron Deficiency

The onset of iron deficiency anemia is usually insidious, and the progression of symptoms is gradual. As a result, patients accommodate remarkably well to advancing anemia and may delay a visit to their physicians for prolonged periods.

Fatigue and Other Nonspecific Symptoms

Iron deficiency anemia can be associated with irritability, palpitations, dizziness, breathlessness, headache, and fatigue. Fatigue is a particularly common complaint among patients. Even latent iron deficiency (i.e., iron deficiency without any anemia at all) has been described to result in fatigue,[297] but others were unable to confirm this observation.[298] Nevertheless, iron therapy has been shown to ameliorate fatigue: a group of 44 nonanemic women reporting fatigue were treated both with iron and with placebo in random order. Symptomatic improvement in women receiving iron was significantly better than that of women given the placebo, but only in women whose iron stores were depleted. In a recent randomized clinical trial of intravenous iron therapy in 90 premenopausal nonanemic women presenting with fatigue, serum ferritin ≤50 ng/ml and Hgb ≥12 g/dl, fatigue scopes decreased significantly within 6 weeks of therapy compared to placebo, particularly in women with baseline serum ferritin ≤15 ng/ml.[299]

Neuromuscular System

Despite the lack of symptoms at rest, investigators have demonstrated that even mild degrees of iron deficiency anemia impair muscular performance, as measured by standardized exercise tests.[173,300] Total exercise time, maximal workload, heart rate, and serum lactate levels after exercise are all affected adversely in proportion to the degree of anemia. Furthermore, work performance and productivity at tasks requiring sustained or prolonged activity are impaired in iron-deficient subjects and improve when iron is administered.[301,302] As a result, measures directed toward iron nutrition of a workforce can produce important economic dividends, more than offsetting the costs of the treatment program.

Abnormalities in muscle metabolism are noted even when deficiency is mild.[303] Blood lactate levels were measured in mildly

iron-deficient female athletes after standardized exercise tests. Peak lactate levels fell significantly after 2 weeks of iron treatment. This observation led to the suggestion that iron deficiency forces the muscles to depend to a greater extent on anaerobic metabolism than occurs in normal subjects.

Animal studies demonstrate that muscle function is disturbed in iron deficiency. The spontaneous activity level of iron-deficient rats decreased,[304] and short-term exercise tolerance in treadmill running tests was reduced,[166,167,303,305] even at mild degrees of deficiency.[306] These abnormalities could not be explained by anemia alone, because they persisted after anemia was corrected by exchange transfusion.[166,167] All were corrected promptly when iron was administered. In contrast, in a patient study no abnormalities of muscle function were noted in six nonanemic patients with long-standing iron deficiency, induced for the treatment of polycythemia vera.[307]

A variety of behavioral disturbances have been observed in iron-deficient children.[174,308,309,310,311,312] These children have been reported to be irritable and disruptive, with short attention spans and a lack of interest in their surroundings. Neurologic development in infants[313] and scholastic performance in older children[314] may be impaired. Cognitive performance is defective in iron-deficient rats.[315] All of these behavioral abnormalities are ameliorated with the initiation of iron therapy.

The ability to maintain body temperature on exposure to cold is impaired in iron-deficient patients[316] and animals.[317] Occasional patients experience neuralgia pains, vasomotor disturbances, or numbness and tingling. In children, iron deficiency has been associated with neurologic sequelae, including developmental delay, ischemic stroke, increased intracranial pressure, papilledema, and the clinical picture of pseudotumor cerebri.[318] The pathogenesis is probably complex, involving severe anemia, thrombocytosis, and reduced levels of tissue iron enzymes.

Epithelial Tissues

Patients with long-standing iron deficiency may develop a constellation of symptoms characterized by defective structure or function of epithelial tissues. Especially affected are the nails, the tongue and mouth, the hypopharynx, and the stomach. These epithelial lesions tend to occur together in the same patients at the same time[319,320] but also may occur as isolated findings.

In iron-deficient subjects, the fingernails may become brittle, fragile, or longitudinally ridged, but these findings are quite nonspecific. Alterations more typical of iron deficiency are nail thinning, flattening, and ultimately the development of koilonychia, concave or "spoon-shaped" nails (Fig. 23.6). Koilonychia is now rarely seen in clinical practice, but of 400 babies attending a well-baby clinic in West Virginia before 1970, 5.5% had koilonychia, and nearly all of these infants appeared to be iron deficient.[321] Koilonychia is a relatively nonspecific finding, which can also result from prolonged repeated exposure to hot soapsuds and other caustic agents.

FIGURE 23.6. Koilonychia in a 1.5-year-old child with iron deficiency anemia.

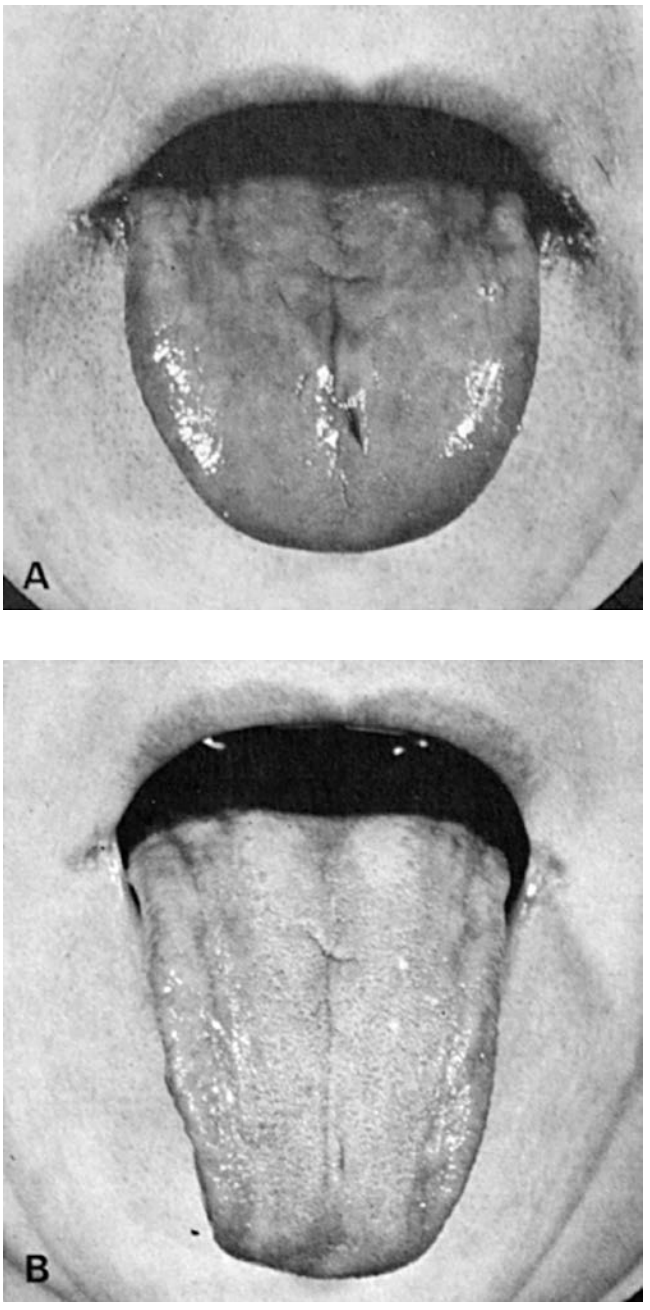

FIGURE 23.7. Tongue of a patient with iron deficiency anemia. Moderately severe papillary atrophy evident before therapy **(A)** and restoration after iron repletion **(B)**. (Courtesy of R. W. Monto, Detroit, MI.)

Oral abnormalities, including atrophy of the lingual papillae, are the most common of iron deficiency–induced epithelial changes (Fig. 23.7, Table 23.7). These may present as soreness or burning of the tongue, either spontaneously or stimulated by food or drink, and by varying degrees of redness.[319] The filiform papillae over the anterior two thirds of the tongue are the first to atrophy and may disappear completely. In severe cases, fungiform papillae also may be affected, leaving the tongue completely smooth and waxy or glistening.[322] These changes are generally reversed after 1 to 2 weeks of iron therapy. Angular stomatitis, characterized by ulcerations or fissures at the corners of the mouth, is a less specific sign of iron deficiency, and it also occurs in riboflavin and pyridoxine deficiencies.

TABLE 23.7

EPITHELIAL LESIONS ASSOCIATED WITH IRON DEFICIENCY

Site	Finding
Nails	Flattening
	Koilonychia
Tongue	Soreness
	Mild papillary atrophy
	Absence of filiform papillae
Mouth	Angular stomatitis
Hypopharynx	Dysphagia
	Esophageal webs
Stomach	Achlorhydria
	Gastritis

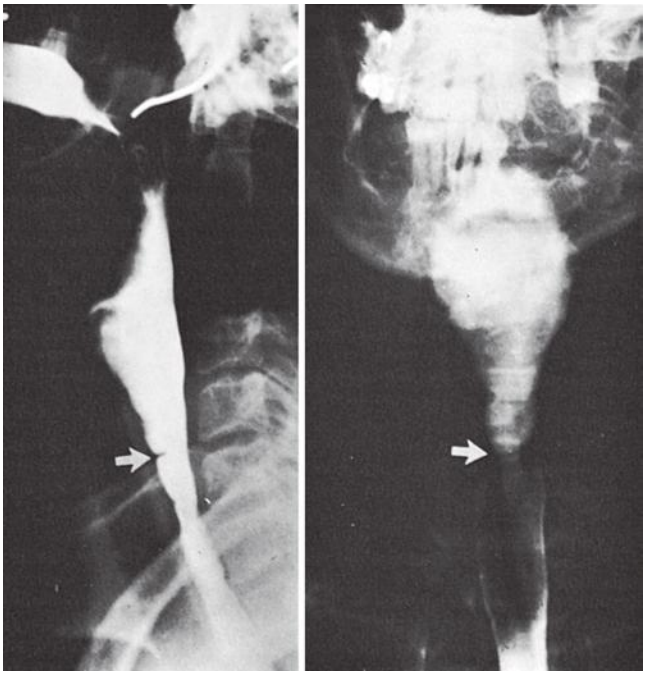

FIGURE 23.8. Esophageal web (*arrows*) in Plummer-Vinson syndrome.

The association of dysphagia, angular stomatitis, and lingual abnormalities with hypochromic anemia was reported as early as the beginning of the 20th century. Dysphagia affects women more often than men and is relatively uncommon in patients younger than age 30 years. However, it has been observed in adolescents[174,319] and even toddlers. Patients with sideropenic dysphagia (also known as Paterson-Kelly syndrome and Plummer-Vinson syndrome) note a gradual onset of difficulty swallowing and describe discomfort localized to the area of the neck near the cricoid cartilage. They experience dysphagia with solid foods but have little problem with liquids. If not treated, the dysphagia worsens, and ultimately the diet is so restricted that it interferes with the maintenance of balanced nutrition.

The most common anatomic lesion is a "web" of mucosa at the juncture between the hypopharynx and the esophagus.[323] These webs, which may be multiple, usually extend from the anterior wall into the lumen of the esophagus, but they may encircle the lumen completely, forming a cufflike structure. In some patients, a benign stricture is noted, and the opening into the esophagus at the cricoid area may be reduced to the size of a pinhole or slit. Postcricoid webs may occur in the absence of documented iron deficiency, but nearly all affected patients were iron deficient in one investigative series.[320] Both webs and strictures may be demonstrated by radiographic examination (lateral view) of the neck after barium swallow (Fig. 23.8). Multiple exposures or cineradiography are required for optimal demonstration of these abnormalities.

At biopsy, the webs appear to be constructed of normal epithelium with underlying loose connective tissue, sometimes showing a chronic inflammatory reaction. In a small percentage, hyperchromatic nuclei and increased mitotic activity are observed in the basal cell layer. Biopsy of the strictures demonstrates chronic nonspecific inflammation and degeneration of striated muscle. Carcinoma in the postcricoid area has been noted as a late complication of the syndrome in 4% to 16% of patients.[319] For relief of the dysphagia, clinicians often must rupture the webs, dilate the stenosis, or both, although treatment with iron supplements relieves dysphagia in mild cases if the associated webs are small.[324,325]

The variation in the prevalence of sideropenic dysphagia suggests that factors other than iron deficiency may contribute to oroesophageal abnormalities. Genetic factors may be important, as may some unrecognized coexisting nutritional abnormalities.

Immunity and Infection

The relationship between iron deficiency and infection is complex.[326,327,328] Iron deficiency clearly results in at least two abnormalities in the immune response: defective lymphocyte-mediated immunity and impaired bacterial killing by phagocytes. Evidence of defective cellular immunity includes as much as a 35% reduction in the number of circulating T cells. Both helper and suppressor T cells are affected.[329] In addition, iron-deficient subjects do not respond as well as normal subjects to certain skin test antigens, such as to Candida, diphtheria, and Trichophyton. These abnormalities can be corrected by the administration of iron. No abnormalities have been noted in testing with tuberculin or dinitrochlorobenzene. Ribonucleotide reductase is an iron-containing enzyme required for the synthesis of DNA for cell division. Some authors have suggested that reduced levels of this enzyme might lead to impaired ability of the T cells to proliferate, thereby accounting for the defects in cell-mediated immunity, but others have reported changes in cytokine production in iron-deficient patients.

The nitroblue tetrazolium dye test of phagocyte function yielded abnormal results in iron-deficient children, and the abnormality could be corrected by iron administration.[330,331] Furthermore, a decrease in the magnitude of the "oxidative burst" accompanying phagocytosis was observed.[332] Finally, killing of several types of pathogenic bacteria by neutrophils was defective.[330,333]

The sequence of changes in neutrophil function was studied as iron deficiency developed in rats. Myeloperoxidase activity was reduced to a greater extent and responded more slowly to iron therapy than did defects in the oxidative burst.[334] Because the oxidative burst is considerably more important in bacterial killing than is myeloperoxidase, the observations suggest that the neutrophil conserves its most important function as the deficiency develops. The defect in the oxidative burst could be demonstrated only with the use of agents that induced phagocytosis; no defect was noted when the burst was stimulated by soluble agents. Thus, phagocytosis, rather than the oxidative burst itself, may be at fault.

In experiments in an iron-deficient mouse model, lack of hepcidin was responsible for the high inflammatory response to lipopolysaccharide treatment.[335] Taken together, these abnormalities provide a basis for an expectation that resistance to infection may be impaired in iron deficiency. However, a clinically relevant relationship between states of iron deficiency and susceptibility

to infections remains controversial.[336] Conversely, considerable data suggest that iron deficiency and iron sequestration by binding proteins protect against infection by depriving the invading organisms of the metal.[337,338] Thus, optimal immune function is highly dependent on iron balance; both iron-deficient and iron overloaded hosts are at higher risk for infection.

Pica

Pica is a striking symptom of iron deficiency. Hippocrates wrote that a "craving to eat earth" was associated with "corruption of the blood." Abnormal eating patterns were also a prominent manifestation of chlorosis. Pagophagia, defined as the purposeful eating of at least one tray of ice daily for 2 months, is a common form of pica. In one study, the ingestion of ice averaged nearly 2 kg/day, and some patients ate an astounding 4 to 9 kg/day.[339] This dramatic symptom was relieved within 1 to 14 days after iron was administered. Another study found that pagophagia was a symptom of iron deficiency in 23 of 38 consecutive adult patients, and iron therapy was curative.[340] Pica is especially striking when the patient consumes bizarre, nonfood substances.[341]

Crosby estimated the incidence of pica in his iron-deficient patients to be 50%.[342] Approximately one half of them ate ice; the rest experienced "food pica." The latter consists of compulsively eating one food, often something that is brittle and makes a crunching sound when chewed.[343] Because patients may be ashamed of this compulsive habit, they often do not volunteer the information during the medical interview. Direct tactful inquiry is necessary to elicit the history of pica.

Genitourinary System

Disturbances in menstruation are common in iron deficiency, and not infrequently, iron deficiency results from, or is exacerbated by, excessive menstrual blood loss. Beeturia, the excretion of a pink to red pigment in the urine after the ingestion of beets, has been reported to be more common in iron-deficient patients than in normal subjects.[344] However, it is likely that a significant fraction of the normal population also has this symptom.[345]

Skeletal System

Changes in the skull similar to those found in association with thalassemia or chronic hemolytic anemia have been reported in children with iron deficiency anemia of long duration.[346,347] The diploic spaces may be widened, and the outer tables thinned, at times with vertical striations producing a hair-on-end appearance. In addition, abnormalities of the long bones are noted, especially the metacarpals and phalanges, with expansion of the medulla and thinning of the cortices.[348] These changes likely result from expansion of the erythroid marrow during bone growth and development.

LABORATORY EVALUATION

Complete Blood Count and Peripheral Smear

The severity of anemia depends on the presenting circumstances of iron deficiency. If discovered when the patient is being evaluated for preadmission testing for elective surgery (Fig. 23.9),[348] or for an underlying or unrelated disease, the anemia can be mild to moderate (Hgb 8 g/dl to 12 g/dl). If symptoms of anemia are the presenting complaint, the blood hemoglobin level may be 8 g/dl or lower.

Anisocytosis is an important early sign in iron deficiency and one that has differential diagnostic value when quantified.[349,350] The red cell distribution width (RDW) is increased in iron deficiency, and this often is useful in distinguishing iron deficiency from thalassemia trait conditions in which the RDW is normal. Both the percentage and the absolute number of reticulocytes may be normal or slightly increased. In experimentally induced iron deficiency in certain animal species, including rats, mice, and pigs, reticulocytosis is pronounced. The chief finding on blood smear is hypochromia, observed as an increase in the size of the region of central pallor (Fig. 23.10). The more severe the anemia, the more severe the hypochromia and the greater the percentage of erythrocytes affected. When hypochromia is extreme, most of the red blood cells appear as mere rings. Tiny microcytes and a moderate number of poikilocytes, particularly tailed and elongated elliptical forms (pencil cells), are also found. In almost all instances, however, a variable number of well-filled red corpuscles are present, and some macrocytes, often polychromatophilic, can be distinguished. The mean corpuscular volume and mean corpuscular hemoglobin values are reduced in most patients, and the mean corpuscular hemoglobin concentration is reduced in long-standing or severe disease. The degree of change in the red cell indices is related in part to the duration and in part to the severity of the anemia. In mild iron deficiency of short duration, the indices may be within normal ranges.

Iron-related Indices

The laboratory diagnosis of absolute iron deficiency has traditionally been based on low serum iron, low percent transferrin saturation, and low ferritin.[143] However, it has long been known that inflammation can mimic some aspects of iron deficiency by impairing the utilization of existing iron stores for red cell production, and inducing an iron-sequestration syndrome and hypoferremia.[351] The molecular mechanisms that underlie the redistribution of iron during inflammation are discussed in Chapter 45, but may center on cytokine-stimulated overproduction of hepcidin, particularly IL-6.[36]

Serum ferritin has the potential to differentiate true iron deficiency from inflammatory iron sequestration. However, both inflammation and intracellular iron accumulation stimulate the production of the iron storage protein ferritin whose soluble form is detectable in plasma and serum. Therefore, interpretation of serum ferritin in patients with inflammation due to comorbidities is more challenging. The generally accepted cut-off level for serum ferritin to indicate absolute iron deficiency has been ≤12 ng/ml.[352] However, studies correlating the presence or absence of stainable iron with serum ferritin in patients and in normal individuals, and also patients with anemia responsive to iron therapy, indicate that this threshold level of ferritin had only a sensitivity of 25% for detecting iron deficiency.[353] The sensitivity could be improved to 92%, with a positive predictive value of 83%, by using a diagnostic cutoff value of ≤30 ng/ml.

The differentiation among absolute iron deficiency, functional iron deficiency, and iron-sequestration syndromes (Fig. 23.11) is important for patient management.[268] Functional iron deficiency is manifest by a fall in iron saturation either during endogenous erythropoietin–stimulated erythropoiesis,[268,354,355] or with initiation of ESA therapy even in normal volunteers with adequate iron stores.[268,356] The manifestation of functional iron deficiency is reduced transferrin saturation, as illustrated in Figure 23.12. Absolute iron deficiency may be the presenting sign of occult blood loss from gastrointestinal lesions including malignancy,[233,357] whereas an iron sequestration phenotype is indicative of an underlying inflammatory disorder. Commonly used laboratory tests such as serum iron, total iron-binding capacity, mean corpuscular volume, transferrin saturation, and ferritin provide limited diagnostic value.[127,358]

Increased soluble transferrin receptor (sTfR) has been reported to be an indicator of iron deficiency,[359] because sTfR is released

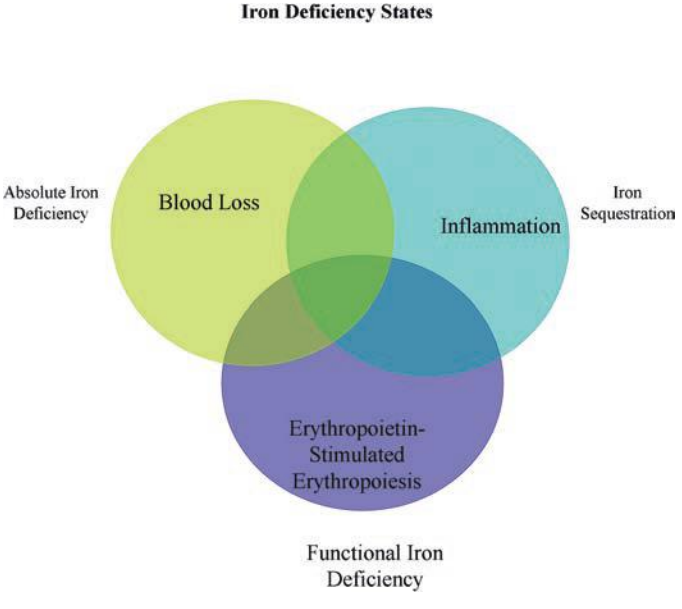

FIGURE 23.11. Iron deficiency states. The relationships between absolute iron deficiency, iron sequestration, and functional iron deficiency are illustrated. Patients can have one or more combinations that all result in iron-restricted erythropoiesis. (From Goodnough LT. Transfusion. 2011 Dec 12 [Epub].)

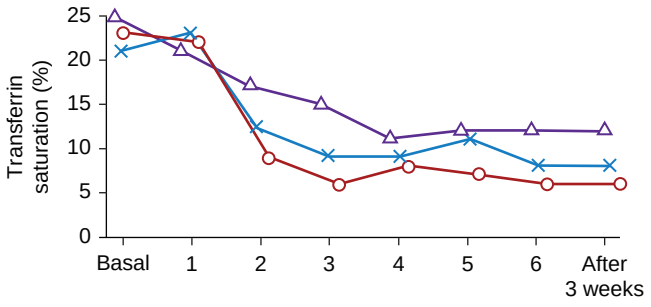

FIGURE 23.12. The impact of endogenous erythropoietin-mediated erythropoiesis or ESA (erythropoiesis stimulating agent) mediated erythropoiesis, on iron saturation. Patients undergoing autologous blood donation prior to elective orthopedic surgery are shown at baseline and after treatment with placebo or one of two doses of recombinant human erythropoietin (rHuEPO) at each visit during the donation period. All patients received supplemental oral iron. Mean transferring saturation in 24 patients receiving placebo (Δ), 300 U per kg rHuEPO (Ƶ), or 600 U per rHuEPO (θ). (From Mercuriali F, Zanella A, Barosi G, et al. Use of erythropoietin to increase the volume of autologous blood donated by orthopedic patients. Transfusion 1993;33:55–60.)

by erythropoietic precursors in proportion to their expansion, and is not increased by inflammation. However, this assay was found to have a specificity of 84% and a positive predictive value of only 58% in a population of patients likely to be typical of the most difficult diagnostic environments for assessing iron status.[353] Interpretation of increased sTfR therefore may be challenging, even in the absence of known causes of increased erythropoiesis other than iron deficiency. Similarly, attempts to combine ferritin and sTfR results (sTfR/log ferritin)[360] still fall short when analyzed for diagnostic sensitivity and specificity, and must be corrected for acute phase reactant changes in the setting of inflammation.[358]

The development of sensitive, accurate, and reproducible immunoassays[43,361] and mass-spectrometric assays[362] for human hepcidin has allowed detailed definition of physiologic and pathologic changes of hepcidin in healthy volunteers and in patients. In contrast to ferritin, changes in hepcidin concentrations are frequently the cause of, rather than the result of, iron disorders. Measurements of hepcidin may be useful for diagnosing absolute iron deficiency or differentiating it from iron-sequestration syndromes. In absolute iron deficiency, serum hepcidin concentrations are very low.[43] Low hepcidin would also identify patients most likely to respond to iron therapy. In iron sequestration syndromes, on the other hand, hepcidin would be expected to be high as the pathogenic mediator of iron restriction in inflammation. In patients with mixed presentations, hepcidin may be regulated by opposing stimuli and its levels tend to be variable.[363] For example, in conditions with mixed iron deficiency and inflammation, hepcidin may be low, normal, or elevated depending on the degree of iron deficiency or inflammation. In resistance to ESA therapy due to chronic kidney disease, hepcidin levels may be high because of decreased hepcidin renal clearance and possibly inflammation. In the absence of inflammation, in conditions of accelerated erythropoiesis due to endogenous erythropoietin or ESA stimulation, hepcidin levels will be low. Thus in patients with mixed conditions, hepcidin levels may not help treating physicians arrive at a definitive diagnosis but may give guidance in identifying patients who are likely to respond to iron (oral vs. IV) therapy (i.e., hepcidin levels are low with marginal storage iron or accelerated erythropoiesis). More complex algorithms will need to be developed and tested to provide optimal guidance in the evaluation and management of anemia.[86,364] Expected changes in hepcidin levels and iron parameters in various clinical conditions, in iron therapy strategies, and in the potential use of hepcidin-targeted therapies in patients with various forms of anemia, are summarized in Table 23.8.

Clinically, it would be helpful to detect the earliest changes in red cell indices that reflect iron-restricted erythropoiesis. One approach would be to identify newly formed iron-deficient cells when they are released from the bone marrow as reticulocytes. Flow cytometric analysis of reticulocytes allows determination of reticulocyte hemoglobin content (CHr)[365,366] or percentage of hypochromic reticulocytes (% HYPO).[367] As illustrated in Figure 23.13, this approach can also identify functional iron deficiency in iron-replete volunteers receiving ESA therapy.[368] The % HYPO measure is regarded as a time-averaged marker of iron-restricted erythropoiesis (20 to 120 day), whereas the CHr measure is a real-time parameter (48 hours).[369] Many existing laboratory analyzers are capable of measuring CHr but may require modification with software patches.

Leukocytes and Platelets

The leukocytes are usually normal in number, but mild granulocytopenia may occur in long-standing cases of iron deficiency. Recent large-volume hemorrhage may cause a slight neutrophilic leukocytosis, and occasional myelocytes may be found in peripheral blood. In iron deficiency due to parasitic infestation, eosinophilia may be present.

Thrombocytosis commonly accompanies iron deficiency.[370] The platelet count often increases to approximately twice the normal level, and values return to normal after iron therapy. The cause of the thrombocytosis of iron deficiency is unknown.

TABLE 23.8

POTENTIAL ROLE OF HEPCIDIN IN DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH IRON-RESTRICTED ERYTHROPOIESIS

Condition	Expected Hepcidin Levels	Iron Parameters	Iron Therapy Strategies	Potential Hepcidin Therapy
Absolute iron deficiency anemia (IDA)	Low	Low TSAT and ferritin	PO or IV if poorly tolerated or malabsorbed	No
Functional iron deficiency (ESA therapy, CKD)	Variable, depending on ± CKD	Low TSAT, variable ferritin	IV	Antagonist (if hepcidin levels not low)
Iron sequestration (anemia of inflammation [AI])	High	Low TSAT, normal-to-elevated ferritin	IV	Antagonist
Mixed anemia (AI/IDA) or (AI/functional iron deficiency)	Variable	Low TSAT, low-to-normal ferritin	IV[a]	Antagonist (if hepcidin levels not low)

[a]Mixed anemia is a diagnosis of exclusion without a therapeutic trial of iron.
CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agent; IV, intravenous; PO, oral; TSAT, transferrin saturation.
From Goodnough LT. Iron deficiency syndromes and iron-restricted erythropoiesis. Transfusion. 2011 Dec 29 [Epub].

Bone Marrow

Macrophage iron is absent or severely reduced in the marrow, spleen, and liver of iron-deficient subjects. Fewer than 10% of the marrow normoblasts are sideroblasts. In addition, the iron-deficient bone marrow is characterized by mild to moderate erythroid hyperplasia. There may be striking nuclear distortions, resembling those found in dyserythropoietic anemias.[371] Karyorrhexis and nuclear budding are particularly common, but multinuclearity, nuclear fragmentation, and even intranuclear bridging may be observed. The individual normoblasts appear small and may have scanty cytoplasm, often with irregular ragged borders. When therapy is given, erythroid hyperplasia initially increases, but as erythropoiesis is restored to normal, the cellularity of the marrow likewise becomes normal.

MANAGEMENT OF IRON DEFICIENCY

Management is primarily focused on repletion of iron stores. Most of the time, this therapy is straightforward, simple, and inexpensive. The response to treatment is predictable and gratifying. There is, however, an important caveat: correction of the iron deficiency is only part of the task confronting the clinician. Particularly in older adults, iron deficiency may be an early sign of a serious illness, such as an occult gastrointestinal malignancy. Clearly, correction of the anemia without recognition and treatment of a possible underlying disease is poorly practiced medicine. The cause of iron deficiency anemia can be identified in the great majority of cases. Once an etiologic diagnosis is made, appropriate therapy can begin.

Iron can be administered orally or intravenously. The oral route is the safest and least expensive. It is important to note that therapeutic doses are quite different for oral and intravenous preparations. Most iron-deficient patients respond well to oral therapy, but intravenous administration of iron may sometimes be required.

Oral Iron Therapy

The most common preparation used orally is ferrous sulfate, which has been a mainstay of treatment for iron deficiency since it was first introduced by the French physician Pierre Blaud in the 19th century. It is effective, reasonably well tolerated, and inexpensive. If equivalent amounts of elemental iron are given, ferrous gluconate and ferrous fumarate are equally satisfactory and have approximately the same incidence of side effects. Although iron deficiency clearly promotes increased absorption, individual variations are great, and absorption may be vastly different at varying degrees of anemia and in the presence of complicating illnesses.

The dose is best calculated in terms of elemental iron. For adults, the optimal response occurs when ~200 mg of elemental iron is given orally each day. The usual ferrous sulfate tablet (325 mg) contains ~65 mg of elemental iron. Iron is absorbed more completely when the stomach is empty; when iron ingestion occurs after or with a meal, absorption decreases substantially.[372] However, gastrointestinal irritation is common when the stomach is empty. Consequently, patients are frequently advised to take oral iron immediately after or even with a meal. The gain in patient acceptance may be more important than the reduced absorption of iron. However, it is important to remember that, whereas absorption is enhanced by the presence of orange juice, meat, poultry, and fish, other substances such as cereals, tea, and milk inhibit it. This is particularly important in toddlers, because administration of oral iron with milk often compromises therapy.

For iron-deficient children, the optimal dosage is 1.5 to 2.0 mg elemental iron per kilogram of body weight given orally three times per day. Palatable elixirs and syrups are the most satisfactory pediatric preparations, although they can stain the teeth if not given carefully. Children usually tolerate this form of therapy on an empty stomach.

In adults, a 200-mg daily oral dose produces a maximal rate of hemoglobin regeneration. However, the maximal rate is not necessarily the only legitimate therapeutic goal. If the underlying disease has been corrected and the anemia is mild to moderate, a slower rate of response may be acceptable. Thus, if such patients cannot tolerate 200 mg/day of elemental iron, it is reasonable to reduce the dose to 100 mg/day.[373] Because less iron is given, tolerance improves. In this circumstance, speed of response is exchanged for increased patient compliance, although it may be necessary to treat for longer. Regardless of the form of oral therapy used, treatment should be continued for at least 3 to 6 months after the anemia is relieved. If treatment does not continue, relapse is common. The continued therapy allows for repletion of iron stores.

Side Effects of Oral Iron Therapy

Some patients given oral iron report gastrointestinal symptoms, including heartburn, nausea, abdominal cramps, and diarrhea. However, functional gastrointestinal symptoms are common in the general population, and patients may incorrectly ascribe them to iron treatment. In one double-blind study, ferrous sulfate, ferrous gluconate, ferrous fumarate, and placebo were administered in identically appearing tablets.[374] No significant differences were found among the three iron salts. Approximately 12% of subjects had symptoms that could reasonably be ascribed to iron ingestion. Often, tolerance of iron salts improves when a small dose is given at first and increased over the course of several days to the full dose. A polysaccharide–iron complex is marketed that is alleged to be as effective as ferrous sulfate while causing fewer side effects. The question of whether it is as well absorbed as ferrous sulfate has not been definitively resolved.

Enteric-coated preparations are designed to reduce side effects by retarding dissolution of the iron. However, this effect may markedly decrease absorption, especially in achlorhydric individuals, whose gastric juice cannot dissolve the coating. Sustained-release preparations also reduce side effects by retarding dissolution, but in so doing, the most actively absorbing regions of the intestine are bypassed. According to most studies,[375] absorption is therefore reduced.

Failure of Oral Iron Therapy

Clinicians often encounter patients said to have iron deficiency anemia unresponsive to oral therapy. The most common explanations for failure to respond to oral iron include (a) incorrect diagnosis, (b) complicating illness, (c) failure of the patient to take prescribed medication, (d) inadequate prescription (dose or form), (e) continuing iron loss in excess of intake, and (f) malabsorption of iron.

In managing a problem of alleged failure to respond to iron, it is important to review the data on which the diagnosis of iron deficiency anemia was based and to take note of any laboratory procedures that might have yielded erroneous information. At times, even though iron deficiency is present, a coexisting cause for anemia may impair response. Examples are iron deficiency as a complication of the anemia of inflammation in rheumatoid arthritis, *H. pylori* infection, as well as so-called dimorphic anemia, in which iron deficiency and pernicious anemia coexist.

In some patients, blood loss is so great that oral iron therapy cannot keep up with it. If this situation is not correctable (e.g., in the case of hereditary hemorrhagic telangiectasia), parenteral therapy must be given. Finally, rare patients may be unable to absorb iron. This is unusual; even patients with sprue or total gastrectomy are usually able to absorb adequate amounts of ferrous sulfate. Patients with iron-refractory iron deficiency syndrome (IRIDA) have a mutation in the protease TMPRSS6 causing increased hepcidin production[177,178,189,190] and are refractory to oral iron therapy but partially responsive to intravenous iron therapy.

In individuals who are compliant with oral therapy and not actively bleeding, but still poorly responsive to treatment, addition of ascorbic acid (usually 500 mg twice a day) may improve iron absorption and the hemoglobin response.[376–378] Subclinical ascorbic acid deficiency has been suggested as an etiology of refractory iron deficiency anemia.[379]

Even under the best of circumstances, oral iron supplementation is poorly tolerated and patients may be noncompliant, not only from side effects of oral iron but because of their diagnosis or the therapy they are undergoing for their disease. Nevertheless, in stable patients with mild to moderate anemia in which there is some time for management strategies, and particularly in those patients in whom diagnostic laboratory testing has not definitively ruled out iron-restricted erythropoiesis, a therapeutic trial of oral iron therapy can be recommended.[380] In general, absorption of oral iron inversely correlates with hepcidin levels.[381,382] Thus, hepcidin measurements may help to determine a priori which patients are good candidates for oral iron therapy. Exceptions may be patients who malabsorb iron because of damage to the intestinal lining such as in celiac disease, and in patients undergoing treatment with proton-pump inhibitors.

In a study of patients with anemia,[353] 5 of 54 who had bone marrow examinations had absent iron stores indicating absolute iron deficiency. There were an additional eight patients who were categorized as iron deficient because of their response to oral iron therapy; half of these had serum ferritins ≥12 ng/ml and one of the patients had a serum ferritin >100 ng/ml. This analysis suggests that in the absence of a diagnostic bone marrow examination, it is difficult to rule out iron deficiency confidently, and an empiric trial of iron therapy may be desirable to identify patients who have absolute iron deficiency for successful patient management, because it may be a sign of serious underlying illness,[231,383] including malignancy.[233,357]

Failure to respond to a trial of oral iron therapy does not rule out iron-restricted erythropoiesis or even true iron deficiency in the setting of inflammation, as inflammatory hepcidin elevation would cause impaired iron absorption.[36] Furthermore, ongoing blood (and iron) losses may exceed even maximal gastrointestinal absorption of iron.[384] Clinical situations are often complex, and blood loss, iron-restricted erythropoiesis and high hepcidin levels can coexist in patients in whom absorption of dietary or oral iron supplements is impaired.[364] In these instances, and in circumstances of ongoing blood loss,[384] intravenous iron therapy may be needed either as a diagnostic trial or as definitive therapy.[385]

Intravenous Iron Therapy

Therapy with ESAs in management of the anemia of chronic renal failure has led to substantial clinical experience in supplemental intravenous iron therapy in this setting.[386,387] Hyporesponsiveness to ESA therapy is a common phenomenon[388,389] due to a variety of comorbid conditions, but particularly related to functional iron deficiency.[354,356] Patients with anemia undergoing dialysis may show suboptimal or no response to oral iron therapy for several reasons. During ESA therapy, although absorption of iron can increase up to fivefold[390] presumably due to hepcidin suppression by increased erythropoiesis, ongoing external iron losses due to hemodialysis and blood testing can exceed the intake.[391,392] Furthermore, some patients have poor compliance with iron therapy or significantly reduced gastrointestinal iron absorption. Absorption of oral iron can be enhanced with ascorbate by at least 30%, because it prevents formation of insoluble and unabsorbable compound and reduces ferric iron to ferrous iron.[392] Iron absorption and release from stores may be impaired due to high hepcidin levels from diminished clearance by the kidneys, not completely corrected by routine hemodialysis, as well as from inflammation.

IV iron administration is recommended in renal dialysis patients undergoing ESA therapy.[393] Patients treated with IV iron (100 mg twice weekly) achieved a 46% reduction in ESA dosage required to maintain hematocrit (Hct) levels between 30% and 34%, compared to patients supplemented with oral iron.[394] To further address the management of iron-restricted erythropoiesis in CKD patients undergoing dialysis, a randomized controlled trial evaluated the efficacy of IV iron supplementation in patients with ferritin between 500 and 1,200 ng/ml.[395] The administration of IV iron (and increasing the dose of ESA by 25%) resulted in a greater correction of anemia compared with increasing the dose of ESA alone. After the end of the trial, there was greater success in reducing the dose of ESA in the patients receiving IV iron, compared to the non-iron-treated arm.

IV iron therapy also improves responses to ESA therapy in patients with inflammatory bowel disease[396] compared to responses in a similar patient group who received oral iron supplementation.[397] Decreased reticulocyte hemoglobin (CHr) is an indicator of the inadequacy of iron supply in the face of increased iron demand stimulated by ESA therapy.[359] The requirement for a kinetic balance between iron delivery and level of erythropoietin stimulation may explain the need for intravenous iron supplemental therapy in ESA-treated patients, even those with replete iron stores.[393] The clinical response to the combination of IV iron and ESA therapy may be attributed to the ability of the parenteral route to circumvent the inflammation-induced block to intestinal iron absorption and deliver a large dose of iron to the reticuloendothelial system, which could increase iron efflux from macrophages, perhaps by increasing the translation of ferroportin mRNA.

Currently approved intravenous iron preparations are listed in Table 23.9.[398] The risk–benefit profile of IV iron continues to undergo evaluation in renal dialysis patients,[393,399] as well as in patients with anemia of chronic diseases.[127] IV iron can allow up to a fivefold greater erythropoietic response to significant blood loss anemia in normal individuals.[400,401] A greater rate of red cell production is probably not possible unless red marrow expands into yellow marrow space, as is seen in patients with hereditary anemias.[402,403] One potential limitation to IV iron therapy may be that much of the administered iron ends up in

the reticuloendothelial system as storage iron, from where it is not readily available for erythropoiesis,[403] particularly if hepcidin concentrations are elevated. However, for patients with iron deficiency, 50% of IV iron is incorporated into hemoglobin within 3 to 4 weeks.[404] For patients with anemia of chronic disease or renal failure, IV iron is mobilized less rapidly from the reticuloendothelial system.[405] Nevertheless, when iron dextran was given intravenously to patients with the anemia of rheumatoid arthritis, cellular hemoglobin concentrations increased significantly.[406]

In patients with malignancy and chemotherapy-induced anemia, five trials have studied IV iron in the setting of therapy with ESAs. In one study[407] of patients undergoing chemotherapy, 155 patients were treated with ESA and randomized to receive either no iron; oral iron as 325 mg if ferrous sulfate twice daily; 100-mg boluses of IV iron dextran weekly until the total calculated iron deficit was administered; or a single of IV iron dextran to the same calculated dose. There were significant improvements in hemoglobin levels and hematopoietic responses in both patient groups treated with IV iron arms, compared to those receiving oral iron or no iron therapy.

Another study[408] assigned 189 patients to receive ESA weekly plus no iron, oral iron as 325 mg of ferrous sulfate thrice daily, or IV ferrous gluconate as 125 mg weekly boluses. The cohort treated with IV iron had improved hemoglobin and hematopoietic responses compared to the other cohorts. A third study[409] randomly assigned 67 patients with lymphoproliferative malignancies not receiving chemotherapy with IV or no iron. Again, IV iron resulted in improved hemoglobin and hematopoietic responses. A fourth study of 398 patients with chemotherapy-induced anemia who were treated with ESA therapy, found significant improvement in hemoglobin levels and hematopoietic responses in the patient cohort treated with IV iron,[410] further confirmed by a fifth study.[411]

Iron-restricted erythropoiesis has been shown to be a consideration at time of cancer diagnosis even before ESA therapy: 17% of carefully screened patients were found to have serum ferritins <100 ng/ml and 59% had transferrin saturations (TSAT) less than 20% at diagnosis.[412] Additionally, renewed attention has been placed on the dose–response relationship between ESA dosage and red cell production responses in ESA-treated patients. Once ESA therapy is administered, even subjects with normal baseline levels develop TSAT and ferritin decreases to levels indicating iron-restricted erythropoiesis.[354,356] Accordingly, guidelines by the National Comprehensive Cancer Network (NCCN) have recommended that iron studies be obtained at baseline in order to identify patients who are candidates for supplemental iron therapy, and that if subsequent hemoglobin levels after 4 weeks of ESA therapy indicate no response (<1 g/dl increase in hemoglobin), then IV iron supplemental therapy should be considered, along with an increase in ESA dose.[413]

Despite these beneficial effects in treatment of iron deficiency, intravenous iron administration may generate oxidative stress and other inflammatory changes.[393] A mouse model showed that red cell transfusion of aged blood resulted in oxidative stress and inflammatory cytokine secretion in response to macrophage-ingested iron from membrane-encapsulated hemoglobin, but not from stroma-free lysate derived from stored red cells.[414] Long-term effects of the intravenous iron preparations will require careful study in relevant clinical settings.[327,415]

The hypoferremia and anemia of inflammation can be viewed as a mechanism of defense against providing iron to unwanted pathogens,[416] and therefore adaptive. On the other hand, others are not convinced that iron deficiency or iron-restrictive anemia should be regarded as a desirable condition that benefits patients with infection or inflammation. Although more evidence is clearly needed, in patients who show symptoms attributable to moderate or severe anemia of inflammation, and who do not suffer from overwhelming or difficult to control infection, iron-restricted erythropoiesis can and should be treated, an argument that is not new.[373] In iron-restricted anemias other than absolute iron deficiency, the optimal treatment is still evolving and may be improved by the ongoing development of hepcidin-targeted therapies.

Important clinical subjects for further study in this area should include improving the diagnosis of various forms of iron-restricted anemia in complex clinical settings, testing optimal combinations of ESA and IV iron treatments, analysis of the relative risk–benefits of ESA and IV iron therapy, and the appropriate

use of adjuncts such as anti-inflammatory therapy or frequent dialysis. Basic scientific insights that could facilitate the progress in this area include understanding the molecular nature of the erythropoietic iron regulator and suppressor of hepcidin, details of the mechanisms by which circulating and stored iron regulates hepcidin, the contribution of hepcidin-independent mechanisms to anemia of inflammation, and the role of genetics in sporadic iron deficiency.

Side Effects of Parenteral Iron Therapy

Side effects may be local or systemic. With intravenous injection, rates of administration greater than 100 mg/minute are associated with pain in the vein injected, flushing, and a metallic taste.[417] Such reactions are brief in duration and relieved immediately by slowing the injection. Systemic reactions may be either immediate or delayed. Immediate side effects include hypotension, headache, malaise, urticaria, nausea, and rare anaphylactoid reactions, particularly to iron dextran. Delayed reactions include lymphadenopathy, myalgia, arthralgia, and fever. Most of the reactions are mild and transient, but the anaphylactoid reactions may be life-threatening.[417,418] For iron dextran therapy, the clinician should be prepared for the possibility of anaphylaxis by having epinephrine, oxygen, and facilities for resuscitation available. Sodium ferric gluconate, iron sucrose, and iron saccharates are generally better tolerated than the iron–dextran complex, as long as the recommended dosages are not exceeded.[143,385]

Response to Therapy

When specific iron therapy is given, patients often show rapid subjective improvement, with disappearance or marked diminution of fatigue, lassitude, and other nonspecific symptoms. This response may occur before any improvement in anemia is observed. Similarly, pica has been reported to be relieved within 1 week of therapy.[339]

The earliest hematologic evidence of response to treatment is an increase in the percentage of reticulocytes and their hemoglobin content. The reticulocytes attain a maximal value on the fifth to tenth day after institution of therapy and thereafter gradually return to normal. The maximal value usually ranges from 5% to 10% and is inversely related to the level of hemoglobin. The reticulocyte response may not be detectable in mild iron deficiency anemia.

The blood hemoglobin level is the most accurate measure of the degree of anemia in iron deficiency. During the response to therapy, the red cell count may increase temporarily to values above normal, but the hemoglobin value lags behind. The red cell indices may remain abnormal for some time after the normal hemoglobin level is restored. As recovery occurs, a normocytic cell population gradually replaces the microcytic cell population, and one of the early signs of response to therapy is an increase in the RDW from pretreatment levels. When treatment is fully effective, hemoglobin reaches normal levels by 2 months after therapy is initiated, regardless of starting values.

Of the epithelial lesions in iron deficiency, those affecting the tongue and nails are the most responsive to treatment. After 1 to 2 weeks, small regenerating filiform papillae are observed. After 3 months, the tongue has usually returned to normal; however, in patients with severe anemia, some atrophy may persist. Koilonychia usually disappears in 3 to 6 months, with the concavity moving toward the end of the nail as the nail grows. Gastritis and the associated defects in gastric secretion often do not respond to therapy, especially in older adults. In patients younger than 30 years of age, gastric acid secretion and normal epithelial architecture may be restored.[215]

Dysphagia may be relieved by iron therapy if the associated postcricoid webs are small or medium sized.[324] The webs themselves are not altered, however, and relapse of the anemia is associated with recurring dysphagia. With more severe lesions, dilatation of the esophagus is required for relief.

Relapse occurs in a significant fraction of patients who respond to iron treatment, in part because of failure to complete the full course of therapy and in part because of recurrence (or continuation) of the predisposing condition or illness.

Preventive Treatment

Certain people are at such high risk for developing iron deficiency that prophylactic measures may be considered. These include infants, pregnant women, adolescents, regular blood donors, women with menorrhagia, and patients receiving continuous, high-dose aspirin therapy. Iron supplementation has been recommended for pregnant women for almost half a century. Although the advantages of this practice have not been definitively established,[419,420] the large iron cost of pregnancy and delivery to the mother (Table 23.6) indicate that it is warranted, evidenced by recommendations by the US preventative services task force that pregnant women be screened for iron deficiency.[211]

In 1999, the Committee on Nutrition of the American Academy of Pediatrics made recommendations for iron supplementation in infants.[281] They suggest that breastfeeding is preferable for the first 5 to 6 months of life if it is feasible, and beyond 6 months of age, breast-fed infants should receive supplemental iron at 1 mg/kg/day. Infants who are not breast-fed should be given formula supplemented with 12 mg/L of iron through the first year of life. The Committee recommends using iron-fortified cereal at the time that a solid diet is begun. Finally, fresh cow's milk should be avoided until after the first birthday.

Recovery from Anemia after Acute Hemorrhage

Morphologic evidence of active red cell regeneration should disappear after 10 to 14 days, if hemorrhage does not recur. The leukocyte count should be normal after 3 to 4 days. Sustained reticulocytosis is suggestive of continued bleeding. Persistent leukocytosis may result from the same cause, from hemorrhage into body cavities, or from complications. The latter, particularly infections, tend to delay the hematopoietic response.

Acute Iron Intoxication

The accidental ingestion of iron compounds by children who have mistaken the tablets for candy is a common problem, particularly with toddlers whose mothers are taking iron-containing prenatal vitamin supplements.[421–423] A few cases have also been reported in adults.[424] At one time, the associated mortality rate was as high as 50%. Those persons who died had swallowed 3 to 10 g or more.

Symptoms of iron intoxication have been classified in four stages. In the first stage, gastrointestinal symptoms predominate (vomiting, diarrhea, and melena). Shock may ensue, followed by dyspnea, lethargy, and coma. These events occur in the first 6 hours after ingestion. In the second stage, lasting from 6 to 24 hours after ingestion, transient improvement occurs and may continue to recovery. In stage three, metabolic acidosis is present. Death may take place 12 to 48 hours after ingestion. Stage four consists of intestinal obstruction as a late complication caused by scarring of the intestine.

These ill effects are the consequence of the local irritative action of the iron, resulting in mucosal ulceration and bleeding. Capillary dilatation and diapedesis of red cells may occur. Many factors cause the shock, including the absorption of iron in amounts far above the binding capacity of the plasma. Serum iron values as high as 3,000 μg/dl have been observed. Late coma is the result of hypoxia, metabolic disturbances, and hepatic damage.

The introduction of deferoxamine as a therapeutic agent has greatly modified the outlook.[425] In the setting of acute iron poisoning this hexadentate chelator, which has a high specific affinity for iron, can be given orally and intravenously. The molecular complex is small and is excreted quickly by the kidneys. Nonetheless, it is prudent to manage iron poisoning in consultation with an experienced toxicologist.

CHAPTER 24

SIDEROBLASTIC ANEMIAS

Sylvia S. Bottomley

The sideroblastic anemias are a heterogeneous group of disorders[1–3] uniquely characterized by pathologic iron deposits in erythroblast mitochondria[4,5] (Fig. 24.1A) that are housed within a distinct, mitochondrial ferritin.[6,7] The iron-glutted mitochondria account for the so-called ring sideroblast, an erythroblast in which numerous Prussian blue–positive granules often appear in a perinuclear distribution, particularly in the later stages of its maturation (Fig. 24.1B).

The basis for the mitochondrial iron accumulation in the various sideroblastic anemias can be regarded as either insufficient generation of heme as a result of primary defects in the heme biosynthetic pathway or from faults in mitochondrial functions that involve iron pathways, creating an imbalance between mitochondrial iron import and its utilization. Iron delivery to the erythroid cell does not appear to be downregulated in the face of these alterations, and iron continues to be transported normally to mitochondria, where it accumulates.[8,9] Globin synthesis is also reduced, but this effect is secondary, as it can be corrected in vitro by the addition of heme.[10,11]

Kinetically, the sideroblastic anemias are characterized by ineffective erythropoiesis, like other erythroid disorders with defective cytoplasmic or nuclear maturation.[12,13] Erythroid hyperplasia of the bone marrow is accompanied by a normal or only slightly increased reticulocyte count. The plasma iron turnover rate is increased, but

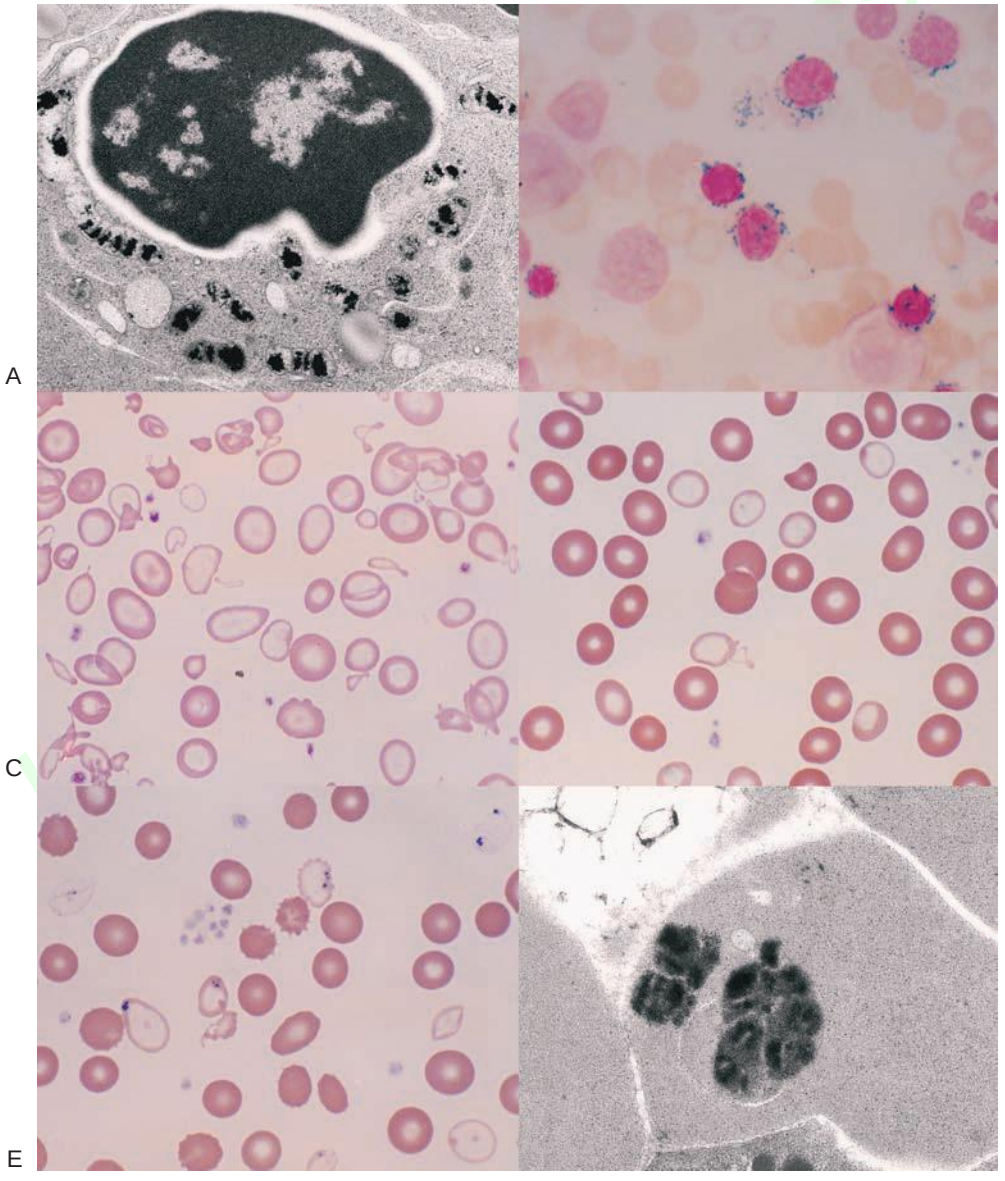

FIGURE 24.1. Morphologic features of sideroblastic anemia. **A:** Electron micrograph of an erythroblast with iron-laden mitochondria. **B:** Bone marrow smear (Prussian blue stain) with ring sideroblasts. **C, D:** Blood smears (Wright stain) of severe and mild sideroblastic anemia. **E:** Siderocytes (Wright stain). **F:** Electron micrograph of a Pappenheimer body in a peripheral red blood cell.

iron incorporation into circulating red cells is reduced. Red cell survival tends to be normal or slightly reduced. Slight hyperbilirubinemia may be noted, as well as an increase in urobilinogen excretion, as a result of a raised erythropoietic component of the "early-label" bilirubin peak.[14] Thus, it can be inferred that a substantial proportion of the developing ring sideroblasts are nonviable, and their expiration through enhanced apoptotic mechanisms within the marrow[15,16,17] accounts for the kinetic abnormalities.

The progeny of surviving ring sideroblasts are often but not always hypochromic and microcytic erythrocytes, a finding that provides morphologic evidence of impaired hemoglobin production as well as an initial clue to the diagnosis. The degree of hypochromia and microcytosis varies considerably from one form of sideroblastic anemia to another (Fig. 24.1C,D). Often, dimorphism is pronounced, with a hypochromic/microcytic population of cells existing side by side with a normal or even a macrocytic one. The siderotic mitochondria of the developing cell may be retained in some circulating erythrocytes (Pappenheimer bodies) and are regularly found with concurrent hypofunction or absence of the spleen; these cells are the nearly pathognomonic siderocytes in the Wright-stained blood smear[18] (Fig. 24.1E,F).

A common feature of many sideroblastic anemias that are not reversible is an excess of total body iron. The serum iron concentration is increased, often to the point of complete saturation of transferrin, and the level of serum ferritin roughly reflects the degree of iron overload. The ineffective erythropoiesis mediates increased intestinal absorption of iron by suppressing hepcidin production.[19,20] The consequent iron overload state is called *erythropoietic hemochromatosis*, and its clinical and pathologic features and course can rival those of hereditary hemochromatosis[21,22] (see Chapter 25). The occasional concomitant presence of alleles for genetic hemochromatosis accentuates the iron overload,[23–25] but their prevalence in patients with sideroblastic anemia does not appear to be greater than in the general population.[22,26–28]

Diverse defects affecting the utilization of iron by the developing red cell are reflected in the various forms of sideroblastic anemia (Table 24.1). Within the congenital group, the majority appear as isolated anemia, the X-linked and a recently identified autosomal recessive type being the most frequent; however, in a large proportion of cases the cause remains unexplained. Very uncommon are several genetically defined syndromic forms involving multiple systems. Acquired sideroblastic anemia is considerably more common than the congenital forms and occurs as a clonal disorder manifesting only anemia or multilineage dysplasia or even myeloproliferative features. Several diverse factors, such as ethanol, certain drugs, copper deficiency, and hypothermia, produce the ring sideroblast abnormality that is fully reversible.

TABLE 24.1

CLASSIFICATION OF THE SIDEROBLASTIC ANEMIAS (SAs)

Congenital SA
X-linked (XLSA)
Mitochondrial carrier protein SLC25A38 deficiency
Glutaredoxin 5 deficiency
Associated with erythropoietic protoporphyria
Cause unknown
Associated with genetic syndromes
X-linked with ataxia (XLSA/A)
Myopathy, lactic acidosis, and sideroblastic anemia (MLASA)
Congenital sideroblastic anemia and B cell immunodeficiency (SIFD)
Pearson marrow-pancreas syndrome
Thiamine-responsive megaloblastic anemia (TRMA)
Acquired Clonal SA
Refractory anemia with ring sideroblasts (RARS)
Refractory anemia with ring sideroblasts and thrombocytosis (RARS-T)
Refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS)
Reversible SA: Associated with
Alcoholism
Certain drugs (isoniazid, chloramphenicol, linezolid)
Copper deficiency (nutritional, malabsorption, zinc ingestion, copper chelation)
Hypothermia

HISTORICAL ASPECTS

The history of sideroblastic anemias can be said to have begun in 1945 with Cooley's report of a family with X-linked microcytic hypochromic anemia[29] (Table 24.2). Near that time iron-containing granules in erythroblasts, including their perinuclear distribution, were described separately,[31,32] and 10 years later were demonstrated to represent iron-laden mitochondria.[4] Over the next two decades these ring sideroblasts were recognized in pyridoxine-responsive anemia and in numerous patients with "refractory" anemia of unknown cause, hereditary or acquired, forming the basis for a 1965 symposium and adoption of the term *sideroblastic anemia*.[1] By then, the iron overload of these disorders had also become fully appreciated.[35,36]

The spectrum of the sideroblastic anemias was widened further by finding various reversible causes of the phenotype as well as by descriptions of certain congenital syndromic forms (Table 24.2). With the advent of molecular biology tools, the genetic causes of several clinically distinct types of congenital sideroblastic anemia and in part their pathogenesis have been elucidated during the last two decades.

HEME SYNTHESIS IN ERYTHROID CELLS

Developing erythroid cells have the greatest requirement of any cell type for heme for hemoglobin, and they produce more than 80% of the heme in the body. The expression and regulation of erythroid heme synthesis are unique in that they are linked (a) to the differentiation events after the signaling action of erythropoietin on erythroid precursors when they acquire the machinery for hemoglobin synthesis, (b) to the availability of iron, and (c) to the production of globin during development of the red cell. As in hepatocytes, 5-aminolevulinate (ALA) synthase and porphobilinogen (PBG) deaminase have considerably lower relative activities than the remaining enzymes in the heme biosynthetic pathway (see Chapter 6) and are sites of pathway regulation.[62] In contrast to the liver, the relative activity of ferrochelatase, the terminal enzyme in the pathway, appears also to be low in erythroid cells.[62] Furthermore, developing red cells express erythroid-specific isozymes or messenger RNA (mRNA) transcripts of the first four enzymes of heme synthesis, namely ALA synthase, ALA dehydratase, PBG deaminase, and uroporphyrinogen III synthase.

ALA synthase, the first and rate-controlling enzyme of heme synthesis, is generated in the cytosol as a precursor protein with an N-terminal signal sequence that is proteolytically cleaved and processed on transport of the protein into the mitochondrial matrix.[63,64] The mature mitochondrial protein catalyzes the formation of ALA from glycine and succinyl coenzyme A (CoA) and requires pyridoxal 5′-phosphate (PLP) as an obligate cofactor. Recently it was discovered that the erythroid-specific mitochondrial carrier family protein SLC25A38 importing glycine across the mitochondrial inner membrane to likely meet the high molar requirement of this substrate by the ALAS enzyme is

TABLE 24.2

MILESTONES IN THE HISTORY OF SIDEROBLASTIC ANEMIAS

First Description or Discovery	Year	Reference(s)
X-linked microcytic hypochromic anemia by T. Cooley	1945	29
Three brothers with pyridoxine-responsive anemia mentioned	1940s	30
Perinuclear iron-positive granules in erythroblasts	1947	31, 32
Case report of pyridoxine-responsive anemia	1956	33
Acquired refractory anemia with sideroblastic bone marrow	1956	34
Iron deposits in erythroblast mitochondria	1957	4
Sideroblastic anemia term adopted at international symposium	1965	1
Associated iron overload	1965	35, 36
Reversible sideroblastic anemia from antituberculosis agents	1965	37
Experimental sideroblastic anemia with antituberculosis drugs	1965, 1974	38, 39
Reversible sideroblastic anemia from chloramphenicol	1967	40
Reversible sideroblastic anemia from alcohol	1969	41
Thiamine-responsive megaloblastic anemia (Rogers syndrome)	1969	42
Sideroblastic anemia in erythropoietic protoporphyria	1973, 1993	43, 44
Sideroblastic anemia from copper deficiency	1974	45, 46
Pearson marrow-pancreas syndrome	1979	47
Sideroblastic anemia associated with hypothermia	1982	48
X-linked sideroblastic anemia with ataxia (XLSA/A)	1985	49
RARS inclusion in classification of myelodysplastic syndromes	1986	50

AR, autosomal recessive; MLASA, myopathy, lactic acidosis, and sideroblastic anemia; RARS, refractory anemia with ring sideroblasts; TRMA, thiamine-responsive megaloblastic anemia; XLSA, X-linked sideroblastic anemia; XLSA/A, X-linked sideroblastic anemia with ataxia.

necessary for normal erythroid heme synthesis.[60] Two separate genes encode the ALA synthase isoenzymes.[65,66] The housekeeping gene (*ALAS1*), located on chromosome 3,[66,67] is expressed ubiquitously,[68] whereas the erythroid-specific gene (*ALAS2*) is on the X chromosome.[65,66,69,70] Expression of the housekeeping gene, at least in hepatocytes, is controlled by glucose levels and is increased by certain steroids, various drugs, and chemicals (see Chapter 26). This gene is repressed by administration of heme, the end product of the pathway, so that heme levels tightly regulate transcription of its mRNA in a feedback manner.[68] Expression of the erythroid gene is essential for hemoglobin production, and ALAS1 cannot compensate if ALAS2 is lacking.[71] *ALAS2* is activated and transcribed in concert with other erythroid genes through the action of erythropoietin[63,68] (Fig. 24.2); it is not repressed by heme but is upregulated by hypoxia.[72] Cellular iron supply may also control ALAS2 mRNA levels,[73] whereas exogenous heme inhibits translation of ALAS2 mRNA,[74] although the mechanisms by which these occur are not known. Translational regulation of erythroid ALA synthase mRNA is mediated through interaction of its *cis*-acting iron-responsive element (IRE)[75,76] with iron regulatory proteins (IRP1 and IRP2; also called IRE binding proteins 1 and 2)[77,78,79] that are modulated through iron-sulfur (Fe-S) clusters generated in mitochondria and by cellular iron status[80,81] (Fig. 24.2) (see Chapter 23). In this manner, regulation of protoporphyrin production is linked to iron availability and to mitochondrial function for the formation of heme. The low ALA synthase activity observed in erythroid cells in iron deficiency is consistent with such a control mechanism.[82] While the signal sequences of the ALAS1 and ALAS2 precursor proteins contain two heme-binding motifs implicated in regulating translocation of the enzyme into mitochondria by interaction of heme with these motifs[83,84] (Fig. 24.2), mitochondrial import of ALAS2 does not appear to be affected by heme.[85] Within the mitochondrion, the ALAS2 isoform uniquely associates with the succinyl-CoA synthetase βA subunit, seemingly to stabilize the ALAS2, to control the generation of its substrate succinyl-CoA, or both.[86] The role of a major splice isoform of ALAS2 that is functional in vivo[87] in the regulation of the enzyme or erythroid heme synthesis remains to be determined.

ALA dehydratase, a cytosolic enzyme, catalyzes the formation of the pyrrole PBG from two molecules of ALA. For this enzyme, two tissue-specific isozymes are produced by a single gene, which contains two promoter regions, generating housekeeping and erythroid-specific transcripts with alternative first noncoding exons (exons 1A and 1B).[88,89] Although both transcripts encode identical polypeptides, the erythroid-regulated form would provide for the production of the large amounts of heme for hemoglobin. Not being a rate-limiting enzyme for heme biosynthesis, its expression in erythroid cells in manyfold excess amounts[62] may also serve as the proteasome inhibitor CF-2 to inhibit protein degradations.[90]

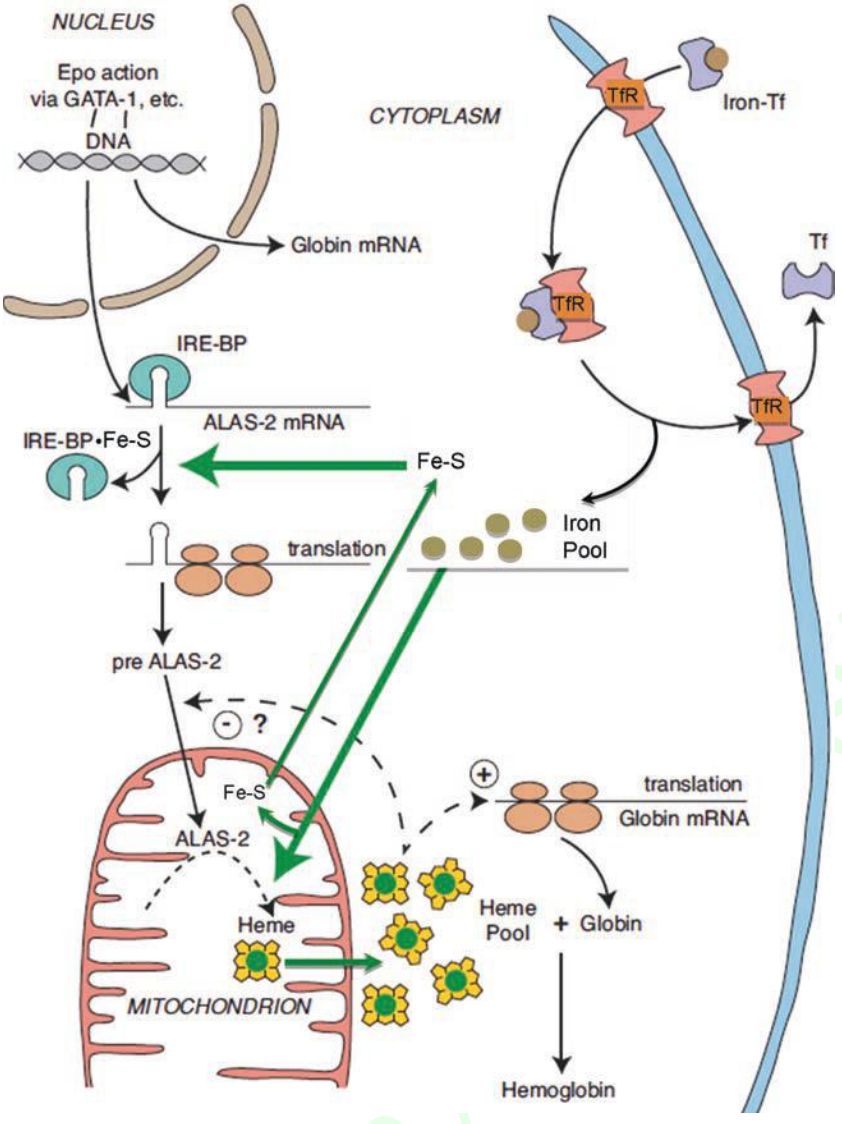

FIGURE 24.2. Pathways of regulation of erythroid 5-aminolevulinate synthase (ALAS2). (Modified from May BK, Dogra SC, Sadlon TJ, et al. Molecular regulation of heme biosynthesis in higher vertebrates. Progr Nucleic Acid Res Mol Biol 1995;51:1–51.)

In the case of PBG deaminase, which acts in the cytosol to form the linear tetrapyrrole hydroxymethylbilane from four molecules of PBG (see Chapter 6), two tissue-specific isoenzymes also are produced by a single gene.[91] The gene has two overlapping transcription units, each with its own promoter: an upstream ubiquitous promoter and another downstream promoter active only in erythroid cells. Two mRNAs are generated by alternative splicing, one encoding the ubiquitous PBG deaminase isoenzyme and the other encoding the erythroid isoenzyme. To what extent the erythroid-specific enzyme has a regulatory role in the overall production of heme in erythroid cells is not known. In response to erythropoietin or hypoxia, bone marrow PBG deaminase activity increased 3.5-fold, apparently by de novo synthesis.[92]

The gene for uroporphyrinogen III synthase likewise has two promoters generating housekeeping and erythroid-specific transcripts with unique 5′-untranslated sequences (exons 1 and 2A).[93] As for ALA dehydratase and PBG deaminase, the erythroid-promoter activity is increased during erythroid differentiation. Uroporphyrinogen decarboxylase, the fifth enzyme of the pathway with its site of action in the cytosol, is not known to have erythroid-regulatory features; however, its mRNA is markedly increased in erythroid tissue[94] and the enzyme activity is higher in erythroid cells than in the liver.[62]

After translation, all three terminal enzymes of heme biosynthesis (coproporphyrinogen oxidase, protoporphyrinogen oxidase, ferrochelatase), like ALA synthase, are transported to their mitochondrial sites of action. Single genes encode these enzymes, and erythroid-specific transcription products are not known for them. However, erythroid-specific regulation of their expression is accommodated by the presence of promoter sequences in their genes for binding of erythroid transcription factors (e.g., GATA-1, NFE-2)[95–97] to enhance production of these enzymes during erythropoiesis.[98] Ferrochelatase, the last enzyme of the heme synthetic pathway, catalyzes the insertion of iron into protoporphyrin to form heme. A repressor sequence in the promoter region of its gene is believed to be involved in the regulation of the binding of the erythroid transcription factors GATA-1 and NFE-2 to their recognition sites.[97] The activity of ferrochelatase relative to the activity of ALA synthase is in considerable excess,[62,99] but the enzyme becomes rate-limiting as a defective protein in erythropoietic protoporphyria (see Chapter 26). As it contains an Fe-S cluster, its expression and stability are also dependent on cellular iron levels and intact Fe-S cluster assembly machinery,[100,101] and its activity is regulated by the essential mitochondrial ATPase inhibitory factior 1 (Atpif1) through modulation of mitochondrial pH and redox potential.[102]

The large amounts of iron required for erythroid heme synthesis are delivered through transferrin receptor–mediated endocytosis of iron transferrin (see Chapter 23), and iron availability ultimately limits the normal rate of heme synthesis in erythroid cells.[103] High expression of transferrin receptors is also linked to erythropoietin-induced differentiation[68,103]; an erythroid-specific isoform of human transferrin receptor has been described[104]; and erythroid-active elements have been identified in the promoter of the murine gene.[105,106] During the height of hemoglobinization, the erythroid cell may not depend upon the "standard" mode for regulation of intracellular iron homeostasis via the IRE/IRP system to ensure a maximal supply of iron to mitochondria.[107] With erythroid maturation and the accumulation of cellular hemoglobin, the transferrin receptor number progressively decreases.[103] While surface transferrin receptors and iron uptake are increased in iron-deficient erythroblasts,[108,109] they are not altered in states of impaired heme synthesis, such as in the presence of succinylacetone[110] or in erythroid cells from patients with sideroblastic anemia.[8] Transport of iron out of the endosome by the divalent metal transporter DMT1 requires an endosomal ferrireductase (Steap3) in erythroid cells.[111] How the further transfer of iron to mitochondria and to apoferritin is accomplished is not understood. It may be facilitated by a cytoplasmic chaperone,[112] or through direct interaction of endosomes with mitochondria.[113] Iron is imported across the mitochondrial inner membrane by mitoferrin 1 that is highly expressed in erythroid cells and stabilized by interacting with the ATP-binding cassette protein ABCB10.[114,115] An oligomeric complex of mitoferrin 1, ABCB10 and ferrochelatase appears to facilitate the incorporation of iron into protoporphyrin to form heme.[116] Iron imported into the mitochondrion is also used for the generation of Fe-S clusters, which in part are exported to the cytosol for their addition to IRP1 in the regulation of cellular iron uptake[81] and translation of ALAS2,[117] and for expression of ferrochelatase.[100,101]

The export of heme out of the mitochondrion into the cytosol for its pairing with globins of hemoglobin and other heme proteins is mediated at least in the mouse by an isoform of the feline leukemia virus C receptor (FLVCR1), named FLVCR1b[118]. This heme exporter is essential for erythropoiesis as its loss leads to heme accumulation in the mitochondrion and termination of erythroid differentiation.

The events coordinating the production of globin chains with the rate of heme synthesis are well understood, and appear to occur at more than one level. Heme is required for initiation of globin mRNA translation and it acts by inhibiting a protein kinase called heme-regulated inhibitor (HRI), which inactivates the translational initiation factor 2 (eIF-2α) in the absence of heme[119] (Fig. 24.2). Moreover, absence of this kinase adversely modifies the phenotype of disorders of heme synthesis (iron deficiency, protoporphyria) and of globin production (β-thalassemia).[119] In addition, heme controls globin gene expression at the transcriptional level.[120,121]

CONGENITAL SIDEROBLASTIC ANEMIAS

Congenital sideroblastic anemias have emerged as not uncommon disorders. They are clinically and genetically heterogeneous, with diverse underlying causes, inheritance patterns, phenotypes, and associated features. Genetic analysis and molecular approaches have revealed a spectrum of specific defects, some appearing as isolated anemia and others involving multiple systems[3,122,123] (Table 24.3). Defined underlying defects affect heme biosynthesis directly or indirectly by disrupting Fe-S cluster biogenesis, or they involve pathways related to mitochondrial protein synthesis. However, in at least one third of cases the root cause remains undiscovered. Severity of anemia is highly variable within some types, and morphologic features overlap among them.

TABLE 24.3

GENETIC AND HEMATOLOGIC FEATURES OF THE CONGENITAL SIDEROBLASTIC ANEMIAS (CSAs)

				Erythrocyte		
	Mode of Inheritance	Defective Enzyme/Protein	Gene/ Chromosomal Location of Gene	Mean Corpuscular Volume	Protoporphyrin	Severity of Anemia
X-linked sideroblastic anemia	X-linked	ALAS2	*ALAS2*/Xp11.21	Decreased[a]	Decreased	Mild to severe
Mitochondrial carrier protein deficiency	Autosomal	SLC25A38	*SLC25A38*/3p22.1	Decreased	Decreased	Severe
Glutaredoxin 5 deficiency	Autosomal	Glutaredoxin 5	*GLRX5*/14q32.13	Decreased	Not reported	Mild to severe
Protoporphyria	Autosomal	Ferrochelatase	*FECH*/18q21.3	Decreased	Markedly increased	Mild
Unknown cause	Varied	?	?	Variable	Variable	Mild to severe
X-linked sideroblastic anemia with ataxia	X-linked	ABCB7 mitochondrial transporter	*ABCB7*/ Xq13.1-q13.3	Decreased	Increased	Mild
Myopathy, lactic acidosis, and sideroblastic anemia	Autosomal	Pseudouridine synthase 1	*PUS1*/12q24.33	Normal/ increased	Not reported	Severe in time
		Mitochondrial tyrosyl tRNA synthetase	*YARS2*/12p11.21	Not reported	Not reported	Severe
CSA and B cell immunodeficiency	Autosomal	?	?	Decreased	Not reported	Severe
Pearson syndrome	Sporadic/maternal	Respiratory chain components	Multiple/ mitochondrial DNA	Increased	Increased	Severe
Thiamine-responsive megaloblastic anemia	Autosomal	Thiamine transporter	*SLC19A2*/1q23.3	Increased	Normal/increased	Mild to severe

[a]Often normal or increased in females expressing the disorder.

Genetic Defects Expressed Only in the Erythron

Inheritance Patterns and Pathogenesis

X-Lined Sideroblastic Anemia

The inheritance follows an X-linked pattern, the anemia occurring most commonly in males and their maternal uncles and cousins.[29,124–128,129,130] Minimal expression of the erythroid abnormality may be seen in carrier females that is consistent with variable X inactivation affecting the mutant locus of the disorder. However, in many kindreds, the anemia has occurred only in females and may have been lethal in hemizygous male conceptions.[131,132,133,134,135,136]

Early observations already implicated defects in ALA synthase as underlying the impaired heme biosynthesis in this form of sideroblastic anemia. In patients who responded to pyridoxine supplementation, the incorporation of glycine, but not of ALA, into heme was reduced in reticulocytes.[30] ALA synthase activity in bone marrow was low before pyridoxine administration and returned to normal or supranormal levels after an erythropoietic response.[129,137–139] It was presumed that the residual activity or stability of a defective erythroid ALA synthase was enhanced by additional supply of its coenzyme PLP through a mass action effect (e.g., if the enzyme had a reduced affinity for the coenzyme[138] or was abnormally sensitive to proteolysis[137]). Usually, pharmacologic amounts of pyridoxine are required when an erythropoietic response occurs, but the response is variable and rarely complete. Individuals may present with profound anemia only in adulthood or even late in life,[129,140,141,142] suggesting that the disorder can progress with time. In some cases, prior additional dietary or medicinal intake of pyridoxine,[143] possible changes in pyridoxine metabolism with advancing age,[144] or initiation of hemodialysis[145,146] can be factors in unmasking mild phenotypes that were not symptomatic at a younger age. In female patients expressing the disease, skewed X inactivation in hematopoietic tissue that occurs with advancing age[147] and involves progressive inactivation of the X chromosome bearing the normal allele has been the explanation as the anemia usually evolved in adulthood[135,136] or late in life.[148] Constitutive skewed X inactivation to account for disease expression in females in childhood is very uncommon.[136]

After the cloning and characterization of the erythroid ALA synthase gene[75,149] and its localization to the X chromosome, linkage of the disorder to the *ALAS2* locus was established,[129,150] and many heterogeneous missense mutations involving invariant or highly conserved amino acid residues in the catalytic domain of the enzyme have been found to cause the disorder[151] (Fig. 24.3). A nonsense mutation in one case,[135] nucleotide deletions, and regulatory mutations in the promoter region and in the intron 1 enhancer sequence[151a] of the *ALAS2* gene have been the exceptions. Hence, in at least four families described up to 68 years ago,[29,125,128,152] the underlying molecular defect in ALAS2 could also be defined.[25,153–155] A majority of the mutations identified to date reside in exons 5 and 9 (Fig. 24.3); the latter contains the PLP-binding lysine (K391) of the enzyme.[156] Among the 66 distinct mutations so far encountered, only 22% occurred in more than one unrelated family or proband, and nearly one third of the probands are female. An apparent somatic mutation in the *ALAS2* gene was found in an older male patient with acquired sideroblastic anemia.[157]

Sites of *ALAS2* mutations and severity of anemia or extent of its responsiveness to pyridoxine supplements can be correlated to a considerable extent. The activity of the recombinant enzyme is reduced for many, but not all, ALAS2 mutants so far examined and is variably enhanced by PLP.[52,129,130,142,153,158,159] Some mutants have altered substrate kinetics[159,160] or fail to bind to the β-subunit of succinyl-CoA synthetase.[86,160] A three-dimensional structure model of the human enzyme[161] and the resolved crystal structure of the significantly homologous ALAS of *Rhodobacter capsulatus*[162] made it possible to explain how altered structure by many of the naturally occurring mutations that give rise to X-linked sideroblastic anemia (XLSA) affects the function of the enzyme. For example, mutations changing an amino acid located in the vicinity of the PLP-binding site exhibit a response to pyridoxine, whereas mutations involving sites of substrate binding, enzyme stability, or folding are refractory to pyridoxine.[162] However, while clinical severity can thus be related at least in part to the effect of a specific mutation on enzyme function, marked variation in severity of anemia has been observed between some kindreds bearing the same mutation as well as within a few

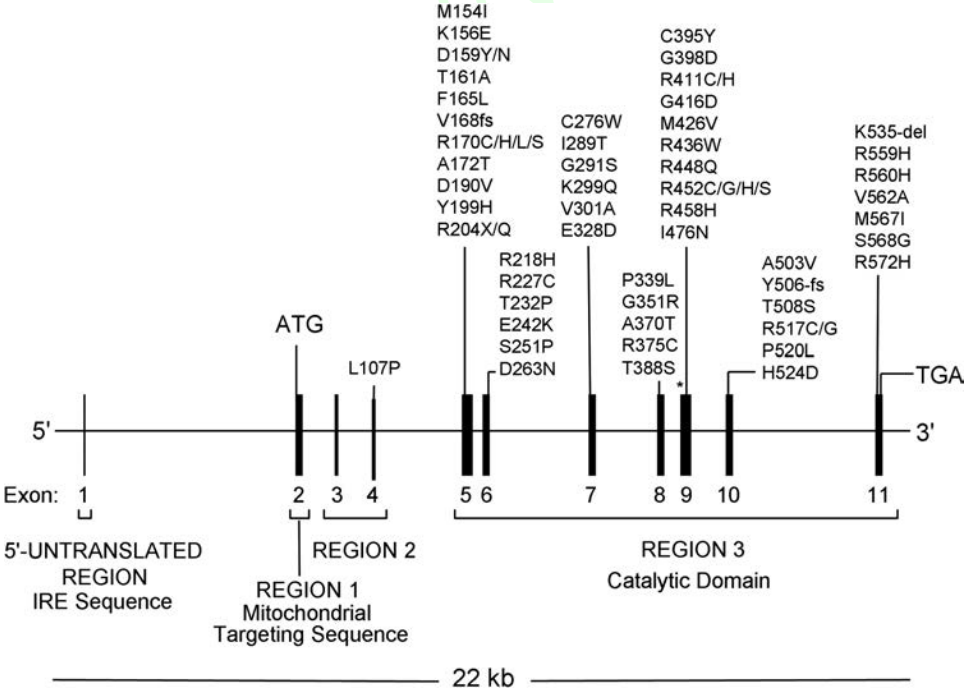

FIGURE 24.3. Diagram of the structure of the human erythroid 5-aminolevulinate synthase gene (*ALAS2*) and the location of mutations identified to date in X-linked sideroblastic anemia. Two mutations in the promoter region (c.-206C>G; c.-91_-44del) and two mutations disrupting the intron 1 enhancer of *ALAS2* are not indicated. kinships,[129,130,163,164] implicating undefined genetic differences or environmental factors for the apparent variable penetrance.

Mitochondrial Carrier Protein SLC25A38 Deficiency

A significant segment of congenital sideroblastic anemias (~15%) is associated with biallelic mutations in the gene encoding the erythroid-specific mitochondrial inner membrane carrier protein SLC25A38.[60,165] The *SLC25A38* gene has an amino terminal targeting signal and three mitochondrial carrier family protein domains that encode six transmembrane helices. From its structural features, the protein is predicated to function as an amino acid transporter. Data so far obtained in the yeast *Saccharomyces cerevisiae* deficient in the protein indicate a heme biosynthetic defect and suggest that it serves as a glycine importer across the mitochondrial inner membrane.[60]

Heterogeneous mutations spread throughout the SLC25A38 protein domains have been reported in 26 families, including three sibling pairs.[60,166] The mutations are missense type occurring in conserved amino acids at substrate contact points as well as nonsense and splicing errors. Two thirds of patients are homozygous and one third are compound heterozygotes for defects.

Glutaredoxin 5 Deficiency

The human counterpart of a zebrafish mutant (*shiraz*) deficient in glutaredoxin 5,[80] which is essential for the synthesis of Fe-S clusters such as for IRP1 and thus ALAS2 translation, was identified in a single patient.[59] A homozygous mutation in the *GLRX5* gene that affects intron 1 splicing and markedly reduces *GLRX5* RNA production was associated with microcytic sideroblastic anemia. The anemia was detected in the fifth decade, became severe by age 60, and improved with iron chelation therapy for the associated iron overload. Studies in cell lines derived from the patient indicated severe impairment of Fe-S cluster biogenesis and also revealed markedly reduced levels of ferrochelatase.[167]

Sideroblastic Anemia in Protoporphyria

Marked deficiency of ferrochelatase underlies erythropoietic protoporphyria as a result of a large variety of mutations in the gene encoding the enzyme (see Chapter 26). The defect is manifested mainly, if not exclusively, in erythroid cells and leads to marked accumulation of free protoporphyrin, the substrate of the enzyme, during the final stages of erythroid maturation when the defective ferrochelatase becomes rate-limiting for heme production.[168] Erythroid heme synthesis appears to be compromised in most patients as reflected in a mild microcytic hypochromic anemia.[169] In ten patients marrow ring sideroblasts with typical mitochondrial iron deposits were observed[43,44] but not in one sibling pair with mild microcytosis without anemia.[168] Bone marrow examination has generally not been performed in this disorder so that the incidence of the ring sideroblast feature is not known. The genetic heterogeneity in protoporphyria may account for the phenotypic variation of hematologic features.

Undefined Congenital Sideroblastic Anemia(s)

It is estimated that at least one third of nonsyndromic cases of congenital sideroblastic anemia are currently molecularly unexplained.[165] These may have autosomal or X-linked defects not yet detectable in the known causative genes, or defects in novel genes to be discovered. Novel genetic defects are also likely in some previously described kindreds. For example, in two families sideroblastic anemia occurred in a vertical distribution including father-to-son transmission and consistent with a dominant trait.[170,171] In another family manifesting the anemia in both genders, a defect in mitochondrial DNA was postulated[172]; the mild anemia was characterized by erythrocyte dimorphism and macrocytosis.

Clinical and Laboratory Features of XLSA and SLC25A38 Deficiency

If severe, XLSA is recognized in infancy or early childhood. However, not infrequently the disorder is milder or asymptomatic and may be discovered only in young adulthood or even in later life. Because severity of anemia can also vary within kindreds,[129,130,164] diagnosis in family members may be delayed or overlooked unless complete pedigree studies or DNA analyses for an *ALAS2* mutation identified in the proband are performed. In contrast, patients with SLC25A38 genetic defects typically present at birth or in early childhood with severe anemia.

All patients develop manifestations of *iron overload*. Linkage to human leukocyte antigen (HLA) is not evident[22] as *HFE* mutations were underrepresented in a series of XLSA patients examined.[26] Mild to moderate enlargement of the liver and spleen is common, but liver function usually is normal or only mildly disturbed at presentation. Liver biopsy reveals iron deposition that is indistinguishable from hereditary hemochromatosis[36] (Fig. 24.4). In the X-linked form the iron burden does not correlate with the severity of anemia, and, not infrequently, well-established but asymptomatic micronodular cirrhosis is discovered in the third or fourth decade.[22,36,134,141,173] Hepatocellular carcinoma developed in two reported cases.[163,174] Clinical diabetes or abnormal glucose tolerance may or may not be related to the iron overload process. Skin hyperpigmentation is uncommon. The most dangerous manifestations of the iron overload are cardiac arrhythmias and congestive heart failure, which usually occur late in the disease course. In severely affected infants or young children, growth and development tend to be impaired.[127]

The hallmark is a microcytic anemia. In severe cases, microcytosis and hypochromia are pronounced (mean corpuscular volume [MCV], 50 to 60 fl), and striking anisocytosis, poikilocytosis, target cells, and occasional siderocytes are prominent findings on blood smear (Fig. 24.1C). The red cell volume distribution is usually abnormally wide and, notably, dimorphism is seen in males with the X-linked form[124] as well as in autosomal forms of the disease.[60,166,170] Some female carriers of the X-linked trait have a biphasic Coulter counter red cell histogram[25,128] (Fig. 24.5), or only a very small microcytic erythrocyte population. However, most women who express XLSA exhibit macrocytosis, although dimorphism may be evident (Fig. 24.1D). Presumably few viable erythrocytes with a markedly defective or nonfunctional mutant ALAS2 enzyme as often encountered in women reach the circulation, so that most of the erythrocytes are progeny of the residual normal clone that are released from the marrow at an accelerated rate in response to the anemic hypoxia. Leukocyte and platelet values usually are normal; they may be reduced in the presence of splenomegaly (hypersplenism). Erythroid hyperplasia is found on marrow examination, and maturation is usually normoblastic with poorly developed cytoplasm. Megaloblastic changes may be observed if complicating folate deficiency is present. Marrow reticuloendothelial iron is increased, and the telltale ring sideroblast emblem is prominent in late, nondividing erythroblasts.[175,176] Transferrin saturation is increased, as is the serum ferritin level, and transferrin levels tend to be decreased. Ferrokinetic studies reflect ineffective erythropoiesis. A reduced serum haptoglobin level is consistent with the ineffective erythropoiesis.

The erythrocyte protoporphyrin level usually is low or normal.[12,131] In one female patient, the low protoporphyrin level was shown to be restricted to the microcytic red cells.[132] Kindreds in which the erythrocyte protoporphyrin is increased[131,170] can be considered to represent disorders other than XLSA or SLC25A38 deficiency.

Treatment and Prognosis

Approximately two thirds of patients with sideroblastic anemia due to identified ALAS2 defects can be expected to respond to

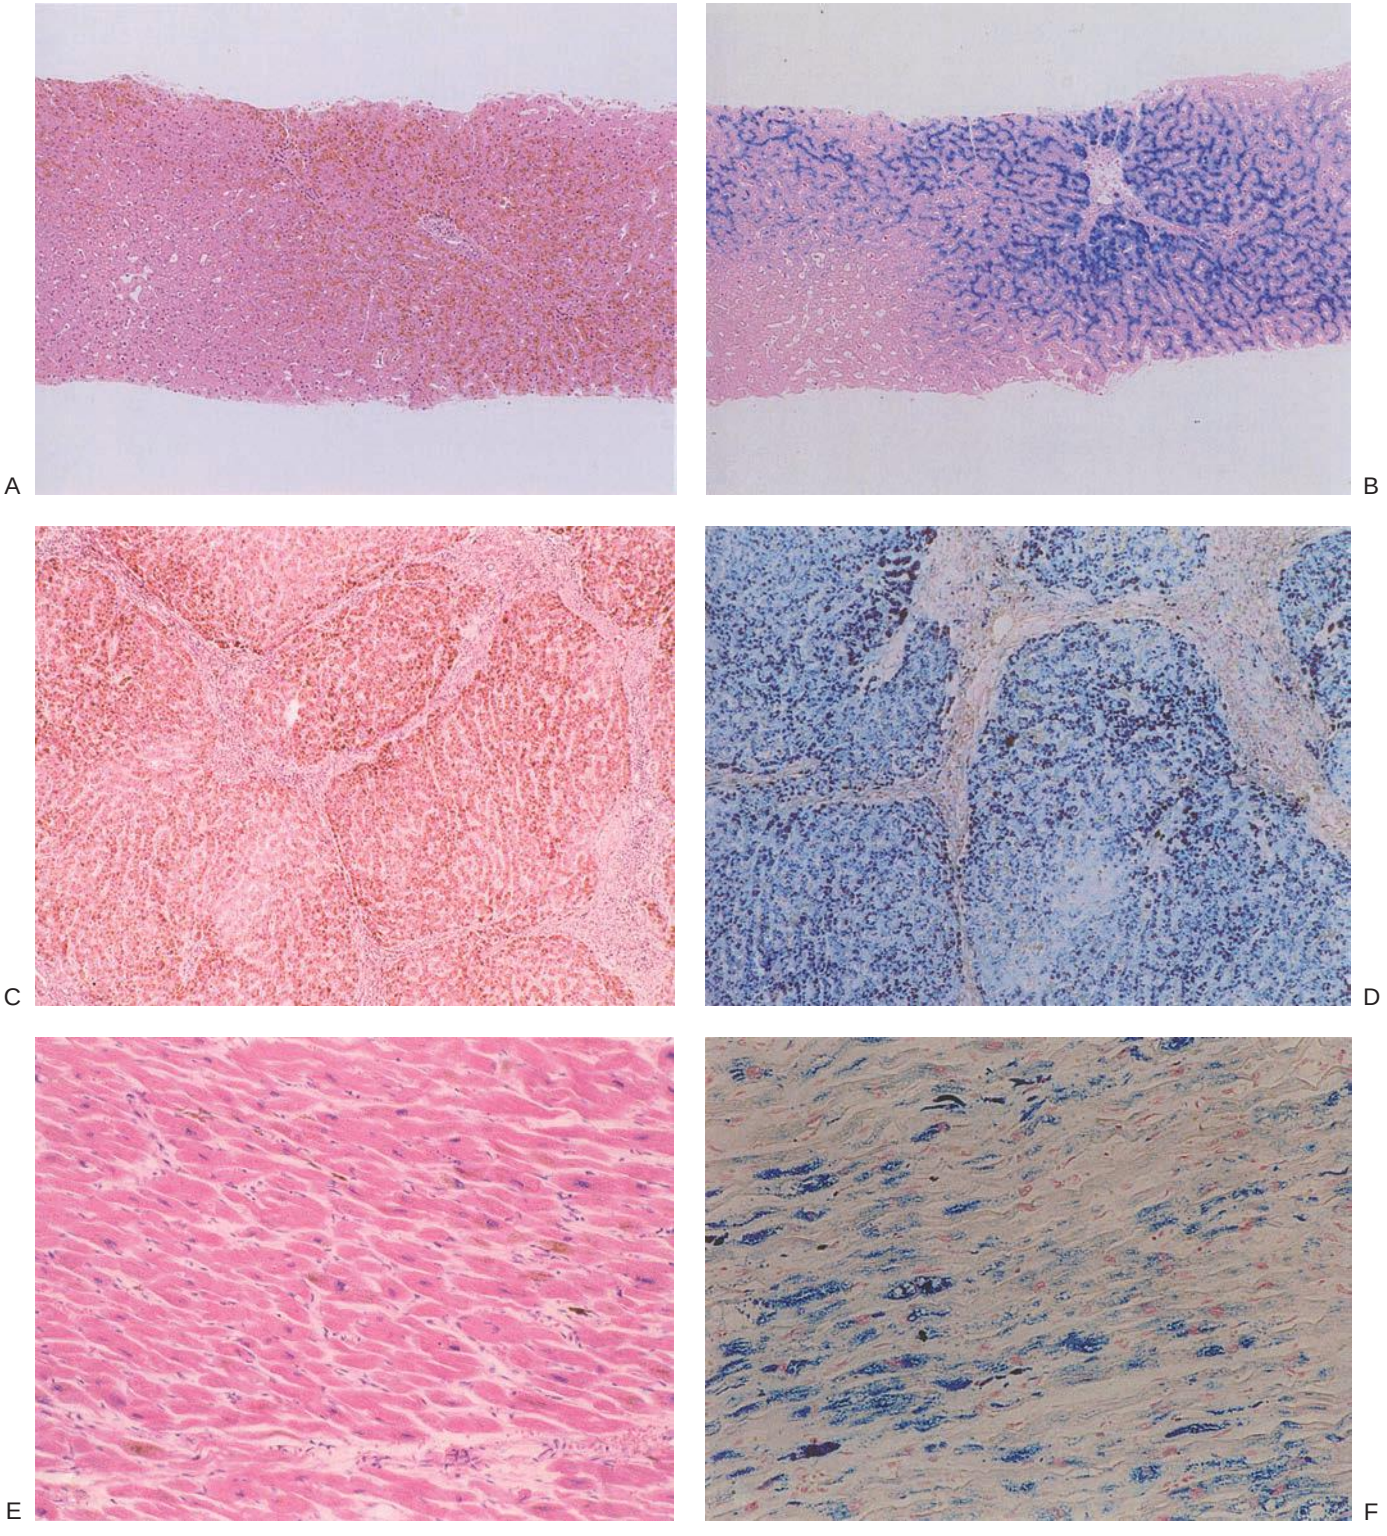

FIGURE 24.4. Histopathology of the iron overload in congenital sideroblastic anemia. A, B: Liver section of a 26-year-old man with SLC25A38 deficiency and moderate hemochromatosis. **C, D:** Autopsy liver section of a 45-year-old man with X-linked sideroblastic anemia, micronodular cirrhosis, and hemochromatosis. **E, F:** Section from the heart of the latter patient with marked hemosiderosis. (**A, C,** and **E:** Hematoxylin stain; **B, D,** and **F:** Prussian blue stain.)

pyridoxine administration. Doses of 50 to 100 mg/day are large compared with the estimated adult daily requirement for vitamin B_6 of 1.5 to 2.0 mg and are sufficient for a maximal response, although in some cases a supplement of only 2 to 4 mg/day was found to be effective.[129] Higher doses may be toxic. No convincing evidence is available that the parenteral route or PLP, the active coenzyme form, is more effective than oral administration. However, the response to pyridoxine is quite variable. With an optimal response, reticulocytosis is observed, blood hemoglobin concentration returns to normal or near-normal levels in 1 to 2 months, and low erythrocyte protoporphyrin levels increase to normal.[12,177] The morphologic red cell abnormalities then

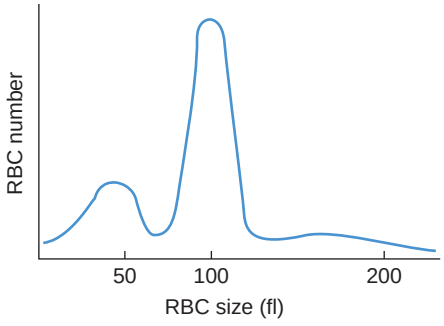

FIGURE 24.5. Dimorphic red cell distribution in a female patient with mild X-linked sideroblastic anemia. Redrawn from the output of a Coulter analyzer. RBC, red blood cell.

diminish but very rarely completely resolve, even when ALA synthase activity and the hemoglobin level are restored with pyridoxine supplementation. Approximately two thirds of responding patients experience a distinct but suboptimal improvement with pyridoxine administration, and the hemoglobin concentration stabilizes at less than normal levels. When an effect of pyridoxine is achieved, continued maintenance treatment is necessary because relapses follow within several months after discontinuance of the vitamin. In a few instances, subsequent remissions with resumed treatment were less complete.[12] In the occasional case with accompanying megaloblastic changes, folic acid should be given, which usually leads to normoblastic maturation, suboptimal reticulocytosis, and some increase in the hemoglobin level. In severely anemic individuals who do not respond to pyridoxine, periodic red cell transfusions are necessary to relieve symptoms and to allow normal growth and development of children. Transfusion of red cells should be kept to a minimum to lessen or delay the development of iron overload.

Based on the assessed extent of iron overload, including liver biopsy, an iron depletion program should be instituted to prevent or stabilize already established organ damage.[134,178,179,180] Therapeutic phlebotomies are well tolerated and preferred in patients with mild or moderate anemia in the absence of contraindications such as heart disease.[134,173,181–183] After the initial removal of all storage iron, maintenance phlebotomies should be continued indefinitely. For patients with severe anemia, or for those who depend on regular transfusions and thus become massively iron loaded,[184,185] an iron-chelating agent is administered. As recommended for thalassemia,[185] deferoxamine is infused over 12 hours subcutaneously or intravenously, at 40 mg/kg/day, and for at least 5 days each week. Although iron removal with deferoxamine is enhanced by ascorbate, large supplements can cause acute cardiac toxicity by facilitating excessive mobilization of ferritin iron, and any intake of the vitamin should be limited to 200 mg daily.[186] The risks of deferoxamine treatment are minimal.[179,187] Occasional local reactions can be controlled with inclusion of small amounts of hydrocortisone in the infusate. Rare hypersensitivity is amenable to desensitization.[188] Reported visual and auditory neurotoxicity is unlikely without excessive doses of the drug. The new, orally active tridentate iron chelator deferasirox (Exjade) has an efficacy similar to deferoxamine or better[180,189]; the recommended initial daily dose is 20 mg/kg and can be increased to 30 mg/kg. Although the long-term safety profile of this agent is not known, it has emerged as a preferred iron chelator. The goal of iron chelation therapy is to maintain the serum ferritin concentration below 500 μg/L. The increased risk of infection with *Yersinia* (and perhaps other organisms) in iron overload, although uncommon, increases further with deferoxamine treatment.[179,190] Removal of the iron excess has occasionally reduced severity of the anemia[8,25,182,183] by improving erythroblast mitochondrial function, such as restoration of secondary ferrochelatase deficiency[183]; by enhancing pyridoxine responsiveness[25]; and by diminishing the ineffective erythropoiesis.[182]

Splenectomy in congenital sideroblastic anemia appears to be invariably complicated by thromboembolic complications and, often, a fatal outcome.[140,141,153,191,192] Factors other than persistent thrombocytosis seem to play a role. Control of the platelet count and anticoagulant therapy usually are not effective, so splenectomy is contraindicated.

These supportive measures provide for a favorable prognosis and often for normal survival. Curative bone marrow transplantation was achieved in seven reported patients without known molecular defects,[193–197] including recovery from chronic graft-versus-host disease after subsequent orthotopic liver transplantation in one of these cases[198]; one patient succumbed to graft-versus-host disease and prior iron overload.[196] Hematopoietic stem cell transplantation has also been successful in several unreported cases with SLC25A38 deficiency.

In contrast to acquired clonal sideroblastic anemia, predisposition to leukemic evolution has not been observed.

Sideroblastic Anemia as a Component of Genetic Syndromes

X-Linked Sideroblastic Anemia with Ataxia

In a large kindred with XLSA associated with nonprogressive ataxia (XLSA/A),[49] linkage to the phosphoglycerate kinase locus at Xq13 was demonstrated[199] and linkage to ALAS2 was excluded using a highly polymorphic repeat sequence within intron 7 of the *ALAS2* gene.[70] Cloning and chromosomal mapping to Xq13.1-q13.3 of the human *ABCB7* gene,[200,201] an ortholog of the *ATM1* gene in yeast that encodes a transporter protein required for mitochondrial iron homeostasis,[202] led to identification of a mutation in this gene as the underlying defect in the kindred.[53] Distinct mutations in the *ABCB7* gene have been identified in three additional families.[203,204,205] All the mutations result in substitutions of conserved amino acids (Ile400Met, Glu433Lys, Val411Leu, Glu209Asp) and affect a region of the protein involved in binding and transport of a substrate. It is postulated that ABCB7 participates in the export of Fe-S clusters generated in mitochondria for assembly of cytosolic Fe-S cluster–containing proteins.[206] Expression of wild-type ABCB7, but not mutant ABCB7, in Atm1p-deficient yeast restores phenotypic defects as well as the production of cytosolic Fe-S proteins.[203] As in yeast,[206] a defective ABCB7 protein leads to mitochondrial siderosis in the human disorder. How heme synthesis becomes impaired in erythroid cells has not been elucidated and may be a consequence of reduced Fe-S cluster biogenesis impacting on the translation of ALAS2.[80,167] Because free protoporphyrin, as well as zinc protoporphyrin, accumulates in erythrocytes,[49,203,204,205] the generation of ferrochelatase,[101,207] an Fe-S-containing protein, is probably affected. Neither ALA synthase nor ferrochelatase has been examined in erythroid cells with the XLSA/A defects. The mechanism for the neural dysfunction in this disorder remains elusive. As in Friedreich ataxia,[208] disrupted mitochondrial iron homeostasis in neural cells is likely involved in the pathogenesis.

Among five kindreds so far encountered, the neurologic features are overriding and include delayed motor and cognitive development, incoordination, and nonprogressive cerebellar atrophy with or without atrophy of pons and medulla.[49,203,204,205,209] The anemia is mild to moderate, and morphologic features are indistinguishable from the isolated heritable forms of sideroblastic anemia, including variable abnormalities in female carriers as observed in XLSA. Both free and zinc-chelated erythrocyte protoporphyrin are increased. Iron overload has not been evident.

Mitochondrial Myopathy, Lactic Acidosis, and Sideroblastic Anemia

This autosomal recessive disorder results from mutations in the genes encoding either pseudouridine synthase (PUS1)[58,165,210,211] or mitochondrial tyrosyl transferase (YARS2).[61,212] In the former, missense or nonsense mutations so far described predict an inactive protein. Mitochondrial and cytoplasmic transfer RNAs lack pseudouridine at the expected sites,[213] likely causing faulty translation of mitochondrial genes of respiratory complexes I and IV. The *YARS2* mutations reduce levels of the enzyme and lead to decreased mitochondrial protein synthesis and respiratory chain dysfunction.[61] How these protein deficiencies lead to mitochondrial iron accumulation and anemia is unclear.

The PUS1 defects have occurred in four families of Jewish Iranian descent, in one family from the Shetland Islands, and in one Italian family[57,58,165,210,211]; in the Iranian families consanguinity was present, and parents of the Italian brothers were distantly related. The disorder is characterized by muscle weakness, basal lactic academia and normocytic sideroblastic anemia with clinical onset in childhood or around adolescence.[57] Some cases have exhibited intellectual impairment and/or craniofacial abnormalities. Diminished oxidative phosphorylation is reflected in decreased activity of mitochondrial enzymes of the respiratory chain as well as in the raised blood lactic acid level. The myopathy and the anemia are variably progressive, and transfusions are usually required by the third decade of life if not earlier.

Based on reports of one family and two further unrelated cases with *YARS2* mutations,[61,212] the myopathy and anemia appear of variable severity. While some cases developed a cardiomyopathy, intellectual impairment or developmental abnormalities were not observed.

Congenital Sideroblastic Anemia and B-Cell Immunodeficiency

A novel syndrome of severe microcytic sideroblastic anemia that is associated with B-cell immunodeficiency, periodic fevers and developmental delay and presents in infancy has been described in 12 children.[213a] In addition, neurologic defects and other multisystem derangements are variably present. Commonly early death was attributed to cardiac or multi-organ failure. The molecular etiology remains to be determined.

Pearson Marrow-Pancreas Syndrome

This progressive, congenital multisystem mitochondrial disorder is associated with sporadic major deletions, rearrangements, or duplications of mitochondrial DNA, leading to the loss of multiple proteins encoded by the mitochondrial genome.[214,215] About one half of cases are heteroplasmic for a 4,977 bp deletion that involves mitochondrially encoded subunits of respiratory complex I (NADH dehydrogenase), complex IV (cytochrome c oxidase), and complex V (ATP synthase) as well as several mitochondrial tRNA genes.[215] Thus, translation of mitochondrial DNA-encoded proteins may be affected. The spectrum of mitochondrial genomic deletions has also extended to other non-overlapping deletions. The heteroplasmic nature of mitochondrial DNA at the cellular and organ levels is considered to account for the high variability of tissues involved over time.

The disorder generally presents within the first 6 months after birth with anemia, metabolic acidosis, and exocrine pancreatic insufficiency. Also common is development of hepatic and renal failure. Some infants lack the metabolic derangements initially and present only with anemia, resulting in oversight of this syndrome. Usually 25% are anemic in the neonatal period; by 6 months of age, anemia is evident in 75% of cases. Any associated neutropenia and thrombocytopenia are mild. The anemia tends to be severe and is normocytic or macrocytic.[216] In the bone marrow, erythroid precursors are often reduced in number but ring sideroblasts are prominent, in which abnormalities in mitochondrial ultrastructure are pronounced.[217] A distinctive feature is the presence of striking vacuoles in myeloid and erythroid precursors.[47] Erythrocyte protoporphyrin values were increased when measured.

Approximately one half of patients succumb to the metabolic derangements. The anemia may improve or remit in up to one third of cases by 10 years of age. Survivors often develop the Kearns-Sayre syndrome.[214,218]

Thiamine-responsive Megaloblastic Anemia

This autosomal recessive syndrome, also known as Rogers syndrome,[42] is caused by mutations in the *SLC19A2* gene, which encodes a 497 amino acid high-affinity thiamine transporter.[54,55,56] The protein is predicted to have 12 transmembrane spanning regions. Twenty-eight distinct mutations have been reported to date.[219] Most of these are nonsense or frameshift type; missense mutations result in proteins that are not properly targeted to the cell membrane for their site of function.[220,221] The dominating megaloblastic feature of the anemia is considered to be due to defective nucleic acid synthesis because limited intracellular thiamine impairs the pentose phosphate pathway and de novo synthesis of ribose-5-P.[222] The unique additional feature of marrow ring sideroblasts may relate to the role of thiamine in the generation of succinyl-CoA, a substrate of ALAS2.[223]

The cardinal clinical characteristic of the syndrome is the triad of megaloblastic anemia, non-type I diabetes mellitus, and sensorineural deafness. Other clinical features have been described in some cases.[219] The disorder has typically manifested between infancy and adolescence.[219,224] Some patients have a milder phenotype, and a few have presented as adults.

Hematologic findings are macrocytic anemia, variable degrees of neutropenia and thrombocytopenia with megaloblastic changes and fewer marrow ring sideroblasts than in other congenital sideroblastic anemias.[224] Thiamine (vitamin B_1) in pharmacologic doses (25 mg/day) usually improves the anemia and the diabetes initially, but it has become ineffective in adulthood.[225]

Animal Models of Sideroblastic Anemia

The first genetically designed animal model of sideroblastic anemia was developed in zebrafish (the *sau* mutant, *sauternes*), in which hematopoiesis resembles that of higher vertebrates also at the molecular level, as hematopoietic gene expression and function are conserved.[226] The chemically induced mutant gene encodes the zebrafish ortholog of human ALAS2 and expresses embryonic hypochromic anemia with severe heme deficiency. The two mutation sites, predicting Val249Asp and Leu305Gln substitutions, are in exon 6 and exon 7, respectively, and represent conserved amino acids across large phylogenetic boundaries, including the human. However, the mutants' blood cells did not reveal ring sideroblasts, perhaps because of species differences in cellular iron metabolism.

A second model in zebrafish (the *sir* mutant, *shiraz*) has a deficiency of glutaredoxin 5, an essential component of Fe-S cluster assembly, and expresses hypochromic anemia.[80] In the absence of the Fe-S cluster, the iron regulatory protein IRP1 blocks ALAS2 translation by binding to the IRE of the ALAS2 mRNA. As in the ALAS2 zebrafish mutant, ring sideroblasts were not observed and may reflect species differences.

In a transgenic mouse model with homozygous deficiency of ALAS2, erythroid differentiation is arrested, and embryos die by day 11.5.[71] Mice chimeric for *ALAS2*-null mutant cells or transgenic mice generated with partial ALAS2 expression[227] exhibit the phenotype of human XLSA, with severe anemia and typical ring sideroblasts in the marrow.

In another mouse model, deletion of the *Abcb7* gene led to fatal neonatal bone marrow failure, demonstrating that Abcb7 is

essential for hematopoiesis.[228] While marrow ring sideroblasts were not observed in these animals or in animals chimeric for the human *Abcb7* mutation Glu433Lys, siderocytes were detected in the peripheral blood.

The combination of isoniazid (INH) and cycloserine administered to guinea pigs produces sideroblastic anemia in a few weeks.[38,39] Blood PLP concentrations become reduced, and bone marrow ALA synthase as well as ferrochelatase activity is diminished.[39] The latter may be secondary to mitochondrial damage by the iron deposits.

The flexed-tail (*f/f*) mouse has a transient embryonic and neonatal anemia associated with siderotic granules (iron-laden mitochondria) in erythrocytes and reduced heme synthesis, which coincides with the physiologic cessation of hepatic erythropoiesis.[229,230] The defect is a frameshift mutation in the *f* gene (sideroflexin, *sfxn1*) that encodes a protein proposed to facilitate transport of a component required for iron utilization into or out of mitochondria.[231]

ACQUIRED CLONAL SIDEROBLASTIC ANEMIA

Since the initial description of acquired idiopathic sideroblastic anemia by Bjorkman,[34] a considerable spectrum of its manifestations has been recognized. The anemia is a component of certain stem cell disorders, namely the myelodysplastic syndromes[50,232,233] and the myeloproliferative diseases.[234,235,236,237] Uncommonly, the ring sideroblast abnormality has been observed in acute leukemia and in erythroleukemia at the time of diagnosis.[238,239] The disorder arises in conjunction with the clonal overgrowth of an altered hematopoietic progenitor cell having a proliferative advantage over the normal cell population and, thus, was included among the myelodysplastic syndromes.[50] Currently three variants are distinguished: refractory anemia with ring sideroblasts (RARS), RARS with thrombocytosis (RARS-T), and refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS) (Table 24.1).

Etiology and Pathogenesis

Clonality

The clonal nature of the disorder was first suggested by the morphologic and kinetic findings of two populations of red cells, the hypochromic, short-lived cell population being the product of the abnormal clone that bears the characteristic ring sideroblasts.[240,241,242] The clonal derivation of the disorder was specifically indicated by the finding of a single glucose-6-phosphate dehydrogenase isoenzyme in hematopoietic cells, but not in fibroblasts, of an individual who was also heterozygous for a glucose-6-phosphate dehydrogenase polymorphism.[243] Further evidence was provided with simultaneous clonality and cytochemical analysis of erythroid progenitors,[244] and cytogenetic studies corroborated the clonality of the abnormal hematopoiesis.[245,246] Chromosomal abnormalities are detectable in bone marrow cells of up to 50% of patients, and deletions in chromosomes 5, 11, and 20 as well as trisomy 8 and loss of Y occur most frequently.[247,248] Although structurally abnormal X chromosomes are uncommon, Xq13 breakpoints were particularly associated with myelodysplasia and ring sideroblasts in one study.[249] Another recurring cytogenetic abnormality is an isodicentric chromosome Xq13.1 (idicXq13.1) occurring only in females.[250] In a few patients, abnormalities of the long arm of chromosome 3 were associated with thrombocytosis.[251,252]

More recently it was found that the RARS-T subtype is associated with the V617F mutation in Janus-associated kinase 2 (*JAK2*), which is common in myeloproliferative disorders,[253] in up to 65% of cases.[254,255,256] How the more active mutant JAK2, by dysregulating the JAK-STAT (signal transducer and activator of transcription) signaling pathway, may play a role in the pathogenesis of the ring sideroblast, if it does at all, is not known. A strong correlation has also been found between somatic mutations in splicing factor *SF3B1*, a core component of the RNA splicing machinery located at the U2snRNP spliceosome catalytic site, and the presence of ring sideroblasts in patients with MDS, ranging from an incidence of 57% to 82%.[257,258,259,260] While mutant SF3B1 thus appears to initiate production of the sideroblastic phenotype, the downstreatm mechanism(s) leading to the dysregulated iron metabolism in the mitochondrion remains to be identified.[260a] It has been suggested that the presence of a *SF3B1* mutation imparts a "benign" clinical phenotype and favorable prognosis.[258,260b]

The natural history of this acquired sideroblastic anemia syndrome is commonly characterized by a chronic, stable anemia and, uncommonly, by a progressive marrow failure state or leukemic evolution.[247,261] An initial genetic change causing expansion of an abnormal hematopoietic clone manifested by defective erythroid cell development is thus insufficient to result in a malignancy, even when persisting for many years. A "second hit" or mutation appears to be necessary for any leukemic evolution[262] that can be reversible, whereas the initial manifested defect expressed in the sideroblastic state persists.[263,264]

Abnormalities in Heme Synthesis

The defective erythropoiesis is characterized at least in part by impaired hemoglobin synthesis, as reflected in the presence of a hypochromic erythrocyte population. Various studies had indicated that the biosynthesis of heme is impaired at the levels of ALA synthase and ferrochelatase. Reduced activity of ALA synthase in marrow cells was the most consistent abnormality in earlier series of patients[138,265–267] and was particularly demonstrable in the youngest erythroblast fraction.[268] In occasional patients, the addition of PLP enhanced the low enzyme activity in vitro, but reported erythropoietic responses to pyridoxine or to PLP administration,[269] as well as restoration of low ALA synthase activity to normal,[265,270] were unusual and may have reflected an inherited defect of ALAS2.[135,142] In a later study, the activity of detergent-solubilized ALA synthase in bone marrow cells was actually somewhat increased,[139] suggesting enhanced translation of the enzyme in response to raised cellular iron levels.

A constant feature is mild to moderate elevation of the erythrocyte protoporphyrin,[240] rarely reaching values encountered in hereditary protoporphyria[62,240,242,271] (see Chapter 26). The latter cases may now be explained by a likely acquired deletion of a ferrochelatase allele due to a cytogenetic abnormality of the clonal disorder.[272] The erythrocyte protoporphyrin increases further after pyridoxine administration but without improvement of the anemia,[240,265,273,274] suggesting a block at the ferrochelatase step. Impaired activity of this enzyme was found in approximately one half of patients studied,[138,267] likely representing a secondary effect of the mitochondrial iron deposition. Studies of iron metabolism in erythroid cells revealed increased accumulation of nonheme iron into membrane or mitochondrial fractions and reduced incorporation of iron into heme.[8,9] Thus, impaired iron utilization for heme biosynthesis remained the common denominator in the pathogenesis.

Subsequently, a defect(s) intrinsic to mitochondria, causing diminished heme production in the abnormal clone as well as accounting for the decreased activity of several other mitochondrial enzymes (i.e., cytochrome oxidase, oligomycin-sensitive adenosine triphosphatase, and mitochondrial serine protease) in granulocytes and erythroblasts[275] was sought. Various heteroplasmic point mutations of conserved nucleotides in mitochondrial DNA, as well as in transfer RNAs and mitochondrial ribosomal RNAs, were found in hematopoietic cells of patients with clonal sideroblastic anemia.[276,277] Many of these affect cytochrome c oxidase and may be implicated in impaired reduction of iron for its incorporation into protoporphyrin by ferrochelatase. Such mitochondrial defects are consistent with the heterogeneity of hemoglobin content found

between individual erythroblasts by scanning microspectrophotometry,[278] as well as with the variable size of hypochromic microcytic erythrocyte and ring sideroblast cell populations in the disorder. A gradual accumulation of affected erythroid precursors and the known higher mutation rate in mitochondrial DNA than in nuclear DNA would provide a basis for the slowly progressive nature of the anemia and its expression in later life, respectively.

A uniformly reduced transcript of the ABCB7 transporter was observed in 33 patients with RARS[279] and may indicate one mechanism leading to this ring sideroblast phenotype. In vitro studies also suggested a link between this ABCB7 down-regulation and *SF3B1* mutations[280] in association with reduced erythroid development and the aberrant expression of mitochondrial ferritin in $CD34^+$ cells that had previously been observed in low-risk myelodysplastic syndromes.[281]

Nuclear Abnormalities

The principal, often macrocytic, red cell population in the blood may represent the progeny of the normal residual erythroid precursors with a shortened marrow maturation time in response to raised erythropoietin levels. The commonly observed morphologic nuclear abnormalities of erythroid precursors and their defective DNA synthesis and mitosis,[282,283] however, suggest that more viable precursors of the dysplastic clone produce the macrocytic erythrocytes, whereas a greater proportion of developing cells expressing impaired heme synthesis is destroyed in the bone marrow. By analogy, various other aberrations of erythroid cell metabolism can occur in dysplastic hematopoietic clones,[284] including altered genetic control of globin chain production. Thus, hemoglobin H disease was acquired in association with erythroleukemia, acute leukemia, and myelofibrosis,[285] as well as in sideroblastic anemia with myeloproliferative features[286] and in patients with sideroblastic anemia before leukemia developed.[287]

Iron Overload

Excessive absorption of dietary iron occurs over time in many, if not all, patients with stable disease and can be attributed to the ineffective erythropoiesis, as in congenital sideroblastic anemias and other long-standing disorders with erythroid maturation defects.[20] The consequent iron accumulation closely resembles that of hereditary hemochromatosis. Although the presence of at least one allele for this disorder would likely contribute to the iron overload,[22] the incidence of *HFE* mutations was no greater than in the normal population in most studies.[22,27,28,288] Inadvertent administration of iron for the anemia and red cell transfusions add predictably to the parenchymal iron deposition.[184,261,289]

Clinical Features

The disorder usually occurs in middle-aged and older individuals, but younger persons, including children, are not spared. The anemia develops insidiously and may be discovered during a routine examination or in association with an unrelated complaint. The older individual more often experiences symptoms of fatigue and angina if there is coexisting coronary artery disease. Physical examination may reveal no abnormality except for pallor. Hepatosplenomegaly is found in one third to one half of patients. With advanced iron overload, usually after repeated red cell transfusions, symptoms and signs of liver decompensation as well as heart failure and arrhythmia occur.

Laboratory Findings

The anemia is usually moderate and may be normocytic but more often is macrocytic (Fig. 24.6). The mean corpuscular hemoglobin concentration is normal or slightly reduced, and a variable population of hypochromic cells is found on blood smear. A particularly

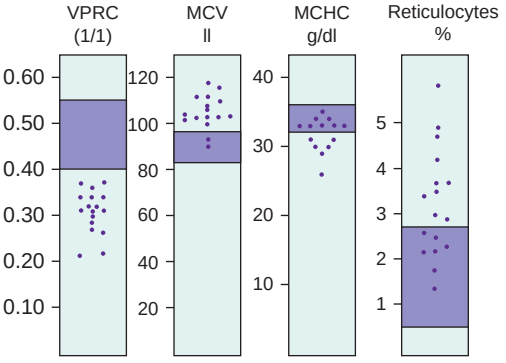

FIGURE 24.6. Characteristics of the anemia in 17 patients with acquired clonal sideroblastic anemia. *Shaded areas,* normal range (mean ± 2 standard deviations). VPRC, volume of packed red cells; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration. (From Kushner JP, Lee GR, Wintrobe MM, et al. Idiopathic refractory sideroblastic anemia. Clinical and laboratory investigation of 17 patients and review of the literature. Medicine 1971;50:139–159.)

characteristic finding is the presence of occasional basophilic stippling in hypochromic cells that stains positive for iron.[23,240] Typical Pappenheimer bodies are uncommon unless there is associated hyposplenism or the spleen is absent. Leukocyte and platelet values are usually within the normal range. The presence of the erythroid abnormalities alone constitutes the RARS subtype of the disorder in the World Health Organization (WHO) classification of myelodysplastic syndromes[233] (see Chapter 73). Associated moderate leukopenia, thrombocytopenia, or both tend to be accompanied by other myelodysplastic features, such as morphologically abnormal leukocytes (e.g., the pseudo-Pelger anomaly) or immature forms in the peripheral blood,[247] and define the WHO category RCMD-RS.[233] The presence of leukocytosis, thrombocytosis, or both is indicative of a mixed myelodysplastic/myeloproliferative disease.[234,235,236,237]

Erythroid hyperplasia is found on bone marrow examination. A feature claimed to be helpful in distinguishing idiopathic sideroblastic anemia from erythroleukemia is the lack of periodic acid-Schiff (PAS)–positive material in the erythroblasts. Mild megaloblastic changes are common and may or may not be related to accompanying folate deficiency. Marrow hemosiderin content is increased, and ring sideroblasts constitute up to 100% of the erythroblasts unless masked by concomitant iron deficiency.[2,240,290,291] In contrast to hereditary sideroblastic anemia, ring sideroblasts are evident at all stages of erythroid maturation.[175] Their distinctive expression of mitochondrial ferritin also permits their detection by flow cytometry methods.[7,292] Because the hematologic phenotype often may be indistinguishable from XLSA in female patients,[135,136] the analysis of X inactivation status and DNA for *ALAS2* defects should be considered.

Serum transferrin saturation is increased in most patients and exceeds 90% in approximately one third of them.[240] Substantially increased deposition of iron is found in the liver, but hepatic dysfunction is rare at presentation. Serum ferritin levels are elevated.

Characteristically, the erythrocyte protoporphyrin is moderately increased, up to 300 μg/dl (normal is 20 to 65 μg/dl). Values ranged from 1,055 to 10,514 μg/dl in the patients with probable acquired deletion of one ferrochelatase allele in the hematopoietic clone, and some had associated dermal photosensitivity.[62,242,271,272]

Treatment and Prognosis

Treatment consists of supportive measures. Pyridoxine administration cannot be expected to be beneficial because ALAS2 defects are not involved in the pathogenesis. Administration of large doses of androgen (e.g., 50 to 300 mg of oxymetholone per day)[240] is rarely useful and tends to produce or worsen fluid retention

and hepatic dysfunction. The effectiveness of erythropoietin has been examined in patients with the myelodysplastic syndromes, including RARS. Most, if not all, patients with uncomplicated sideroblastic anemia have high levels of endogenous erythropoietin, and it would appear unlikely that additional administration of the hormone would be beneficial. However, prolonged administration of recombinant erythropoietin, with or without granulocyte colony-stimulating factor, can lead to gratifying improvement or even correction of the anemia in around 40% of patients,[293,294] in particular in individuals who have a low or intermediate-1 International Prognostic Scoring System (IPSS) score.[295] A response is also more likely to occur if the endogenous serum erythropoietin level is not commensurate with the degree of the anemia,[296] and large doses may be required.

Many studies evaluating various drug regimens for the myelodysplasias included the RARS subtypes. The drugs used have included the hypomethylating agents 5-azacytidine and decitabine, anti-tumor necrosis factor (TNF) fusion protein (etanercept), antithymocyte globulin (ATG), thalidomide and its derivative lenalidomide, and valproic acid.[297–299] On average, major responses with improved erythropoiesis or hematopoiesis have been less than 50% (see Chapter 73).

Many patients are not significantly incapacitated by the anemia. Without abnormalities of the other hematopoietic cell lines and with minimal iron overload, often no progression occurs for many years.[247] Such individuals frequently succumb to other concurrent diseases, but continued medical follow-up is indicated. Iron status should also be assessed with laboratory studies once per year. Transfusion of packed red cells is necessary for patients with symptomatic anemia, but it should be kept to a minimum because it accelerates the iron overload.

Iron overload, particularly when accentuated by repeated transfusions, can be a significant cause of morbidity and mortality (liver failure or heart failure)[261,300] and is improved with chelation.[301,302] When the serum ferritin level is approximately 500 μg/L or higher, along with the increased transferrin saturation, it should be countered. Histologic and chemical determination of iron in the liver biopsy provides the optimal assessment of the degree of iron overload. In mildly or moderately anemic individuals, iron removal can be accomplished with graded phlebotomies. Patients with more severe anemia or who are transfusion-dependent require iron chelation as described for congenital sideroblastic anemias. Because each unit of blood deposits 200 mg of iron, iron overload develops fairly rapidly with regular transfusions, and it is controlled more easily if treatment with an iron chelator is begun after approximately 20 units of blood have been given. In some cases, anemia was improved after iron removal[8,303,304,305]; an independent effect of deferoxamine on erythropoiesis was also implicated.[304,305]

The survival of patients with isolated anemia who are stable and not transfusion-dependent may not differ from that of healthy individuals. A prospective study of 232 patients, which validated the proposal of the two types of the disorder, provided prognostic information.[247] In *pure sideroblastic anemia*, with the marrow failure restricted to the erythroid cell lineage and now called RARS, overall survival was the same as in age-matched controls, and leukemic transformation was not observed. In RARS with features of impaired granulopoiesis, megakaryopoiesis, or both, survival was reduced to 56% at 3 years, and, in approximately 5% of cases, evolution to acute leukemia occurred. Other factors associated with the development of leukemia are the presence of few ring sideroblasts, more severe ineffective erythropoiesis, and impaired bone marrow colony formation.[247,261] The probability of leukemic transformation is also increased in the presence of certain bone marrow karyotype abnormalities (e.g., monosomy 7, deletion 20q, or complex defects).[247,248,306] When sideroblastic anemia followed therapy for various malignant disorders, leukemic evolution tended to be the rule.[307,308]

REVERSIBLE SIDEROBLASTIC ANEMIAS

Alcoholism

Anemia associated with alcoholism usually has numerous causes.[309] A ring sideroblast abnormality is never the sole cause but occurs in 25% to 30% of anemic alcoholic patients[310,311] and probably only in the presence of malnutrition and folate deficiency.[41,311]

The production of heme is impaired by ethanol, as indicated by the ability of heme to restore the concomitantly inhibited globin synthesis in reticulocytes[312] and by the observation that the heme-regulated inhibitor activity of globin translation increases.[313] Inhibitory effects of alcohol have been observed at several steps of the heme biosynthetic pathway. Reduced activity of erythrocyte ALA dehydratase[314] was believed to be related to zinc depletion.[315] Activity levels of erythrocyte uroporphyrinogen decarboxylase, leukocyte coproporphyrinogen oxidase, and ferrochelatase are also decreased in alcoholic patients; those of ALA synthase and PBG deaminase are increased.[314,316] Certain abnormalities of vitamin B_6 metabolism have been observed. Serum levels of PLP are low in chronically ill alcoholic persons[317] but do not correlate with the presence or absence of ring sideroblasts.[311] Acetaldehyde enhanced the degradation of PLP,[317,318] and, in one study, alcohol-induced sideroblastic anemia responded to PLP but not to the combination of folic acid and pyridoxine.[319] The colony formation of early (burst-forming unit–erythroid) and late (colony-forming unit–erythroid) human erythroid progenitor cells is preferentially suppressed by ethanol and acetaldehyde over that of myeloid cell progenitors at concentrations found in vivo and is partially reversed by folinic acid and pyridoxine.[320] Thus, a direct role of vitamin B_6 deficiency in the sideroblastic change is uncertain. Important in the pathogenesis may be the direct effects of ethanol, acetaldehyde, or both on the heme biosynthetic steps or on mitochondrial metabolism, because these agents also inhibit hepatic mitochondrial protein synthesis.[321]

Blood hemoglobin values range from 6 to 10 g/dl, and the MCV is normal or increased. The transient sideroblastic change is commonly evident in dimorphic circulating erythrocytes. Siderocytes, present in approximately one third of patients, are a specific finding[309] and provide the most persistent clue for the ethanol-associated ring sideroblast defect. Megaloblastic hematopoiesis resulting from folate deficiency is frequent but is not always present.[309] A striking finding is vacuolization of pronormoblasts. The percentage of marrow ring sideroblasts ranges up to 70%, and they typically represent later stage normoblasts.[41] Marrow iron stores usually are increased, as are the serum transferrin saturation and the serum ferritin level.

Withdrawal of alcohol is followed by disappearance of ring sideroblasts within a few days to 2 weeks[310] (Fig. 24.7). Recovery from the anemia may occur over several weeks and also depends on the presence of other erythroid defects induced by alcohol[310] as well as any associated medical illness that affects erythropoiesis (see Chapter 41). A prompt recovery phase may exhibit reticulocytosis and erythroid hyperplasia in the bone marrow resembling hemolytic anemia.[310]

Drugs

Antituberculosis Agents

Reversible sideroblastic anemia occurs in association with the treatment of tuberculosis with INH; in a few patients, pyrazinamide and cycloserine also were implicated.[322] These drugs interfere with vitamin B_6 metabolism, and deprivation of PLP reduces ALA synthesis and, thus, heme production.[322] INH reacts with pyridoxal to form a hydrazone and inhibits pyridoxal phosphokinase. Bone marrow ALA synthase activity is also inhibited

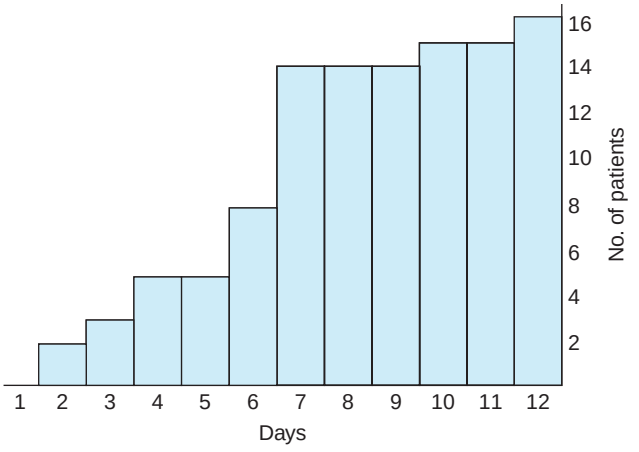

FIGURE 24.7. The rate of clearance in days of ring sideroblasts in 16 alcoholic patients after alcohol intake ceased. (From Eichner ER, Hillman RS. The evolution of anemia in alcoholic patients. Am J Med 1971;50:218–232.)

by INH in a dose-dependent manner in vitro and is restored by PLP.[138] Cycloserine inhibits PLP-requiring enzyme reactions and directly inactivates pyridoxal.[322] Pyrazinamide appears to have anti–vitamin B_6 properties, but a specific mechanism has not been determined.

The relative incidence of anemia in relation to the extensive use of these drugs appears to be low, perhaps because of the regular concomitant administration of pyridoxine. Unknown contributory factors or another hematologic disorder may render certain individuals more susceptible to the antipyridoxine effects of the drugs.[322] In one study, ring sideroblasts or increased erythroblast iron was found in 58% of all patients treated for tuberculosis.[323] Anemia has occurred from 1 to 10 months after institution of INH treatment. It is moderately severe (volume of packed red cells, 0.20 to 0.26 L/L), the red cell indices are usually reduced, and the erythrocytes show dimorphic morphologic features with prominent hypochromia and microcytosis.[324] Ring sideroblasts are invariably present in the bone marrow. Serum pyridoxal concentrations were subnormal in most patients studied.[325] Transferrin saturation tends to be increased. The anemia usually is promptly and fully reversed on withdrawal of the drug or by administering large doses of pyridoxine while continuing use of the drug.

Chloramphenicol and Linezolid

In contrast to the sporadic or idiosyncratic and usually fatal aplastic anemia occurring within weeks or months of chloramphenicol use, the dose-dependent and reversible hematologic toxicity of the drug is predictable and is characterized by suppression of erythropoiesis[326] and by the ring sideroblast abnormality.[40,327] A primary mitochondrial injury by the agent impairs heme synthesis as well as erythroid differentiation and proliferation. Therapeutic concentrations of chloramphenicol (10 μg/ml) inhibit the synthesis of mitochondrial membrane proteins, such as cytochrome a + a_3 and b, and, thus, mitochondrial respiration.[328,329] Impaired heme synthesis is evident in reduced activities of ferrochelatase[330] and ALA synthase,[331] which appear to be secondary effects as these enzymes are synthesized in the cytosol. The greater sensitivity of erythroid cells to chloramphenicol has been demonstrated in vitro, in that therapeutic concentrations of the drug inhibit erythroid colony growth but not granulocyte colony growth.[332]

The anemia may reach moderately severe levels. Bone marrow study reveals variable degrees of hypocellularity and ring sideroblasts as well as prominent vacuolization of early erythroid precursors. Erythrokinetic parameters reflect a hypoproliferative state. Reticulocytopenia, increased serum iron values, and prolonged plasma iron clearance are characteristic.[326] These abnormalities, as well as the ring sideroblasts and anemia, disappear upon withdrawal of the drug.

Linezolid causes reversible myelosuppression and the ring sideroblast abnormality has also been observed.[333] Its toxicity resembles that of chloramphenicol in that it inhibits mitochondrial protein synthesis (mRNA translation), although it blocks assembly of the initiation complex, while chloramphenicol inhibits peptidyl transferases and thus peptide elongation.[334] Vacuolization of erythroid precursors is common, and the hematologic abnormalities disappear upon discontinuation of the drug.

Other Drugs

Several miscellaneous drugs have been implicated in producing sideroblastic anemia in a few patients. These include fusidic acid, busulfan, melphalan, penicillamine and triethylene tetramine dihydrochloride.

Copper Deficiency

Deficiency of copper generally does not occur in humans because requirements are low relative to its wide distribution in food.[335] However, copper deficiency anemia is encountered in various clinical settings and typically leads to sideroblastic anemia and neutropenia. It has developed after prolonged parenteral nutrition[45,46,336,337] and forced enteral feeding[338,339] if copper was not included in the formulations, and in association with intestinal malabsorption[340]; some patients have had prior gastrointestinal operations, e.g., gastrectomy, bariatric surgery.[341,342] Copper deficiency also occurs with the use of copper-chelating agents[343] and after prolonged ingestion of zinc, such as in the form of zinc supplements[344] and with the chronic use of denture cream containing zinc.[345,346] In six instances, the deficiency developed from ingestion of coins and was attributed to their zinc content.[347,348–351]

A novel syndrome of severe sideroblastic anemia with the neurologic manifestations of central nervous system demyelination, or peripheral neuropathy with optic neuritis, or myelopathy and profound copper deficiency was recognized only 10 years ago[352,353,354] and was proposed to represent another combined system disorder resembling vitamin B_{12} deficiency.[355] Subsequently numerous cases with this syndrome were reported.[341] In some, excess zinc ingestion was present and not infrequently remote prior gastric resection was noted.[341] Myeloneuropathy has been the most frequent neurologic abnormality.

The pathogenesis is understood in part from extensive studies of the severe anemia that develops late in the course of dietary copper deficiency in swine.[356] In these animals the anemia is microcytic and hypochromic and is associated with several defects of iron metabolism. Intestinal absorption and mobilization of iron from reticuloendothelial cells and hepatocytes to transferrin are impaired because of the associated lack of ceruloplasmin (ferroxidase). In reticulocytes of deficient animals, protoporphyrin production from glycine and ALA and ferrochelatase activity are not reduced,[357] but iron metabolism in erythroid mitochondria is impaired in that heme synthesis from ferric iron and protoporphyrin is decreased.[358] It was postulated that the reduction of ferric iron to ferrous iron is defective, being somehow linked to the diminished levels of cytochrome oxidase also observed. Low levels of intracellular copper enzymes, such as cytochrome oxidase, may interfere with hematopoiesis in other ways and also account for the neutropenia as well as the neuropathology in humans. The cause of copper deficiency after ingestion of excess zinc has been attributed to induction of the intestinal protein metallothionein by zinc,[359] which preferentially binds copper,[360] prevents its absorption, and enhances its excretion.[361]

The anemia is progressive and may be profound if untreated. The MCV usually is normal or slightly increased at presentation;

hypochromic microcytic erythrocytes may be detectable on the blood smear. The granulocytes are commonly <1,000/mm^3; the platelet count is usually normal. The bone marrow tends to be hypoplastic, with impaired myeloid maturation.[45,46] Vacuolization of early erythroid and granulocytic precursors is a prominent finding, as are large iron-positive cytoplasmic inclusions in plasma cells.[45,354] In most instances, moderate numbers of ring sideroblasts are observed, in particular if the anemia is sufficiently severe. The hematologic features have occasionally led to the erroneous diagnosis of a myelodysplastic syndrome before the copper deficiency was recognized.[354,362,363]

Serum iron levels and transferrin saturation are normal. The serum copper and ceruloplasmin levels are uniformly low. In cases of zinc-induced copper deficiency, serum zinc levels are increased from two- to threefold above the mean normal value.

With correction of the copper deficit, recovery of the hematologic abnormalities is uniformly prompt and complete. In some cases, recovery followed discontinuation of the excess zinc intake alone. Zinc as a therapeutic agent should thus be prescribed with caution,[364,365] and its use as a stimulus for general well-being should be discouraged. Moreover, the zinc content has been removed from denture cream products. The neurologic abnormalities may improve or only stabilize with continued copper supplementation.[341,353,354,362] The usual dose of copper may not be sufficient for all patients as relapse has occurred,[366] and long-term follow-up is advised for all patients.

Hypothermia

In 1982, O'Brien et al. described three patients who, during episodic hypothermia, exhibited erythroid hypoplasia and ring sideroblasts as well as thrombocytopenia in the presence of a normal number of megakaryocytes.[48] As the body temperature returned to normal, these changes slowly reversed. The ring sideroblast abnormality might be explained by the well-known inhibition of the translocation of proteins into mitochondria by reduced temperature.[48,367] Heme synthesis[368] and iron incorporation into hemoglobin by reticulocytes[369] have also been shown to be diminished at lowered temperatures.

ANEMIA FROM DEFECTS IN ERYTHROID HEME SYNTHESIS WITHOUT RING SIDEROBLASTS

Anemia of Lead Poisoning

Lead poisoning has occurred from a wide array of sources, including lodged bullets, inhaled fumes in various industries or lead particles in a firing range, ingested contaminated herbs and food supplements, and beverages containing lead solubilized from glazes of utensils and linings of stills.[370,371] In children, the primary source was ingestion of lead-based paint chips. Organic lead is acquired by absorption through the skin or by gasoline sniffing. Heterozygotes of hereditary ALA dehydratase deficiency are said to be more susceptible to lower levels of lead exposure,[372] as are persons with one or both genes for the less common allele (*ALAD2*) of the enzyme.[373] Although lead has been eliminated from various consumer products and occupational exposure is monitored, it may still remain the most common cause of occupational poisoning worldwide.[374]

The anemia that accompanies lead poisoning (plumbism) is in part the result of various inhibitory effects of lead on heme biosynthesis.[375,376] Most enzymes in the heme biosynthetic pathway are inhibited by lead to varying degrees. Presumably, lead displaces an essential metal or reacts with active-site thiol groups of the enzymes, but the precise mechanism is not worked out in most cases. ALA dehydratase is most sensitive to lead in vitro and in vivo, followed by ferrochelatase, coproporphyrinogen oxidase, and PBG deaminase, respectively. The effects of lead on the production of heme are also interrelated with iron metabolism. In erythroid cells, lead impedes the intracellular delivery of iron to waiting ferrochelatase, and the surrogate metal zinc is inserted into protoporphyrin by ferrochelatase as in iron deficiency[377] so that zinc protoporphyrin accumulates. These events probably account for the usual absence of the ring sideroblast abnormality in persons with lead intoxication. Ferrochelatase may be directly inhibited in acute and more severe lead intoxication, and, only then, nonchelated protoporphyrin accumulates in erythrocytes.[378,379] Lead also impairs globin synthesis.[380] With prolonged lead exposure, erythroid hypoplasia may occur.[381]

Other effects of lead increase the rate of red cell destruction. Changes in the spatial arrangement of red cell membrane proteins caused by lead are believed to inhibit adenosine triphosphatase, leading to cellular loss of K^+.[382] If the lead burden is sufficiently severe (i.e., with blood lead concentrations of 200 μg/dl or greater), impaired erythrocyte pyrimidine 5′-nucleotidase activity causes accumulation of nucleotides that inhibit the pentose phosphate shunt[383] and promote hemolysis as in the genetically determined deficiency of the enzyme (see Chapter 28).

The typical clinical manifestations are autonomic neuropathy causing abdominal pain and ileus (lead colic) and motor neuropathy (lead palsy).[384] A lead line may be seen on the gums and tonsils. Occasionally, renal dysfunction (lead nephropathy) may prompt the diagnosis. These classic features denote advanced lead toxicity, and more common are insidious, nonspecific musculoskeletal and neuropsychiatric complaints.[370]

The hematologic changes in lead poisoning are variable and can be attributed to the multiplicity of toxic actions on the erythron. More recently, anemia was present in only 25% of adult patients.[370] Anemia in children is also a late sign of lead poisoning by current standards[385] and frequently is superimposed on pre-existing iron deficiency.[386] The severity of the anemia ranges from mild to moderate, and the red cells tend to be mildly hypochromic and microcytic (Table 24.4). The reticulocyte count may be raised in patients with overt hemolysis.[384] Coarse basophilic stippling may be prominent (Fig. 24.8), representing polysomal aggregates that presumably are retained because RNA degradation is impaired as a result of the pyrimidine 5′-nucleotidase deficiency, but it is not always present and does not correlate with the lead burden.[385,387] Osmotic fragility of the erythrocytes is decreased; mechanical fragility is increased consequent to the membrane injury.[387] An electrophoretically "fast" hemoglobin similar to hemoglobin A_3 may be found.[388] The bone marrow usually reveals erythroid hyperplasia, but it may be hypoplastic. Authentic ring sideroblasts are uncommon, if they occur at all.

The mean red cell life span is reduced with a random pattern of destruction despite problems with the accelerated ^{51}Cr elution from red cells due to lead effects on the red cell membrane.[389] Serum iron levels tend to be normal or slightly increased unless the patient has associated iron deficiency. The findings of ferrokinetic studies are consistent with ineffective erythropoiesis accompanied by mild hemolysis.[389]

Parameters of heme biosynthesis reflect the inhibition of the various enzymatic steps and correlate with the lead burden.[375] ALA dehydratase activity in erythrocytes is reduced in proportion to blood lead levels, and, in contrast to the hereditary deficiency of the enzyme, its in vitro activity is restored to normal by reducing agents such as glutathione or dithiothreitol.[375] As a consequence of the reduced activity, urinary ALA is greatly increased, whereas levels of PBG are rarely increased, a combination that distinguishes plumbism from acute porphyrias, in which PBG is excreted in greater excess than ALA. Urinary coproporphyrin, and to a lesser degree uroporphyrin, levels are also increased in

TABLE 24.4

HEMATOLOGIC CHANGES IN THE ANEMIA OF LEAD POISONING IN ADULTS

		Normal (Range)	Lead Poisoning (Range)
Hemoglobin (g/dl)	Male	14.0–18.0	10.7
	Female	12–16	8–13
Volume packed red cells (L/L)	Male	0.40–0.54	0.35
	Female	0.37–0.47	0.29–0.43
Mean corpuscular volume (fl)		89 (83–96)	79 (70–92)
Mean corpuscular hemoglobin concentration (g/dl)		34 (32–36)	31 (27–36)
Reticulocytes (%)		1.6 (0.6–2.7)	4.4 (1.5–11.6)
Stippled cells (%)		Rare	1.8 (0.1–7.5)
Leukocytes ($\times 10^9$/L)		4–11	4–15

Adapted from Dagg JH, Goldberg A, Lochhead A, et al. The relationship of lead poisoning to acute intermittent porphyria. QJM 1965;34:163–175 and Griggs RC. Lead poisoning: hematologic aspects. Prog Hematol 1964;4:117–137.

lead poisoning. The zinc protoporphyrin level in erythrocytes is increased more than in iron deficiency.

The upper limit of the "normal" level of blood lead, which is mostly contained in erythrocytes, is 30 μg/dl of whole blood. Adults with concentrations of 30 to 75 μg/dl show decreased ALA dehydratase activity, increased urinary excretion of ALA, and an increase in erythrocyte protoporphyrin,[390] and may have nonspecific symptoms of lead poisoning. Clear symptoms usually are associated with concentrations that exceed 75 μg/dl. Concentrations in urine >0.1 mg/24 hours also establish the diagnosis of lead intoxication. When urinary lead excretion is borderline, response to slow intravenous infusion of 25 mg/kg (not to exceed 2 g) of the chelator calcium disodium ethylenediaminetetraacetic acid can confirm the diagnosis; excretion of more than 0.2 mg of lead in 24 hours indicates an increased lead burden.

Treatment consists of removal of the lead source and administration of ethylenediaminetetraacetic acid, 50 mg/kg/day in two divided doses, by slow intravenous infusion with ample fluids for 5 days.[371,390] This regimen may be repeated in 3 to 4 weeks, depending on the response of blood lead levels. Renal function should be monitored. Recovery usually is prompt. An oral chelating agent, 2,3-dimercaptosuccinic acid, is also available.[391]

Certain Porphyrias

Heme biosynthesis is strikingly perturbed in the various porphyrias that result from heterogeneous molecular defects in each of the enzymes in the pathway (see Chapter 26). Tissue-specific differences of expression and of regulation of these enzymes likely account for the absence of anemia in most porphyrias, as the defective enzymes do not become rate-limiting in the erythroid cell. In a few of them, erythroid heme production may be minimally compromised, as noted for protoporphyria previously; or accumulation of biosynthetic intermediates perturbs erythroid cell development, survival, or both.

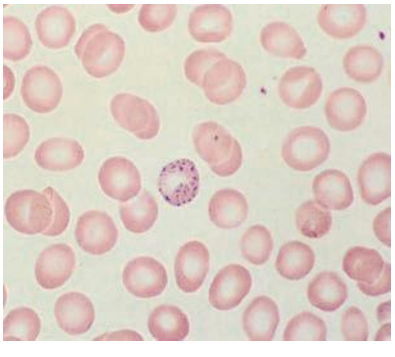

FIGURE 24.8. Hypochromia and red cell stippling in lead poisoning.

Congenital Erythropoietic Porphyria

In this rare disorder, expressed as an autosomal recessive trait, erythroid heme biosynthesis is not diminished.[392,393] Because of the low residual uroporphyrinogen III synthase activity, uroporphyrin I accumulates, mainly in erythroid cells. Variable anemia is associated with dyserythropoiesis and varying degrees of peripheral hemolysis. The porphyrin accumulates in the nuclei of developing erythroblasts and is believed to affect their maturation. Anemia often is not the principal clinical problem. In some patients, the hemolytic process was improved by splenectomy.

Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria represents the homozygous deficiency of uroporphyrinogen decarboxylase and is expressed as a variably severe form of porphyria cutanea tarda typically manifesting during infancy or early childhood.[394] About 40 cases have been reported, and anemia was noted in more than 50% of patients.[395] Severe anemia or a hemolytic process is the exception. The level of erythrocyte protoporphyrin, primarily as zinc protoporphyrin, is increased and is attributed to a relatively increased conversion of uroporphyrinogen III to protoporphyrin late in erythroid maturation when iron supply may become rate limiting. The anemia has not been characterized.

Harderoporphyria

Anemia has been encountered in this erythropoietic variant of hereditary coproporphyria, in which large amounts of the tricarboxylic harderoporphyrin accumulate.[396,397,398] Affected individuals carry distinctive homozygous or compound heterozygous mutations in the coproporphyrinogen III oxidase gene, and the mutant enzyme has 18% to 24% residual activity.[397] Clinically, neonatal hemolytic anemia with hyperbilirubinemia and hepatosplenomegaly is followed by mild microcytic anemia and variable photosensitivity in adulthood. Neurovisceral symptoms of acute porphyria may occur.[398] Expression of the defect is usually limited to erythroid tissue and is characterized by impaired heme synthesis and dyserythropoiesis with associated iron overload.[397]

KEY CLINICAL SUMMARY POINTS

- **General Definition of Sideroblastic Anemia (SA)**

Sideroblastic anemia comprises a wide spectrum of heritable or acquired erythropoietic disorders. Regardless of clinical and peripheral blood abnormalities, the unifying feature of all forms of SA is the presence of bone marrow ring sideroblasts.

- **Prompt Diagnosis of a Sideroblastic Anemia**

Consider in all adults and children/infants with unexplained anemia of any severity from history, clinical examination, and basic laboratory data. Certain features are suggestive: history of chronic anemia; exposure to factors causing reversible SA (Table 24.1); family history of anemia; presence of neurologic abnormalities, myopathy, lactic acidosis, immunodeficiency in children or young adults.

Suspect a congenital SA in the presence of microcytosis without evidence of iron deficiency or thalassemia; the MCV and erythrocyte morphology are most accurate before any red cell transfusion (Fig. 24.9).

Establish the diagnosis of SA by performing a Prussian blue stain on the bone marrow aspirate smear.

- **Differential Diagnosis**

If ring sideroblasts are evident in the marrow, review the patient's constellation of clinical findings to narrow the differential diagnosis (Table 24.1, Fig. 24.9).

Where the causative gene is known, mutation analysis provides definitive diagnosis of a congenital SA; some molecular genetic tests are available in several clinical laboratories listed on the www.genetests.org website, others may be available in certain research laboratories.

Evaluate for iron overload with serum iron profile and ferritin; assess parenchymal organ involvement as indicated.

- **Treatment**

Withdraw an identified reversible cause.

Recommend a therapeutic trial of pyridoxine (adult dose 50 to 100 mg/day) in patients with microcytic SA until the genetic cause can be determined; the vitamin is only effective in some cases with XLSA.

For symptomatic anemia, provide supportive treatment with red cell transfusion.

Remove excess body iron by phlebotomy if anemia is mild; by use of iron chelation in patients with severe/transfusion-dependent anemia.

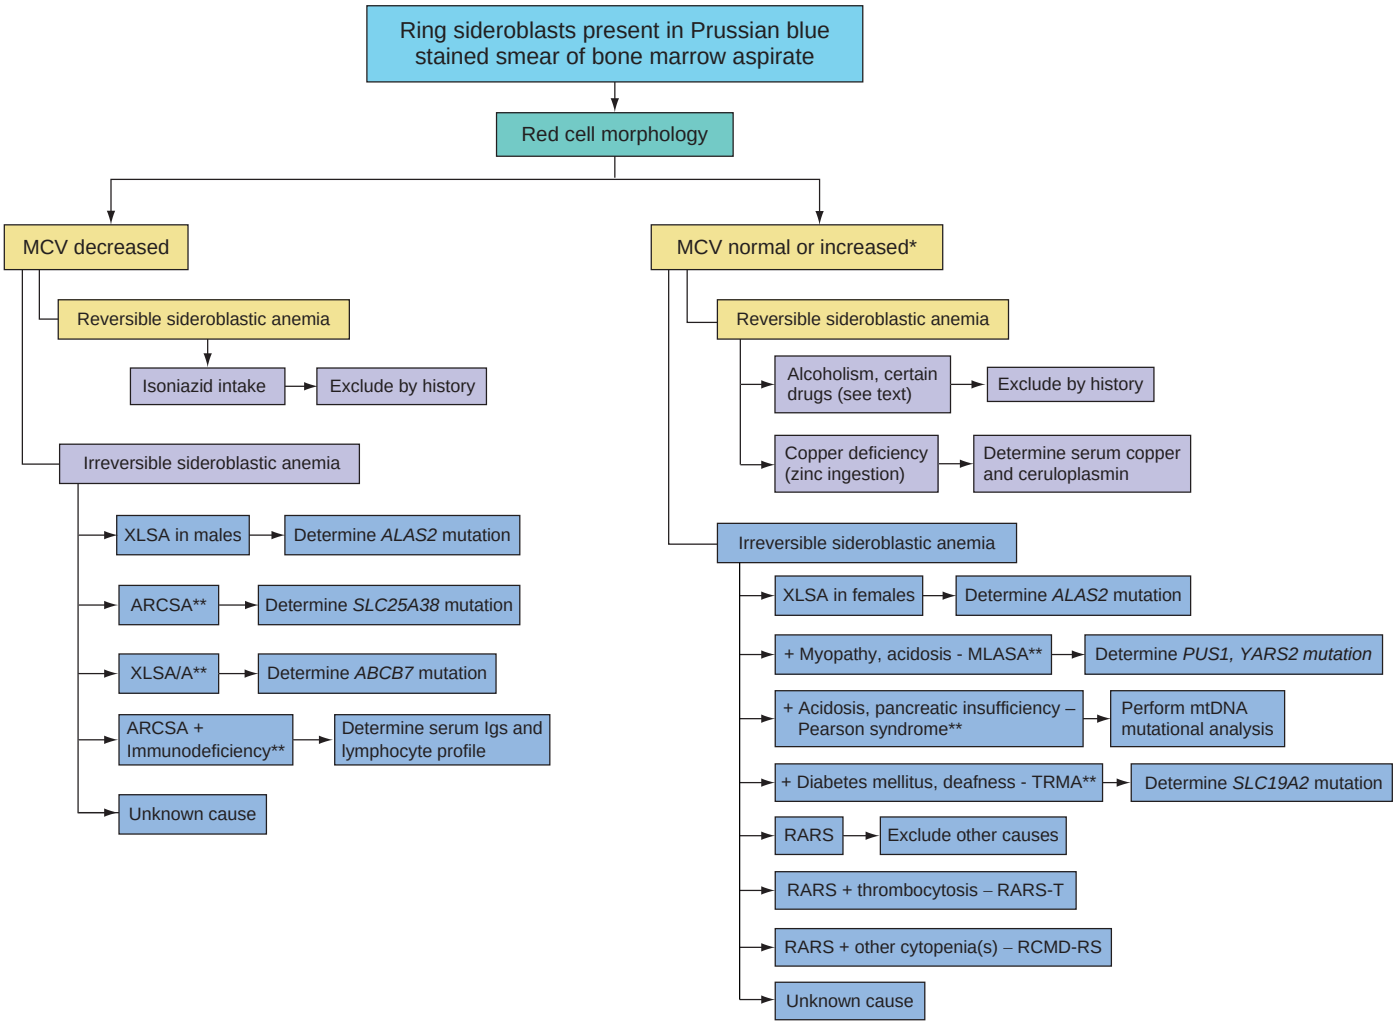

FIGURE 24.9. Schema for diagnostic evaluation of patients with a sideroblastic anemia. MCV, mean corpuscular volume; XLSA, X-linked sideroblastic anemia; ARCSA, autosomal recessive sideroblastic anemia; XLSA/A, X-linked sideroblastic anemia with ataxia; Igs, immunoglobulins; MLASA, myopathy, lactic acidosis, and sideroblastic anemia; mtDNA, mitochondrial DNA; TRMA, thiamine-responsive megaloblastic anemia. *Microcytic hypochromic red cells may be present in the blood smear in many, but not all, of these disorders. **Typically present in infancy or childhood.

Prescribe thiamine (25 mg/day) in the TRMA syndrome.

Manage the clinical aberrations associated with the syndromic forms of congenital SA with available supportive measures.

- **Follow-up**

Educate the patient and family about the disease and relevant inheritance.

Encourage patients to keep records of diagnostic studies and recommended therapy.

In cases with congenital SA, provide for examination of family members and for their genetic testing as indicated.

CHAPTER 25

HEMOCHROMATOSIS

Corwin Q. Edwards, James C. Barton

IRON OVERLOAD

Iron overload can result from any process that causes iron accumulation in excess of iron loss. Examples of such processes include (a) erythrocyte transfusions in individuals who do not experience blood loss (e.g., patients with hemolytic anemia, aplastic anemia, and sideroblastic anemia); (b) absorption of excessive amounts of normal dietary iron (hemochromatosis types 1 through 4, disorders of ineffective erythropoiesis); and (c) absorption of increased amounts of excessive dietary iron (e.g., high-dose medicinal iron and African iron overload).

Definition

The definition of iron overload typically includes a description of an individual's iron phenotype, such as (a) an elevated serum ferritin concentration; (b) excessive iron in the liver or myocardium (estimated histologically or by chemical methods); and (c) the requirement of a greater than normal number of phlebotomies to induce iron-limited erythropoiesis.

HEMOCHROMATOSIS

Hemochromatosis Type 1, *HFE* Hemochromatosis

The definition of "classical," autosomal recessive hemochromatosis (type 1) typical of Western European whites once required demonstration of the rare triad of cutaneous hyperpigmentation ("bronzing"), diabetes mellitus, and cirrhosis that was presumed to represent complications of severe iron overload. The eventual ability to measure iron in liver and other tissues, serum, and by phlebotomy to achieve iron depletion revealed that hemochromatosis was more common than previously believed and that the diagnosis could be defined by severity of iron overload. In 1996, it was discovered that most patients with this type of hemochromatosis were homozygous for a common missense mutation (C282Y) of the *HFE* gene on chromosome 6p21.3. Thus, most current definitions of hemochromatosis in Western European whites include specification of the iron phenotype and *HFE* genotype. Three important relationships of phenotype and genotype definitions are: (a) *HFE* C282Y homozygosity is a genetic configuration that markedly increases the risk that iron overload will eventually develop without other readily demonstrable cause; (b) iron phenotypes and organ-specific complications of *HFE* C282Y homozygotes vary greatly due to genetic and environmental factors; and (c) iron overload, not *HFE* C282Y homozygosity or abnormal HFE protein, causes tissue injury in target organs.

Hemochromatosis Type 2, Juvenile Hemochromatosis

Hemochromatosis type 2 is characterized by nontransfusion iron overload, often severe, that typically occurs in children or young adults.

Type 2a, Mutations of Hemojuvelin Gene (HJV)

Hemochromatosis type 2a is an autosomal recessive disorder due to pathogenic mutations in the hemojuvelin gene (*HJV*; chromosome 1q21).[1,2] The iron overload phenotype of patients with *HJV* hemochromatosis is much more severe at the same age than the phenotype of typical patients with hemochromatosis due to *HFE* C282Y homozygosity and the penetrance of hemochromatosis type 2a genotypes (risk to cause iron overload) is also greater. Hemochromatosis type 2a often causes abdominal pain and hepatomegaly in children, hypogonadotrophic hypogonadism in teenagers, arthropathy, and severe heart failure, cardiac arrhythmias, and cirrhosis before the age of 30 years.[3] Based on the volume of blood removed to achieve iron depletion in some patients, it can be deduced that they absorbed 3.2 to 3.9 mg of dietary iron per day.[4] In severe *HFE* hemochromatosis, 2 mg of iron or less is absorbed daily.[5,6]

Two pathogenic *HJV* mutations (either homozygous or compound heterozygous configuration) occur in each patient. The most common *HJV* mutation causes a change in nucleotide 959G→T, which codes for substitution of the normal glycine by valine in position 320 of the polypeptide sequence of the HJV protein (*HJV* G320V). This mutation has been detected in patients with juvenile-onset hemochromatosis of diverse European ethnicities.[7,8] About 30 pathogenic *HJV* mutations have been reported. Many are novel (not detected in unrelated patients with hemochromatosis type 2a.)[7–11] Some *HJV* hemochromatosis patients also have an abnormal *HFE* genotype but the latter does not account for iron overload in most cases.[12]

Hemojuvelin is involved in the up-regulation of hepcidin synthesis, not in the regulation of HFE function. Decreased hemojuvelin activity decreases hepcidin synthesis, thus decreasing hepcidin binding and inactivation of ferroportin. Consequently, regulation of iron transport out of absorptive enterocytes into the plasma via ferroportin is decreased, even in the presence of increased storage iron.

Type 2b, Mutations of Hepcidin Gene (HAMP)

Hemochromatosis type 2b is associated with iron overload of variable severity and age of onset and is also transmitted as an autosomal recessive trait.[12,13] This disorder is rare. Hemochromatosis type 2b is due to mutations in the hepcidin gene (*HAMP*, chromosome 19q13). *HAMP* is an acronym for hepcidin antimicrobial peptide. The word hepcidin is derived from hepatic bactericidal protein.

The first reported *HAMP* mutation (nucleotide 208T→C) causes substitution of the normal cysteine by arginine at amino acid 70 (C70R).[14] Approximately 12 other *HAMP* mutations have been reported.[15–18] Mutant hepcidin has decreased ability to bind to ferroportin, its only receptor. Consequently, ferroportin is not degraded and thus continues to transport iron across the basolateral membrane of absorptive enterocytes in the presence of excess iron stores.[19] Some hemochromatosis type 2b patients, usually those heterozygous for pathogenic *HAMP* promoter or coding region mutations, also have *HFE* mutations that contribute to the pathogenesis of iron overload ("digenic" hemochromatosis).

Hemochromatosis Type 3, Mutations of Transferrin Receptor-2 Gene (*TFR2*)

Hemochromatosis type 3 is a rare autosomal recessive disorder reported in persons of European or Asian ancestry caused by mutations of the transferrin receptor-2 gene (*TFR2*) located on chromosome 7q22.[20] The clinical phenotype is moderately variable and resembles either that of *HFE* hemochromatosis or that of juvenile hemochromatosis types 2a and 2b. Fewer than 20 pathogenic *TFR2*

mutations have been reported.[20–24] The penetrance of hemochromatosis type 3 genotypes is relatively great. Consanguinity has been identified in some affected families. *TFR2* Y250X and R455Q have been detected in individuals or kindreds who were not closely related.[20] Pathogenic *TFR2* mutations either result in gain-of-function or in decreased quantities of functional transferrin receptor-2. TFR2 protein is thought to modulate the signaling pathway that controls hepcidin expression[25] with consequent low hepcidin[26] and increased iron absorption and deposition in hepatocytes.

Hemochromatosis Type 4, Mutations of Ferroportin Gene (*SLC40A1*)

Hemochromatosis type 4 is an uncommon heterogeneous disorder transmitted as an autosomal dominant trait. It is caused by mutations of a gene of the solute carrier family 40 (member #1) (*SLC40A1,* chromosome 2q32), which encodes the synthesis of ferroportin, the sole receptor of hepcidin.[27–30] There are two distinct ferroportin hemochromatosis phenotypes. Loss-of-function *SLC40A1* mutations encode ferroportin that either is not presented normally to the cell surface or has defective iron transport activity. Such mutations decrease iron absorption from the intestine and inhibit iron egress from macrophages. Phenotypes of affected patients include normal or low transferrin saturation, mild anemia, and predominance of iron retention in macrophages. Gain-of-function mutations encode ferroportin that cannot bind hepcidin normally or be internalized after hepcidin binding (*hepcidin resistance*). This increases iron absorption and stimulates iron export by macrophages. Affected patients have elevated transferrin saturation and iron deposition in hepatocytes.

Ferroportin mutations are cosmopolitan. Most reported mutations are restricted to single families. *SLC40A1* V162del has been reported in persons with iron overload from Australia, Europe, and Asia. *SLC40A1* A77D has been reported in persons with iron overload in Italy, Australia, and India. *SLC40A1* Q248H occurs as a polymorphism in natives who reside in diverse areas of sub-Saharan Africa and in African Americans, but probably does not cause iron overload.[31]

HISTORY

Hemochromatosis Type 1, Classical, Hereditary

The first report of a person with hemochromatosis was included in a discussion of diabetes mellitus in 1865.[32] The patient was a 28-year-old Parisian man who sold newspapers and who died of a febrile illness that complicated his diabetes. His autopsy revealed hepatomegaly and hypertrophic cirrhosis. The second case of hemochromatosis was reported in 1871 and described a 51-year-old man who lived in Paris.[33] He had skin bronzing of his face and hands. His autopsy revealed a chocolate-colored, enlarged liver. Microscopic examination of his liver showed pigment granules inside and outside of hepatocytes. In 1886, the term *pigmentation cirrhosis* was used to describe the triad of skin bronzing, diabetes mellitus, and hepatic cirrhosis.[34] The name *hämochromatose* was first used by von Recklinghausen in his 1889 description of 12 individuals who had pigmentation of multiple organs.[35] He believed that the iron that accumulated in organs came from red blood cells.

ETIOLOGY

Cloning of the *HFE* Gene

In 1996, the hemochromatosis gene was isolated by positional cloning and two common mutations that account for most cases of hemochromatosis in persons of Western European descent were discovered.[36] The gene was named *HFE* (H = hemochromatosis; Fe = iron).[37,38] The cloning of *HFE* was reported more than 130 years after the first case description of hemochromatosis at autopsy and confirmed reports during an interval of more than two decades that hemochromatosis was transmitted as an autosomal recessive condition linked to the HLA locus on the short arm of chromosome 6.[39–47]

Function of the *HFE* Gene

The normal *HFE* gene encodes normal HFE protein which is expressed in duodenal crypt cells and reticuloendothelial cells.[48] In a normal individual, HFE protein binds to β_2-microglobulin, which decreases the affinity of cell membrane transferrin receptors for transferrin.[49–52] This decreases iron absorption. In iron deficiency, HFE protein synthesis is decreased, binding of HFE protein to β_2-microglobulin is decreased, the affinity of the transferrin receptor for transferrin is increased, and thus duodenal crypt cells absorb more iron.

Effects of *HFE* Gene Mutations

The HFE protein binding site for the β_2-microglobulin binding site has two cysteine molecules that form a disulfide bridge. In *HFE* C282Y homozygotes, tyrosine replaces a cysteine molecule at amino acid position 282 in the product of both *HFE* gene copies (maternal and paternal) and thus the disulfide bridge is absent. This prevents binding of the abnormal HFE protein to β_2-microglobulin on the cell surface. Excessive iron is then absorbed through the crypt cells and passed into the circulation.[53–58] Despite these observations, the full function and participation of the HFE protein in iron absorption has not been elucidated. Studies of penetrance of hemochromatosis demonstrate that *HFE* C282Y homozygosity is necessary but probably not sufficient for iron overload to develop.

PATHOPHYSIOLOGY

Normal adults absorb an amount of iron each day that precisely balances daily losses (men ~1 mg, women 1 to 3 mg). In healthy children and infants, daily iron absorption corresponds to the iron requirements of growth and development. In acute blood loss or iron deficiency, daily iron absorption increases until the total body deficit has been replaced. In persons with hemochromatosis, the absorption of dietary iron is inappropriately great in comparison with quantities of total body iron. In some persons with *HFE* hemochromatosis and iron overload, daily iron absorption may exceed 2 mg at a time when iron absorption should have decreased to nearly zero.[59,60] In some children with juvenile hemochromatosis, average daily iron absorption may exceed 3 mg/day. Phlebotomy therapy to achieve iron depletion in hemochromatosis may increase iron absorption to 10 mg/day and iron absorption may remain inappropriately elevated long after iron deficiency resolves.[61–63] Iron loading in hemochromatosis types 1 to 4 is caused either by an abnormality in hepcidin synthesis or a decrease of its activity via decreased function of ferroportin. HFE, HJV, and TFR2 probably all have a contributory role in regulating hepcidin synthesis.

Effects of Hepcidin

Hepcidin, the central regulator of iron absorption, is a low-molecular–weight thionin-like, defensin-like peptide with many cysteine pairs encoded by the *HAMP* gene. Hepcidin has antimicrobial activity against bacteria and fungi, is present in plasma, and is excreted in urine. Hepcidin is synthesized in hepatocytes in response to anemia, hypoxia, and inflammatory stimuli mediated by interleukin 6,[64–68,69,70,71] and in the presence of adequate or increased amounts of iron.[72–75] It is also involved in the abnormalities of iron metabolism that occur in the anemia of chronic disease.[76–79] Hepcidin levels are inversely related to iron absorption.

Ferroportin, the sole receptor for hepcidin, occurs as a multimer on the surfaces of cells responsible for gathering and recycling iron: enterocytes (basolateral surfaces), macrophages, hepatocytes, and placental syncytiotrophoblasts. The binding of cell surface ferroportin by hepcidin results in ferroportin tyrosine phosphorylation at the plasma membrane, dephosphorylation, and degradation by ubiquitination.[19,69,80] Thus, hepcidin participates in regulation of plasma iron levels and tissue distribution of iron by post-translational regulation of ferroportin.

Hepcidin Effect in Iron Deficiency

In iron deficiency, hepcidin production is down-regulated so the amount of hepcidin available to bind ferroportin is reduced. More iron is exported from absorptive enterocytes by ferroportin than usual, resulting in increased absorption of iron through duodenal enterocytes into the plasma.[81]

Hepcidin Effect in Iron Repletion

In normally iron-replete humans, the production of hepcidin is up-regulated. The hepcidin bonds with ferroportin inducing ferroportin internalization and degradation.[19,69,80] Consequently, the amount of ferroportin is reduced and iron absorption from duodenal enterocytes into plasma decreases.

Hepcidin Effect in Hemochromatosis

Dysregulation of hepcidin production underlies the pathophysiology of most types of hemochromatosis (types 1, 2a, 2b, and 3). In iron-loaded individuals with *HFE* hemochromatosis, for example, hepcidin expression by the liver is inappropriately low[82,83] and thus iron absorption continues despite increased iron stores. Hepcidin levels are decreased in all types of hemochromatosis except in patients with "classical" ferroportin hemochromatosis (type 4). In those patients, iron overload is caused by a mutation in the ferroportin gene (*SLC40A1*) that results in diminished or absent functional quantities of ferroportin.[81] In such cases, hepcidin production and regulation are normal.

Molecular Basis of Increased Iron Absorption in Hemochromatosis

Several factors in the duodenum contribute to inappropriately high iron absorption in *HFE* hemochromatosis. In enterocytes, DMT1 (divalent metal transporter-1) transports iron across the apical microvillous membrane into the cell in the presence of hydrogen ions derived from gastric acid and ferroportin transports iron across the basolateral membrane into the plasma. Untreated C282Y homozygotes have inappropriate up-regulation of DMT1 and ferroportin mRNA expression in proportion to their serum ferritin level.[84] Absorption of heme iron is also increased in proportion to serum ferritin levels.[5,60] The interaction of transferrin, transferrin receptor, and HFE protein at the basolateral membranes of duodenal absorption cells may play a minor role in regulating iron absorption in persons with *HFE* hemochromatosis.[85] *SLC40A1* mutations that encode ferroportin that either is not presented normally to the cell surface or has defective iron export activity are associated with loss-of-function, normal or low transferrin saturation, and predominance of iron retention in macrophages. Such mutations decrease iron absorption from the intestine and inhibit iron export from macrophages.

The complicated interactions of HFE, DMT1, transferrin, transferrin receptors, hemojuvelin, hepcidin, and ferroportin in regulating iron absorption in normal individuals and in persons with hemochromatosis are a topic of intense and productive research.[75,80,86–90]

ORGAN AND CELLULAR INJURY DUE TO IRON OVERLOAD

After many years of increased iron absorption, hepatocyte and Kupffer cell iron storage sites become overloaded and iron accumulates progressively in the myocardium, pancreas, anterior pituitary, spleen, and other organs. Cardiac myocytes, beta-cells of the pancreatic islets, and gonadotroph cells of the anterior pituitary have especially great affinity for otherwise unbound iron. Some individuals with severe iron overload due to hemochromatosis have body iron burdens that are more than 10 times normal. Usually, such individuals do not develop symptoms or signs of illness until after they have had iron overload for three to five decades. Exceptions include the organ damage and death that can occur before the age of 30 years in persons with severe iron overload due to juvenile hemochromatosis.

Iron that is bound to transferrin or stored in modest amounts in ferritin is not toxic. In the presence of excessive iron stores, non–transferrin-bound or non-ferritin iron occurs and generates reactive oxygen species (oxyradicals), especially the hydroxyl radical.[91–97] It is likely that hydroxyl, alkoxyl, and peroxyl radicals are involved in lipid peroxidation which damages microsomes, mitochondria, and lysosomes. Hydroxyl radicals are also thought to be involved in iron-related damage of enzymes, proteins, nucleic acids, and polysaccharides. Lipid peroxidation then results in disruption of membrane-dependent functions of lysosomes, mitochondria, endoplasmic reticulum, cell membranes, and DNA.[91,94] Excess iron and iron-induced oxyradicals may also activate stellate cell transformation to fibroblasts in the liver and act as carcinogens in hepatocytes or extrahepatic parenchymal cells.

DIFFERENTIAL DIAGNOSIS OF IRON OVERLOAD

Many heritable or acquired disorders are associated with increased body iron stores. Some of these disorders appear in Table 25.1,[1,12,13,20–24,26,27,36,72–74,98–135,136,137–200] including gene location, mode of heritability, and gene mutation responsible for the disorder. Table 25.1 provides guidance for physicians who are evaluating and managing patients with iron overload.

HFE HEMOCHROMATOSIS GENE

HFE Location

The *HFE* gene is located approximately 4 megabases telomeric to the HLA region on the short arm of chromosome 6(6p). *HFE* is structurally similar to other HLA class I-like genes. *HFE* is composed of seven exons, of which the first six encode for the six domains of the *HFE* protein. The seven exons of *HFE* result in formation of a messenger RNA transcript of 4.2 kilobases. This in turn results in the synthesis of the HFE product, a protein of 343 amino acids. The most common mutation of *HFE* (C282Y) associated with iron overload is caused by a mutation of one nucleotide base 845G→A in exon 4 of the *HFE* gene.[36]

HFE Mutations

More than 60 mutations of the *HFE* gene have been reported.[15,36,201–205,206,207–222,223,224–239] The most common mutation that occurs in people who have hemochromatosis is a change in nucleotide 845 from the normal guanidine to adenine in exon 4 of the *HFE* gene (referred to as *845G→A*). This nucleotide change results in the substitution of tyrosine in place of the normal cysteine in amino acid position 282, referred to as *Cysteine282Tyrosine*, *Cys282Tyr*, or *C282Y*. This mutation causes the majority of iron accumulation in subjects who have hemochromatosis.[36]

TABLE 25.1

HERITABLE AND ACQUIRED DISORDERS ASSOCIATED WITH IRON OVERLOAD: DIFFERENTIAL DIAGNOSIS

Heritable Disorder	Chromosomal Assignment	Heritability	Cause of Iron Loading	References
HFE Hemochromatosis	6p21.3	Autosomal recessive	Mutations of *HFE*	36
Juvenile Hemochromatosis				
HJV Hemochromatosis	1q21	Autosomal recessive	Mutations of hemojuvelin	1,12,98–101
HAMP Hemochromatosis	19q13	Autosomal recessive	Hepcidin antimicrobial peptide gene mutations	13,72–74
TFR2 Hemochromatosis	7q22	Autosomal recessive	Inactivation of transferrin receptor 2	20–24,26,102
SLC40A1 Hemochromatosis	2q32	Autosomal dominant	Ferroportin gene mutations	27,101,103–107
H-Ferritin Hemochromatosis	11q 12-q13	Autosomal dominant	H-ferritin gene mutations	108
Porphyria cutanea tarda	1p34	Autosomal dominant or sporadic	Heterogeneous	109,111–126,128,129
African iron overload	Unknown	Autosomal dominant	Unknown	130–136,137
Neonatal iron overload	Unknown	Heterogeneous	*In utero* iron transfer	138–144
Atransferrinemia	3q21	Autosomal recessive	Transferrin gene mutations and red cell transfusions	145,146
Aceruloplasminemia	3q23-q24	Autosomal recessive	Ceruloplasmin gene mutations	147–154
Hereditary hyperferritinemia and cataract syndrome	19q13.1-q13.3.3	Autosomal dominant	L-Ferritin gene mutations	155–165
Friedreich ataxia	9p23-p11,9q13	Autosomal recessive	Frataxin gene mutations	166–173
Panthothenase kinase-associated neurodegeneration	20p13-p12.3	Autosomal recessive	Pantothenase kinase gene mutations	174,175
β-Thalassemia major	11p15.5	Autosomal recessive	β-Globin gene mutations, chronic hemolysis, red cell transfusions	—
Other chronic hemolytic anemias				
Hereditary X-linked sideroblastic anemia	Xp11.21	X-Linked	δ-Aminolevulinic acid synthase gene mutations	176–178
X-Linked sideroblastic anemia with ataxia	Xq13.1-q13.3	X-Linked	ABCB7 mutations[a]	179–182
MLASA syndrome[b]	12q24.33	Autosomal recessive	Pseudouridine synthase-1 mutations	183,184
GLRX5 sideroblastic anemia	14q32.13	Autosomal recessive	Glutaredoxin 5 mutations	185,186
DMT1 iron overload[c]	12q13	Autosomal recessive	*SLC11A2* mutations[d]	187,188
Pyruvate kinase deficiency	1q21	Autosomal recessive	Pyruvate kinase gene mutations	189–191
G6PD deficiency[e]	Xq28	X-Linked	G6PD gene mutations	192,193
Congenital dyserythropoietic anemias	Type I 15q15.1-q15.3	Autosomal recessive	Ineffective erythropoiesis	194,195
	Type II 20q11.2	Autosomal recessive	Ineffective erythropoiesis	196–198
	Type III 15q21	Autosomal dominant	Ineffective erythropoiesis	199,200
Acquired Disorder	**Cause of Iron Loading**			
Transfusions	Red cell iron infusion			
Medicinal iron	Excessive iron ingestion			
Iron injections	Parenteral injection			
Myelodysplasia with ring sideroblasts	Excessive iron absorption; transfusion			
Portacaval shunt	Excessive iron absorption			
Hemodialysis	Iron infusion			
Nonalcoholic fatty liver disease	Excessive iron absorption			

[a]ABCB7, ATP-binding cassette, subfamily B, member 7.
[b]MLASA, myopathy with lactic acidosis and sideroblastic anemia.
[c]*DMT1*, divalent metal transporter-1.
[d]SLC11A2, solute carrier family 11, member 2.
[e]G6PD, glucose-6-phosphate dehydrogenase.

The second most common *HFE* gene mutation in hemochromatosis patients is a change in nucleotide 187 from the normal cytidine to guanidine 187C→G in exon 2. This results in substitution of aspartate for the normal histidine at amino acid position 63. Both the C282Y and H63D mutations were identified in the initial report of the isolation and cloning of *HFE*.[36]

Of the reported mutations of the *HFE* gene, 31 are missense mutations that result in substitution of the normal amino acid by another. There are 27 reported nonsense mutations of *HFE*, 12 of which are splice errors that are associated with intron sequence variants. Eight mutations involve a nucleotide change that does not result in an amino acid substitution (synonymous mutations). Some important *HFE* gene mutations are given in Table 25.2. Other mutations occur in noncoding regions of *HFE*.[240] It is expected that other rare mutations of the *HFE* gene will be identified in adults with hemochromatosis phenotypes.

HFE Mutations in Hemochromatosis Patients and in Different Populations

In the first report of the *HFE* gene and its mutations, 83% of subjects with hemochromatosis were C282Y homozygotes.[36] The prevalence of homozygosity for C282Y varies from 33% to 100% among groups of hemochromatosis patients. In the United States, 59% to 89% of hemochromatosis patients are C282Y homozygotes. The percentage of hemochromatosis patients from 14 countries who have the C282Y and H63D genotypes is presented in Table 25.3.[36,98,228,241–276]

The prevalence of *HFE* mutations is high in some populations, such as those of Central, Western, and Northern Europe, and in countries that were populated predominantly by people who originated in these areas of Europe, including the United States, Canada, and Australia.[241,277] It is predicted that the prevalence of *HFE* mutations is very low in parts of the world with little or no ancestry from Central and Western Europe, including sub-Saharan Africa (Native Africans), the Middle East, the Orient, and Native Americans in North, Central, and South America. The frequency of homozygosity for the *HFE* C282Y mutation in the United States varies from 0% to 1.00% in whites, 0% to 0.22% in Mexican Americans, and 0% to 0.06% in blacks (Table 25.4). The prevalence of C282Y, H63D, and wild-type *HFE* genotypes from nine studies in the United States is presented in Table 25.4.[211,242,244,278–283] Extensive data about genotype frequencies in many countries, and from different regions within countries, have been published.[241,277,284]

Hemochromatosis and Iron Overload Screening Study

The largest study of the prevalence of *HFE* mutations and of serum iron tests was recently completed and published. It is called the HEIRS Study (Hemochromatosis and Iron Overload Screening Study).[136,285,286,287,288,289] Tests for the C282Y and H63D mutations of *HFE*, serum iron concentration, transferrin saturation, and serum ferritin concentration were measured in about 102,000 outpatients in the United States and Canada. Participants were recalled for additional evaluation if they were C282Y homozygotes or if they had elevated results of transferrin saturation (percent

Prevalence rates were derived with Hardy–Weinberg proportions within the five ethnic groups who were not C282Y homozygotes.
[a]Data from participants with complete information on *HFE* C282Y and H63D mutations, transferrin saturation, and serum ferritin levels, except 1,457 who heard about the study from a participating family member, were included.
Modified from Adams PC, Reboussin DM, Barton JC, et al. Hemochromatosis and iron-overload screening in a racially diverse population. N Engl J Med 2005;352:1769–1778.[287]
Used with permission.

saturation >50% in men, >45% in women) or elevated serum ferritin (>300 μg/L in men, >200 μg/L in women).

The Study centers were Washington DC; Birmingham, Alabama; Irvine, California; Portland, Oregon; Honolulu, Hawaii; and London, Ontario, Canada. Of 99,711 study subjects, 44,082 were Caucasians, 27,124 were blacks, 12,772 were Asians, 12,459 were Hispanics, 698 were Pacific Islanders, and 648 were Native Americans.

The prevalence of C282Y homozygosity was highest in Caucasians (0.44%, 4.4 per 1,000) and lowest in Asians (0.39 per 1,000,000), followed by Pacific Islanders (0.012%), blacks (0.014%), Hispanics (0.027%), and Native Americans (0.11%). The prevalence of the C282Y/C282Y, C282Y/H63D, and H63D/H63D genotypes in the study participants is presented in Table 25.5.[287] Among Caucasians, the H63D/H63D and the C282Y/H63D genotypes were about 4 times and 3.5 times as common, respectively, as the C282Y/C282Y genotype.[287]

Prevalence of HFE Mutations in Other Large Population Studies

In a study of 65,238 Norwegians, 0.68% were C282Y homozygotes.[290] In a study of 41,038 participants in a Southern California health appraisal clinic, the prevalence of C282Y homozygosity among 30,418 whites was 0.46% (139 homozygotes).[278]

Association of Iron Loading and *HFE* Mutations

Some mutations are associated with severe iron loading, such as C282Y, R330M, IVS3 (+1) G→T, E168X, C282S, R74X, and G93fs (Table 25.2). Some mutations are believed to have a modest or moderate effect on iron accumulation, for example, H63D, S65C, G93R, I105T, and E168Q. Other *HFE* mutations have been identified in individuals without iron overload or in whom the effect of the mutation on iron accumulation could not be determined, such as V53M, V59M, Q127H, E277K, and in several intron sequence variants. Some mutations code for the normal amino acid (synonymous mutations) and do not affect iron absorption. The *HFE* mutations with severe, mild, or unknown effects on iron accumulation are shown in Table 25.2.

Interaction of Mutations of *Hfe* and of Other Genes

Interaction of Mutations of HFE and Hepcidin

Mutations of *HFE* and other genes involved in maintaining iron homeostasis can have a synergistic effect on iron accumulation in hemochromatosis. A striking example of this is the heavy iron loading that occurred in an individual who had C282Y homozygosity and a mutation of the hepcidin gene (a *HAMP* mutation resulting in deletion of four nucleotides and methionine50deletion, an intron sequence variant in exon 2 and intron 1, referred to as M50del IVS2+1(–G), a frameshift deletion). This represents a "digenic" configuration of a mutation in each of two autosomal recessive genes, neither of which alone would likely cause heavy iron accumulation. This digenic genotype caused massive iron overload by age 27 years.[291] The affected man underwent removal of 27 g of iron for 4 years before his serum ferritin concentration became normal (at diagnosis 1,645 μg/L, after treatment 40 μg/L). Mutations of other genes, such as the transferrin receptor-2 or ferroportin, can also result in heavy iron accumulation in individuals who also have *HFE* mutations.

Some investigators reported that a variant in the D-loop of mitochondrial DNA (mtDNA) where a T→C substitution occurred at nucleotide 16189 (mtDNA 16189T→C) was associated with more severe iron phenotypes in patients with hemochromatosis.[292] Other investigators did not confirm this report.[293] It seems likely that additional mutations in diverse genes will be found to explain increased or decreased rates of iron absorption in C282Y homozygotes.

FREQUENCY OF HEMOCHROMATOSIS IN MEN AND WOMEN

Hemochromatosis is transmitted as an autosomal recessive condition and therefore there should be equal numbers of male and female homozygotes. Overt iron overload, organ injury, and illness occur more frequently in men than in women with this disorder. Men with hemochromatosis have approximately two and a half times as much mobilizable body storage iron as women. Most women are protected from severe iron overload by the menstrual loss of 15 to 25 mg of iron each month and by the transfer of approximately 750 mg of iron to the fetus during pregnancy. Regardless, menstrual blood losses and pregnancy do not explain all of the differences in body iron stores between male and female homozygotes. Testosterone suppresses hepcidin production[294] and this could account in part for the tendency of men with hemochromatosis to develop more severe iron overload than women.

CLINICAL FEATURES OF HEMOCHROMATOSIS

Symptoms

The presence or absence of symptoms in persons with hemochromatosis is related to the stage at which the diagnosis is established. Individuals diagnosed to have hemochromatosis during a routine office visit are expected to have no organ injury and many of them are not heavily iron loaded, if at all. This is common among women, young men, children, and the healthy siblings who undergo family screening after a proband is diagnosed. Subjects in whom the diagnosis is established after they seek medical attention due to symptoms are typically ill (Table 25.6).[245,295–302] These persons usually have iron overload and evidence of organ injury. The frequency of symptoms, physical signs, and laboratory abnormalities in subjects with hemochromatosis (sick probands)

compared with probands who were identified during screening and compared with their homozygous relatives who were identified during family evaluation (clinically unselected homozygotes) are given in Table 25.7.[303] Approximately 90% to 98% of people who are found to have hemochromatosis during screening are asymptomatic.

The most common symptom in nonscreening hemochromatosis patients at diagnosis is arthralgias, (approximately 40% of homozygotes).[245] The joints most commonly involved with typical hemochromatosis arthropathy are metacarpal–phalangeal (MCP) joints, especially the second and third.[304] Pain or other manifestations can also occur in knees, hips, shoulders, and other diarthrodial joints. Weakness, fatigue, and lethargy are common but nonspecific symptoms. Weight loss, abdominal pain, loss of libido in men, and palpitations also occur in some iron-loaded homozygotes. The prevalences of arthralgias, abdominal pain, loss of libido or impotence, and palpitations in different study populations are displayed in Tables 25.6 and 25.7.

Physical Examination Abnormalities

Gray or bronze pigmentation is the most common physical examination abnormality in hemochromatosis homozygotes diagnosed in nonscreening settings (35% to 84%). Other common findings include arthropathy (13% to 68%), hepatomegaly (54% to 93%), splenomegaly (10% to 55%), irregular heartbeat, congestive heart failure, telangiectases, and loss of midline body hair or testicular atrophy. The frequency of physical abnormalities in hemochromatosis from nine studies is shown in Table 25.6. The prevalence of self-reported illness according to *HFE* genotype in two very large US and US–Canadian population screening studies is given in Tables 25.8[301] and 25.9.[278]

Laboratory Abnormalities

The most common laboratory abnormalities in subjects with hemochromatosis are elevations of serum iron concentration, percent transferrin saturation, and serum ferritin concentration.[136,305] Transferrin saturation may be elevated in children or teenage homozygotes before serum ferritin elevation occurs, long before symptoms or physical examination abnormalities develop. This is attributed to the increased release of iron by macrophages via ferroportin in the presence of low hepcidin levels. The typical values of transferrin saturation according to the method of ascertainment in 291 Utah homozygous probands are presented in Table 25.10.[245] The results of transferrin saturation and serum ferritin concentration in normal individuals, C282Y heterozygotes, C282Y/H63D compound heterozygotes, and H63D homozygotes according to *HFE* genotype from a large US population screening study are shown in Table 25.11.[278]

In untreated C282Y homozygotes, the average hemoglobin concentration is greater than that of control subjects without common *HFE* mutations.[306,307] Likewise, the value of mean corpuscular volume of untreated C282Y homozygotes is elevated, sometimes above the upper reference limit, even in patients without liver disease.[306] The mean red blood cell count and mean coefficient of variation of mean corpuscular volume (RDW) are lower in C282Y homozygotes.[308] These erythrocyte-associated characteristics, usually more pronounced in men than women, are due to the ample amounts of iron constantly available to marrow erythroblasts via transferrin, the saturation of which is increased in most C282Y homozygotes. Genome-wide linkage analyses confirm that a locus (loci) on chromosome 6p21 is significantly associated with hemoglobin concentration.[309] This locus is presumed to be *HFE*.

Radiographs of hands are often abnormal in homozygotes who have arthralgias. Approximately 50% of homozygotes have radiographic changes. The plain films reveal narrowing of the MCP joint spaces, subperiosteal bone resorption, and periarticular demineralization. Plain films of knees may reveal chondrocalcinosis, linear calcium deposition in the cartilage that is visible across the joint space.

The next most common laboratory abnormality in untreated hemochromatosis patients diagnosed in nonscreening venues is elevation of serum levels of alanine aminotransferase and aspartate aminotransferase (8% to 92%). The prevalence of this abnormality varies markedly according to the method of ascertainment (Tables 25.6 and 25.7). Usually, these enzyme levels are elevated two to five times the upper limit of normal in nonscreening subjects. The significance of elevated serum levels of hepatic transaminases is often different in C282Y homozygotes detected in screening programs than in nonscreening patients. In HEIRS Study participants with hyperferritinemia, mean serum levels of transaminase activities were significantly lower in C282Y homozygotes than nonhomozygotes. The probability of being a C282Y homozygote increased as the transaminase activities decreased. Thus, study participants with hyperferritinemia detected in screening are more likely to be C282Y homozygotes if they have normal liver transaminase activities.[310] If hepatic failure is present, serum transaminase

and bilirubin levels may be very elevated. Other common laboratory abnormalities include elevation of serum glucose concentration (0% to 82%); arrhythmia on electrocardiography; cardiomegaly on chest radiography; decreased ejection fraction on echocardiography; elevated or very low thyroid-stimulating hormone in hypothyroidism or hyperthyroidism, respectively; and blood test evidence of hypogonadism, usually the hypogonadotrophic type with decreased serum concentrations of testosterone, dihydrotestosterone, luteinizing hormone, and follicle-stimulating hormone.[311] Tables 25.6 and 25.7 show the frequency of lab abnormalities in individuals who have hemochromatosis.

Liver Biopsy Findings

Liver morphology by microscopy is usually normal in homozygotes whose serum ferritin is not elevated. When serum ferritin concentration is elevated, the hepatic parenchymal cell stainable iron is usually increased. The same comments apply to the measured hepatic iron concentration. Many 40- to 50-year-old male homozygotes have hepatic fibrosis when hemochromatosis is diagnosed (2% to 32%) (Table 25.12).[245] A range of 0% to 92% of male homozygotes have cirrhosis at the time of diagnosis, usually the sick individuals (Tables 25.6 and 25.7). Most women with hemochromatosis do not have fibrosis or cirrhosis at diagnosis. Cirrhosis is not expected to occur until the hepatic iron concentration is elevated to approximately 22,000 μg (22 mg) of iron per gram of liver dry weight (normal, approximately 1,000 μg iron per gram dry weight).[312] Hemochromatosis homozygotes who are only identified because they participated in screening studies rarely have heavy liver iron overload or hepatic fibrosis (Tables 25.7 and 25.12).[245,285,303]

In hemochromatosis patients, an elevated serum concentration of collagen type IV correlates strongly ($p < 0.0001$) with hepatic fibrosis or cirrhosis.[313] Serum collagen type IV levels in a group of 42 hemochromatosis patients were compared to those of 19 control subjects. A serum concentration of collagen type IV >115 ng/ml had a sensitivity of 100% and a specificity of 69% for far-advanced hepatic fibrosis (grade 3) and cirrhosis (grade 4).[313] Among homozygotes who are diagnosed very late, 10% to 29% of those with cirrhosis develop hepatocellular carcinoma.[314–317] Hepatocellular carcinoma in hemochromatosis may be multifocal rather than focal and may not cause marked elevation of α-fetoprotein that is common in individuals who have a large nodular hepatoma. Multifocal hepatocellular carcinoma may not be visible by ultrasonography until the diameter of the nodules reaches 1 cm. The frequency of hepatic fibrosis, cirrhosis, and hepatocellular carcinoma in hemochromatosis patients is presented in Tables 25.6, 25.7, and 25.12.

TABLE 25.10

TRANSFERRIN SATURATION AND SERUM FERRITIN CONCENTRATION VALUES OF HEMOCHROMATOSIS HOMOZYGOTES ACCORDING TO THE METHOD OF ASCERTAINMENT: UTAH STUDIES OF 505 HOMOZYGOTES

HFE MUTATIONS AND OTHER CONDITIONS

Arthropathy

Arthropathy is common in patients diagnosed to have hemochromatosis in nonscreening settings and is a major cause of morbidity in some individuals.[18,21–24] The proportion of nonscreening patients who have severe iron overload is relatively high and the prevalence of hemochromatosis arthropathy is significantly greater in patients whose serum ferritin levels are greater than 1,000 μg/L at diagnosis than in those with lower serum ferritin levels.[20,26] Hemochromatosis homozygotes with arthropathy usually experience symmetrical arthralgias in the second and third MCP and proximal interphalangeal (PIP) joints.[318] MCP joint swelling, decreased range of motion, and decreased ability to make a fist are typical physical findings. Radiographic findings include hypertrophy and related abnormalities of MCP and PIP joints, subchondral cysts with sclerotic margins at the metacarpal heads, and joint space narrowing, usually with asymmetric cartilage loss. Other degenerative changes that occur in some cases include chondrocalcinosis, involvement of radiocarpal joints, osteophytes at severely affected MCP joints, and generalized osteoporosis of affected hands.[2,319,320] Approximately two-thirds of patients with hand arthropathy have or will develop hip or knee arthropathy. Knee radiographs often reveal chondrocalcinosis.[320] Many patients with hip or knee arthropathy eventually require joint replacement. Other diarthrodial joints are affected less frequently (e.g., shoulders, elbows, ankles, and toes).

In persons diagnosed to have hemochromatosis in screening programs, the proportion who have severe iron overload is relatively low and thus typical hemochromatosis arthropathy is not common. Among the 98,529 participants in the HEIRS screening study (36,474 men and 62,055 women), there was no significant difference in the incidence of self-reported arthritis between groups of C282Y homozygotes and participants without *HFE* mutations.[287] In another large questionnaire study, there was no significant difference in the prevalence of arthropathy between 45 C282Y homozygotes who were identified by screening and 9,299 control subjects.[278] The results of another screening study were similar.[321]

Modified from Bulaj ZJ, Ajioka RS, Phillips JD, et al. Disease-related conditions in relatives of patients with hemochromatosis. N Engl J Med 2000;343:1531.[245]

The prevalence of common *HFE* mutations did not differ significantly in 1,000 patients who had inflammatory arthritis and in 1,000 normal control subjects.[322] In another study of patients without a diagnosis of hemochromatosis, the prevalence of *HFE* C282Y was greater in those with radiographic evidence of hand osteoarthritis than in control subjects. Serum ferritin levels were similar in patients with and without hand osteoarthritis.[41] Some *HFE* C282Y homozygotes develop rheumatoid-factor–positive rheumatoid arthritis,[323] psoriatic arthritis, gouty arthritis, or other types of arthropathy not attributable to iron overload. Osteoporosis defined by decreased bone mineral density was present in 34% of 38 C282Y homozygotes and C282Y/H63D compound heterozygotes who had not undergone iron depletion therapy. Osteopenia was present in 79%. Vitamin D and parathyroid hormone values were normal. Hypogonadism was present in 13%.[324]

Diabetes Mellitus

Diabetes was reported in early accounts of hemochromatosis[32–34] and for years was considered to be essential for establishing a diagnosis of hemochromatosis. Diabetes remains common in patients with hemochromatosis who have severe iron overload and cirrhosis (Tables 25.6 and 25.7).[299,300,315,325] Siderosis of pancreatic islets, pancreatic fibrosis, and cirrhosis contribute significantly to diabetes pathogenesis in such cases but other factors also influence diabetes risk and expression. Some hemochromatosis homozygotes who have diabetes have elevated body mass index and decreased insulin secretory capacity.[326,327] Similar abnormalities occur in mouse models of hemochromatosis.[328] Cirrhosis contributes to insulin resistance and hyperglucagonemia. A family history of diabetes in first-degree relatives is a significant predictor of diabetes risk among persons with hemochromatosis,[329,330] consistent with observations that diabetes and hemochromatosis segregate independently as genetic traits.[39] Diabetes is associated with decreased survival after diagnosis in nonscreening patients with hemochromatosis and C282Y homozygosity.[331]

As hemochromatosis case definition has changed from that of a rare, severe iron overload phenotype to a relatively common disorder defined primarily by *HFE* C282Y homozygosity, the prevalence of diabetes in hemochromatosis case series has decreased to a level that approaches that of the general age- and sex-matched population.[332] Among the 98,529 participants in the HEIRS Study (36,474 men and 62,055 women), there was no significant difference in the prevalence of self-reported diabetes between groups of C282Y homozygotes and the participants with normal *HFE* genotypes.[287] In a study of 22,347 control subjects without *HFE* mutations, 8.4% reported having diabetes, whereas 5.6% of 124 C282Y homozygotes reported having diabetes. Similarly, 7.0% of C282Y/H63D compound heterozygotes had diabetes.[278] The prevalence of *HFE* C282Y in groups of patients with diabetes is similar to that in corresponding control subjects.[278,333–338]

Other Endocrinopathy

Hypogonadism, thyroid disease, and adrenal insufficiency occur in some hemochromatosis patients, usually those who have been heavily iron loaded for decades. Of nondiabetes endocrinopathy in hemochromatosis, the second most common type is hypogonadism (Tables 25.6 and 25.7). This is usually of the hypogonadotrophic type.[311,339] Iron is deposited selectively in the gonadotroph cells of the anterior pituitary.[295,311,339–347] In a group of 141 iron-loaded hemochromatosis patients, 9 patients (6%) had abnormally low testosterone levels. Of these nine patients, eight (89%) also had low values of luteinizing hormone and follicle-stimulating hormone. These findings are characteristic of hypogonadotrophic hypogonadism.[311] Hypothalamic dysfunction occurs in some patients.[119,311,339,344,348–353] Other patients with hemochromatosis have primary gonadal failure typically unrelated to iron overload. In a different study of 181 unrelated men who were *HFE* C282Y homozygotes, none had hypogonadism.[354] It seems reasonable to evaluate for hemochromatosis in individuals who have hypopituitarism of unknown cause.[355]

In the HEIRS Study, hypothyroidism was detected in 1.7% of 176 *HFE* C282Y homozygotes and 1.3% of 312 control subjects who did not have C282Y. None of the C282Y homozygotes and 1% of the controls had hyperthyroidism. These minor differences in prevalence were not statistically significant.[356]

Polycystic ovary syndrome (PCOS) affects approximately 5% of white women and is often associated with decreased serum hepcidin concentration. Homozygosity for the *HFE* C282Y mutation also is associated with decreased serum hepcidin. In a study of 107 unrelated women who were C282Y homozygotes, a 13-year-old and a 16-year-old had PCOS. Each had elevated serum ferritin concentration and grade 3 to 4 hepatic parenchymal stainable iron.[354] It seems likely that low serum hepcidin concentration due to both PCOS with loss of menses at a very young age and *HFE* hemochromatosis contributed to early-onset iron overload.

Hepatocellular Carcinoma

The relative risk of hepatocellular carcinoma in patients with hemochromatosis who have cirrhosis is 219-fold higher than in patients with hemochromatosis who do not have cirrhosis.[315,357] Among patients who have both end-stage hemochromatosis and cirrhosis, 10% to 29% develop hepatoma.[314–317,358,359] About 3% to 4% of patients with hemochromatosis complicated by cirrhosis develop hepatocellular carcinoma per year.[357,360] There are also reports of hepatoma in hemochromatosis patients who did not have cirrhosis.[361–366] The histology of primary liver cancer in hemochromatosis is heterogeneous. Although the majority of primary liver cancers in hemochromatosis are of the hepatocellular type, biliary cancers also occur, including cholangiocarcinoma and combined hepatocellular cholangiocarcinoma.[317,366]

In some reports, the proportion of patients with hepatocellular carcinoma who also have C282Y homozygosity [367,368] or C282Y heterozygosity is significantly increased.[368–370] In another report, the prevalence of *HFE* mutations in patients with hepatocellular carcinoma was similar to that in control subjects.[371] Positive associations of *HFE* mutations, chronic viral hepatitis, and hepatocellular carcinoma have been reported.[367,370] Recent guidelines have been published about the evaluation and management of patients who have hepatocellular carcinoma.[372,373,374]

Colorectal Polyps and Colorectal Cancer

In the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, a study of 679 persons with advanced distal adenoma and 697 control persons revealed no significant relationship of C282Y and H63D or dietary iron intake on the risk of advanced distal adenomatous colorectal polyps.[375] In a study of 475 case patients and 833 control subjects, C282Y and H63D mutations were associated with an increased risk of colon cancer.[376] In a cohort study of 28,509 participants, C282Y homozygotes had twofold increased risk for colorectal cancer and female C282Y homozygotes were at twofold increased risk for breast cancer.[377]

Other Types of Cancer

Iron can be carcinogenic. Possible mechanisms of carcinogenesis include redox cycling of iron, that produces reactive oxygen species and free radicals, which in turn cause lipid peroxidation and damage to proteins and DNA.[378] Iron may facilitate tumor cell growth and modify immune system responses.[379] The results of some studies suggested that *HFE* mutations were associated with

colorectal or breast or other carcinomas,[377,380–382] whereas results of some studies did not identify *HFE* mutations as a risk factor for cancer.[383,384,385,386] In the cohort study of 28,509 participants cited above, male C282Y homozygotes did not have increased risk for prostate cancer.[377] C282Y/H63D compound heterozygotes and C282Y heterozygotes did not have increased risk for colorectal, breast, prostate, or other cancers.[377] In a meta-analysis of the risk of 66,263 people with *HFE* mutations to develop 31 different disorders, compared with 226,515 control subjects without *HFE* mutations, there was no identifiable risk for the development of cancers other than hepatocellular carcinoma.[384]

Porphyria Cutanea Tarda

The most common type of porphyria is sporadic porphyria cutanea tarda. An elevated amount of storage iron is characteristic of this disorder. The interaction of iron and porphyria cutanea tarda has been reviewed.[112,387–389] In addition, the presence of one or two *HFE* C282Y or H63D mutations is common in subjects with sporadic porphyria cutanea tarda and increased storage iron. Some patients with porphyria cutanea tarda (either sporadic or familial) and heavy iron loading are homozygous for *HFE* mutations.[109,111,390–393]

Porphyria cutanea tarda occurs in individuals who have decreased activity of uroporphyrinogen decarboxylase which results in the accumulation of uroporphyrinogen I. In the presence of excess iron, accumulated uroporphyrinogen undergoes iron-mediated oxidation, resulting in production of uroporphomethene. Uroporphomethene then further inhibits the already decreased activity of uroporphyrinogen decarboxylase.[394,395] An association of the uroporphyrinogen decarboxylase gene on chromosome 1q and hemochromatosis alleles on chromosome 6p was first reported in 1989.[109] This was substantiated after *HFE* was cloned and sequenced and *HFE* mutations were identified.[111,112,396] In a study of 108 subjects in Utah who had porphyria cutanea tarda, 19% were C282Y homozygotes and 7% were C282Y/H63D compound heterozygotes.[111] The *HFE* mutation(s) causes increased iron absorption which further depresses the already decreased activity of the enzyme uroporphyrinogen decarboxylase. This results in the accumulation of uroporphyrin I in organs. Deposition of porphyrin in skin causes photosensitivity, blistering, and scarring.

Risk factors for the expression of porphyria cutanea tarda include common *HFE* mutations,[396–403] hepatitis C, alcoholism, oral estrogen therapy (but possibly not transdermal estrogen),[110,387,398] and tamoxifen.[397] Hepatitis C infection, a potent risk factor, occurs in 28% to 74% of individuals with porphyria cutanea tarda. A 2002 study from Galveston was performed to assess the factors involved in the expression of porphyria cutanea tarda.[399] In 39 consecutive patients with porphyria cutanea tarda, 9% had *HFE* genotype C282Y/C282Y, 9% had C282Y/wt, 12% had C282Y/H63D, 9% had H63D/H63D, and 26% had H63D/wt. None had the S65C mutation. Among these patients, 79% drank alcohol, 73% of 11 women took estrogens, 86% were smokers, and 74% were positive for the hepatitis C antibody. The authors concluded that *HFE* mutations were common and that the expression of porphyria cutanea tarda was multifactorial. Three or more risk factors for expression of porphyria cutanea tarda were detected in 92% of the 39 patients.[399]

The prevalence of the C282Y, H63D, and S65C mutations of *HFE* and antibody to the hepatitis C virus was compared in 65 patients with sporadic porphyria cutanea tarda and in 108 control subjects.[400] Of the porphyria patients, 17% had the C282Y mutation (4% of controls). There was no significant difference in the prevalence of the H63D and S65C mutations or compound C282Y/H63D heterozygosity between groups. Hepatitis C antibodies were detected in 28% of the patients with porphyria cutanea tarda. In another study of porphyria cutanea tarda patients in France, hepatitis C was identified as the major risk factor for porphyria.[401]

In a study of 190 German patients with sporadic porphyria cutanea tarda and 115 age-matched healthy blood donors, 39% of patients with porphyria had *HFE* C282Y (3% of control subjects) and 12% were C282Y homozygotes (0% of controls).[402] The H63D mutation was present in 45% of patients with porphyria (10% of controls) and 9% of patients with porphyria were C282Y/H63D compound heterozygotes. In studies among the Basque population in Spain, patients with porphyria cutanea tarda did not have increased frequency of *HFE* C282Y, H63D, or S65C mutations. Hepatitis C was present in 35% of the porphyria patients.[403]

Tamoxifen therapy in patients with breast cancer has been associated with the occurrence of porphyria cutanea tarda.[397,404,405] A woman with porphyria cutanea tarda that was caused by oral contraceptives only experienced full remission of porphyria while undergoing anastrazole therapy for metastatic adenocarcinoma of the breast.[404]

Steatohepatitis

Many reports of the prevalence of *HFE* gene mutations and/or hyperferritinemia in subjects with nonalcoholic steatohepatitis were reviewed recently.[406,407,408,409–421] In 36 men in Massachusetts who had nonalcoholic steatohepatitis, 2.8% were C282Y homozygotes, 17.0% were C282Y heterozygotes, 5.6% were H63D homozygotes, and 44.0% were H63D heterozygotes.[419] In 348 control subjects, none was a C282Y homozygote, 11.0% were C282Y heterozygotes, 2.9% were H63D homozygotes, and 26.0% were heterozygous for the H63D mutation. Individuals with nonalcoholic steatohepatitis who had a *HFE* mutation had higher levels of transferrin saturation and serum ferritin, and those with C282Y had significantly higher levels of alanine aminotransferase and a greater level of hepatic fibrosis than those without C282Y.[419] Insulin resistance syndrome is common in people who have nonalcoholic steatohepatitis, with or without mutations of *HFE*.[415,417,420–422]

Hereditary Spherocytosis

Individuals who have hereditary spherocytosis may develop severe iron overload and hepatic cirrhosis if they are *HFE* C282Y homozygotes or heterozygotes.[393,423–433] Iron overload can also occur in patients with hereditary spherocytosis who do not have common *HFE* mutations.[434,435] In a Utah family, for example, two brothers with C282Y homozygosity had iron overload.[424] Iron overload in the propositus with both hemochromatosis and hereditary spherocytosis was much more severe than that of his brother who had hemochromatosis without hereditary spherocytosis. The son of the propositus was a C282Y heterozygote who also had hereditary spherocytosis. His serum ferritin concentration and liver iron stores were modestly elevated.

β-Thalassemia Minor

β-Thalassemia minor and hemochromatosis sometimes occur in the same person. In one family, an index patient with β-thalassemia minor and hemochromatosis had a brother with β-thalassemia minor who was a C282Y homozygote. The proband's wife was also a C282Y homozygote. One of their children had β-thalassemia minor and hemochromatosis, whereas the other had hemochromatosis alone. The proband's brother married a woman who was a C282Y/wt heterozygote. Both of their children were C282Y homozygotes.[436] Some persons with β-thalassemia minor who have common *HFE* mutations develop iron load.[437–442] In a study of 22 iron-loaded Italian patients with β-thalassemia minor and 62 relatives, β-thalassemia trait appears to worsen the iron-related complications of C282Y homozygosity. It is believed that the mild ineffective erythropoiesis of

β-thalassemia trait exaggerates the amount of iron absorbed by the duodenum. C282Y heterozygotes and H63D heterozygotes with β-thalassemia trait did not develop iron overload.[437] In some other populations, heterozygosity for common *HFE* mutations appeared to be unassociated with development of iron overload in persons who also had thalassemia minor.[443–446]

On the island of Sardinia, an area not reached by Celtic migrations, *HFE* C282Y is very rare. The H63D mutation prevalence is similar to that of other populations, [277] and the prevalence of β-thalassemia minor is 13%.[438] Among 152 Sardinian men who had β-thalassemia minor, approximately 2.6% were H63D homozygotes, 29.5% were H63D/wt heterozygotes, and 68% were wt/wt (normal *HFE* genotype). Concurrent control subjects were not studied.[438]

In a study from Turin, 71 subjects with transfusion-dependent β-thalassemia major and 200 control subjects were tested for C282Y and H63D.[439] None of the patients (or controls) was a C282Y homozygote. One patient (1.4%) was a C282Y/H63D compound heterozygote (similar to 0% among controls); 21.0% of patients (20.0% of controls) were H63D heterozygotes; and one patient (1.4%) was a H63D homozygote (1.0% in controls). The latter patient had greater iron overload than expected. The authors concluded that H63D homozygosity caused the heavy hepatic iron accumulation and advanced hepatic fibrosis. Individuals with either *HFE* H63D or C282Y were more heavily iron loaded than could be explained by transfusion-dependent homozygous β-thalassemia alone.

Refractory Anemia with Ringed Sideroblasts

Iron accumulation varies in this myelodysplastic disorder.[158] In 40 patients from Switzerland, Greece, and France who had refractory anemia with ringed sideroblasts and nontransfusion iron overload, 1.25% had C282Y. This prevalence was similar to that in 200 normal control subjects (2.50%). The prevalence of the H63D mutation was also similar in patients and controls (19% and 13%, respectively).[447] Ineffective erythropoiesis alone may account for the increased intestinal absorption of iron in most nontransfused patients with refractory anemia with ringed sideroblasts.

X-Linked Sideroblastic Anemia

Some men with X-linked sideroblastic anemia (mutations of the aminolevulinate synthase gene, (*ALAS2*) with ringed sideroblasts and heavy iron overload also have *HFE* mutations. Coinheritance of X-linked sideroblastic anemia and *HFE* gene mutations was first described in a 59 year-old French man who had hepatic iron overload and C282Y/H63D compound heterozygosity. His iron overload was much more severe than that of his 61 year-old brother who had X-linked sideroblastic anemia but no *HFE* mutation.[448]

Among 18 unrelated patients with X-linked sideroblastic anemia, 17.0% had *HFE* C282Y (5.5% in white controls) and 23.0% had H63D (15.0% in controls).[449] Prevalence of the C282Y mutation was significantly greater in the patients with sideroblastic anemia than in controls, but prevalence of H63D was similar in both groups. After iron depletion, the responsiveness of anemia to pyridoxine supplementation increased in some patients. Coinheritance of one or more *HFE* mutations and a mild mutation of *ALAS2* can result in heavy iron overload.[450] The iron status of patients with mutations of *ALAS2*, with or without *HFE* mutations, has been reviewed.[451–453,454]

Infections in Hemochromatosis Patients

Individuals who have hemochromatosis, especially those with cirrhosis, are susceptible to infection by organisms that rarely cause illness in people with normal body iron stores, including *Vibrio vulnificus* and *Yersinia enterocolitica*.[455–467,468] *Listeria*,[469,470] *Escherichia coli*,[471] and zygomycosis[472–474] may also cause severe and sometimes unusual infections in hemochromatosis patients.

Vibrio vulnificus

V. vulnificus is a motile free-living, Gram-negative bacillus that grows as normal flora in warm coastal saline waters worldwide. It usually does not cause infection in humans except in persons who have iron overload, cirrhosis, compromised immunity, or renal insufficiency. When ingested with raw shellfish (especially oysters), it can cause gastroenteritis, septic arthritis, or fatal septicemia.[466,467,468,475,476] Serious wound infections have also occurred in patients with hemochromatosis.[468] Invasive organisms are encapsulated. The organism thrives in blood that has elevated iron content[460] but can also derive iron for its own metabolism from erythrocytes or hemoglobin. Most infections in patients with hemochromatosis have been reported from states adjacent to the Gulf of Mexico and from Northern Australia. In both areas, *HFE* hemochromatosis is common in whites and *V. vulnificus* is abundant in coastal waters.

Yersinia enterocolitica

Y. enterocolitica belongs to the family *Enterobacteriaceae*. It can cause transfusion-associated sepsis, gastroenteritis, septic arthritis, hepatic abscesses, osteomyelitis, or bloody diarrhea. It is usually ingested in contaminated water, pork, milk, bean sprouts, or chocolate.[477,478] Unlike *V. vulnificus*, *Yersinia* is often present in colder climates or occurs as a contaminant in any climate. In patients with hemochromatosis, *Yersinia* can cause severe infections,[404] including bacteremia[477] and multiple hepatic abscesses.[470,478–483]

IgG Deficiency

Some patients with hemochromatosis and *HFE* C282Y homozygosity have frequent, severe, or unusual infections and common variable immunodeficiency or immunoglobulin (Ig) G subclass deficiency.[484] Approximately 30% of probands have selective IgG isotype deficiency, especially that of subclasses IgG_1 or IgG_3. Deficiency of IgA or IgM is uncommon. Mean values of age, transferrin saturation, and serum ferritin at diagnosis and phlebotomy units required to induce iron depletion were similar in probands with or without CVID or IgGSD; phlebotomy had no effect on IgG levels.[484] There was concordance of Ig and hemochromatosis phenotypes in probands and respective human leukocyte antigen (HLA)-identical siblings and a significant positive association of selective IgG deficiency to C282Y-bearing chromosome 6p HLA haplotypes that included HLA-A*03, B*07. This suggests that a gene that modulates IgG subclass levels occurs on these hemochromatosis-associated chromosomes.[484]

Coronary Artery Disease

Hemochromatosis can cause cardiac arrhythmias or congestive heart failure due to siderosis of conducting fibers and cardiac myocytes.[297,300,302,485–492] This complication is much more prevalent in juvenile hemochromatosis than in *HFE* hemochromatosis. It was estimated that German adults with hemochromatosis had a 300-fold increased risk of developing cardiomyopathy.[315] In a more recent Swedish study of nationwide, population-based health and census registers, the risk of cardiomyopathy in persons with hemochromatosis was significantly elevated (hazard ratio 3.2 [95% CI 2.15 to 4.81]), but the risk of ischemic heart disease was barely elevated.[493] Neither cardiomyopathy nor ischemic heart disease risk was increased in first-degree relatives of persons with hemochromatosis.[493] Most studies have revealed no association between coronary

artery disease and *HFE* mutations.[494,495–505] Other studies suggest that an association exists.[506,507] Total mean serum cholesterol and low-density lipoprotein levels were lower in C282Y homozygotes than in *HFE* wild-type participants in the HEIRS Study.[508] Whether these differences influence manifestations of coronary or peripheral atherosclerosis in C282Y homozygotes is unknown.

DIAGNOSIS

History and Physical Examination Findings

Recent guidelines and reviews have been published about screening and about the evaluation and management of individuals in whom hemochromatosis is suspected, and for relatives of a person who has *HFE* hemochromatosis.[360,509,510,511,512,513] A large percentage of *HFE* C282Y homozygotes who are identified during screening studies do not have symptoms of illness and do not have persistently elevated serum ferritin concentration.[136,278,287,514,515] Currently, screening of the general population for hemochromatosis is not recommended.[516]

Hemochromatosis with iron overload may be suspected in an individual who has some combination of the following: arthralgias, right upper quadrant abdominal pain, impotence, palpitations, unexplained fatigue or weight loss, gray-bronze skin, hepatomegaly, stigmata of portal hypertension, diabetes, or hypogonadism. Most hemochromatosis homozygotes do not have these findings. Individuals in whom the diagnosis is established during routine screening are nearly always asymptomatic and have no physical examination abnormalities. People in whom the diagnosis is established after seeking evaluation due to illness usually have several of the symptoms and physical examination abnormalities stated above. Only heavily iron-loaded patients with far-advanced organ injury have all of the above symptoms and physical examination abnormalities. The wide variation in the frequency of symptoms and signs of hemochromatosis from 12 reports appears in Tables 25.6 through 25.9.

Laboratory Findings

Transferrin saturation is the first blood test to become elevated in hemochromatosis homozygotes and usually is greater than 60% in symptomatic men and greater than 50% in symptomatic women.[245,302,303,517] Unbound iron-binding capacity is usually decreased in untreated homozygotes.[518–521] In iron-loaded patients, serum ferritin concentration is elevated. Liver stainable iron and the hepatic iron index are also elevated in iron-loaded homozygotes. The sensitivity of elevated transferrin saturation to identify a patient with hemochromatosis is 94% to 98%, and its specificity is 70% to 98%.[303,517] Typical results of transferrin saturation and serum ferritin concentration in different groups of hemochromatosis homozygotes are displayed in Tables 25.10 and 25.11. *HFE* C282Y homozygosity was present in 89% of hemochromatosis patients in the Utah studies, whether or not iron overload was present.[245]

Evaluation of Relatives

After the diagnosis of hemochromatosis is established in an index patient (proband), it is important to study his or her siblings. Test selection is the same as for the index patient: transferrin saturation; serum ferritin concentration; and *HFE* mutation analysis to identify C282Y, H63D, and S65C alleles. Young homozygous siblings of a hemochromatosis proband may have a normal serum ferritin concentration.[245] Serum ferritin levels should be measured at 2- or 3-year intervals. When serum ferritin becomes elevated, it is reasonable to begin intermittent phlebotomy therapy to prevent accumulation of excess iron in the liver and other organs.

HFE homozygous relatives who have marked elevation of serum ferritin concentration greater than 700 μg/L[522] or greater than 1,000 μg/L[523,524] and elevated serum concentrations of hepatic transaminases may have hepatic cirrhosis. Liver biopsy in such individuals is usually necessary to determine the presence or absence of hepatic fibrosis or cirrhosis and allows measurement of hepatic iron stores. Typical liver biopsy findings in iron-loaded homozygotes appear in Figure 25.1 and Table 25.12. The great majority of homozygous relatives identified during family screening are less iron loaded and have fewer complications than their corresponding probands. Authors of a recent article made recommendations about when and for whom to advise liver biopsy in these settings.[525]

Heterozygous Relatives

HFE heterozygotes do not become iron loaded unless they have an additional disorder that increases iron accumulation.[526] There was no difference in the amount of heme iron or non-heme–iron absorption in C282Y heterozygotes and normal control subjects. Similarly, differences in non-transferrin–bound iron, transferrin saturation, or serum ferritin levels did not differ significantly between C282Y heterozygotes and normal controls.[527] Transferrin saturation and serum ferritin concentration measurements in large numbers of C282Y heterozygotes and normal individuals are displayed in Table 25.11.[278]

Because approximately 10% of whites of Central, Western, and Northern European ancestry are C282Y heterozygotes, the occurrence of hemochromatosis in whites in consecutive generations is common. It seems reasonable to measure transferrin saturation or unbound iron-binding capacity in the interested parents and adult children of homozygotes, in addition to all siblings of the proband.

Homozygous Relatives

In a study of the relatives of 291 hemochromatosis probands, 214 homozygous relatives were identified.[245] When these 214 clinically unselected individuals were stratified by age and sex, it became apparent that 90% of the homozygous male relatives were iron loaded by age 40 years, and 52% had iron-related organ injury. Clinically unselected female homozygous relatives became iron loaded on average approximately one decade later

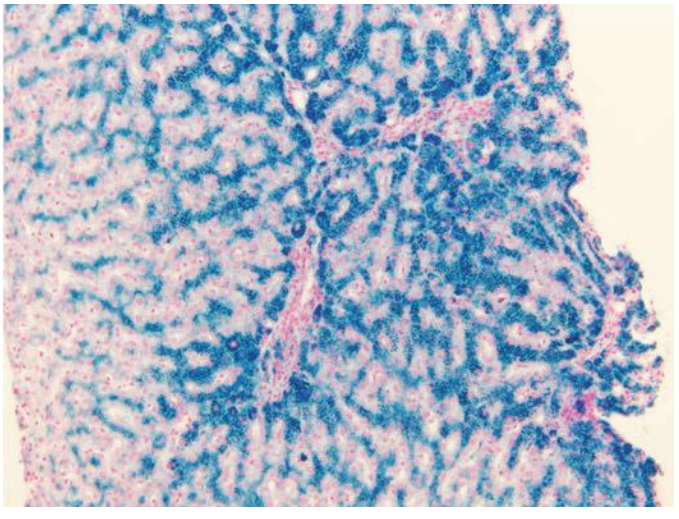

FIGURE 25.1. Grade 4 hepatic parenchymal cell stainable iron in a 30-year-old asymptomatic *HFE* C282Y homozygous woman who was evaluated after her sick brother was found to have hemochromatosis.

than men. After age 50, 88% of clinically unselected female homozygous relatives became iron loaded and 16% of them had iron-related organ injury.[245] The results of transferrin saturation and serum ferritin concentration tests in 291 probands and their 214 clinically unselected homozygous relatives in the Utah studies are displayed in Table 25.10.

MANAGEMENT

Phlebotomy Therapy

Detailed discussions of phlebotomy therapy for hemochromatosis patients have been published.[303,528] Overall, men require approximately twice as many units of phlebotomy to induce iron depletion as women.[301,303,529] Complications of hemochromatosis that respond to and complications that do not improve after phlebotomy therapy are displayed in Table 25.13. Treatment for specific problems usually should be managed as in patients who do not have hemochromatosis.

Initial Weekly Phlebotomy Schedule

The main treatment of iron-loaded hemochromatosis patients is phlebotomy therapy.[303,528,529] In a phlebotomy of 500 ml of whole blood with a hematocrit of 40%, 200 ml of packed red blood cells are removed. Because each 1 ml of packed red cells contains about 1 mg of iron, each 500-ml phlebotomy removes about 200 mg of iron. When the diagnosis of iron overload due to hemochromatosis is established, it is important to start the first phase of phlebotomy therapy. Serum ferritin level, not serum iron or transferrin saturation levels, should be used to monitor levels of storage iron during phlebotomy.[530]

Most iron-loaded homozygotes tolerate removal of 500 ml of whole blood each week. Some women, small individuals, or elderly patients may only tolerate removal of 250 ml of whole blood each week. Twice-weekly phlebotomy may be performed for very heavily iron-loaded patients who have cardiac arrhythmias or hepatic failure in an effort to improve cardiac and hepatic function quickly. Phlebotomy therapy should be continued until the hemoglobin drops by approximately 1 to 2 g/dl below baseline, the mean corpuscular volume drops by approximately 3 to 5 fl below baseline, and serum ferritin concentration drops to 20 to 50 μg/L. These findings provide evidence of iron-limited erythropoiesis, which concludes the initial rapid sequence phase of phlebotomy therapy. The patient then enters the second, life-long maintenance phase of phlebotomy therapy.[303,528–532]

Life-long Maintenance Phlebotomy Schedule

After the initial iron depletion is accomplished, the patient enters the life-long maintenance phase of phlebotomy therapy. Removal of 500 ml of whole blood every 2 to 4 months (every 3 to 6 months in women) prevents re-accumulation of excessive organ storage iron. The goals of life-long maintenance phlebotomy therapy include maintenance of a normal hemoglobin level and main-

TABLE 25.13

CLINICAL CHANGES EXPECTED FOLLOWING PHLEBOTOMY THERAPY

Observed Complications of Iron Overload	Expected Treatment Outcome
No complications	Prevention of complications of iron overload; normal life expectancy.
Weakness, fatigue, lethargy	May resolve if only due to iron overload.
Elevated hepatic transaminases in serum	Resolution or marked improvement.
Hepatomegaly	Resolution often occurs.
Hepatic cirrhosis[a]	Usually no change.
Increased risk for primary liver cancer[b]	May persist in presence of cirrhosis.
Right upper quadrant pain[c]	Resolution if only due to iron overload.
Arthropathy	Arthralgias may improve; joint deformity not expected to resolve; worsening sometimes occurs.
Hypogonadotrophic hypogonadism	May resolve if pituitary injury is not extensive.
Diabetes mellitus	Occasional improvement, often temporary.
Hyperthyroidism, hypothyroidism	Resolution is rare.
Cardiomyopathy	Resolution sometimes occurs.
Hyperpigmentation	Resolution usually occurs.
Hyperferritinemia[d]	Resolution.
Hyperferremia	Usually decreases, then rises again after cessation of phlebotomies.
Excess absorption and storage of nonferrous metals[e]	Little or no change.
Infection with *Vibrio vulnificus or* other bacteria	Little or no change.

[a]Regression was reported in some patients. Falize L, Guillygomarch A, Perrin M, Laine F, Guyader D, Brissot P, Turlin B, Deugnier Y. Hepatology 2006;44:472–477.[446]
[b]Increased risk is usually only in those who have hepatic cirrhosis.
[c]Right upper quadrant pain that is only due to iron overload usually improves, but not if the pain is due to hepatocellular carcinoma, portal vein thrombosis, gallbladder disease, or other non-iron causes.
[d]Serum iron levels may be normal or subnormal in persons with hemochromatosis due to severe iron deficiency, chronic inflammatory or infectious disease, vitamin C deficiency, or prolonged fasting.

tenance of the serum ferritin concentration less than 300 μg/L in men and less than 200 μg/L in women.[533] A very low serum ferritin and the presence of anemia indicate that the frequency of phlebotomy therapy can be decreased to 4- or 6-month intervals.

Patients and physicians often want to estimate the duration of weekly phlebotomy therapy to achieve iron depletion. Based on a study of the correlation of serum ferritin to the number of grams of iron removed by phlebotomy therapy, 1 μg/L of pretreatment serum ferritin corresponded to ~8 mg of mobilizable iron.[522] A person whose pretreatment serum ferritin concentration is 600 μg/L is likely to have ~4,800 mg (8 × 600 mg) of mobilizable storage iron. Each ml of centrifuged red blood contains about 1 mg of iron and each 500-ml unit of blood with a hematocrit of 40% contains approximately 200 mg of iron. Therefore, a patient whose serum ferritin is 600 μg/L is predicted to undergo ~24 units of phlebotomy to achieve iron depletion ([8 × 600 mg] = 4,800 mg/200 mg/unit = 24 units). This simple estimate holds reasonably well except in patients whose serum ferritin is elevated out of proportion to storage iron due to hepatic necrosis or another source of inflammation that causes hyperferritinemia. After patients achieve iron depletion by phlebotomy, the number of units of whole blood removed, multiplied by 200 mg iron per phlebotomy, provides a reliable calculation of the number of grams of iron that were removed.

Hemochromatosis Homozygotes as Blood Donors

Experts in the Department of Transfusion Medicine at the National Institutes of Health in Bethesda studied hemochromatosis patients as blood donors for patients treated at the National Institutes of Health.[534] They evaluated 1,402 units of blood from hemochromatosis donors and concluded that if such individuals do not have serologic results necessitating deferral, they do not pose a health risk for recipients. The authors also noted that these donors could significantly augment the blood supply at the Institutes. After 27 months of study, blood from hemochromatosis donors represented 14% of all blood donations. In another report, an ethicist at the Centre for Environmental Philosophy and Bioethics of the University of Ghent, Belgium concluded that hemochromatosis patients can be free, voluntary, altruistic blood donors if they do not request any benefit other than blood removal.[535] When phlebotomy therapy is performed in a setting other than a blood bank, the blood cannot be collected and processed properly for future transfusion.

Clinical Changes after Iron Depletion

If hepatic cirrhosis and arthropathy were not present before iron depletion therapy, these complications of hemochromatosis may be preventable by initial iron depletion followed by life-long maintenance phlebotomy therapy. An important question is whether hepatic fibrosis or cirrhosis can diminish following iron depletion. Regression of hepatic fibrosis was studied in 36 hemochromatosis patients who underwent two liver biopsies, the first one before and the second after iron depletion, with an interval of at least 2 years between biopsies.[536] Regression of fibrosis occurred in 9 of 13 patients whose initial fibrosis was far advanced (grade 3), and in 8 of 23 whose initial biopsy showed cirrhosis (grade 4). The clinical changes that may occur following iron depletion appear in Table 25.13.[528]

Dietary Recommendations

Persons with hemochromatosis have increased risk to develop a life-threatening infection with *V. vulnificus* from raw shellfish (see the section, "Infections"). It is prudent to advise these individuals not to consume raw shellfish, although consumption of cooked shellfish is safe. Much more iron can be removed in each 500-ml whole blood phlebotomy each week than can be absorbed during that week. For this reason, it is not necessary to impose severe dietary restrictions in an attempt to avoid all foods that contain iron. Regardless, heme iron of meat, especially red meat, is readily absorbed. It is reasonable to advise patients to eat red meat in moderation, to decrease dietary intake of saturated fat and animal protein, and to increase consumption of fresh vegetables and fruit, as for anyone else who follows a prudent cardiovascular diet.[528]

Alcohol Intake

Alcohol can be hepatotoxic. Individuals with hepatic damage from iron overload may benefit from avoiding drinks containing alcohol. It is estimated that 30 g[317,537] or greater than 60 g[538,539] of alcohol per day can worsen iron-related liver damage. Consumption of these amounts of alcohol by a person with cirrhosis may also increase the risk of hepatocellular carcinoma.[317,538,539]

Vitamins

It is reasonable to advise hemochromatosis patients to avoid medicinal intake of vitamin C (ascorbic acid) because it can increase the absorption of dietary iron, mobilization of storage iron, or production of free radicals.[540–544] Vitamin C also may cause oxidative damage of the myocardium and cardiac conduction system, resulting in rare fatal arrhythmias in iron-loaded patients who have hemochromatosis or thalassemia major.[541,544–547] It seems reasonable for hemochromatosis patients to not take multiple vitamins that contain iron.

PROGNOSIS

The outlook for an iron-loaded hemochromatosis patient is related to whether the patient undergoes iron depletion therapy before the development of cirrhosis or diabetes mellitus. In a study of 111 hemochromatosis patients in England, the average survival of 85 people who underwent phlebotomy therapy was 63 months, compared with 18 months in the 26 subjects who did not become iron depleted.[314] In a study of survival among 251 hemochromatosis patients in Germany, survival of those who became iron depleted was similar to that of the background population.[300] Hemochromatosis patients with diabetes had a 10-year survival of 65%; in patients without diabetes, the survival was 90%. The 10-year survival of hemochromatosis patients with cirrhosis was 72%, whereas survival of patients without cirrhosis was 82%. Iron overload that could not be depleted within 18 months from the onset of phlebotomy therapy was also associated with decreased survival. In 422 hemochromatosis probands homozygous for *HFE* C282Y, serum levels of ferritin greater than 1,000 μg/L at diagnosis were positively associated with male sex and cirrhosis. Even with treatment, the relative risk of death from iron overload was fivefold greater in probands with serum levels of ferritin greater than 1,000 μg/L.[548] Additional reports of survival and prognosis of hemochromatosis patients have been published.[299,325,549,550]

IMAGING OF THE LIVER

Computed Tomographic Scanning of the Liver

Single-energy computed tomographic (CT) scanning is not adequately sensitive to distinguish hepatic iron overload from a fatty liver. CT scanning also has very limited value in the assessment of sources of hepatic inhomogeneity, including edema, regenerative nodules, perfusion abnormalities, iron, fibrosis, or cirrhosis.[551] Similarly, density histogram analysis of unenhanced hepatic CT does not distinguish among most diffuse liver diseases.[552]

Dual-energy CT scanning is able to distinguish hepatic iron from fat.[553] In a dual-energy CT scan, an iron-loaded liver appears brighter than paraspinous muscles.

Magnetic Resonance Imaging of the Liver

Magnetic resonance (MR) imaging has largely replaced CT scanning in the evaluation of livers that are presumed to be cirrhotic. Some of the advantages of MR scanning include superior contrast resolution, multiplanar capability, greater sensitivity and specificity in the detection and characterization of abnormalities, and no use of ionizing radiation.[551] MR imaging can be used to identify hepatic cirrhosis, regenerating nodules, increased iron, and hepatocellular carcinoma in subjects who have hemochromatosis.[554–564]

Iron is a paramagnetic element that becomes magnetized in a magnetic field. The result is that the transverse (T2) relaxation time of iron becomes shortened compared with the longitudinal (T1) relaxation time. In an iron-loaded liver, the shortened T2 relaxation time causes a decrease in signal intensity. The result is that an iron-loaded liver appears darker than paraspinous muscles on T2-weighted MR images. The proton transverse relaxation rate (R2) is related to the presence of iron. For this reason, the R2 value is expected to allow measurement of a wide range of liver iron concentrations on MRI machines that have a magnetic field strength of 1.5 Tesla.[555] Comparison of both MR imaging and biomagnetic liver susceptometry in 23 patients yielded a high correlation over a wide range of hepatic iron concentration.[556]

Gradient-echo MR scanning after gadolinium is considered to provide the most useful information about iron stores, using both T1- and T2-weighted images. An MR magnet strength of 1.5 tesla provides better predictive ability than a 0.5-tesla magnet. The intensity of the signal in liver is often compared to signal intensity in paraspinous muscles. Iron causes increased attenuation of the gradient-echo signal in hepatocytes,[551,554,557,559,560] which means that iron-loaded liver tissue appears darker than paraspinous muscle. Whereas CT cannot quantify iron stores less than five times normal, gradient-echo MR allows quantification of iron stores that are minimally increased.[555,557,561–564]

Gradient-echo sequences allow quantification of storage iron that correlates well with chemical measurement of iron in a liver biopsy sample. Thus, MR scanning can provide credible estimation of the hepatic iron concentration in patients who, for any reason, do not undergo liver biopsy. After iron depletion, there is a decreased amount of attenuation of the gradient-echo signal, so the liver appears lighter than before.[561–564] Conventional T1-weighted and T2-weighted spin-echo MR[565] or MR T2-star (T2*) imaging[565–568] can identify increased amounts of iron in myocardium and liver. Organs that are iron loaded have low signal intensity, so they appear dark on T2* MR images.

CHAPTER 26

PORPHYRIAS

Sylvia S. Bottomley

The *porphyrias* are diverse disorders that arise from various inherited enzyme defects in the heme biosynthesis pathway (Fig. 26.1). The first authentic cases of porphyria were described in 1874.[2,3] Since that time, eight genetically distinct forms of porphyria have been characterized (Fig. 26.1; Table 26.1), each caused by a partial deficiency, and in one type by activation, of a different enzyme within the pathway (Table 26.2). The genes encoding these enzymes have been cloned, their chromosomal location is defined, and DNA analyses have revealed many heterogeneous molecular defects in all the porphyrias. The biosynthetic blocks resulting from the defective enzymes are expressed either in the liver or in the bone marrow, the sites where most of body heme is produced. The clinical and pathologic phenotype of each porphyria is dictated by effects of the associated enzyme defect and the mode of inheritance (Table 26.2) and is often influenced by certain metabolic and environmental factors that affect the tightly regulated heme pathway. In some "late-onset porphyrias," acquired clonal hematopoietic disorders may harbor a somatic mutation involving a heme synthesis enzyme that contributes to the expression of the porphyria.

Although the pathophysiologic mechanisms of the clinical manifestations of the porphyrias are only partly understood, two cardinal features prevail: cutaneous photosensitivity and neurologic symptoms of intermittent autonomic neuropathy, motor nerve palsies, and central nervous system disturbances. The cutaneous photosensitivity is a manifestation of the unique fluorescent properties of the porphyrins (the oxidized forms of the natural porphyrinogens in the heme synthesis pathway) that accumulate in those porphyrias in which the enzyme defects cause porphyrin accumulation (Fig. 26.1). The neurologic manifestations are associated with increased production of the porphyrin precursors 5-aminolevulinic acid (ALA) and porphobilinogen (PBG), which characterize the acute or inducible porphyrias. Among some of these, however, photosensitivity occurs as well if the enzyme defect also leads to accumulation of porphyrins. The distinguishing clinical manifestations of the porphyrias form the basis for the classification in Table 26.1. The diagnosis of a specific porphyria is ascertained by its characteristic profile of accumulated and excreted metabolic intermediates of the heme synthesis pathway (Table 26.2). It can be further confirmed by the activity of the affected enzyme but best by identification of the molecular defect causing the porphyria.

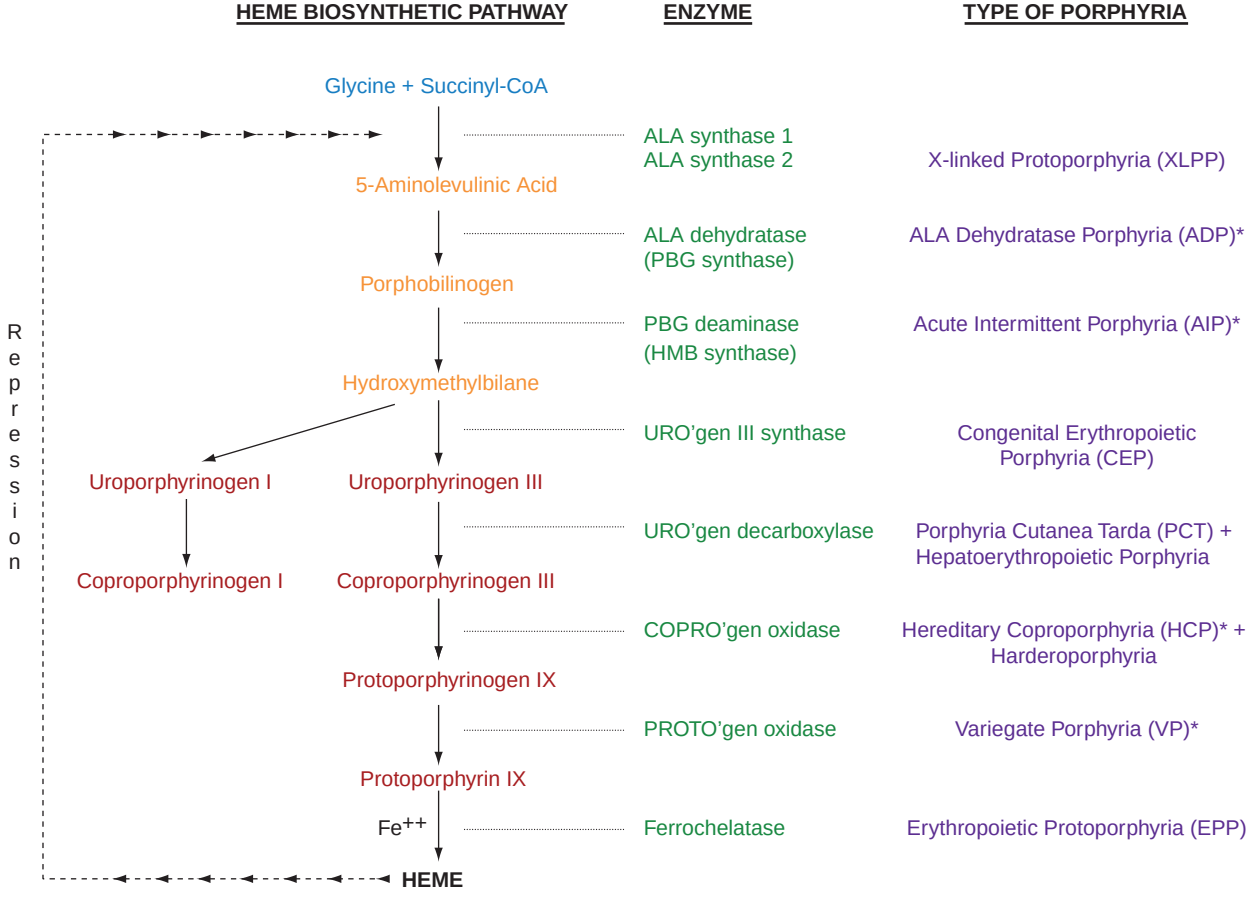

FIGURE 26.1. The heme biosynthetic pathway, its enzymes, and the eight forms of human porphyria associated with genetic defects of these enzymes. The major compound accumulated and excreted in excess in the seven porphyrias beyond the ALA synthase step is the substrate of the respective deficient enzyme; genetic defects in the erythroid ALA synthase (ALAS2) causing increased enzyme activity lead to increased flux of intermediates through the pathway and accumulated protoporphyrins. In the acute or inducible porphyrias (*), increased hepatic ALA production results from release of the normal negative feedback on ALA synthase exerted by heme,[1] indicated by the trail of arrows. ALA, 5-aminolevulinic acid; Fe^{++}, ferrous iron.

TABLE 26.1

CLASSIFICATION OF THE PORPHYRIAS

I. Porphyrias with only cutaneous photosensitivity
- Congenital erythropoietic porphyria (CEP)
- Porphyria cutanea tarda (PCT); hepatoerythropoietic porphyria (HEP)
- Erythropoietic protoporphyria (EPP)
- X-linked protoporphyria (XLPP)

II. Acute porphyrias with only neurologic manifestations
- Acute intermittent porphyria (AIP)
- ALA dehydratase porphyria (ADP)

III. Acute porphyrias with both neurologic manifestations and cutaneous photosensitivity
- Variegate porphyria (VP)
- Hereditary coproporphyria (HCP)

IV. Dual porphyrias

PORPHYRIAS WITH CUTANEOUS PHOTOSENSITIVITY

Congenital Erythropoietic Porphyria

Congenital erythropoietic porphyria (CEP; Gunther porphyria), the second least common of the porphyrias, is characterized by a marked accumulation in erythroid precursors of uroporphyrin and coproporphyrin, which are predominantly of the isomer I type because defects reside in the gene for the enzyme uroporphyrinogen III synthase (UROS; Fig. 26.1). Many marrow erythroblasts and immature circulating erythrocytes exhibit intense red fluorescence in ultraviolet light. The large amounts of porphyrins released from these cells cause the most intense photosensitivity of all the porphyrias.

Probably first recognized by Schultz[2] and Baumstark[3] in 1874, CEP was described comprehensively and distinguished from other porphyrias by Gunther in 1911.[4] It is a very rare disease, with less than 200 cases reported. It occurs with equal frequency in males and females and in a wide variety of racial groups. Usually, the illness is first detected in infancy[5] but, in a number of instances, was not apparent until later in life.[6] All evidence is consistent with transmission of the disorder as an autosomal recessive trait.[5,7]

Molecular Basis and Pathogenesis

The pattern of porphyrin accumulation in CEP reflects a defect in the conversion of PBG to uroporphyrinogen III. This conversion requires two enzymes: PBG-deaminase (PBGD) and UROS (Fig. 26.1). Affected individuals are homozygotes or compound heterozygotes for mutations in the *UROS* gene that result in markedly reduced activity of UROS (1% to 20% of normal), leading to the overproduction of uroporphyrinogen I through nonenzymatic cyclization of the substrate hydroxymethylbilane in erythroid precursors.[5,7] In heterozygotes (parents and some siblings of

TABLE 26.2

GENETIC AND METABOLIC FEATURES OF THE PORPHYRIAS

Type of Porphyria	Inheritance	Defective Enzyme	Gene (Symbol/ Location[a])	Enzyme Activity (%)[b]		Porphyrin/ Precursor Accumulated/ Excreted[d]	Route of Excretion	Tissue Source
				Heterozygote	Homozygote[c]			
X-linked protoporphyria	X-linked	5-Aminolevulinate synthase 2	*ALAS2*/ Xp11.21	2 to 3 times normal		**Free and zinc protoporphyrin**	**Feces**	Bone marrow
ALA dehydratase	Autosomal recessive	ALA dehydratase (PBG synthase)	*ALAD*/9q33.1	50	<10	**ALA**, coproporphyrin	**Urine**	Liver
Acute intermittent	Autosomal dominant	PBG deaminase (HMB synthase)	*HMBS*/11q23.3	50	1–16	**PBG, ALA**	**Urine**	Liver
Congenital erythropoietic	Autosomal recessive	Uroporphyrinogen III synthase	*UROS*/10q25.2-q26.3	50	1–20	**Uroporphyrin I,** coproporphyrin I	**Urine**	Bone marrow
Cutanea tarda	Autosomal dominant, or acquired	Uroporphyrinogen decarboxylase	*UROD*/1p34	50	3–27	**Uroporphyrin I + III, 7-COOH porphyrin**	**Urine**	Liver
Hereditary coproporphyria	Autosomal dominant	Coproporphyrinogen oxidase	*CPOX*/3q12	50	2–10[e]	**Coproporphyrin III[f], PBG[f], ALA[f]**	**Feces, urine**	Liver
Variegate	Autosomal dominant	Protoporphyrinogen oxidase	*PPOX*/1q22	50	0–20	**Protoporphyrin Coproporphyrin[f] PBG[f], ALA[f]**	**Feces Urine**	Liver
Protoporphyria	Autosomal recessive	Ferrochelatase	*FECH*/18q21.3	50	<10	**Free protoporphyrin**	**Feces**	Bone marrow
Protoporphyria	"Pseudodominant"[g]	Ferrochelatase	*FECH*/18q21.3	50–70	20–30	**Free protoporphyrin**	**Feces**	Bone marrow

ALA, 5-aminolevulinic acid; PBG, porphobilinogen; HMB, hydroxymethylbilane.
[a]Gene symbol and chromosomal location as listed in the Human Gene Mutation Database, located at http://www.hgmd.org.
[b]Percentage of normal.
[c]Often a compound heterozygote.
[d]The major metabolite and route are shown in boldface. The route of porphyrin excretion is determined by the number of carboxyl groups on the porphyrin and hence by its water solubility.
[e]In harderoporphyria the activity is 18% to 24% of normal (see text).
[f]Increased in urine during acute attack; in VP urine coproporphyrin is increased when symptoms are only cutaneous.
[g]One allele is mutant and the other allele is usually underexpressed (see text).

patients with the disease), the activity of the synthase is intermediate (approximately 50%) between that found in affected individuals and that in normal subjects.[8] The *UROS* gene resides on chromosome 10 (10q25.2–q26.3)[9] and has alternative promoters that generate identical housekeeping and erythroid-specific transcripts.[7] Forty-six distinct mutant alleles have been identified and molecular defects include point mutations, deletions, insertions, splicing defects, intron branch chain mutations, and erythroid-specific promoter mutations.[5,7,10] Approximately one third are homoallelic and about 20% of alleles remain undefined. The most common mutation (Cys73Arg) has occurred in one third of alleles (and in nearly one half of homoallelic cases) and correlates with the most severe phenotype of nonimmune hydrops fetalis, transfusion-dependent anemia from birth, or both, particularly in homoallelic cases.[5] In most instances, mild forms of the disease have been heteroallelic or only one mutant allele could be identified. Residual enzyme activity of the mutant proteins expressed in prokaryotic systems, or gene promoter-reporter activities in cases of promoter mutations, have provided more precise genotype/phenotype correlations.[5,7,11] However, in two instances marked divergence of phenotypic expression among siblings suggested undefined modifying factors.[12,13] In another family it was demonstrated that the clinical phenotype is markedly affected by co-inheritance of an activating (gain-of-function) mutation in the erythroid-specific 5-aminolevulinate synthase (ALAS2) gene.[14]

In addition, variant genetic forms of the CEP phenotype are described. (1) In two patients porphyrin patterns and enzyme assays were consistent with a uroporphyrogen decarboxylase (UROD) rather than a UROS defect, and the presence of a second dyserythropoietic defect was suggested to account for the clinical severity.[15,16] (2) A variant caused by a mutation in the X-linked erythroid transcription factor GATA binding protein 1 (GATA1) demonstrated that CEP can result from a genetic defect in a *trans*-acting factor.[17] (3) CEP has occurred as a milder form in later life.[6,18] Of 16 such cases, 8 were associated with a myelodysplastic syndrome; the pattern of excess porphyrins was characteristic of childhood-onset CEP but at lower concentrations and erythrocyte UROS activity was normal.[18] Presumably UROS mutations could not be identified if only a minor clone of uroporphyric cells harbors a somatic mutation; alternatively another gene that determines UROS activity remains a possibility. This late-onset form of CEP has been termed "erythropoietic uroporphyria secondary to myeloid malignancy."[18]

Although defective UROS operating in the erythron characterizes the primary inherited abnormality, no overall deficiency of heme production is evident, perhaps because normal UROS activity appears to be the highest relative to all other heme biosynthetic enzymes in erythroid cells. It is more than 1,000 times greater than the activity of ALA synthase,[19] the rate limiting enzyme, so that even very low residual enzyme activity seems to be sufficient to support normal or even increased rates of heme synthesis. Uroporphyrin I is the predominant urinary porphyrin, but increased excretion of uroporphyrin III also invariably occurs, implying up-regulation of the UROS or of enzymes higher up in the pathway. These findings are consistent with the idea that the pathophysiology of CEP is a result of the accumulation of uroporphyrin I rather than of subnormal production of uroporphyrinogen III and heme.[20] However, it is unclear why uroporphyrin I, not coproporphyrin I, is the main porphyrin excreted, which may relate to the relative UROD activity in normal erythroid cells being on the order of one tenth of that of UROS.[19]

The large amounts of porphyrins released from erythroid cells and deposited in multiple tissues[21] exert the principal damage in the skin and subcutaneous regions through oxygen-dependent phototoxic reactions on excitation by light (see section "Porphyria Cutanea Tarda").[22,23] This relentless process leads in varying degrees to the formation of subepidermal bullae, secondary infection, scarring, epidermal atrophy, and resorption of acral structures. Laboratory parameters of hemolysis correlate with severity of anemia. Associated splenic sequestration leads to splenomegaly and variable leukopenia and thrombocytopenia. Whether photolysis of the porphyrin-laden erythrocytes occurs in vivo is not known.

Clinical Description

The first sign of this affliction is often discoloration of the infant's diapers by the urine, which ranges in color from pink to deep burgundy and fluoresces under Wood's light.[24] The most prominent manifestation is pronounced cutaneous photosensitivity. Exposure to visible light is followed by the development of vesicular or bullous lesions containing a porphyrin-rich, fluorescent fluid. The lesions tend to heal slowly, leaving pigmented scars (Fig. 26.2A). Often, they become infected, ulcerated, and necrotic. Over a period of years, patients develop progressive mutilation and disfigurement with loss of portions of the fingers, nose, eyelids, or ears (Fig. 26.2B). Corneal scarring can lead to blindness.[5] Skin not exposed to light is unaffected. Hypertrichosis is prominent and fine hair growth may cover much of the face and extremities. The patients often adopt extreme precautions to avoid the sun. Deposition of porphyrin in the dentin of the teeth causes them to appear red (erythrodontia), brown, or yellowish. Even if discoloration is not apparent in ordinary light, the teeth exhibit red fluorescence in ultraviolet light. At necropsy, the entire skeleton has this red fluorescence.[21] Osteopenia and osteolytic lesions can occur.[25]

Anemia, the result of both hemolysis and ineffective erythropoiesis, is detected in most patients, and usually the spleen is enlarged. The most severe phenotypes are transfusion-dependent.

Laboratory Findings

The anemia is normocytic, normochromic, and of variable severity. Detailed morphologic descriptions of the blood and bone marrow have been reported in a few patients. Anisocytosis, poikilocytosis, polychromasia, basophilic stippling, and nucleated erythrocytes are fairly common features of the peripheral blood.[26] Following splenectomy, needlelike fluorescent red cell inclusions that may represent precipitated porphyrin have been observed.[27] Morphologic abnormalities of the bone marrow range from erythroid hyperplasia to striking dyserythropoiesis.[5,17,26,28] Nuclear inclusions containing hemoglobin may be present.[15,28] Results of studies of the marrow with light and fluorescence microscopy suggest the coexistence of normal and abnormal erythropoietic cells.[15,28] Fluorescence is restricted to the morphologically abnormal cells and is most marked in cell nuclei.[15,28,29] Evidence of a dual nature of the erythroid precursors has been supported by ultrastructural studies in two cases.[15,30] Kinetically, the anemia is characterized by both a shortened red cell survival and ineffective erythropoiesis.[31] Its morphologic and kinetic features closely resemble those of congenital dyserythropoietic anemia type I (Chapter 40).

The most characteristic metabolic abnormality is greatly increased urinary excretion of uroporphyrin I, a biologically useless isomer that cannot be converted to heme. Urinary excretion of uroporphyrin III and coproporphyrins I and III is also increased but to a lesser extent than uroporphyrin I.[5,20] Total urinary porphyrin excretion may exceed 100,000 μg daily (normal is $<$300 μg), and the urine usually fluoresces on exposure to ultraviolet light. Fecal excretion of porphyrins, especially coproporphyrin I, is greatly increased.[20] The concentration of uroporphyrin I is increased in erythrocytes and plasma, but the marrow porphyrin content exceeds that of the peripheral blood or other tissues.[20]

Treatment

Splenectomy may partially or completely relieve the hemolytic anemia and may also lead to reduced porphyrinuria and

photosensitivity.[26–28] However, this operation is not always beneficial[32] and is not always warranted by the degree of anemia. Suppression of erythropoiesis by transfusion decreases porphyrin excretion.[5,33] A young boy with CEP was successfully treated with chronic hypertransfusion;[34] transfusion-induced iron overload was avoided by means of concomitant iron chelation therapy. After puberty, his relapse on this regimen was controlled with the addition of hydroxyurea.[35]

Another patient was treated successfully with long-term orally administered charcoal at a dose of 60 g three times daily.[36] Oral charcoal appeared to act by binding porphyrins excreted in bile and serving as a sump that diverted circulating and skin porphyrins to a fecal route of elimination in two cases[37,38] but had no effect in others.[5] In two patients, severe anemia improved with administration of the antioxidants α-tocopherol and ascorbic acid.[25] Hematopoietic stem cell transplantation (HSCT) remains the only known curative treatment and to date was successful in 17 of 21 patients.[5,7,39]

In theory, the most definitive method to control the disease would be transfer of the normal gene into hematopoietic stem cells of the affected patient. After in vitro correction of the enzyme defect by viral transfer of the normal gene into deficient cells, long-term correction of the disease in CEP mice had provided support for hematopoietic stem cell gene therapy clinical trials, and gene correction of CEP-derived iPSCs (induced pleuripotential stem cells) was recently achieved to circumvent potential proviral insertional leukemogenesis.[40] In another approach, the function of the common mutant protein Cys73Arg could be rescued with a proteasome inhibitor in cultured cells.[41] Prenatal diagnosis or exclusion of the disorder is possible with enzyme assay or DNA analysis of amniotic fluid cells.[42,43]

Most patients must rely on avoidance of exposure to sunlight. They should be instructed to wear photoprotective clothing, including gloves and broad-brimmed hats. Conventional sunscreen agents are ineffective because they do not screen out the wavelengths in the Soret band of the nearly visible spectrum (around 400 nm) that are responsible for inducing porphyrin-mediated photosensitivity.[44] To be effective, a local agent must be visible on the skin. Reflective materials, such as zinc oxide and titanium oxide, are useful, as is ordinary pigmented theatrical makeup.[45] Preparations containing substituted quinones (such as 2-hydroxyl-1,4 naphthoquinone, also known as hemotannic acid or Lawsone) and dihydroxyacetone turn the skin a cosmetically acceptable brownish-tan and may be effective. Therapy with β-carotene beadlets may also offer some protection from the deleterious effects of light (see section "Erythropoietic Protoporphyria"). A single-observer clinical study of 29 CEP cases together with a proposal for a management algorithm derived from the patient cohort has recently been presented.[39,46]

Congenital Erythropoietic Porphyria in Animals

CEP (pink tooth) in cattle appears to be milder than the human disorder. The disease is inherited as an autosomal recessive trait, and heterozygous animals are clinically and biochemically normal,[47,48] although an increased ratio of coproporphyrin I to coproporphyrin III in the urine was reported.[49] Photosensitivity of the skin areas not covered by pigmented hair and hemolytic anemia are observed. The teeth and bones are stained red. UROS activity is severely impaired in erythrocyte lysates.[50]

A similar disorder has been observed in pigs and cats.[51,52] A naturally occurring feline CEP was recently characterized by clinical phenotype, biochemical analysis, and molecular studies.[53] In the fox squirrel (*Sciurus niger*), as part of the apparently normal physiology of the species, large amounts of uroporphyrin I are deposited in the tissues and excreted in the urine.[54] As in human CEP, the normoblasts and young erythrocytes show a red fluorescence; however, hemolytic anemia is lacking, and the fox squirrel seems to suffer no ill effects. Erythroid UROS activity is lower than that found in the closely related but nonporphyric gray squirrel (*Sciurus carolinensis*).[54]

In knockin mouse models of patient mutations, the phenotypes closely resemble the human disorder.[55,56] These mice would appear suitable for studies of pathogenesis and therapies in CEP.

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is the most commonly encountered porphyric disorder. It results from reduced activity of UROD (Fig. 26.1) in the liver, leading to accumulation of uroporphyrins (oxidized uroporphyrinogens), their release into plasma, and excretion in the urine.[20] Clinical manifestations are limited to the skin in the form of a photosensitive bullous dermatosis as a consequence of the circulating uroporphyrins. Neurovisceral symptoms never occur. Symptoms usually arise in mid- or later life (hence the name *tarda*) and are nearly always brought on by genetic and environmental factors, most often hepatic siderosis, alcohol abuse, hepatitis C virus, and estrogen therapy. Since the first comprehensive description of the disease in 1937.[57], three variant forms of the illness have been recognized: familial, sporadic, and toxic.

Molecular Basis and Pathogenesis

Among the variants of the disorder, a genetic basis has been established for one, designated *familial PCT* (type II), but it accounts on average for only 20% to 30% of cases.[58,59,60,61] Studies of patients with subnormal UROD activity in both hepatic and extrahepatic tissues, and their relatives, revealed that the enzyme defect is inherited as an autosomal dominant trait.[62–65] Enzyme activity is one-half normal in all tissues, as is the amount of UROD protein detected with antibodies.[66–68] In the rare homozygous form, designated *hepatoerythropoietic porphyria (HEP)*, residual enzyme activity ranges from 3% to 27% of normal,[20,68–71] but immunoreactive enzyme is variable.[67,68,72] Since the cloning of the human *UROD* gene,[73] located on chromosome 1 (1p34),[74] at least 113 different mutations in the gene have been identified.[10,75] Usually, a given mutation is found in one or in a few kindreds only. The majority are various point mutations in the coding region of the gene or splice site mutations, resulting in changes of amino acids, frameshifts, or deletions; in some instances, large nucleotide deletions were detected. The defects usually result in the production of an unstable or inactive enzyme from the mutant allele. Functional consequences of many of the mutations have been defined or predicted on the crystal structure of the enzyme.[76,77] In the homozygous version among about 40 cases reported, 15 different mutations have been identified.[10,75,78] The mutations are homoallelic or heteroallelic, causing instability or impaired catalytic activity of the enzyme, and survival hinges on residual enzyme activity encoded by the alleles.

When reduced UROD activity is restricted to the liver and a genetic basis for the disorder is not evident, it is called *sporadic PCT* (type I).[64,66,79] Both the catalytic activity and the immunoreactivity of erythrocyte UROD are normal in this variant.[67,79] In the liver, catalytic activity of UROD is subnormal, but immunoreactive enzyme is present in normal or increased amounts.[79] After prolonged remission is induced by phlebotomy therapy, both catalytic activity and immunoreactivity become normal.[80] These findings, coupled with lack of a family history in most cases of sporadic PCT, have implied that this form of the disease is acquired and not inherited. At the molecular level, no mutations could be found in the *UROD* gene or its promoter region.[81] However, in a few families, clinically manifest PCT was associated with decreased UROD activity in liver and normal activity in erythrocytes and other tissues.[75] These cases were called *type III PCT*; molecular studies have not identified *UROD* mutations in them.[82]

The cutaneous damage produced by the accumulated uroporphyrins in plasma and skin of patients with PCT is the consequence of the fundamental properties of the porphyrins. As they absorb light at 400 to 410 nm (Soret band), not only does their photoexcitation yield energy as fluorescence, but in the aerobic environment of tissues, reactive oxygen species (superoxide anion and other reactive metabolites) are produced[44] that are damaging to cells. In vivo, superoxide anions are generated by activation of xanthine oxidase.[83] The complement system is light activated in vitro in sera containing porphyrins and in vivo in the skin of porphyric patients, promoting release of proteases from dermal mast cells.[23] Chemotactic activity is also generated under these conditions, and the peroxides produced by photoexcitation of the porphyrin and those arising from polymorphonuclear leukocytes with activation of the complement system may act synergistically to contribute to the development of the cutaneous lesions. As a consequence of these events, the dermal–epidermal junction becomes disrupted and leads to skin fragility and the formation of vesicles and bullae that easily rupture. Sclerodermoid changes of the skin result from a light-independent effect (the "dark effect") of the uroporphyrin on collagen synthesis by skin fibroblasts.[84] The pathogenesis of the hyperpigmentation, hypopigmentation, and hypertrichosis is not understood.

Most family members carrying a defective gene of familial PCT do not have clinically apparent disease but a significant number have increased excretion of porphyrins;[77] in occasional pedigrees, overt manifestations of the disease were noted in several generations.[63] Clinical expression of both familial and sporadic PCT is nearly always associated with prevalent confounding factors that cause hepatic injury, so the disorder remains silent without these. In large series of PCT, most patients had more than one of four cardinal hepatotoxic risk factors, namely hepatic iron excess, excessive alcohol use, viral infection (hepatitis C), and medicinal estrogens,[60,61,85] although these are far more common than the estimated frequency of PCT (approximately 1 per 25,000).[20]

Hepatic Iron

The central role of iron in the clinical expression of PCT has been recognized for 52 years.[86,87] Numerous studies documented hepatocellular siderosis in most patients with significant uroporphyrinuria.[88,89,90] The iron deposits generally are moderate in amount, 1.5 to 4 times normal, but are usually greater with co-inheritance of hemochromatosis susceptibility alleles (Chapter 25).[88,91–93] Except for the geographic variation in the frequency of the hemochromatosis *HFE* alleles,[75,94] on average, 35% of patients with PCT are heterozygous for the Cys282Tyr mutation, and 15% are homozygous or double heterozygotes with the His63Asp mutation.[60,61,85,94] The cause of excess hepatic iron in the remaining cases appears to result from down-regulation of hepcidin expression regardless of iron status and consequent to the oxidative stress associated with the other risk factors for PCT.[95] However, in another study serum hepcidin levels were found increased.[96] Transfusional iron overload also promotes clinical expression of PCT.[97]

Depletion of iron by repetitive phlebotomy[98] or by administration of deferoxamine[99] uniformly induces both clinical and biochemical remissions. Replenishment of iron stores promptly reignites symptoms in patients in whom a remission has been induced by phlebotomy.[88,100] The explanation for the provoking influence of iron is based on studies in mouse models, which indicate that the hepatic UROD activity of 50% in UROD-deficient animals must be reduced to 20% or less of normal in order for PCT to be manifest and is achieved by concomitant iron overload.[101,102] An inhibitor of the enzyme was found in liver cytosol of these animals, as well as of PCT patients, and is a porphomethene that is generated by iron-dependent partial oxidation of uroporphyrinogen via catalysis by cytochrome P4501A2 (CYP1A2) or another enzyme.[103,104] This is consistent with the diminished hepatic UROD activity without reduction in enzyme protein in symptomatic PCT patients and the restoration of hepatic UROD activity to its genetically determined level after iron depletion.[60,79,80] The mechanism for the generation of sufficient inhibitor in patients with sporadic PCT that does not occur in iron overload states in general remains to be defined. The oxidative environment in the

hepatocyte generated by the common environmental risk factors accompanying clinical expression of the disorder, as well as other traits such as the allele variants of CYP1A2 and G51M1A,[105] probably play an important role.[94]

Alcohol

Ethanol exacerbates PCT. Heavy alcohol intake was found in 25% to 100% of patients in many studies,[60,61,85,89,94,106] and hepatic cirrhosis is not uncommon.[89,90] Yet the porphyria is an uncommon complication of alcoholic liver disease, occurring in only approximately 2% of cases.[107] The association of clinically expressed PCT with alcoholism would relate to its hepatotoxicity and its effect of stimulating iron absorption.[108] In this regard, PCT is particularly common among the Bantu population of South Africa, where it is associated with excessive consumption of alcoholic beverages brewed in iron containers,[109] thus providing a double threat to susceptible people. Studies have suggested that an undefined hemochromatosis gene plays a role in the iron overload of this population when iron intake is excessive (Chapter 25).[110]

Hepatitis C

A striking association between symptomatic PCT, familial and sporadic, and hepatitis C is well recognized but is variable around the world. Although most patients with hepatitis C infection do not have the porphyria, as many as 80% of PCT patients are chronically infected with the virus in some locations.[60,61,75,94,111] This infection elicits oxidative stress in hepatocytes as well as down-regulation of hepcidin expression[94] and would explain, at least in part, the liver damage often found in PCT. Association of PCT with human immunodeficiency virus (HIV) infection also occurs,[112] and such patients may be infected with both HIV and the hepatitis C virus.[94,112,113] Dual infection causes more severe hepatic disease; whether the HIV virus per se plays a role in the expression of PCT is not known. Thus, patients should be evaluated for the presence of hepatitis C and HIV at the time of diagnosis.

Estrogens

The association of estrogen ingestion and expression of PCT has been reported numerous times but occurs only in a very small percentage of patients who ingest estrogens, consistent with an underlying predisposition to the disease. The cutaneous symptoms have occurred with the use of estrogen as a post-menopausal supplement,[60] for contraception,[114] and for prostatic carcinoma.[115] Uncommonly, patients present with the disorder during pregnancy,[116] but pregnancy has also not exacerbated PCT.[117] The mechanism of the estrogen effect is thought to relate to its adverse effects on the liver such as steatosis and steatohepatitis. It is generally a lesser factor, as venesection alone has brought about full recovery. Most women needing estrogen supplements at the usual dose can probably use them, provided that storage iron is removed and maintained at a low level.

Other Susceptibility Factors

Additional susceptibility factors that are positively associated with PCT are smoking, allele variants of CYP1A2 and GSTM, and ascorbic acid deficiency.[61,105,118,119] Several diverse drugs and radiation have also been implicated in precipitating PCT in a few cases.

Renal Failure

PCT occurs in patients with renal failure undergoing hemodialysis.[120] Symptoms may first arise in this setting for several reasons. Iron overload is not uncommon in such patients, and intravenous iron used in conjunction with erythropoietin for the anemia may precipitate clinical PCT.[121] Hemodialysis or peritoneal dialysis does not effectively clear circulating plasma uroporphyrins,[122,123] presumably because porphyrins are bound to proteins.[124] The uremic state may also contribute to an inhibited UROD and uroporphyrin accumulation independent of an underlying enzyme defect or inhibition.[125] In most reported cases, the lack of family or molecular studies makes it difficult to classify the porphyria.

Clinical Description

Cutaneous changes represent the clinical manifestations of PCT.[20,89] Skin lesions are found predominantly on light-exposed areas such as the face and hands and, in women, on the legs and feet as well. There is little discomfort with sun exposure per se, and blue (visible) light triggers only an insidious cutaneous damage. The most common complaint is marked skin fragility in areas subjected to repeated minor trauma, such as the hands and forearms (Fig. 26.3). Vesicles and bullae form primarily on the dorsa of the hands and may erode, leaving atrophic scars that often display zones of both hyperpigmentation and hypopigmentation. Small, 1- to 2-mm, firm, whitish papules (milia) are commonly noted on the hands and, at times, on the face.

Facial hypertrichosis occurs in most patients, is generally more noticeable in women, and may be an isolated presenting feature.[126] Hypertrichosis, sometimes striking, is occasionally observed on areas of the skin that are rarely exposed to the sun, such as the trunk and legs. Other findings include hyperpigmentation of facial skin, alopecia, and scleroderma-like changes on the skin of the face, neck, and hands. The histologic appearance of the scleroderma-like lesions is identical to that seen in patients with systemic scleroderma.[89] Occasionally, patients have overt signs and symptoms of underlying liver disease, but no good correlation exists between the degree of liver disease and the occurrence or severity of the porphyria.

In the homozygous form of familial PCT, or HEP, the skin changes just described usually occur before the age of 5 years and photosensitivity may be severe, resembling CEP and including disfigurement.[75,78] Developmental delay and seizures have also been reported. Other features are pink urine, dental fluorescence, and occasionally hepatosplenomegaly. Severity of clinical manifestations can vary in affected children within a family; in some instances the clinical phenotype is unusually mild.[78,127]

Laboratory Findings

Patients with symptomatic PCT excrete greatly increased amounts of porphyrins in the urine. Uroporphyrin and heptacarboxylic porphyrin predominate, with lesser amounts of coproporphyrin and small amounts of 5- and 6-carboxylate porphyrins.[89,128] Usually, the daily urinary excretion of uroporphyrin is approximately 3,000 μg (normal, <50 μg), but considerably higher values may be found. Uroporphyrin in the urine is predominantly isomer I, whereas the heptacarboxylic porphyrin is predominantly isomer

FIGURE 26.3. Porphyria cutanea tarda in a 60-year-old man. Note denuded skin areas over the fingers, an erosion, blisters, and milia.

III.[20,89] Photosensitive cutaneous symptoms rarely occur when the daily urinary excretion of uroporphyrin is <1,000 μg. Urinary coproporphyrin rarely exceeds 600 μg daily.[89] An unusual and distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces,[129] and a slight increase may be noted in total fecal porphyrin excretion.[20] Plasma porphyrin level is typically increased, with a fluorescence peak at neutral pH near 619 nm. Homozygotes for the defect have mild anemia; it was severe in three cases.[75] The erythrocyte protoporphyrin was found to be moderately increased when measured and is primarily zinc protoporphyrin.[75,78]

The serum iron concentration and, hence, transferrin saturation are commonly increased as is the serum ferritin level.[60,89] Values for liver function tests vary considerably from one case to another. Some patients have mild degrees of jaundice and slight to moderate elevations in serum transaminase levels. Liver biopsy specimens display characteristic reddish-pink fluorescence.[89,90,130] On microscopic examination, siderosis, periportal inflammation, focal necrosis, fatty infiltration, and some evidence of fibrosis are common findings.[89,90,130,131] Often, fluorescent and birefringent needle inclusions are noted.[131] Electron microscopic studies reveal needlelike lucent areas, which appear to be in lysosomes.[132] Microscopic examinations of skin biopsy specimens show bullae formed by the separation of the epidermis from the dermis; periodic acid-Schiff–positive, diastase-resistant material around vessel walls in the upper dermis; and a sparse inflammatory cell infiltrate.[89,133] Immunofluorescence studies display deposition of immunoglobulin G (and less often immunoglobulin M) or complement around upper dermal vessels and at the dermal–epidermal junction.[133]

Treatment

Exposure to alcohol and excessive estrogen supplements in women, as well as smoking, should be avoided. Abstinence from alcohol can lead to remissions in some patients with the porphyria associated with alcoholic liver disease, but removal of iron by phlebotomy can induce remissions even if alcohol intake continues.[98,134] It is of interest that occasionally remission has been achieved in patients with PCT and hepatitis C after antiviral treatment alone.[135] Conversely, poor response to interferon-α is common in patients with hepatitis C and PCT.[136] Transdermal administration of estrogen was found to be safe in a small number of patients[137] and avoids any possible first-pass effects of the hormone on the liver.

The definitive treatment of both sporadic and familial PCT is the removal of iron stores by phlebotomy, which leads to clinical and biochemical remission in virtually every case and may improve concomitant hepatitis C virus infection. It is recommended that any antiviral therapy be deferred until a de-ironed state is reached.[94] If there are no contraindications, 500 ml of blood is removed every 1 to 2 weeks. Initial serum transferrin saturation and ferritin values are obtained to estimate the iron burden. Liver biopsy must also be considered to assess the disease status of associated viral hepatitis and hemochromatosis. Clinical remissions often occur after the removal of approximately 3 L of blood; [89,98] patients who also have hemochromatosis usually require considerably more therapy and indefinite regular maintenance phlebotomies. The optimal approach is to achieve mild iron deficiency, defined by onset of iron-limited erythropoiesis in which the mean corpuscular volume is decreased to low normal, the serum transferrin saturation is low normal, and the serum ferritin is near 20 μg/L or lower. Although further overproduction of uroporphyrins is halted thereafter, the chronically accumulated, relatively hydrophobic porphyrins are released slowly from the liver. Patients should be advised that formation of new skin lesions ceases gradually, and full recovery often extends over several months to a year or more.[89] Remissions for years are the rule[89,98] and are permanent when the known precipitating factors are avoided or removed; any clinical and biochemical relapse responds to another course of phlebotomies.[89,98]

Hydroxychloroquine and chloroquine have also been used in the treatment of PCT. After the administration of chloroquine (0.5 to 1.0 g/day) for several days, a large amount of the porphyrins stored in the liver was mobilized and excreted in the urine.[138] This purging effect results from the formation of an easily excreted water-soluble complex between uroporphyrin and the drug.[139] The chloroquine effect was often accompanied by malaise, anorexia, fever, and signs of hepatocellular damage. Subsequent use of lower doses made it possible to avoid the toxic response without impairing efficacy,[140] but this maneuver does not always preclude toxicity.[89] Because of the potential danger of the hepatic reaction to antimalarials and because phlebotomy is usually safe and effective, administration of low doses of hydroxychloroquine or chloroquine should be reserved for patients for whom phlebotomy is unsuitable. Moreover, patients with HFE hemochromatosis appear not to respond to this therapy.[141]

The use of sunscreen agents effective in the Soret band of the spectrum and avoidance of sunlight through protective clothing can be useful until the beneficial effects of phlebotomy are achieved. These measures are the principal means to help patients with the homozygous form of PCT in whom phlebotomy is not effective. The antimalarials may be beneficial in these individuals.[75] Severe anemia and cutaneous symptoms responded to erythropoietin in one case.[142] Efforts toward somatic gene therapy were initiated by demonstrating correction of the enzyme defect with retroviral gene transfer in vitro in transformed B-cell lines[143] and may become a prospect in vivo as noted for CEP. Prenatal exclusion of HEP has been possible.[144]

Treatment of patients with PCT and renal failure presents special challenges. The disorder may be particularly severe because such patients lack the renal excretory pathway for porphyrins, leading to higher porphyrin levels in plasma and tissues. Chloroquine–porphyrin complexes are not filtered out by standard hemodialysis. High-flux hemodialysis appears to remove porphyrins from plasma better and may be of some benefit.[145] The treatment of choice is administration of recombinant erythropoietin to mobilize stored iron and relieve the anemia so that phlebotomies can be performed as necessary to induce remission.[146,147] This method is preferable to the alternative of depleting iron stores with iron chelation.[147] In patients refractory to these treatment methods, the porphyria fully resolved after renal transplantation.[148]

Toxic Porphyria Cutanea Tarda

In Turkey between 1956 and 1961, an epidemic of acquired porphyria affecting more than 3,000 people occurred as the result of exposure to flour contaminated with a seed-wheat fungicide, hexachlorobenzene.[149–151] Members of both sexes were affected, and many of the subjects were children. Affected people developed hepatomegaly, hypertrichosis, hyperpigmentation, uroporphyrinuria, and a photosensitive dermatosis. Uroporphyrinuria and a variety of other signs and symptoms persisted in some individuals for more than 25 years,[152,153] and no effective therapy has been devised for this toxic porphyria. Studies in animals demonstrated that hexachlorobenzene, or one of its metabolites, is a potent inhibitor of hepatic UROD.[154,155] Iron magnifies this inhibitory effect,[154] and clear genetic susceptibility to this type of acquired porphyria has been shown in mice.[156]

Other polyhalogenated aromatic hydrocarbons also have produced a toxic porphyria in humans. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin, a by-product in the manufacture of the herbicides 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, and some polychlorinated biphenyls have proved porphyrinogenic for humans.[157] Animal studies indicate that compounds

of this class inhibit hepatic UROD activity.[158] As in the case of hexachlorobenzene-induced porphyria, iron magnifies the inhibition of UROD, and iron depletion minimizes the inhibitory effect of these agents.[159] The parallel between the permissive effects of iron in these toxic porphyria models and the role of iron in the pathogenesis of both familial and sporadic PCT is striking.

Hepatocellular Carcinoma

An increased frequency of hepatocellular carcinomas is recognized in patients with PCT,[160,161,162] and such tumors are associated with a long symptomatic period before the start of treatment as well as with the presence of cirrhosis or chronic active hepatitis.[161] The body iron status is not known in these cases, but iron overload could also play a role. Thus, in the presence of hepatitis or cirrhosis, surveillance for hepatocellular carcinoma with regular hepatic imaging is indicated.

In contrast, documented evidence supports a PCT-like illness as a manifestation of porphyrin-producing hepatoma in an otherwise normal liver (paraneoplastic PCT) in several cases.[163,164,165,166] When the tumor could be surgically removed, the cutaneous symptoms and biochemical abnormalities remitted.[163,166]

Animal Models of Porphyria Cutanea Tarda

The first genetically designed animal model of PCT and HEP was developed in zebrafish, designated *yquem*.[167] Heterozygous and homozygous mutants have 67% and 36% of wild-type UROD activity, respectively. The enzyme deficiency was linked to a missense mutation in the *UROD* gene, predicting a Met38Arg substitution that involves a conserved amino acid across all species examined, including humans. The mutant phenotype could be rescued by transient and germline expression of the wild-type allele.

Transgenic mice with one disrupted *UROD* allele ($UROD^{+/-}$) have half the wild-type hepatic UROD protein and enzyme activity but no accumulation of porphyrins.[101] However, in response to iron loading, hepatic porphyrins accumulate, and UROD activity declines to 20%. When bred to $HFE^{-/-}$ mice, $UROD^{+/-}/HFE^{-/-}$ animals developed a porphyric phenotype with further reduction of UROD activity to 14%, resembling the human condition.

$HFE^{-/-}$ mice that are fed ethanol also develop uroporphyria and reduced hepatic UROD activity, seemingly mediated by effects of ethanol on hepatic iron metabolism.[168] Additional mouse models have been informative for understanding the susceptibility factors in PCT. CYP1A2 knockout mice are highly resistant to developing uroporphyria induced by chemicals.[169] In mice that are genetically unable to synthesize ascorbic acid, a threshold of body iron was demonstrated at which a biphenyl-induced uroporphyrin accumulation occurs despite ascorbate repletion.[170] Extensive study of such animal models of hepatic uroporphyria has provided a paradigm of the complex interactions among genetic factors, chemicals, drugs, and endogenous factors including iron homeostasis.[171]

PCT was identified in a flock of German Blackface sheep with clinical features similar to human PCT.[172] It is associated with a point mutation in the ovine gene, predicting the amino acid substitution Leu131Pro, which is located in the active site cleft of the UROD protein.

Erythropoietic Protoporphyria

Erythropoietic protoporphyria (EPP), the third porphyric disorder with only cutaneous manifestations, is not uncommon, with an estimated prevalence of 1 per 75,000 to 200,000. Since the first clear description of the disease by Magnus et al. in 1961,[173] hundreds of cases have been reported throughout the world.[20,174,175,176] Defects in the gene encoding ferrochelatase (FECH), the last enzyme in the heme biosynthetic pathway (Fig. 26.1), underlie most cases and result in accumulation of free protoporphyrin, mainly in erythroid tissue. The cutaneous manifestations are distinctive, but considerable individual variation is noted in clinical severity as well as in biochemical abnormalities. Three patterns of inheritance are recognized for the disorder (Table 26.2), and two variants occur.

Molecular Basis and Pathogenesis

Subnormal FECH activity is found in all tissues examined from patients with EPP, namely bone marrow,[177] reticulocytes,[178] liver,[179] cultured skin fibroblasts,[179] and lymphocytes.[180] However, the protoporphyrin accumulates principally, if not entirely, in erythroid cells,[181] whose contribution to heme production far exceeds that of all other tissues. Although the normal relative activity of FECH in erythroid tissue, in contrast to liver, is the second lowest among the enzymes of the heme biosynthetic pathway and is only three times higher than 5-aminolevulinate synthase,[19] defective FECH in EPP does not appear to be rate limiting until late in erythroid development.[177] Patients often exhibit a mild hypochromic-microcytic anemia as a consequence of the FECH deficiency that in turn appears to limit iron assimilation.[177,182,183,184] Protoporphyrin begins to accumulate in bone marrow erythroblasts just before the nucleus is lost,[185] and reticulocytes and young erythrocytes probably are the major source of protoporphyrin in plasma on its rapid release from these cells.[186,187] Because of its low water solubility, the protoporphyrin is not excreted in urine but is taken up by the liver and excreted exclusively through the biliary tract.

Based on clinical features and FECH activity in many pedigrees, inheritance of this porphyria was first believed to most often follow an autosomal dominant pattern with incomplete penetrance.[183,188] In a few families, autosomal recessive inheritance was evident.[174,189] However, FECH activity in tissue lysates from patients with clinical EPP is always only 20% to 30% of normal,[20,181] not the 50% value expected for an autosomal-dominant enzyme deficiency. Neither levels of FECH activity nor levels of erythrocyte and fecal protoporphyrin consistently correlate with severity of symptoms. Moreover, most obligate carriers of the disorder have no symptoms. Their erythrocyte and fecal protoporphyrin levels are usually normal, and tissue FECH activity is approximately 50% of normal.[20,179,181] To explain these findings, it was proposed that more than one allele is involved in the full expression of the disease.[174,190]

Upon the cloning and characterization of the human *FECH* gene,[191] which is located on chromosome 18 (18q21.3),[192] at least 187 different molecular defects have been identified and are highly heterogeneous, commonly as missense/nonsense mutations, nucleotide deletions and insertions, and intronic point mutations near intron/exon splice sites in one *FECH* allele.[10,192a] Most often, the defects lead to frameshifts or deletions, resulting in a truncated protein ("null allele"). The entire *FECH* gene was absent in one patient as a result of a chromosome 18q deletion.[193] Two types of regulatory defects in the gene have also been reported, impairing transcription due to hypermethylation of the promoter region[194] or a point mutation affecting transcription factor binding in the promoter.[195] In about 4% of cases a mutation is present on each allele, defining recessive inheritance,[10,196] where the majority are missense mutations. Although these few double heterozygotes clarify the phenotypic differences between symptomatic and asymptomatic family members, all other manifesting cases usually coinherit a "low-expression" normal *FECH* allele *trans* to a deleterious mutant allele.[197,198] The low-expression allele is highly associated with a specific ancestral haplotype involving a single nucleotide polymorphism site in the *FECH* gene (IVS3-48T/C) that influences the use of a constitutive aberrant acceptor splice site in the gene.[199] The aberrantly spliced RNA fraction is degraded, decreasing the steady-state level of FECH mRNA expressed by the allele by ≥20%. Hence the term

"pseudodominant EPP" came into use for patients with a *FECH* mutation *trans* to a hypomorphic IVS3-48C allele, to distinguish them from those with *autosomal recessive EPP* who are hetero- or homoallelic for *FECH* mutations. The frequency of the hypomorphic IVS3-48C allele differs widely between ethnic groups, ranging from 67.8% in Japanese to <1% in West Africans, and in general correlates with prevalence of clinical EPP among individuals with a mutant *FECH* allele in the different populations.[176] When a low-expression allele is not found, a dominant-negative effect of *FECH* mutants may be operative.[200] Because the enzyme activity is restricted to its homodimers,[201] a mutant monomer may generate nonfunctional homodimers and impaired or unstable heterodimers, resulting in residual enzyme activity of <50% of normal.[202,203] Thus, the ultimate effect of a specific mutation in the *FECH* gene depends on how it affects the integrity of the protein and whether the nonmutated allele is expressed at a lower level to reduce FECH activity to below a threshold of around 30% of normal as found in clinically overt EPP.

More recently a third pattern of inheritance of EPP that is X-linked was described and is referred to as *X-linked protoporphyria (XLPP)*.[204] In the United Kingdom and in the US, the disorder accounts for 2% and 10% of unrelated EPP patients, respectively.[192a,205] FECH enzyme activity is normal but erythrocyte protoporphyrin concentrations are higher than in EPP due to FECH deficiency. Around 40% is zinc protoporphyrin, indicating that the supply of the iron substrate as well as ferrochelatase activity becomes rate limiting. To date, five distinct mutations have been identified in exon 11 of the erythroid-specific 5-aminolevulinate synthase gene (*ALAS2*) (Fig. 26.1), which resides on the X chromosome, and lead to predicted amino acid sequence disruption or deletion of up to 40 C-terminal amino acids of the enzyme.[192a,204,205a] The recombinant mutants have two- to three-fold increased activity,[205b] explaining the protoporphyrin overproduction. This gain-of-function in the enzyme contrasts with all other previously described *ALAS2* mutations that decrease enzyme activity and cause X-linked sideroblastic anemia (Chapter 24). It also reflects a critical role of the C-terminal structure of ALAS2 for its activity and thus erythroid heme synthesis.

About 5% of EPP families in a large cohort were mutation-negative for *FECH* and *ALAS2*.[205] However, in these the disease was strongly associated with inheritance of the IVS3-48C allele and decreased FECH activity, suggesting that most may have mutations in regions of the *FECH* gene that are not included in current strategies for mutation detection. In one case mild photosensitivity was ascribed to the IVS3-48CC genotype alone.[205]

The pathophysiology of EPP is mediated by the accumulated protoporphyrin. As it leaks out of erythroid cells into plasma, it gains entry into tissues. It is extracted solely by the liver and secreted unchanged into the bile. The liver is capable of clearing large amounts of protoporphyrin, but its secretion across the canalicular membrane and into the bile appears to be rate limiting.[206] Yet despite microscopic evidence of hepatobiliary changes in many EPP patients, cholestasis leads to cirrhosis and hepatic failure in only a few (<5%).[207] This complication tends to be an abrupt event, is unrelenting, and is not predictable from prior biochemical features or the clinical course of the patient. However, it occurs more commonly in compound heterozygotes for two mutations[196] and in XLPP[204] than in heterozygotes. Profoundly reduced ferrochelatase activity predisposes to liver failure.[208] In an analysis of 112 EPP patients, all 18 who developed liver disease carried a null allele mutation, whereas none of 20 patients having missense mutations had liver disease as yet.[209] Undetected molecular derangements[194] or undefined hepatic factors,[210] including a greater hepatic source of the excess protoporphyrin related to the defect, can be postulated. Excess alcohol intake[211] and viral hepatitis,[212] as well as hyperthyroidism,[212a] also accentuate the genetic disorder.

In the skin, the hydrophobic protoporphyrin transfers to endothelial cells of capillaries to produce the light-induced skin damage in patients with EPP.[213,214] Porphyrin-sensitized, oxygen-dependent histochemical reactions and the activation of complement eliciting an inflammatory response are involved in the pathogenesis.[22,23] The extensive double-bond structure of the protoporphyrin renders it particularly photoactive, resulting in the unique acute epidermal phototoxicity,[173] in contrast to the porphyrins that accumulate in the other porphyrias with cutaneous photosensitivity. The activated porphyrin also stimulates fibroblast proliferation, accounting for a characteristic waxy thickening of the sun-exposed skin [23]

Variant Erythropoietic Protoporphyria

The presence of an abnormal transcript of mitoferrin 1 (MFRN1) associated with reduced FECH activity was identified in a series of 7 patients with the EPP phenotype but without genetic defects in FECH in 6 of them, although no cause for the aberrant splicing of MFRN1 mRNA was found in the MFRN1 sequence.[215] Four patients also had a previously reported C-terminal deletional ALAS2 mutation, and 4 cases had advanced liver disease. MFRN1, which transports iron into mitochondria, is highly expressed and regulated in erythroid cells.[216] A molecular complex of FECH protein, MFRN1 and ABCB10 (a MFRN1 stabilizer) integrates mitochondrial iron import with heme synthesis.[217] Thus, aberrant MFRN1 can contribute to the EPP phenotype in some patients, apparently by reducing FECH activity.

Late-onset Erythropoietic Protoporphyria Variant

EPP that is clinically indistinguishable from the inherited forms has developed in later years in the setting of a myelodysplastic syndrome[218] including the sideroblastic anemia subtype (Chapter 24),[19] or a myeloproliferative disorder.[219] Two cases were associated with severe cholestatic liver disease.[219,260] In several instances acquired deletion of one *FECH* gene was demonstrated.[218–220] An associated low-expression allele or a mutation in the other *FECH* allele, or altered erythroid heme biosynthesis in the dysplastic clone, likely contributes to the clinical expression in such cases. One case with late-onset XLPP has also been reported.[220a]

Clinical Description

EPP typically first manifests in childhood or early adolescence.[20,183,221] The cutaneous features of photosensitivity are unlike those seen in patients with other porphyrias; bullae, scarring, sensitivity to trauma, hypertrichosis, and hyperpigmentation are extremely unusual.[213] In some cases, the symptoms are only subjective.[222.223] Exposure to the sun (or to UV light) for periods of a few minutes up to several hours induces diffuse, intensely unpleasant sensations of prickling, itching, or burning (photoparesthesias) followed by the development of erythema, urticaria, and edema.[183,213] Less commonly, solar urticaria, a confluent, hivelike rash, occurs within minutes of exposure and lasts approximately 30 minutes.[173,213] In general, the signs and symptoms involve only the uncovered areas of the body and subside in the course of hours or days without significant sequelae.

Occasionally, these early reactions are followed within a day or two by vesicular eczematous lesions (solar eczema) that become crusted, last for several weeks, and heal with scar formation.[224] Chronic skin changes may include shallow pitted scars or pseudovesicles over the cheeks and nose and thickened leathery skin (pachydermia) over the dorsa of the hands (Fig. 26.4A and B).[183,213,224] Many cutaneous manifestations of EPP do not differ greatly from those found in patients with photosensitivity of unknown cause (so-called polymorphic light eruptions), which is common and is not associated with abnormal porphyrin metabolism. In one study of over 600 light-sensitive patients, only 8% were found to have laboratory evidence of EPP.[225]

A number of EPP patients have been identified with palmar keratoderma.[226] They represent a subtype of EPP, which is characterized by seasonal palmar keratoderma, relatively low erythrocyte protoporphyrin concentrations, and recessive inheritance

with different hetero- or homoallelic FECH mutations. These individuals appear to carry a lower risk of liver disease than other patients with recessive EPP.[226]

Cholelithiasis tends to develop early in life[183] and ultimately occurs in approximately 10% of patients. The gallstones fluoresce and consist, in part, of precipitated protoporphyrin.[20,227]

Although EPP is generally a benign disorder with clinical manifestations limited to the skin, as noted above a small subset of patients (<5%) develops progressive liver disease, leading to a fatal cirrhosis in the second to fourth decades of life.[207,209] At autopsy, massive hepatic deposits of protoporphyrin are found.[207,228] Associated with the fulminant liver failure are ris-

ing blood protoporphyrin levels with progressive cholestasis, hemolysis, increasing photosensitivity, and neurologic crises resembling those of the acute porphyrias.[207,229,230] The neurologic dysfunction was best correlated with a markedly increased level of plasma protoporphyrin and was believed to cause neurotoxicity, leading to axonal degeneration.[230]

Laboratory Findings

The free erythrocyte protoporphyrin (FEP) concentration is greatly increased in symptomatic patients. Reported values range from 600 to 4,500 μg/dl (normal, <50 μg/dl).[20,183] However, in the XLPP form of EPP about 40% of the protoporphyrin is in the form of zinc-protoporphyrin and total erythrocyte protoporpyrin values ranged from 1,130 to 11,000 μg/dl.[204] Increased levels of erythrocyte protoporphyrin are observed in certain other conditions, especially iron deficiency anemia and in lead poisoning, but only rarely do they exceed 300 μg/dl; the excess protoporphyrin is present as the zinc chelate[231] and is distinguished spectrally from the nonchelated FEP that is found in EPP and XLPP.[232] Plasma protoporphyrin is usually increased as well, and a normal plasma porphyrin in a patient with increased erythrocyte protoporphyrin may exclude EPP. In asymptomatic carriers, the FEP ranges from normal values to 200 μg/dl.[20] The life-threatening liver disease may be predicted by increasing FEP and plasma protoporphyrin levels along with altered liver function tests. In patients with severe protoporphyric liver disease, the FEP concentration generally exceeds 2,000 μg/dl, and values >8,000 μg/dl have been reported.[207]

Fluorescence microscopy of a dilute suspension of freshly obtained blood reveals fluorescence in a variable proportion of erythrocytes (Fig. 26.4C).[173] Protoporphyrin is increased chiefly in young erythrocytes[186] but is heterogeneous, and a population of reticulocytes without protoporphyrin is also present, reflecting a nonuniform expression of the genetic defect at the cellular level.[187] In asymptomatic carriers, a small population of such fluorocytes may be detected even when the FEP concentration is normal.[174]

Most patients with EPP have mild, slightly hypochromic anemia and reduced iron stores.[182,183,184,225] Studies of red cell survival and iron kinetics have failed to detect a characteristic abnormality,[20,225] but hemolysis was occasionally reported.[233] Severe hemolytic anemia may occur with advanced hepatic disease that is exacerbated by photo-oxidative stress occurring during the prolonged operative procedure of liver transplantation.[234] Why some cases exhibit the ring sideroblast abnormality in erythroblasts (Chapter 24)[235,236] but others do not[177] is not clear and may relate to the nature of the defect. This feature has not been systematically studied.

Fecal protoporphyrin excretion usually is increased in symptomatic patients.[183] Values may be as high as 1,400 μg/g (dry weight; normal, <100 μg/g) and vary widely from patient to patient, although variations in a given patient are not great.[237] In some carriers, fecal protoporphyrin is increased even when the FEP is normal. An increasing ratio of FEP to fecal protoporphyrin and an increasing ratio of biliary protoporphyrin to biliary bile acids may also suggest impending hepatic decompensation.[207,237,238] Urinary porphyrin and porphyrin precursor concentrations are normal.

The majority of patients with EPP have no clinical evidence of liver disease, although 20% to 30% have slight elevations of liver enzymes; in the eight families with XLPP a higher percentage of liver dysfunction was noted.[204] However, in most if not all cases, the liver contains dark brown pigment deposits (Fig. 26.4D) in hepatocytes, Kupffer cells, and portal macrophages as well as within the lumens of ductules and interlobular ducts that exhibit the characteristic red fluorescence of protoporphyrin when transilluminated with light of wavelength 380 to 500 nm.[239] These deposits are crystalline in nature on electron microscopy. They also exhibit a distinctive type of birefringence, not shared by any other pigment known to occur in the liver, that is demonstrable in routinely fixed and stained paraffin-embedded sections and is as sensitive as the red fluorescence (Fig. 26.4E).[239] Not infrequently, the pigmentation is accompanied by bile stasis and varying degrees of portal inflammation, fibrosis, and ductular proliferation. In patients who have developed the protoporphyric liver disease, liver histology shows micronodular or macronodular cirrhosis and massive deposits of the pigment throughout.[207]

DNA analysis with amplification of exons and flanking intronic sequences has detected FECH or ALAS2 mutations in about 95% of patients with EPP.[176,205] As large intragenic deletions in *FECH* are not uncommon their identification requires the use of a gene dosage analysis method.[240] EPP patients are at risk of vitamin D deficiency and monitoring 25-hydroxyvitamin D is advised.[241,242]

Treatment

Therapy is directed at reducing the consequences of sun exposure and minimizing the hepatotoxic effects of protoporphyrin. Topical sunscreens must be effective in the 400-nm portion of the spectrum to be useful. The only readily available effective topical preparations are opaque formulations containing oxidates of zinc or titanium. Most proprietary sunscreens contain compounds that reduce transmission only of the sun-burning portion of the spectrum between 290 and 320 nm. The induction of carotenemia (serum carotene levels above 400 μg/dl) can be effective in reducing photosensitivity,[213] although some studies suggested lack of efficacy.[243] Carotenemia is best induced by the administration of synthetic β-carotene beadlets (Lumitene™, Tishcon Corporation, Westbury, NY) in adults at a dose of 120 to 180 mg/day, but doses up to 300 mg/day may be needed.[244] The ability of carotene to quench photoexcited oxygen and to scavenge highly reactive free radicals probably explains its action.[245] Increased tolerance to sunlight occurs after 3 to 4 weeks of treatment, and the protective effect may last 4 to 8 weeks after cessation of the drug.[213] In northern climates, this therapy may be required only in spring and summer, but winter sports enthusiasts may benefit from more prolonged therapy. To date, no significant side effects have been reported in patients using β-carotene.

In patients unresponsive to β-carotene, narrow-band ultraviolet B (TL-01) phototherapy and psoralen and ultraviolet A light treatment have been effective.[246,247] Two patients experienced marked reduction in photosensitivity with administration of pyridoxine.[248] Oral cysteine also appears to be effective as a free radical quencher,[249] and, in a preliminary report, a flavonoid mixture (hydroxyethylrutosides) was effective as an antioxidant.[250]

An α-melanocyte-stimulating-hormone analog, afamelanotide (Scenesse™, Clinuvel, Melbourne, Australia), is probably the most effective agent for alleviating the photosensitivity of EPP by promoting melanin synthesis and increasing skin pigmentation.[251,252] It has become available in some European countries and is currently in a Phase 3 clinical trial in the United States. The preparation is a 16-mg sustained-release resorbable implant (grain of rice size) formulation of afamelanotide that is inserted subcutaneously. Studies to date showed that this prophylactic treatment significantly increased sunlight tolerance and improved quality of life.

Multiple attempts to minimize the hepatotoxic effects of protoporphyrin have been directed at both reducing the amount of protoporphyrin presented to the liver for excretion and depleting hepatic protoporphyrin stores. Suppression of erythropoiesis and the erythrocyte protoporphyrin accumulation can be achieved with transfusion therapy,[253] but the hazards of transfusion-induced iron overload and the risk of transfusion-related infectious disorders make this form of therapy undesirable. Administration of iron with the rationale of enhancing porphyrin conversion to heme was followed by decreases in stool

and erythrocyte porphyrins and improved liver function,[254] but the disease was aggravated by oral iron therapy in others.[255] The use of nonabsorbable porphyrin binders, namely cholestyramine and activated charcoal, aimed at reducing enterohepatic recirculation of porphyrin, and/or bile acids, to promote fecal porphyrin excretion have benefited selected patients.[256–258] None of these approaches is well established, owing to inconsistent or uncertain efficacy and experience in relatively few cases.

In some patients with liver failure, the circulating protoporphyrin burden could be reduced by hemin infusion, plasma exchange, red cell exchange, or by extracorporeal albumin dialysis [259,260]; parenteral and oral n-acetyl cysteine was beneficial in one case.[261] Once severe liver damage has occurred, usually no form of medical therapy is effective. Thus, liver transplantation was undertaken as a life-saving measure.[262,263] The results have been favorable in part, with patient and graft survival rates up to 66% at 5 years.[263,264,265] However, the protoporphyrin burden from erythroid tissue remains and recurrence of protoporphyrin hepatopathy is common, supporting most evidence that the primary if not the only contribution of the excess protoporphyrin is from bone marrow. Moreover, in a case with EPP due to heteroallelic FECH mutations and coincidental acute leukemia, a successful marrow transplant from a sibling carrying one FECH mutation cured the patient's manifestations of the porphyria.[266] HSCT has also been performed in four EPP patients with a prior liver transplant to treat or prevent disease recurrence in the graft.[267,268] Although in three of the four cases successful engraftment led to clinical and biochemical resolution, two succumbed to infectious complications. In a fifth patient bone marrow transplantation following medical control of severe progressive protoporphyrin cholestasis was curative.[269] Apart from its inherent risks, HSCT would appear to be the ideal treatment in EPP patients prone to severe liver disease before liver transplantation becomes necessary. Identification of patients at risk of severe liver disease remains the principal challenge.

The most definitive treatment for the disease would be replacement of the defective gene in affected tissues. Targeting the hematopoietic stem cells with gene therapy will probably suffice once it is technically feasible. In vitro studies have demonstrated effective transfer of normal FECH complementary DNA into cultured fibroblasts from patients with EPP with correction of the biochemical defect.[270,271] Genetic analysis of EPP patients' spouses for carrier status of a *FECH* mutation and a low-output *FECH* allele allows assessment for the probability of clinical disease in offspring as well as prenatal testing or pre-implantation genetic diagnosis.

Erythropoietic Protoporphyria in Animals

Bovine EPP was described in 1977[272] and is transmitted as an autosomal recessive trait.[273] Affected calves have acute photosensitization during the first few weeks of life, the erythrocyte and fecal protoporphyrin is greatly increased, and FECH is reduced to 10% in all tissues examined.[181] The animals do not develop anemia or hepatobiliary disease. Carrier dams have approximately half the normal FECH activity. DNA analysis revealed a novel stop codon mutation (X417L).[274]

A protoporphyric disorder occurs in mice that are fed a diet containing 2.5% by weight of griseofulvin and exhibits a pronounced hepatic component.[275] It is similar in many respects to the human disease, and the hepatic histopathologic abnormalities are indistinguishable by light or electron microscopy.[276–278] Another murine EPP (*fch*) is produced by chemical mutagenesis with ethylnitrosourea.[279] It is characterized by photosensitivity, severe hepatobiliary dysfunction in early life, and microcytic hypochromic anemia as well as a redistribution of storage iron to the spleen.[280] FECH activity in various tissues is 2.7% to 6.3% of normal in homozygotes and approximately 50% in heterozygotes. A point mutation has been identified in the *FECH* gene (*Fechm1Pas*), and prokaryotic expression studies have substantiated it as the basis for the porphyria.[281] Bone marrow transplantation is effective in this mouse model.[282] Moreover, reversal of the phenotype and restoration of normal hematopoiesis have been achieved with pre-selective gene therapy[283,284] as well as with the use of a dual gene therapy technology.[285] A third mouse model exhibiting a protoporphyria is produced by targeted deletion of iron-regulatory protein 2 (IRP2).[286] The phenotype is manifested by iron-limited erythropoiesis, marked overexpression of ALAS2 from loss of IRP-dependent translational repression, and markedly increased levels of free and zinc protoporphyrin. These features closely resemble those of XLDPP.

A genetically designed model of EPP was developed in zebrafish named *dracula*.[287] Protoporphyrin IX accumulates in the mutant embryos, and the phenotype shows light-dependent hemolysis and liver disease. The mutation is a G to T transversion at a splice donor site in the *FECH* gene and creates a stop codon.

ACUTE OR INDUCIBLE PORPHYRIAS WITH NEUROLOGIC MANIFESTATIONS

Porphyrias manifesting neurologic and psychiatric illness are called *acute porphyrias* to reflect the often abrupt onset of symptoms. They are also referred to as *inducible porphyrias* because symptoms are usually brought on by endogenous or exogenous factors that stimulate heme biosynthesis through certain biochemical mechanisms. These disorders are deficiencies of the remaining four enzymes of the heme synthetic pathway that restrict the capacity for the production of heme in the liver and lead to derepression of ALA synthase: PBGD, ALA dehydratase (ALAD), coproporphyrinogen oxidase (CPOX), and protoporphyrinogen oxidase (PPOX) (Fig. 26.1). During acute attacks, hepatic ALA synthase is markedly induced, and the porphyrin precursors ALA and PBG accumulate because PBGD becomes rate limiting, normally having the second lowest relative activity among the enzymes of the hepatic heme synthetic pathway.[19] These events are best understood in the liver, and they may occur in neural tissue. Deficiencies of CPOX and PPOX also result in accumulation of their respective porphyrin substrates and therefore can be accompanied by photosensitivity, whereas only the precursors accumulate with deficient PBGD and ALAD, and photosensitivity does not occur.

Acute Intermittent Porphyria

Patients with *acute intermittent porphyria* (AIP; pyrroloporphyria, Swedish porphyria) were probably reported by Gunther.[4] The extensive family studies in Sweden by Waldenström provided the first comprehensive description of the disorder.[57] It is transmitted in an autosomal dominant manner with low penetrance and results from mutations in the gene encoding PBGD (hydroxymethylbilane synthase, uroporphyrinogen I synthase) (Fig. 26.1).[288] The prevalence of the trait in most countries had been estimated at 1 to 2 per 100,000.[20] More recent population screening studies in northern Europe with enzyme assays and DNA analysis indicate a much higher prevalence of carriers, ranging from 1 to 2 per 10,000, and an even higher prevalence in Sweden and France.[20] A study of psychiatric patients in the United States showed a higher prevalence of AIP than in the general population (approximately 0.21%).[289]

Molecular Basis and Pathogenesis

A decreased conversion of PBG to porphyrins observed in liver tissue from patients with AIP provided the first evidence that the enzyme PBGD is defective.[290] Decreased catalytic activity of PBGD to approximately half of normal was subsequently demonstrated

in all tissues examined, including liver,[291] erythrocytes,[292] cultured skin fibroblasts,[293,294] cultured amniotic cells,[294] and mitogen-stimulated lymphocytes.[295] Considerable heterogeneity of the defect became evident from biochemical and immunologic studies of the enzyme in erythrocytes from patients with AIP. Up to 10% of unrelated and clinically affected individuals had either normal or indeterminate levels of erythrocyte PBG-D activity.[296,297,298] Overlapping enzyme activity levels could be resolved with internal family reference values,[299] consistent with apparent genetic regulation of the enzyme activity.[300] Patients with normal erythrocyte PBGD activity responded to an ALA loading test with increased excretion of PBG and reduced excretion of fecal protoporphyrin, just like patients with low PBGD activity in erythrocytes, suggesting that the defect is expressed in the liver but not in erythrocytes.[301] Approximately 80% of patients with half-normal PBGD catalytic activity were found to have half-normal PBGD protein concentration, referred to as *cross-reacting immunologic material negative*, and approximately 20% of pedigrees were *cross-reacting immunologic material positive* (i.e., the PBGD catalytic activity was half-normal, but the PBGD protein was normal or even increased).[288,302] In addition, molecular heterogeneity was indicated by detection of differing restriction haplotypes for the *PBGD* gene locus.[288,303]

After the cloning and sequencing of the *PBGD* gene,[304] the molecular basis for two isoforms of the enzyme was established,[305,306,307] and genetic defects responsible for AIP could be identified. A single *PBGD* gene, located in the chromosomal region 11q23.3,[308] under the control of two independently regulated promoters, produces two transcripts through alternative splicing. In the mRNA of the enzyme produced in all cells (ubiquitous mRNA), exon 1 is spliced to exon 3, whereas exon 1 is excluded in the transcript in erythroid cells, and translation begins in exon 3 (Fig. 26.5). Thus, the erythroid-specific protein lacks the 17 amino acids that are encoded by exon 1 for the ubiquitous enzyme.

Close to 400 different mutations have been identified in the *PBGD* gene, most of which were found in single pedigrees.[10,288,309] High frequencies of a few mutations in restricted geographic areas (e.g., Sweden, The Netherlands, Switzerland, Canada, Argentina) are believed to represent founder effects.[288] On the other hand, approximately 3% of all index cases with AIP may have de novo mutations.[310] Approximately two thirds of mutations are single-base substitutions, and the remaining mutations consist of insertions or deletions, resulting in a spectrum of splice defects of transcripts, frameshifts, stop codons, unstable proteins, or reduced catalytic activities of the enzyme; a few are in the promoter region of the gene.[10,288,309,311] The least common mutations (i.e., involving the exon 1–intron 1 junction or exon 1) restrict the PBGD defect to nonerythroid tissues and account for the normal activity of the enzyme in erythrocytes observed in such cases. In four families, double heterozygotes or homozygotes for point mutations had severe PBGD deficiency.[312,313,314,315] Although, in general, no correlation between the genotypes and phenotypes has been found, some prevalent mutations exhibit higher penetrance.[316,317] Using the knowledge of the three-dimensional structure of PBGD, structural and functional outcomes of the mutations can be predicted.[318,319] For instance, many mutations change amino acids in the vicinity of the active site of the enzyme, and a number of these are involved in binding the primer or substrate of the enzyme; others perturb conformation of the protein.

The genetic lesion and its wide spectrum underlying AIP are well defined; however, the pathogenesis of the clinical manifestations remains poorly understood. Several mechanisms have been postulated for the neurovisceral symptoms and signs that characterize the disorder.[20] The prevailing one is that the porphyrin precursor ALA, which accumulates after the induction of hepatic ALA synthase (ALAS1)[320,321] in response to diminished cellular heme because of the PBGD deficiency, is toxic to the nervous system. Studies in animals indicate that ALA can alter neural structure and function as an agonist for γ-aminobutyric acid receptors,[322,323] it inhibits release of neurotransmitters at neuromuscular junctions[324,325] and spinal cord synapses,[326] and it exerts lethal effects on neuronal and glial cells in culture.[327] Additional support for ALA as the responsible neurotoxin are the observations that patients with severe ALAD deficiency (see below) and patients with hereditary tyrosinemia,[328] both of whom excrete excess ALA but not PBG, display neurologic features similar to those of patients with AIP. Furthermore, the finding that liver transplantation in patients with AIP promptly normalizes the

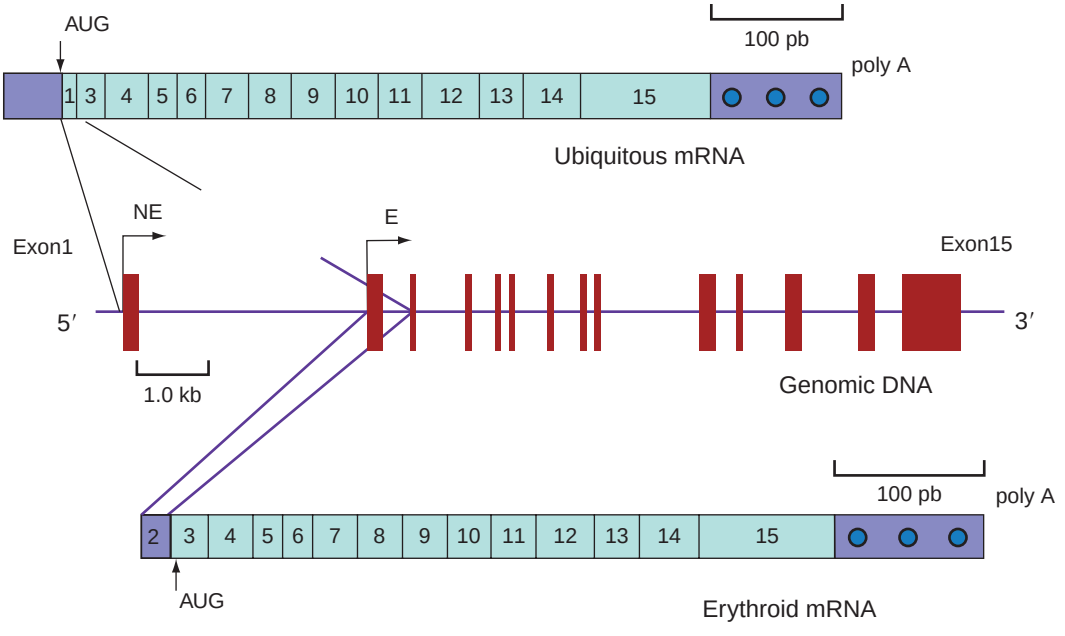

FIGURE 26.5. Structure of the human PBG deaminase gene and its two transcripts produced by alternative splicing. E, erythroid promoter; NE, nonerythroid promoter. (From Deybach J-C, Puy H. Acute intermittent porphyria: from clinical to molecular aspects. In: Kadish KM, Smith KM, Guilard R, eds. The porphyrin handbook–medical aspects of porphyrins, vol. 14. Amsterdam: Academic Press, 2003;14:23–41, with permission.)

overproduction of ALA and PBG and eliminates chronic debilitating neurovisceral attacks has established the hepatic overproduction of the porphyrin precursors as the cause of the neurologic symptoms.[329,330,331] On the other hand, urine and serum levels of ALA, along with PBG, correlate only roughly with symptoms and signs.[321] It has not been possible to produce an acute porphyric attack by administering ALA to animals,[332] a normal human subject,[333] or even patients with latent porphyria,[334] although convulsion can be induced by intraventricular injection of ALA and PBG in rats.[334,335]

A second postulated mechanism has been that episodic depletion of cellular heme from marginal to critical levels deprives enzymatic oxidations and energy-producing reactions involving hemoproteins in neural tissues.[320,336] Experimental inhibition of the heme biosynthetic pathway in dorsal root ganglia cultures causes severe segmental degeneration.[337] The administration of heme to patients suffering an acute porphyric attack usually reverses the neuropathic manifestations, but this effect more likely results from inhibition of the hepatic ALA overproduction by the heme (Fig. 26.1); it is not known whether intravenously administered heme enters the brain.

Another mechanism was suggested by studies in animals that implicated accumulation of neurotoxic levels of tryptophan and serotonin. Heme depletion impairs catabolism of tryptophan by the heme-dependent enzyme hepatic tryptophan pyrrolase.[338,339] In one study, patients with attacks of AIP had serum levels of tryptophan, serotonin, and urinary 5-hydroxyindoleacetic acid that were above normal and that declined after heme administration.[340] Levels of melatonin, implicated in the regulation of the circadian rhythm, were found to be decreased. Results of studies in animals and in cultured pineal glands suggested that melatonin may also be involved in the regulation of heme synthesis in some manner.[341]

Most people (approximately 90%) heterozygous for the PBGD defect never have symptoms, but certain precipitating factors cause both biochemical and clinical evidence of the porphyric diathesis. Steroid compounds, both endogenous and synthetic, and medications are the most commonly identified precipitating factors of symptoms.[20] Gonadal hormones, especially the 5-β steroids and ovarian hormones or their metabolites, are most significant and are potent inducers of hepatic ALA synthase.[20] They probably account for the typical onset of symptoms in early adulthood, as well as for the susceptibility of women to porphyric attacks during the luteal phase of the menstrual cycle, when progesterone is high. Hence, the benefit of agonistic analogs of luteinizing hormone-releasing hormone (LHRH) can be attributed to induction of pituitary refractoriness to LHRH to suppress production of progesterone and its 5-β metabolites.[342] The barbiturates and sulfonamides head the list of countless drugs that can provoke porphyric attacks and usually do so by inducing hepatic cytochrome P450 enzymes for their metabolism via microsomal hydroxylation, thereby increasing the need for hepatocellular heme and leading to induction of ALA synthase,[20] or by direct transcriptional activation of ALA synthase.[343] However, the response of patients is highly variable.[20,344] Dieting or decreased caloric intake with intercurrent illness may precede acute attacks. With carbohydrate administration, through high doses of glucose, the urinary excretion of ALA and PBG often strikingly decreases, and symptoms tend to improve.[321,345] The missing link of this fasting-feeding response by the liver was found to be in the regulation of hepatic ALA synthase by PGC-1α.[346] Although this transcriptional co-activator mediates hepatic gluconeogenesis and fatty acid oxidation in response to fasting, it also induces ALA synthase.

Clinical Description

The clinical features of the defect are typically acute symptoms and signs reflecting neurovisceral and psychiatric deficits (Table 26.3).

TABLE 26.3

SIGNS AND SYMPTOMS OF ACUTE INTERMITTENT PORPHYRIA

Signs and Symptoms	Incidence (%)
Abdominal pain	85–95
Vomiting	43–88
Constipation	48–84
Tachycardia	28–80
Muscle weakness	42–68
Mental changes	40–58
Hypertension	36–54
Extra-abdominal pains	50–52
Sensory deficit	9–38
Fever	9–37
Convulsions	10–20
Respiratory paralysis	9–14

Data from three reports, 417 patients: Stein JA, Tschudy DP. Acute intermittent porphyria. A clinical and biochemical study of 46 patients.Medicine 1970;49:1–16; Waldenström J. The porphyrias as inborn errors of metabolism. Am J Med 1957;22:758–773; and Goldberg A. Acute intermittent porphyria: a study of 50 cases. QJM 1959;28:183–209.

They are more common in women and are highly variable, even among affected siblings. Attacks usually last for several days to even several months and are separated by symptomless intervals varying from months to decades. Patients may have as few as three attacks in a lifetime or several per year (Fig. 26.6).[321] Most often, the acute attack is an autonomic neuropathy manifested by moderate to severe abdominal pain that is unrelenting, at times cramping, variable in location, and characteristically accompanied by constipation, which may be severe, and often vomiting (Table 26.3). In some cases, pain is predominant in the back and limbs. The abdomen is usually soft, with no rebound tenderness or other signs of peritoneal irritation, and dilated bowel loops may be palpable. The abdominal radiograph may show evidence of segmental intestinal dilation and spasm. Other common findings are tachycardia, labile hypertension or hypotension, and urinary retention.[321] The pulse

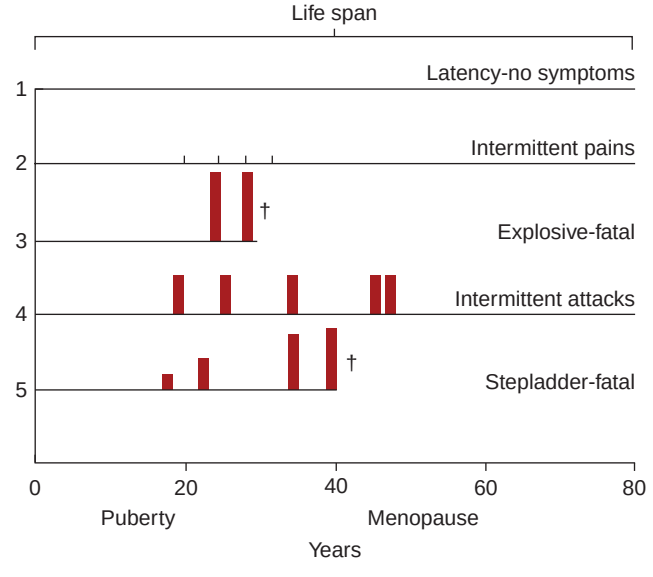

FIGURE 26.6. Typical courses of acute intermittent porphyria. (From Moore MR, McColl KEL, Rimington C. Disorders of porphyrin metabolism. New York: Plenum, 1987:79, with permission.)

rate is often considered a good index for judging the activity of the disease and even the diagnosis.[347]

Less often, and with prolonged or more severe attacks, peripheral motor neuropathy occurs. Symptoms include weakness in one or more extremities, especially the upper extremities and proximal musculature, that may progress to flaccid quadriparesis.[348,349] Bulbar and respiratory muscle paralysis can be life-threatening. Blindness has resulted from both occipital lobe and optic nerve involvement.[321,350,351] Sensory abnormalities occur less often. The extreme variability of neurologic abnormalities is further indicated by manifestations of central nervous system disturbances. Acute anxiety and emotional lability with progression to confusion, frank psychosis, and coma occasionally dominate the clinical presentation.[349,352–354] Tonic-clonic seizures occurred in 17% to 32% in two series of patients,[321,355] whereas lifetime prevalence of seizures among patients in Sweden was only 5%.[356] Seizures may result from profound hyponatremia caused by inappropriate antidiuretic hormone secretion, reflecting hypothalamic dysfunction, or may be a cerebral manifestation of the metabolic defect.[20,321] Death may occur when psychomotor manifestations intensify, or from cardiac arrhythmia.[321]

In older reports, the mortality rate from neurologic involvement was approximately 30%.[357] Improvement in supportive care in the 1970s reduced the mortality rate to approximately 10%,[344,345] and the introduction of therapy with intravenous heme reduced the mortality rate further.[355,358] Nevertheless, delayed diagnosis of severe attacks in particular continues to occur up to the present, leading to marked disability or a fatal outcome.[359,360] If peripheral nerve deficits develop, they may clear slowly, over months or years, or never completely. Depression, including suicidal tendencies, may occur with frequent attacks or with chronic symptoms.[355]

Chronic hypertension and renal impairment develop in up to 50% of patients with AIP as late complications.[344,356,361,362] The hypertension may predispose and nephrotoxic effects of porphyrin precursors may contribute to renal insufficiency.[363] Moreover, end-stage renal disease is associated with higher plasma ALA/PBG levels and accumulation of plasma porphyrins, leading to progression of peripheral neuropathy and even cutaneous lesions resembling PCT. In such cases combined liver and kidney transplantation should be considered.[331,364]

Several studies indicate a significant association between *primary liver cancer* and AIP in European countries.[362] In Sweden, where the incidence of AIP is high, in the latest analyses the annual occurrence of hepatocellular carcinoma in AIP gene carriers was 0.8%,[365,365a] and in France and Switzerland 0.3% and 0.16%, respectively.[366] Liver cirrhosis and other risk factors, such as alcohol and viral hepatitis, were uncommon in these series.[362,366] Impaired detoxification capacity of mutagenic substances by the liver with impaired heme synthesis or toxicity of ALA are thought to enhance a genetic change over time. In Sweden it is recommended that all patients carrying an acute porphyria gene be screened yearly for hepatocellular carcinoma after age 50 using liver imaging.[365] In one patient with hepatoma but not porphyria, the tumor produced large amounts of PBG as an apparent paraneoplastic feature.[367]

The few reported children homozygous for the genetic defect[313,314,315,368] manifested central nervous system defects, including hypoplasia of brain structures and altered postnatal cerebral myelination, with variable developmental delay and neurologic deficits. Neurovisceral features were not observed.

Laboratory Findings

Results of routine hematologic measurements usually are within normal limits; however, leukocytosis occasionally is observed during acute attacks,[321] a finding that may support an erroneous impression of an abdominal condition requiring an emergency operation. Anemia is an uncommon finding and, when present, may not be related to the porphyria.[321] Some patients have an unexplained reduction in both the plasma volume and the red cell mass even though the volume of packed red cells is normal.[369] Red cell survival is normal, suggesting that the decreased red cell mass results from reduced erythropoiesis.

The telltale urinary overexcretion of the porphyrin precursors, PBG and, to a lesser extent ALA, is diagnostic. The ratio of PBG to ALA in urine is usually 3:1, whereas in lead poisoning, ALA dehydratase porphyria (see below) and hereditary tyrosinemia urinary ALA is markedly increased but PBG is normal or only slightly raised. Normally, <7 mg of ALA and <4 mg of PBG are excreted in 24 hours regardless of the analytic method used. During acute attacks, the urinary excretion of PBG generally ranges from 20 to 200 mg daily.[321,370] In one study, 21 symptomatic patients excreted an average of 83 mg of PBG in 24 hours (range, 8 to 150 mg).[321] A rough correlation exists between the amount of PBG excreted and the severity of clinical symptoms. ALA and PBG excretion diminishes during remission and may return to normal. In 12 asymptomatic patients, the average urinary PBG excretion was 32 mg in 24 hours (range, 12 to 60 mg), and ALA excretion was 10 mg in 24 hours (range, 6 to 18 mg).[321] Serum normally contains only trace amounts of ALA and PBG, but patients with AIP may have serum PBG concentrations as high as 300 μg/dl during acute attacks.[20] Increases in the liver content of ALA and PBG have been noted at autopsy in patients who died during acute attacks.

A rapid qualitative method of detecting excess PBG in urine is the Watson-Schwartz test.[370] This test yields negative results in normal subjects and positive results when PBG excretion exceeds approximately 6 mg/L.[371] Other urinary chromogens, particularly urobilinogen, as well as certain drugs and drug metabolites may also form a similar color when they react with Ehrlich reagent, but only the PBG–Ehrlich complex is water soluble and cannot be extracted with chloroform and butanol. When properly performed and interpreted, the Watson-Schwartz test is reliable. In inexperienced hands, false-positive results are common; in one referral center, 75% of patients with supposedly positive findings had normal values when quantified by chromatography.[321] The commercial PBG Test Kit (Thermo Fisher Scientific Inc., Middleton, VA) is recommended for rapid detection of PBG in urine.[372] The urine should also be saved for subsequent quantitation of ALA and PBG by ion exchange chromatography[373] and of porphyrins for specific diagnosis of the type of acute porphyria.

Because PBG is a colorless compound, freshly excreted urine from patients with AIP appears normal in color. On exposure to light and air, two reactions are accelerated that cause PBG-containing urine to darken on storage. First, PBG is oxidized to porphobilin, a dark brown, amorphous product.[374] Second, PBG may be nonenzymatically converted to a mixture of porphyrins, especially uroporphyrin, a reaction favored at acidic pH, and quantitation of uroporphyrin and coproporphyrin in urine then detects mild to moderate elevations.[371] Therefore, the so-called urine porphyrin screen commonly carried out is also positive. However, it merely detects an increased concentration of coproporphyrin, which is associated with a variety of illnesses, and thus of no diagnostic value. Fecal porphyrin excretion is normal or only slightly increased.[20,375]

Another useful measurement for diagnosis and detection of relatives with the latent defect, in whom urinary PBG excretion is often normal,[292,298] is the erythrocyte PBGD activity, provided it is recognized that the erythrocyte value may be indeterminate or normal in up to 10% of cases because of heterogeneity of *PBGD* mutations and, rarely, because the enzyme is not affected in red cells.[296,297,298,299] If biochemical studies indicate the presence of AIP, DNA analysis is encouraged to identify the

disease-causing mutation.[376] The marked genetic heterogeneity encountered precludes the feasibility of a routine genetic test for diagnosis, although molecular techniques have been refined to localize the region of a mutation and simplify sequencing of the relevant DNA segment of new probands. Then, carriers within the family are easy to detect for preventive measures.

Hyponatremia, reduced blood volume, and mild elevation of blood urea nitrogen often are observed during acute attacks.[321] The findings may be attributed to vomiting. The syndrome of inappropriate antidiuretic hormone secretion has been documented[20,321] and is presumably the result of a hypothalamic abnormality. When carefully sought, other evidence for hypothalamic involvement is found, such as disturbed regulation of growth hormone and adrenocorticotropic hormone secretion. However, the increased antidiuretic hormone secretion may be an appropriate response in patients with unexplained reduction in total blood volume,[377] and fluid restriction would not be proper therapy for such patients. In one study of 45 patients hospitalized for acute porphyric attacks, hyponatremia was more often related to vomiting, poor intake, and excess renal sodium loss than to inappropriate secretion of antidiuretic hormone.[378] Hypomagnesemia associated with tetany has also been reported.[345]

Abnormal electroencephalographic patterns are a common laboratory sign of the neurologic dysfunction. Diffuse nonspecific slowing of the wave pattern was found in 14 of 24 patients during an acute attack.[321] In the presence of encephalopathy, magnetic resonance (MR) imaging studies have usually shown reversible contrast-enhancing subcortical white matter lesions of variable size with normal diffusion-weighted MR images, interpreted to represent vasogenic edema.[379,380] In some cases with cortical blindness, similar lesions were limited to the occipital lobes.[381] The cerebrospinal fluid usually is normal. The peripheral neuropathy is a "dying back" process in which neuron damage follows axonal demyelination.[20,348] Electrophysiologic studies and microscopic examination of nervous tissue[382–384] indicate that the acute attack affects primarily neuronal bodies, leading to an acute axonal degeneration of peripheral and autonomic nerves and to neuronal loss and gliosis in the central nervous system. In patients with latent porphyria, slower motor and sensory conduction velocities are detectable,[385] as is parasympathetic dysfunction of peripheral nerves when assessed with bedside tests of cardiovascular reflexes.[386] Parasympathetic dysfunction has also been demonstrated by spectral analysis of heart rate variability,[387] which may predispose to arrhythmias in symptomatic and latent disease.

Treatment

When an acute attack occurs, patients usually require hospitalization because the clinical course is difficult to predict, and causes for the symptoms other than porphyria must be excluded. Precipitating factors should be removed, but often the specific factor in a particular attack cannot be identified. Pain should be treated with safe analgesics and narcotics such as morphine. Fluid, electrolyte, and caloric deficits should be restored. Carbohydrate is administered intravenously (as 10% dextrose) so that the equivalent of 300 to 500 g of glucose is given daily.[321,345,376] Propranolol has been effective in reducing tachycardia and hypertension in some patients[388] but must be used very cautiously if at all in patients with hypovolemia.[389] Maintenance of the patient's morale and alleviation of fear are also important and facilitate recovery.

Although carbohydrate loading may suffice for mild attacks, for most acute attacks the very effective therapy with intravenous hemin (a soluble hydroxyl derivative of heme) should be started.[376] This compound has been used in therapeutic trials since the early 1970s,[390,391] with the rationale being to correct the apparent heme deficiency and repress hepatic ALA synthase and thus the overproduction of porphyrin precursors. Hemin became commercially available in 1983 (Panhematin™, currently supplied by Lundbeck, Inc., Deerfield, IL, 313 mg of hemin/vial), and its use in the treatment of the acute attack was a major advance. Early initiation of this therapy leads to a more rapid response and fewer residual neural deficits.[376,392] The lyophilized hemin is best reconstituted with albumin to enhance stability[393] and is administered at a dose of 3 to 5 mg/kg body weight once daily for 4 to 5 days. Phlebitis at the site of injection may occur.

After infusion of hemin, dramatic reductions in ALA and PBG concentrations in serum and urine are observed, and clinical symptoms often improve within 24 to 48 hours. Because of instability of the hemin in solution, thrombocytopenia and a mild transient coagulopathy manifested by prolongation of both the partial thromboplastin time and the prothrombin time occurred with some regularity during hemin infusion therapy and are attributed to degradation products of hemin.[394,395] Reconstitution of the compound with albumin decreases the incidence of phlebitis and prevents the anticoagulant effect.[376,393] A Finnish preparation, heme arginate, is more stable and does not produce coagulopathy.[396] This product is not available in the United States but has been introduced in Canada (Normosang™, distributed by Medunik Canada). The patient's therapeutic and clinical course is best monitored with plasma PBG determination.[397] Tin protoporphyrin, an inhibitor of heme oxygenase, in combination with heme arginate restored efficacy when tolerance to the heme developed, but it is not widely available.

The management of seizures is a considerable challenge. If they are related to metabolic disturbances of hyponatremia and hypomagnesemia, correction of these derangements may control them. However, if seizures are related to the porphyric diathesis or are a chronic associated problem, their management may be difficult because most anticonvulsants are contraindicated.[398] An agent such as clonazepam appears to be safe, but its efficacy in the control of grand mal seizures is not documented. Magnesium sulfate was used effectively in one reported case.[399] Several antiepileptic drugs (gabapentin, vigabatrin, and levetiracetam) are not metabolized by the liver and are the treatment of choice for epilepsy in acute hepatic porphyrias.[400,401]

Prompt diagnosis of the symptomatic patient is of essence to guide specific therapy and reduce morbidity or mortality. The disorder is often not recognized and diagnosis is delayed because the clinical features mimic many other conditions, or may be atypical as when dominated by encephalopathy or new onset seizures.[359,360,380,402,403] Prevention of acute attacks is the cornerstone of treating the patient in whom the diagnosis has been established and includes identification of carriers among relatives. Avoidance of most drugs is important, as thoroughly discussed by Hift et al.[404] Patients should receive a list of safe and unsafe drugs (Table 26.4) or be provided with access information to updated drug lists. Extensive lists of drugs and their status are found at the web sites www.porphyriafoundation.com (in the United States) and www.porphyria-europe.com (in European Union countries, South Africa, and Canada), and a guide for drug prescription at www.drugs-porphyria.org. For anesthesia purposes, an adequate number of agents that are considered safe have been evaluated.[406] Patients should be warned that fasting may induce attacks; they should regularly take in sufficient calories to maintain a normal body weight and promptly consult a physician whenever adequate oral intake is interrupted by intercurrent illness. Two nutritional hepatic markers, insulinlike growth factor 1 and transthyretin, have been found useful for assessment of disease morbidity and severity in the clinical follow-up of AIP patients.[407] Rarely prevention of frequent recurrent attacks may require weekly or biweekly infusions of hemin.[376] Treatment with recombinant erythropoietin reduced PBG excretion, increased well-being, and decreased severity of attacks in anemic patients in one study.[408]

TABLE 26.4

SOME MAJOR DRUGS CONSIDERED UNSAFE OR SAFE IN THE ACUTE PORPHYRIAS

Unsafe		
Alcohol	Fentanyl	Novobiocin
Barbiturates[a]	Glutethimide	Phenylbutazone
Carbamazepine	Griseofulvin[a]	Primidone
Carisoprodol	Ketoconazole	Progesterone, synthetic progestins
Clonazepam (high doses)	Lamotrigine	Pyrazinamide
Danazol	Mephenytoin[a]	Pyrazolones (aminopyrine, antipyrine)
Diclofenac, other NSAIDs	Meprobamate[a]	Rifampin
Diphenylhydantoin[a]	Mebutamate	Succinimides
Enalapril	Tybutamate	Sulfonamide antibiotics[a]
Ergot preparations	Methyprylon	Tramadol
Estrogens	Metoclopramide	Trimethadione
Ethchlorvynol	Nifedipine	Valproic acid
Safe		
Acetaminophen	Digoxin	Penicillin and derivatives
Aspirin	Erythropoietin	Propanolol
Atropine	Estrogens (natural/endogenous)	Phenothiazines
Chloral hydrate	Gabapentin	Ranitidine
Cimetidine	Gentamycin	Streptomycin
Colchicine	Glucocorticoids	Tetracyclines
Coumarins	Insulin	Thiouracil
Cytarabine	Levetiracetam	Thyroxine
Daunorubicin	Narcotic analgesics	Vigabatrin

Note: Statements about drugs in acute porphyria are based on experience with patients, on tests in animals with experimental porphyria, and on studies in cell cultures; a system for prediction of drug porphyrogenicity from structural and functional information is proposed.[405] As most drugs have not been tested, the extensive list of unsafe and safe drugs at www.drugs-porphyria.com should be consulted.
[a]Drugs that have most often been cited as agents precipitating acute attacks.
Adapted from References 20 and 376.

In women whose attacks are related to the menstrual cycle, prevention may be achieved by suppression of ovulation with oral contraceptives.[20,321] Paradoxically, oral contraceptive steroids can also worsen symptoms in some women.[20,376] Long-acting LHRH agonists that permit suppression of ovulation without the administration of exogenous steroids can be highly effective in women who have frequent cyclical attacks.[342,376,409] Pregnancy is generally uncomplicated,[410] although one study reported an excess risk of perinatal death.[411] Meticulous prenatal and perinatal care can ensure a good outcome.[344,412] Hemin can be administered safely during pregnancy.[413] Low-dose estrogen replacement is probably safe in women with an acute porphyria who are naturally menopausal.[414]

Liver transplantation has become established as a treatment option for severe refractory AIP in carefully selected patients as it leads to phenotypic cure.[329,330,331] Recently an increased incidence of hepatic artery thrombosis associated with the procedure was reported, with the recommendation to use antiplatelet therapy after transplantation.[415] Domino liver transplantation has also been performed, from donors with AIP.[416] As expected, recipients developed AIP, confirming that the liver is the source of the neurotoxin in the disorder.

Administration of recombinant human PBGD was found to be safe and effective in removing PBG from plasma and urine in asymptomatic AIP carriers.[417] It has not been investigated for efficacy in patients during overt disease. Studies toward gene therapy with nonviral gene delivery in human and murine PBGD-deficient fibroblasts have demonstrated restoration of PBGD activity.[418]

Acute Intermittent Porphyria in Animals

Several lines of cats with naturally occurring porphyria clinically resemble CEP, but the biochemical and molecular findings were found to be typical of AIP.[419] Both autosomal dominant and recessive inheritance is associated with distinct mutations in the *PBGD* gene.

The neurologic syndrome of AIP related to the PBGD defect was verified in transgenic mouse experiments.[420] The PBGD-deficient mice exhibit the typical biochemical characteristics as well as the neuropathologic features of the human disease when treated with phenobarbital.[421] The data suggested that heme deficiency and consequent dysfunction of heme proteins can cause porphyric neuropathy. Moreover, the limited heme synthesis in the PBGD-deficient mice impairs activation of cytochrome P450 genes by phenobarbital,[422] whereas zinc mesoporphyrin represses the induced hepatic ALA synthase and reduces heme oxygenase activity,[423] making this compound a potential candidate for treatment of acute porphyrias. Administration of recombinant PBGD enzyme can reduce PBG excretion by 75%,[424] and adenoviral-mediated expression of PBGD in liver restores enzyme activity and protects against the phenobarbital-induced neuropathy in this animal model.[425–427] These results suggest that gene therapy for AIP targeting only the liver could be sufficient to control the human disease.

5-Aminolevulinic Acid Dehydratase Deficiency Porphyria

ALA dehydratase deficiency porphyria (ADP; plumboporphyria) is the least common porphyria and has been described in seven unrelated cases. It is inherited as an autosomal recessive trait, and mutations in both *ALAD* alleles result in the disorder. The clinical phenotype is strikingly similar to that of AIP.

Molecular Basis and Pathogenesis

ALAD (PBG synthase) is the second enzyme in the heme biosynthetic pathway (Fig. 26.1) and is encoded by a single gene, located on chromosome 9 (9q34).[428] The *ALAD* gene contains two promoter regions that generate housekeeping (ubiquitous) and erythroid-specific transcripts by alternative splicing of a separate exon 1 in each case to exon 2, and both transcripts encode identical ALAD polypeptides.[429] In eight reported patients (including two siblings), the erythrocyte enzyme activity was <10% of normal, and, in the asymptomatic parents and relatives carrying the trait, it was approximately 50%,[430–435,436] in keeping with an earlier study of a family with heterozygous ALAD deficiency and absence of clinical manifestations.[437] Immunologic studies demonstrated considerably more enzyme protein (20% to 33%) than catalytic activity, implying that a structural defect affects the active site of the enzyme.[436,438–440] In five of the cases, mutations have been identified in both alleles of the *ALAD* gene,[10,435,436,441,442,443] and they were compound heterozygotes. The mutations often occurred near the catalytic site of the enzyme and were thought likely to affect binding of the structural zincs of the enzyme. However, subsequent research indicated that all the mutations so far associated with the porphyria favor a variable shift of the wild-type octameric structure of the enzyme to a much less active hexamer as the mechanism for the impaired enzyme activities, representing the first example of a conformational disease.[444]

In an asymptomatic child heterozygous for a novel *ALAD* mutation, enzyme activity was only 12%, whereas it was 30% in family members carrying the mutation.[445] In the case with late onset,[433] likewise, only a single mutation was identified, ALAD activity was 1% of normal, and the late clinical expression of the disease was considered to be related to the patient's coincidental acquisition of the clonal disorder polycythemia vera.[446]

Heterogeneity of the genetic defects probably accounts for the phenotypic variation among the patients. The mechanism for the dominating neurologic features present in all the cases appears to be similar to those discussed for AIP, and the large accumulation of ALA caused by the biosynthetic block supports its implicated importance as a neurotoxin in the pathogenesis. The neuropathies of hereditary tyrosinemia[328] and lead intoxication are likewise associated with ALA accumulation, and ALAD is the enzyme in the heme synthetic pathway that is most susceptible to lead. The role of the two common alleles of human ALAD (*ALAD1* and *ALAD2*), resulting in three polymorphic isozyme phenotypes[447,448] in these conditions, is not defined.

Clinical Description

The clinical findings have differed among the small number of cases with ADP. Two unrelated male patients who were reported as the first described cases of the disease had onset of major symptoms of abdominal pain and motor neuropathies, with some respiratory muscle involvement, in adolescence;[430] they were reported as surviving more than 20 years later.[449] Four other young males also manifested acute episodes of symptoms and courses resembling the variable neural manifestations of acute porphyrias.[434,435,436] In contrast, a child was afflicted with recurrent severe neurovisceral manifestations as well as severe respiratory muscle compromise since birth.[431] Motor neuropathy but no abdominal symptoms first developed in a man at age 63, persisted, and progressed in association with development of a clonal hematopoietic disorder.[433,446] Heterozygotes for ALAD deficiency are asymptomatic.

Laboratory Findings

The distinguishing laboratory finding in ADP is a markedly increased urinary excretion of ALA that has ranged from 8 to 80 times the normal value and correlates with clinical severity; the PBG values are slightly increased, up to six times normal.[430,431,434,435,436,443] Plasma ALA concentration is increased approximately 10-fold.[433] Urinary coproporphyrin (isomer III) is also typically raised 10- to 70-fold but remains unexplained. Fecal porphyrins are normal in most cases. The erythrocyte zinc protoporphyrin is increased, from 3 to 30 times normal.

This spectrum of biochemical abnormalities closely resembles those found in lead poisoning, although in the latter the abnormal values are usually considerably lower; blood lead determinations would exclude this diagnosis. Despite the defects in both alleles, erythropoiesis does not appear to be compromised but hemoglobin values were often not reported. Heterozygotes for an ALAD defect have no biochemical abnormalities except for the reduced levels of ALAD activity.[437]

Treatment

Supportive measures as outlined for AIP are generally helpful for acute episodes of ADP as well. Heme infusions have been of benefit in alleviating the neuropathic symptoms.[432,435,436] In the small child, the disease was reported to impair nutrition and normal development markedly. At age 6, liver transplantation was performed to attempt to reduce the metabolic abnormalities.[450] The high basal urinary excretion of ALA and porphyrin was not influenced by this procedure, indicating that these products originated mainly in extrahepatic tissues. However, clinical challenges with drugs and intercurrent illnesses no longer increased the urinary ALA and PBG, so heme synthesis does not appear to be induced in nonhepatic tissues.[450] It was hypothesized that a bone marrow transplant might more effectively remove the major source of the abnormal metabolites.

ACUTE OR INDUCIBLE PORPHYRIAS WITH BOTH NEUROLOGIC AND CUTANEOUS MANIFESTATIONS

Variegate Porphyria

Variegate porphyria (VP; South African porphyria) is inherited as an autosomal dominant trait with low penetrance and is caused by mutations in the gene encoding PPOX, the enzyme that catalyzes the penultimate step of heme biosynthesis (Fig. 26.1). Consequent proximal backup in porphyrins leads to skin fragility and photosensitivity. Because the production of heme also becomes reduced and ALA synthesis is induced, acute neurovisceral attacks occur that closely mimic the picture of AIP. The disorder is called variegate because it can present with neurologic attacks, photocutaneous lesions, or both.

Although Gunther[4] and Waldenström[57] recognized cases of porphyria in which neurologic and cutaneous manifestations occurred together, the extensive investigations of Dean and Barnes in South Africa first provided the most complete information about this disease and clearly distinguished it from AIP. They identified 300 patients whose lineage was traced to a single couple having migrated from Holland in 1688.[109] This common ancestor of almost all South African patients explained the prevalence of the disease of approximately 3 per 1,000 among the white (Afrikaner) population;[451] the sobriquet South African porphyria stems from this prevalence. VP is less common outside South Africa, but hundreds of cases have been reported from other countries.[452] The prevalence of VP in Finland has been estimated at 1.3 per 100,000.[453] In the United States and Europe, it has probably been underestimated or overlooked[454,455] because the cutaneous manifestations tend to be more mild in temperate and cold latitudes than in South Africa. Indirect evidence suggested that George III of England and other members of the royal houses of Stuart, Hanover, and Prussia suffered from this form of porphyria (often called *the royal malady*).[456] Attempts at retrospective diagnosis with DNA material from deceased relatives of George III were undertaken but have not proved conclusively that he had VP.[457] An analysis of hair from the king had revealed high concentrations of arsenic, and its source was considered consistent with the king's medications as was its likely contribution to his illness by interfering with heme metabolism.[458] Measured against the nature of VP as currently understood, the case for porphyria in George III is now largely discredited.[459]

Molecular Basis and Pathogenesis

PPOX activity is half-normal in cultured skin fibroblasts[460] and blood lymphocytes[461] and accounts for the observed pattern of porphyrin excretion (Table 26.2). The gene for the enzyme was the last of the heme synthesis enzymes cloned and characterized,[462–465] and it has been mapped to chromosome 1 (1q22).[462,464] To date, 179 distinct mutations in the *PPOX* gene have been identified in patients with VP throughout the world[10,452] and include missense and nonsense mutations, insertions, deletions, and splice site mutations. Most of the mutations occur in single pedigrees, and only approximately 8% occur in four or more families. One mutation (C452T) in exon 3 of the gene, causing replacement of arginine by tryptophan in codon 59 (Arg59Trp), is found in 95% of VP patients in South Africa.[466] It is also found in Holland, and extended haplotype studies in South African and Dutch VP families carrying the mutation

have confirmed their common ancestry.[467] When expressed in *Escherichia coli*, the mutant protein had an almost undetectable catalytic activity, presumably related to its location in the binding motif of flavin adenine dinucleotide, an essential co-factor for the enzyme.[468] On average, mutations in heterozygotes are associated with a PPOX activity of 50%, with loss of all enzyme activity from the mutant allele, and thus are referred to as *severe* mutations. In double heterozygotes and homozygotes, enzyme activities are <20% of normal, which would be contributed by residual activity of the mutant protein encoded by at least one of the alleles in heteroallelic cases or by residual activity from both alleles in homoallelic cases. Such mutations are referred to as *mild*. The functional consequences of many of the mutations have been predicted on the structure of the crystallized protein.[469,470]

The photosensitivity symptoms result from the accumulating porphyrins, which are released into plasma and exert the photochemical reactions in the skin.[23] Protoporphyrinogen is a competitive inhibitor of CPOX[471] and, as such, is believed to account also for the accumulation and increased excretion of coproporphyrin.

The neurovisceral symptoms in VP are attributed to an associated relative deficiency of hepatic PBGD.[472] This enzyme is inhibited by coproporphyrinogen and protoporphyrinogen in an allosteric manner, and their accumulation can account for the relative PBGD deficiency.[473] The inhibition is insufficient to produce biochemical changes of increased ALA and PBG excretion during quiescent periods. Together with increased demands for heme and induction of ALA synthase by endogenous or exogenous porphyrinogenic agents, the PBGD step is considered to become rate limiting so that the porphyrin precursors accumulate, accounting for the neurovisceral manifestations as in AIP. That the liver is the principal site for the accumulation of heme synthesis intermediates appeared to be confirmed in a patient with VP who was considered recovered from the porphyria following liver transplantation for alcohol-associated cirrhosis.[474]

Clinical Description

VP is rarely expressed before puberty, and it is not uncommon for the disease to remain clinically and biochemically latent throughout life.[452] Previously, in South Africa, 90% of patients were symptomatic, and cutaneous involvement was the initial feature in one half of patients.[451] More recent experience reflects a changing pattern with <10% of VP patients experiencing a neurovisceral attack,[475,476] and, with the advent of genetic testing, up to 60% are asymptomatic.[452] The changes are attributed to more sensitive diagnostic testing, physician and patient education, and less use of drugs that precipitate symptoms. In the United States and Europe, skin manifestations are uncommon and, when present, tend to be mild and rarely are the initial manifestation of the disease.[452,453]

The characteristic cutaneous feature is severe mechanical fragility of the skin that is limited to sun-exposed areas, especially the face and hands (Fig. 26.7), and is often indistinguishable from PCT. Trivial mechanical trauma to these areas results in detachment of the epidermis from the dermis, with formations of bullae or erosions. The light microscopic and ultrastructural changes in the skin of patients with VP are also similar to those found in PCT. Vascular walls are particularly affected, and the pathologic changes are observed in asymptomatic patients with increased porphyrin excretion.[477] In addition, facial hypertrichosis and hyperpigmentation are common.

The neurovisceral attacks of VP do not differ in any important respect from those of AIP, although hyponatremia was quite common;[451] psychiatric features are uncommon.[452] Acute attacks are less common in VP than in AIP and usually occurred after exposure to a porphyrinogenic drug (Table 26.4).[358,451,478] In early studies, the mortality rate during an acute attack approached 25% but was subsequently reduced dramatically.[358,479]

FIGURE 26.7. Cutaneous manifestations of variegate porphyria. A: Bulla on index finger, pigmented scars, and collapsed blisters at fingertips of a 27-year-old woman. **B:** Hands of a 36-year-old man. Note erosions on back of hands, depigmented scars of past lesions, and subungual involvement. (Courtesy of Dr. Lennox Eales, University of Cape Town, South Africa.)

Hepatocellular carcinoma developed in six reported cases;[480] four of them were elderly individuals (age ≥70). Because VP presenting in old age is uncommon, it is possible that the porphyria manifested a paraneoplastic feature in some of them, as observed in PCT. Regular screening for the tumor in patients with VP is suggested.[480]

To date, 13 unrelated compound heterozygotes and two homozygotes for PPOX defects have been encountered.[10,452] The major clinical features are severe photosensitivity and, commonly, mental retardation, seizures, sensory neuropathy, retarded growth, and skeletal abnormalities. With onset in adolescence, the permanent neurologic features are absent, but neurovisceral attacks may occur.

Laboratory Findings

Patients with symptomatic VP with skin disease or with neurovisceral features uniformly have abnormal biochemical findings. The most characteristic laboratory abnormality is the excretion of large amounts of protoporphyrin and coproporphyrin in the feces.[20,451,479] In South African patients, fecal protoporphyrin excretion reached 1,500 μg/g dry weight, and fecal coproporphyrin excretion reached 1,300 μg/g dry weight (normal total fecal porphyrin excretion is <200 μg/g).[451] A significant feature is the presence of 5-COOH porphyrins.[481] The diagnosis of VP can be established by fecal analysis during an acute attack, during periods when only cutaneous manifestations are present, or during a

clinically latent stage of the disease with high-performance liquid chromatography techniques. However, up to 30% of asymptomatic patients have normal fecal porphyrin profiles.[452] Measurement of porphyrins in bile sampled by duodenal aspiration was shown in a series of patients to provide a clearer differentiation between patients or carriers and normal subjects, particularly in people in whom fecal porphyrin values are indeterminate.[482] The mean biliary porphyrin value in patients with VP was 68.0 μmol/l, as compared with 0.7 μmol/l in normal controls, and the lowest patient value was more than nine times the highest control value.

Because the plasma porphyrins are commonly increased in VP, examination of plasma for the characteristic fluorescence emission spectrum (emission maximum, 626 nm, at neutral pH)[20] is probably the fastest way to establish the diagnosis in symptomatic patients. For the detection of asymptomatic carriers, this method was found to be 100% specific and 86% sensitive in one study.[483] It was not considered sufficiently sensitive in another study[484] or when it was compared to DNA analysis.[485]

During acute attacks, ALA and PBG are excreted in large amounts in the urine, as in AIP. However, the demonstration of excessive urinary ALA or PBG justifies only the diagnosis of acute porphyric attack, and a more specific diagnosis is not possible without analysis of the feces or plasma. In contrast to AIP, urinary excretion of ALA and PBG generally returns to normal after an acute attack[20,451,452] and usually is normal or only slightly increased in patients in whom the only clinical manifestations are cutaneous. During latent periods, urinary porphyrin excretion is usually normal; during acute attacks, or in the presence of superimposed liver dysfunction, it may be greatly increased.[20,451,479] When cutaneous symptoms alone are present, coproporphyrin is the major urinary porphyrin, but uroporphyrin excretion may also be increased.[451] During acute attacks, nonenzymatic conversion of PBG to uroporphyrin may occur, giving rise to an artifactually dramatic elevation of urinary uroporphyrin excretion.[451]

Measurement of PPOX activity can establish the diagnosis. Because it is a mitochondrial enzyme, the assay requires nucleated cells, such as Epstein–Barr-transformed lymphocytes.[472,473] Time and costs involved make it impractical as a routine diagnostic test. The erythrocyte protoporphyrin is somewhat increased in heterozygotes. In homozygotes or double heterozygotes, it ranges from five to ten times above normal; anemia is usually absent.

Treatment

Acute attacks should be prevented and treated as outlined for AIP. Hemin or heme arginate is used for severe attacks and is most effective if administered early in the course of the attack.[392] Glucose may be of benefit.[451] Protection against sun exposure is the only practical way to deal with the photosensitivity.

Identifying abnormal gene carriers in families is important because, as in AIP, most acute attacks can be prevented by avoiding precipitating drugs or other factors. Because biochemical studies apart from assay of the PPOX enzyme are often inconclusive in asymptomatic individuals, mutational analysis is the definitive approach for detection of carriers.

Animal Models of Variegate Porphyria

A mouse model for South African VP with the Arg59Trp mutation has been established by targeted gene replacement.[486] The biochemical features closely resemble the human disease.

A zebrafish mutant (*montalcino*) with a defect in the *ppox* gene has been isolated and displays a recessive inheritance pattern.[487] The mutant also has hypochromic anemia, which could be partially rescued by the human gene.

Hereditary Coproporphyria

Hereditary coproporphyria (HCP) is transmitted as an autosomal dominant trait with a low penetrance. Mutations in the gene encoding CPOX (Fig. 26.1) result in impaired activity of the enzyme and lead to accumulation and excessive excretion of coproporphyrin. Analogous to VP, the porphyrin produces photosensitivity, and neurovisceral attacks occur with induction of heme biosynthesis.

Excessive fecal excretion of coproporphyrin by a patient with porphyria was first noted in 1936,[488] clinical features were recorded in 1949,[489] and the first comprehensive description of the disorder was that of Berger and Goldberg.[490] A review describing clinical and laboratory findings in 111 patients with HCP appeared in 1977.[491] The disorder is less common than AIP and VP.

Molecular Basis and Pathogenesis

CPOX activity is reduced to half-normal in all tissues examined, including cultured skin fibroblasts,[492] mixed leukocytes,[491] lymphocytes,[493] liver,[494,495] and kidney.[495] In homozygotes, enzyme activity was 10% of normal.[496,497] The cloning and characterization of the *CPOX* gene,[498–500] which is located on chromosome 3 (3q12),[501] led to the identification of numerous mutations in the gene. To date, 64 different mutations have been reported, and almost all have been restricted to single families.[10,502] The mutations are predominantly missense mutations affecting enzyme function or stability or leading to production of incomplete proteins. Despite the marked allelic heterogeneity at the molecular level and a wide range of residual enzyme activities of mutant proteins, clinical features are similar.

The pathogenesis of the clinical features can be viewed as the same as in VP, with induction of ALA synthase during attacks.[503] The photosensitivity occurs mainly during periods of a neurovisceral attack, probably because plasma levels of the photosensitizing coproporphyrin become sufficiently elevated. Coproporphyrin is transported efficiently from the hepatocyte into bile or plasma and does not accumulate in the liver.[504]

Clinical Description

The disease is generally latent before puberty, and two thirds of patients have no symptoms.[491,505] In one patient, the first attack occurred at age 84.[505] Acute attacks are usually precipitated by drugs,[506] and acute peripheral neuropathy may be the only manifestation.[507,508] The neuropathic findings are similar to those of AIP[509,510] but are generally less severe; occasionally, only psychiatric features are evident.[506] Photosensitivity is less common than in VP, and unlike in the latter, it tends to occur mainly in the presence of neurovisceral episodes. Rarely, intermittent episodes of cutaneous symptoms may be the only clinical manifestation of the disease.[491] They are similar to those of VP and PCT. The few homozygotes reported had early manifestations.[490,496,497]

One case of hepatocellular carcinoma associated with HCP has been reported.[511] After surgical resection, no recurrence was observed at 5 years of follow-up.

Laboratory Findings

The fecal coproporphyrin level is usually increased after puberty and may approach or exceed 10,000 μg/g dry weight during an attack. An increase in the fecal coproporphyrin isomer III-to-isomer I ratio is uniformly a distinguishing feature, including latent cases in whom fecal coproporphyrin may be normal.[502,512] During acute attacks, urinary coproporphyrin excretion may be profoundly increased but usually is normal during remissions. As in VP, urinary ALA and PBG are typically increased only during attacks.

Treatment

HCP should be managed as described under AIP and VP. Heme arginate is effective for acute attacks[513,514] as well as for needed

maintenance therapy with regular infusions.[515] Detection of affected relatives of patients is important because avoiding specific drugs will probably prevent overt symptoms. CPOX assay is not available as a clinical test, leaving stool porphyrin determinations as the only practical method for screening carriers short of molecular analysis when the mutation in the family can be identified.

Erythropoietic Harderoporphyria

In this clinically distinct variant of HCP, unique kinetic characteristics of the CPOX enzyme are associated with accumulation of a tricarboxylic coproporphyrin, harderoporphyrin.[516,517] In five affected patients the enzyme activity ranged from 18% to 24%.[517] The two missense mutations reported, predicting the codon changes Lys404Glu and His327Arg, affect the second decarboxylation of coproporphyrinogen III to protoporphyrinogen IX with the inappropriate release of harderoporphyrin, the intermediate substrate of the reaction, from the enzyme.[517,518,519]

Homozygotes for the Lys404Glu mutation, or double heterozygotes paired with a C*POX* null allele, had transient neonatal hemolytic anemia and mild microcytic anemia with variable photosensitivity in adulthood; neurologic symptoms were absent. Associated iron overload is attributed to presumed ineffective dyserythropoiesis.[517] Erythrocyte porphyrins are increased two- to threefold. Urine coproporphyrin plus harderoporphyrin is increased about twentyfold. Fecal porphyrins are increased severalfold and the predominant porphyrin is harderoporphyrin. The infant homoallelic for the His327Arg mutation with a harderoporphyria phenotype and massively increased urine porphyrins succumbed early to an apparent acute porphyric attack.[519] Heterozygotes have a normal phenotype.

DUAL PORPHYRIA

During the last three decades, a number of families were discovered to have defects of two distinct porphyrias. In two families, individuals had one or the other trait. Two cases of PCT were described in a family in which five other members had VP.[520] In a second instance, the father had PCT and the daughter had typical EPP.[521]

Based on clinical and biochemical studies and a few mutational analyses, 10 different combinations have been described in which patients possessed two porphyria defects (Fig. 26.8). The first such type reported involved the occurrence of VP and PCT.[522] In South Africa, 25 of 106 patients with VP excreted porphyrins typical of PCT as well. The clinical features and subsequent enzyme assays[523] were consistent with those of both porphyrias. Biochemical data in further cases were also consistent with concomitant defects of VP and PCT, but family studies were not reported.[524,525] Additional dual porphyrias consisting of an acute form plus a cutaneous form that have been encountered include AIP with PCT, with clinical manifestations of both defects;[526] HCP with PCT;[527] HCP with CEP in a child manifesting hepatosplenomegaly, hemolytic anemia, severe photodermatosis, and impaired growth and mental development;[528] and AIP with possible EPP and severe neurovisceral manifestations that were fatal.[529] In the latter case, biochemical studies reflected a PBGD defect as well as FECH deficiency. Analysis of the sciatic nerve revealed reduced PBGD activity coupled with increased activity of ALA synthase, representing the first such data in human neural tissue.

In 1985, a large kindred of 200 descendants stemming from a marriage in 1886 was encountered in Chester, Scotland, in which clinical presentations had been typical of AIP and, in some cases, were severe and fatal.[530–532] Biochemical studies reflected values ranging from those observed in AIP to those found in VP. Clinically affected patients had both deficient PBGD and PPOX activities in peripheral blood leukocytes, although there appeared to be some overlap with control values in some cases.[530] A linkage analysis with polymorphic markers suggested that the locus for the disease is on chromosome 11 and separate from the *PBGD* gene.[533] Later DNA analyses of this family revealed a nonsense mutation in the *PBGD* gene but a defect was not detected in the *PPOX* gene.[534] A second form of two co-existing acute porphyria defects involved PBGD and CPOX.[535] Among 17 family members examined, the dual enzyme deficiency was found in five, PBGD deficiency alone in four, and CPOX deficiency alone in two.[535] Only the proband with both defects suffered mild acute attacks of porphyria and had the most marked changes in porphyrin and porphyrin precursor

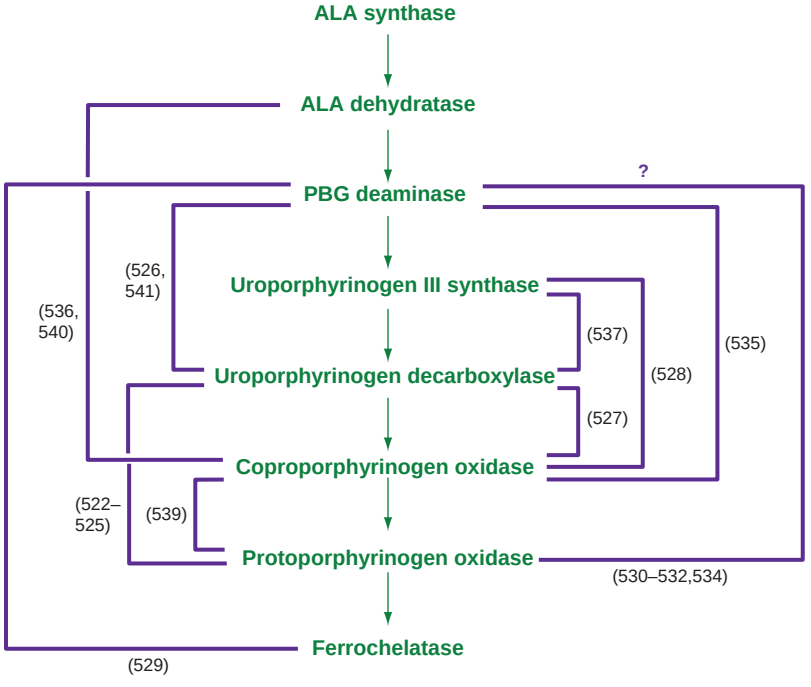

FIGURE 26.8. Enzyme defects in dual porphyrias. Pairs of the respective enzymes involved in the 10 reported forms of dual porphyria are joined by brackets. ALA, 5-aminolevulinic acid; PBG, porphobilinogen. (Reference numbers in parentheses.)

excretions, probably involving a precipitating factor. In a third example, HCP with partial ALAD deficiency was characterized by a severe neurologic attack.[536] A boy had a deficiency of enzymes representing two nonacute porphyrias, UROS and UROD, which caused severe photosensitivity and hemolytic anemia,[537] with subsequent development of severe osteoporosis, renal and liver siderosis, and nephrotic syndrome.[538] A last reported family with digenic inheritance of HCP and VP was confirmed at the molecular genetic level.[539] Identification of specific molecular defects had substantiated two other forms of dual porphyria mentioned above.[540,541]

The occurrence of these combinations of porphyrias, for the most part, probably represents coincidental inheritance of two defects. In some instances, consanguinity of parents was noted. Atypical findings of porphyrins and their precursors encountered in the diagnostic evaluation may indicate the presence of a complex porphyric state.

KEY CLINICAL SUMMARY POINTS

Broad Definitions of the Eight Porphyrias

The porphyrias comprise a group of distinct genetic disorders, each resulting from the partial deficiency (with one exception) of a specific enzyme in the eight-step heme biosynthetic pathway (Fig. 26.1) with its root cause known at the molecular level. The pathophysiology of clinical manifestations rests on the toxicity profile of the accumulated pathway intermediate(s) (Table 26.2) caused by the enzyme deficiency, much like roadwork causing a traffic jam in front of the roadwork. Additionally, although heme synthesis is essential in all cells, the metabolic block of a defective enzyme in porphyrias is expressed either in the liver or in the erythroid tissue, the principal sites of body heme production. Thus,

Acute hepatic porphyrias (AIP, VP, HCP, ADP) are clinically expressed when the impaired heme pathway in the liver is taxed further through its marked induction by factors such as drugs (P450 inducers), progesterone, and dietary restrictions so that PBG and neutrotoxic ALA accumulate, leading exclusively to neurovisceral manifestations. The sites of the primary biosynthetic block in VP and HCP account for porphyrin accumulations also causing cutaneous photosensitivity.

Porphyria cutanea tarda (PCT), or chronic hepatic porphyria, is expressed in the liver and is linked to deficient UROD in combination with various hepatotoxins (iron, alcohol, viral hepatitis, estrogen), causing insidious, protracted skin fragility and a bullous photodermatosis due to uroporphyrin accumulation. Although familial PCT (Type II), associated with inherited UROD deficiency, is less common than the sporadic (Type I) form, a genetic basis for the latter has not been identified.

Erythropoietic protoporphyria (EPP) is expressed in erythroid cells where the deficient FECH enzyme becomes rate limiting for heme synthesis. The nature of the accumulated protoporphyrin uniquely elicits acute cutaneous photosensitivity without blistering or skin fragility. Fulminant protoporphyric liver disease occurs unpredictably in ≤5% of patients.

X-linked protoporphyria (XLPP), as EPP, is expressed in erythroid tissue but is much less common. It is unique among the porphyrias in that it is caused by genetic gain-of-function defects in the erythroid ALAS (ALAS2) enzyme. The overactive, rate controlling enzyme of the erythroid heme pathway drives the pathway excessively so that FECH and iron become rate limiting. Both free and zinc protoporphyrin accumulate in greater amounts and protoporphyric liver disease is more frequent than in EPP.

Congenital erythropoietic porphyria (CEP) is expressed in erythroid cells where the roadblock due to marked UROS deficiency coupled to the site of 85% of body heme production results in massive uroporphyrin and coproporphyrin accumulation, causing the most severe photodermatosis of the cutaneous porphyrias with usual onset in early life.

In the presence of clinical manifestations, accurate diagnosis of each porphyria can be established with characteristic laboratory test abnormalities.

Diagnosis and Treatment of Acute Hepatic Porphyrias (AIP, VP, HCP)

Diagnosis

Consider an acute porphyria attack in all adults with unexplained symptoms seen in acute porphyria (Table 26.3). Suggestive features are as follows: abdominal pain, muscle weakness, CNS disturbance, seizures, hyponatremia, dark or orange-red urine.

Test for *increased urine PBG* in single-voided sample with Rapid PBG Test Kit (Thermo Fisher Scientific Inc., Middleton, VA), which is singularly specific for diagnosis of an acute attack in AIP, VP, and HCP. Then save same urine sample to establish the porphyria type by quantitation of ALA, PBG, and porphyrin levels together with measurements of plasma porphyrin, fecal porphyrins, and erythrocyte PBGD (Table 26.2).

During remission, these quantitative tests can usually but not always establish the diagnosis. Suggestive but inconclusive results can be confirmed by mutational analysis.

Treatment

For a documented *acute attack*: (1) Usually hospitalize patient for control of acute symptoms: withdraw unsafe medications (Table 26.4), correct dehydration/electrolyte imbalance; provide nutritional support and narcotic analgesics for pain, phenothiazine for nausea/vomiting, β-adrenergic blockers for hypertension; consider seizure precautions. (2) Begin hemin (3 to 4 mg/kg/day for at least 4 days) as soon as possible; give intravenous glucose (10%, 300 g/day) for mild attacks or while awaiting hemin delivery. (3) Monitor patient closely for respiratory and neurologic status; serum electrolytes, magnesium, and renal function; bladder distention.

Follow-up

(1) Educate patient and family about the disease, its inheritance, precipitating factors, and important preventive measures. (2) Encourage patient to wear medical alert bracelet and to keep records of diagnostic studies and recommended therapy. (3) Treat chronic manifestations such as pain and depression, and disability. (4) Provide access to genetic testing for patient and family members. (5) Consider monitoring for hepatocellular carcinoma with hepatic imaging. (6) For severe recurrent attacks unresponsive to supportive therapy, consider curative liver transplantation as last resort.

Diagnosis and Treatment of Porphyria Cutanea Tarda (PCT)

Diagnosis

Consider in all patients with symptoms of cutaneous fragility, blister formation, poorly healing ulcerations.

Plasma porphyrin is increased. Urine uroporphyrin with 7-carboxylate porphyrin is usually ≥1,000 μg/24 hrs. In Type II PCT erythrocyte UROD activity is ~50% of normal and is normal in Type I PCT.

Assess for factors precipitating clinical disease: iron overload with serum transferrin saturation, serum ferritin, DNA analysis for genetic hemochromatosis; hepatitis C, HIV; alcohol excess; estrogen use; chronic renal disease.

Treatment

(1) Discontinue any risk agents. (2) Perform one unit (500 ml) phlebotomy every 2 weeks to serum ferritin level of ~20; if phlebotomy is contraindicated or not tolerated, use oral hydroxychloroquine (100 mg twice a week) or chloroquine (125 mg twice a week). (3) In presence of chronic renal disease, facilitate phlebotomy with erythropoietin. (4) Provide sunscreen agent against the 400 to 420 nm light spectrum until primary therapy is effective. (5) Treat any concomitant hepatitis after patient is de-ironed.

Follow-up

(1) Educate patient about the disease and preventive measures. (2) Monitor plasma porphyrin yearly for potential symptom recurrence. (3) In the presence of hepatitis or cirrhosis, monitor yearly for hepatocellular carcinoma with hepatic imaging. (4) Consider mutation analysis if Type II PCT likely, then genetic testing of family members.

Diagnosis and Treatment of Erythropoietic Protoporphyria and X-linked Protoporphyria

Diagnosis

Consider in infants/children with cutaneous symptoms of intense burning pain often within minutes of sun/light exposure, with or without redness or swelling. Chronic changes of sun-exposed skin include shallow facial scars and/or leathery skin over dorsal hands. Very rarely advanced liver disease may be the predominant presenting feature. In adults the clinical phenotype suggests late onset disease associated with a clonal hematopoietic disorder.

In EPP, free erythrocyte protoporphyrin is ≥600 μg/dl; plasma porphyrin is usually increased. In XLPP, erythrocyte protoporphyrin is ≥1,000 μg/dl, ~60% as free and ~40% as zinc-protoporphyrin. Fecal porphyrins may be increased or normal.

Assess hepatic function.

Treatment

(1) Avoid sunlight (including long-wave UV light that passes through windows) with protective clothing. (2) Suggest a tanning product that increases pigmentation. (3) Advise a trial of synthetic β-carotene (Lumitine™, Tishcon Corp., Westbury, NY) to improve sunlight tolerance. (4) Prescribe the α-melanocyte-stimulating hormone analog afamelanotide (Scenesse™, Clinuvel, Melbourne, Australia) upon its approval; it is available in Europe and in clinical trial in the United States. (5) Prevent vitamin D insufficiency with supplementation if blood levels are low. (6) Avoid cholestatic agents (e.g., estrogens) if hepatic dysfunction present.

For severe liver disease: cholestyramine and other porphyrin absorbents, plasmapheresis and intravenous hemin may be helpful; liver transplantation and/or HSCT may be required.

Follow-up

(1) Educate patient and family about the disease. (2) Provide patient and family members access to genetic testing. (3) Monitor erythrocyte protoporphyrin(s) and hepatic function yearly; if cholelithiasis is suspected, monitor with imaging.

Diagnosis and Treatment of Congenital Erythropoietic Porphyria

Diagnosis

Consider in infants/children with symptoms of marked skin fragility, bullous photodermatosis prone to infection, disfigurement of face and hands in time; red, fluorescent diaper discoloration may be an initial clue for the disorder. Beginning in adults, the cutaneous symptoms most likely reflect late onset disease associated with a clonal hematopoietic disorder.

Measurement of erythrocyte, plasma, urine, and fecal porphyrins reveals massively increased levels of uroporphyrin I and coproporphyrin I.

Evaluate for hemolytic anemia and test for dental fluorescence.

Treatment

(1) Rigorously protect from sunlight and treat infected skin lesions. (2) Give red cell transfusions for symptomatic anemia; splenectomy may be necessary for marked hypersplenism. (3) Erythrocyte hypertransfusion reduces porphyrin accumulation and requires management of attendant iron overload. (4) Porphyrin binders (e.g., oral charcoal) may decrease the porphyrin burden. (5) Consider HSCT for severe progressive disease; it has been successful and curative in 17 of 21 patients so treated.

Follow-up

See Reference 39.

Mutation Analysis

After biochemical studies have defined the type of porphyria, DNA analysis to identify the disease causing mutation(s) is recommended, permitting rapid and accurate detection of asymptomatic at-risk family members. Mutation analysis is available for each porphyria at The Mount Sinai Porphyria Diagnostic Laboratory, toll-free at 866-322-7963.

CHAPTER 27

HEREDITARY SPHEROCYTOSIS, HEREDITARY ELLIPTOCYTOSIS, AND OTHER DISORDERS ASSOCIATED WITH ABNORMALITIES OF THE ERYTHROCYTE MEMBRANE

Patrick G. Gallagher, Bertil Glader

This chapter focuses on hemolytic disorders and abnormalities of red blood cell (RBC) shape resulting from alterations of the erythrocyte membrane. The major emphasis is on the hereditary spherocytosis (HS) and hereditary elliptocytosis (HE) syndromes because these are most commonly encountered by clinicians.[1] The traditional classification of these disorders, retained in this chapter because of its clinical applicability (Fig. 27.1), has been based on RBC shape changes. There has been an explosion of knowledge regarding the biology of the erythrocyte membrane, providing a better understanding of membrane structure and function as well as revealing the heterogeneous and diverse pathobiology of these disorders. Readers should consult prior editions of this text for details of previously cited primary references.

THE ERYTHROCYTE MEMBRANE

The erythrocyte membrane, because of its easy accessibility, is the most studied biologic membrane. Composed of a lipid bilayer and an underlying cortical membrane skeleton (Fig. 27.2), the erythrocyte membrane provides the red cell with the deformability and stability required to withstand its travels through the circulation. The erythrocyte is subjected to high sheer stress in the arterial system, dramatic changes in size in the microcirculation with capillary diameters as small as 7.5 μm, and marked fluctuations in tonicity, pH, and pO_2 as it travels through the body.[2]

The lipid bilayer is composed primarily of phospholipids intercalated with unesterified cholesterol and glycolipids. Phospholipids are asymmetrically organized, with the choline phospholipids, phosphatidylcholine (PC) and sphingomyelin (SM), primarily in the outer half of the bilayer; and the amino phospholipids, phosphatidylethanolamine (PE) and phosphatidylserine (PS), in the inner half of the bilayer.[3] In pathologic states, such as thalassemia, sickle cell disease, and diabetes, loss of phospholipid asymmetry with externalization of PS leads to activation of blood clotting via conversion of prothrombin to thrombin and facilitates macrophage attachment to erythrocytes, marking them for destruction.[4]

Lipids are arranged in domains within the bilayers, as large, lipid-rich macroscopic domains, protein-bound microscopic domains, or domains associated with the detergent-resistant fraction of the membrane (called DRM or lipid rafts).[5,6] The role(s) of these domains has yet to be elucidated, but DRM domains may facilitate malarial invasion of the erythrocyte.[7,8]

The erythrocyte membrane contains about 15 major proteins and hundreds of minor ones.[9–11] One erythrocyte proteomic study found 340 of 527 proteins were membrane-associated.[12] A human erythrocyte proteome database is maintained at the Max-Planck Unified (MAPU) proteome database: http://www.mapuproteome.com/rbc.[13] Typically, membrane proteins are classified as *integral*, penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or *peripheral*, interacting with integral proteins or lipids at the membrane surface but not penetrating into the bilayer core. The integral membrane proteins include the glycophorins, the Rh proteins, Kell and Duffy antigens, and transport proteins such as band 3 (AE1, anion exchanger 1), Na^+,K^+-ATPase, Ca^{2+}-ATPase, and Mg^{2+}-ATPase. An assortment of membrane receptors and antigens are present on various integral membrane proteins. Peripheral membrane proteins include the structural proteins of the spectrin–actin-based membrane skeleton.[14]

The membrane skeleton, composed of an intricately interwoven meshwork of proteins, interacts with both integral membrane proteins and the lipid bilayer.[14] The major proteins of the membrane skeleton include spectrin, actin, ankyrin, protein 4.1R, and protein 4.2 (Fig. 27.2 and Table 27.1).

Spectrin is the principal structural component of the membrane skeleton, as well as its most abundant protein, comprising 25% to 30% of membrane protein. Spectrin functions include provision of structural support for the lipid bilayer, maintenance of cellular shape, and regulation of lateral movement of integral membrane proteins.[9] Spectrin is composed of α and β chains, which, despite a number of similarities, including both containing 106 amino acid α-helical "spectrin repeats" composed of triple-helices linked by short connecting regions, are distinct proteins encoded by separate genes. $\alpha\beta$-Spectrin chains intertwine in an antiparallel manner to form 100-nm long heterodimers. These $\alpha\beta$-spectrin heterodimers self-associate with other $\alpha\beta$-spectrin heterodimers to form $(\alpha\beta)_2$ heterotetramers, the functional spectrin subunit in the erythrocyte.[15] Tetramers provide significant flexibility and structural support for the lipid bilayer, helping maintain cellular shape.[9,16] Spectrin heterodimer–tetramer interconversion is governed by a simple thermodynamic equilibrium that favors tetramer formation.[17]

The primary linkage of spectrin to the plasma membrane is via binding of spectrin tetramers to ankyrin, which in turn binds to the integral protein band 3.[18] Protein 4.2 binds to band 3 and probably to ankyrin, presumably promoting their interactions.[19]

A second linkage of spectrin to the plasma membrane is mediated by its association with the "junctional complex," a multiprotein complex that includes spectrin, actin, adducin, and protein 4.1R.[20] Protein 4.1R directly interacts with both spectrin and actin, as well as other proteins of the junctional complex and the plasma membrane including band 3, glycophorin C (GPC), p55, calmodulin, CD44, pIC1n, CASK, mature parasite-infected antigen, and phosphatidylserine. Other important junctional complex proteins include the β subtype of actin, tropomyosin, tropomodulin, p55, and adducin.[9] Adducin is a heterodimer of structurally

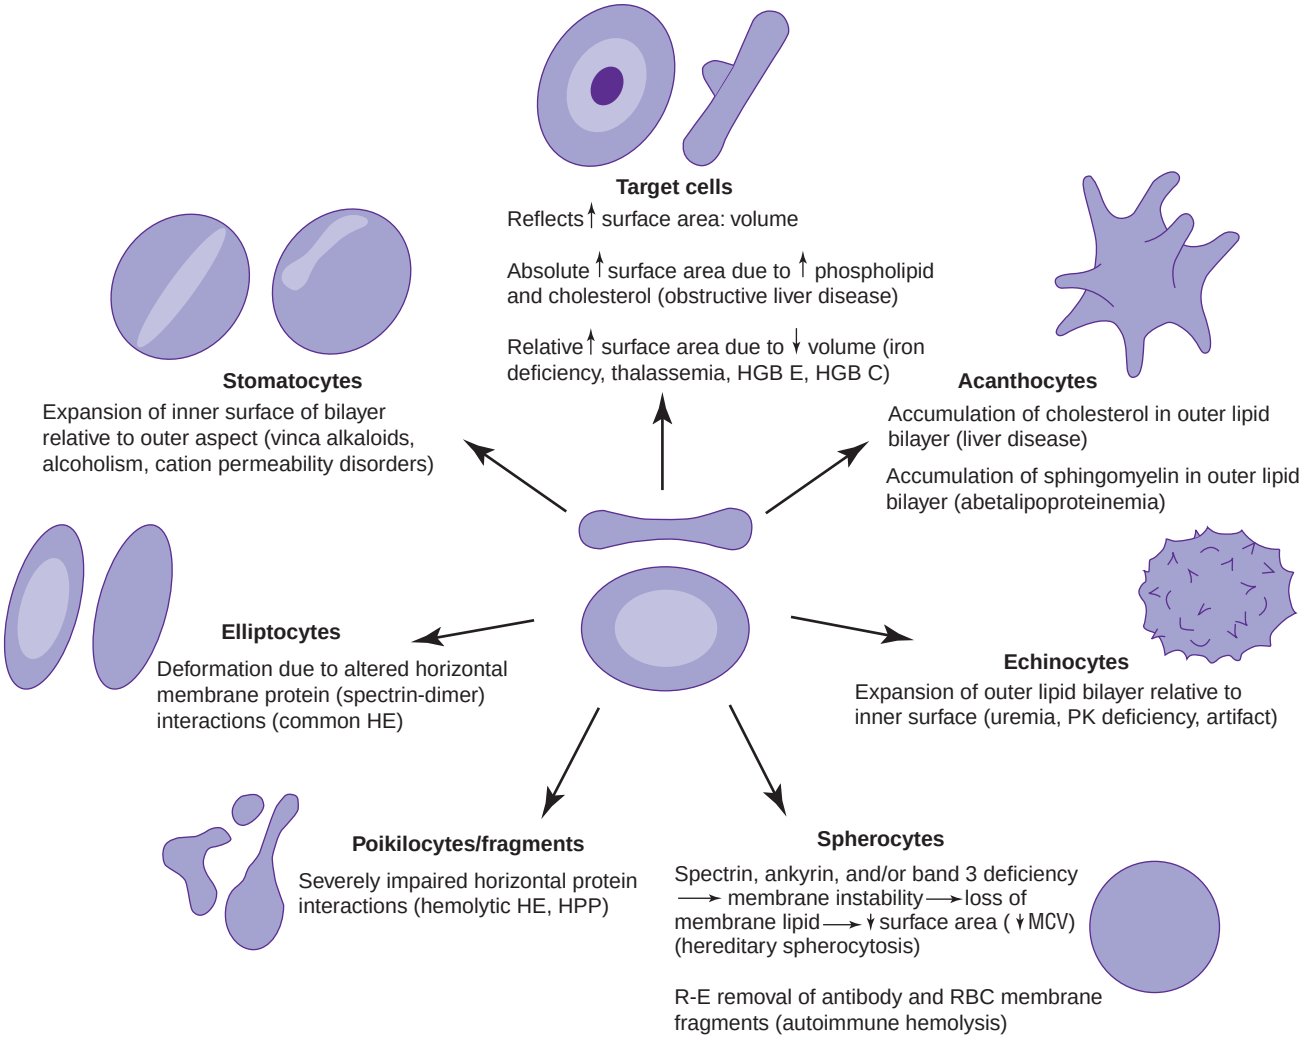

FIGURE 27.1. Diagrammatic representation of abnormal cells associated with alterations in the erythrocyte membrane. HE, hereditary elliptocytosis; HGB, hemoglobin; HPP, hereditary pyropoikilocytosis; MCV, mean corpuscular volume; PK, pyruvate kinase; RBC, red blood cell; R-E, reticuloendothelial.

related proteins, α-, β-, or γ-adducin, which functions in the early assembly of the spectrin/actin complex by capping the ends of fast-growing actin filaments and by recruiting spectrin to the ends of actin filaments.[20,21]

Another membrane skeleton linkage to the plasma membrane is mediated via binding of a multiprotein complex containing the Rh proteins, the RH-associated glycoproteins, CD47, LW, glycophorin B, and protein 4.2 to ankyrin.

Erythrocyte membrane disorders result from alterations in the quantity or quality (or both) of individual proteins and their dynamic interactions with each other.[2,22] Disruption of the vertical protein–protein interactions of the membrane, i.e., the spectrin–ankyrin–band 3 linkage or the band 3–protein 4.2 interaction, leads to uncoupling of the membrane skeleton from the lipid bilayer. This leads to membrane instability with loss of lipids and some integral membrane proteins, resulting in loss of membrane surface area and the phenotype of spherocytosis (Fig. 27.2). Disruption of the horizontal interactions of membrane skeleton proteins, including perturbation of spectrin self-association or junctional complex protein–protein interactions, leads to membrane instability, altered membrane deformability and mechanical properties, and the phenotype of elliptocytosis (Fig. 27.2).[23]

Development of biochemical techniques has allowed the separation and quantification of membrane proteins (Fig. 27.3) and the detection of membrane protein abnormalities in many hereditary red cell disorders. Advances in molecular biology have allowed determination of the precise genetic defects in many cases.

HEREDITARY SPHEROCYTOSIS

HS is a hemolytic disorder characterized by anemia, intermittent jaundice, splenomegaly, and responsiveness to splenectomy.[24,25] There is marked clinical heterogeneity, ranging from an asymptomatic condition to a fulminant hemolytic anemia. The morphologic hallmark of HS is the spherocyte, created by loss of membrane surface area and characterized by abnormal erythrocyte osmotic fragility (OF) in vitro. The interesting history of HS is recounted in detail by Dacie[26] and by Packman.[27] The earliest clinical account of the disorder is probably the 1871 report of Vanlair and Masius,[28] and the 1934 studies of Haden drew attention to a probable structural abnormality of the membrane as the basis for hemolysis.[29] Subsequent investigation of HS afforded important insights into the structure and function of cell membranes and the role of the spleen in maintaining erythrocyte integrity.

Prevalence and Genetics

HS is the most common of the hereditary hemolytic anemias among people of northern European descent. In the United States, the incidence of the disorder is approximately 1 in 3,000 to 5,000.[24,25] When mild and asymptomatic forms of the disease are considered, the incidence is closer to 1:2,000.[30,31] The disease is encountered worldwide, but its incidence and prevalence in other ethnic groups are not clearly established.

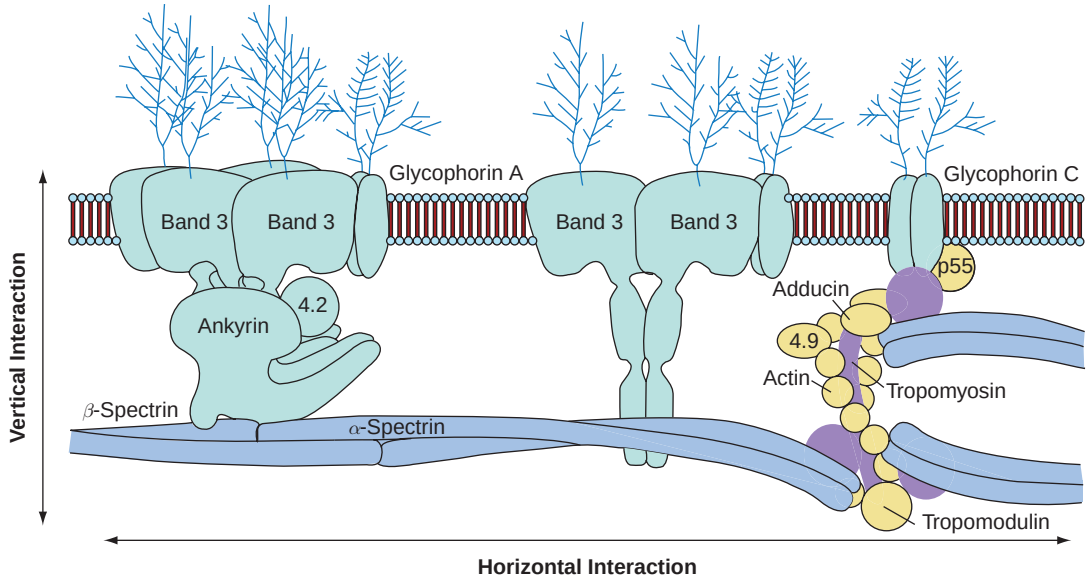

FIGURE 27.2. The erythrocyte membrane. A model of the major proteins of the erythrocyte membrane is shown: α- and β-spectrin, ankyrin, band 3 (the anion exchanger), 4.1R (protein 4.1R) and 4.2 (protein 4.2), Rh (Rhesus polypeptide), RhAG (Rh-associated glycoprotein), LW (Landsteiner-Weiner glycoprotein), actin, and glycophorin. Membrane protein–protein and protein–lipid interactions are often divided into two categories: (1) *vertical interactions*, which are perpendicular to the plane of the membrane and involve spectrin–ankyrin–band 3–protein 4.2 interactions and weak interactions between spectrin and the negatively charged lipids of the inner half of the membrane lipid bilayer; and (2) *horizontal interactions*, which are parallel to the plane of the membrane and include interactions between junctional complex proteins and spectrin or other membrane proteins. (Reprinted with permission from Perrotta S, Gallagher PG, Mohandas N. Hereditary spherocytosis. Lancet 2008;372:1411.)

In the majority of affected families, HS is transmitted in an autosomal dominant manner. Up to 25% of HS patients demonstrate nondominant inheritance, and the parents of these patients are clinically and hematologically normal.[32,33] In many of these patients, HS is due to a de novo mutation. In others, it is inherited in an autosomal recessive fashion, typically linked to abnormalities in the α-spectrin or protein 4.2 genes. A few cases of severe, homozygous HS have been reported, usually in cases where there is parental consanguinity.[34,35]

Pathogenesis

The pathogenesis of HS involves the interplay between an intrinsic erythrocyte membrane protein defect and an intact spleen that selectively retains, damages, and eventually destroys abnormal HS erythrocytes.

Membrane Protein Defects

The primary lesion in HS erythrocytes is caused by membrane protein defects that result in membrane instability. The first biochemical defect recognized in patients with HS was spectrin deficiency, and the degree of spectrin deficiency was found to correlate with the extent of spherocytosis, the degree of abnormality of the OF test, and the severity of hemolysis (Fig. 27.4).[32,33,36–38] In some cases, spectrin deficiency is the result of impaired synthesis, whereas in other instances, it is caused by quantitative or qualitative deficiencies of other proteins that integrate spectrin into the cell membrane, especially ankyrin. In the latter case, free spectrin is degraded, thereby leading to spectrin deficiency. Analysis of red cell membrane proteins in patients with HS has identified several major abnormal patterns: spectrin deficiency alone, combined spectrin and ankyrin deficiency, band 3 deficiency, protein 4.2 deficiency, or no obvious biochemical abnormality. Each of the variant subsets is associated with mutations that result in different protein abnormalities and varied clinical expression (Table 27.2).[39] A tabulation of these mutations, searchable by gene or phenotype, maintained by investigators from Yale University and the National Human Genome Research Institute of the National Institutes of Health, is available at http://research.nhgri.nih.gov/RBCmembrane/.

Spectrin Deficiency

In the erythrocyte, α-spectrin is synthesized in three- to four fold excess with β-spectrin synthesis rate-limiting for membrane assembly of αβ-spectrin heterotetramers.[40,41] Excess α-chains normally are degraded. Clinical abnormalities caused by α-spectrin deficiency are found only in the homozygous or compound heterozygous state, as heterozygotes produce sufficient normal α-spectrin to balance β-spectrin production and maintain a normal phenotype. In contrast, defects of β-spectrin are clinically apparent in the heterozygous state because synthesis of β-spectrin is rate-limiting. Red cell membranes from patients with autosomal recessive HS due to α-spectrin deficiency have only 40% to 50% the normal amount of spectrin, whereas spectrin levels range from 60% to 80% in patients with autosomal dominant HS due to β-spectrin defects.[24,25]

Determination of the precise genetic defects in α-spectrin–linked HS has been slow. The large size of the α-spectrin gene (52 exons) and decreased mRNA associated with presumed null alleles has made mutation detection difficult. However, several variant alleles have been associated with α-spectrin–deficient, nondominant HS.[42,43] These include spectrin$^{\text{Bug Hill}}$, an alanine to aspartic acid substitution in the αII domain, and spectrin$^{\text{LEPRA}}$, low-expression Prague, a C to T substitution associated with increased utilization of an alternative acceptor splice site in intron 30. Whether these are disease-causing variants or are in linkage disequilibrium with other, as yet uncharacterized mutations, has not been determined.

Mutations of β-spectrin impair β-spectrin synthesis or produce truncated β-spectrin chains that are unstable or do not bind to ankyrin and, thus, are not assembled onto the membrane skeleton.[44,45] One HS-associated β-spectrin variant, β-Spectrin$^{\text{Kissimmee}}$, is a point mutation that leads to defective binding of spectrin to protein 4.1R.[46] Occasionally, cases of β-spectrin–linked HS arise de novo.[47]

Ankyrin Defects

Combined spectrin and ankyrin deficiency is the most common biochemical abnormality found in the red cell membrane in cases

of typical, autosomal dominant HS.[48] Ankyrin is the principal binding site for spectrin on the red cell membrane, and studies of membrane skeleton assembly indicate that ankyrin deficiency leads to decreased incorporation of spectrin on the membrane despite normal spectrin synthesis. As expected, there is proportional deficiency of spectrin and ankyrin in these erythrocytes (Fig. 27.5).

Ankyrin gene mutations are the most common defect associated with dominant HS. The majority of ankyrin defects are private point mutations in the coding region of the ankyrin gene associated with reduced or absent expression of the mutant allele.[34] Around 15% to 20% of these mutations arise de novo.[49] A few cases of spectrin/ankyrin–deficient HS are associated with mutations in the ankyrin gene erythroid promoter.[50,51,52]

HS has been associated with karyotypic abnormalities involving deletions or translocations of the ankyrin-1 gene locus on chromosome 8p. Ankyrin deletions may be part of a contiguous gene syndrome associated with HS, mental retardation, typical facies, and hypogonadism.[53,54]

Band 3 Deficiency

Heterozygous band 3 mutations are found in 10% to 25% of patients with autosomal dominant HS.[55,56] Erythrocyte membranes demonstrate a 20% to 40% decrease of band 3 content and decreased or absent protein 4.2. Red cell anion transport is decreased proportional to the band 3 deficiency. Numerous band 3 gene mutations spread throughout the regions encoding both the cytoplasmic and membrane-spanning domains have been described. Many of these are null mutations associated with markedly reduced or absent band 3 mRNA. Others are missense mutations that disrupt band 3–membrane protein interactions or disrupt normal band 3 cellular trafficking from the endoplasmic reticulum to the plasma membrane.[56,57]

Affected patients typically exhibit mild to moderate HS.[24,25] Mushroom-shaped or "pincered" red cells on peripheral smear have been associated with band 3–deficient HS. Homozygotes or compound heterozygotes for band 3 mutations usually exhibit more severe HS. Band 3 alleles that influence band 3 expression have been reported that, when inherited in trans to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical phenotype.[58–60] Although band 3 is expressed in the distal tubules of the kidney, only a few patients with band 3–associated HS exhibit defects in urinary acidification.[61,62]

Protein 4.2 Deficiency

Autosomal recessive HS has been described in a subset of patients, primarily those of Japanese ancestry, whose erythrocyte membranes demonstrate marked deficiency of protein 4.2.[63] In some cases, there is co-existing deficiency of band 3 and ankyrin. Clinical severity and red cell morphology are variable,

Inheritance pattern and clinical response to splenectomy as a reflection of erythrocyte spectrin deficiency in hereditary spherocytosis. N Engl J Med 1986;315:1579.)

with spherocytes, elliptocytes, or sphero-ovalocytes on peripheral smear. A few mutations of the protein 4.2 gene have been described in these patients, primarily null or missense mutations. One missense mutation, Protein 4.2^{Nippon}, associated with a spherocytic, ovalocytic, and elliptocytic hemolytic anemia, is relatively common in Japan.[64] Protein 4.2 deficiency also occurs in association with HS-associated mutations in the cytoplasmic domain of band 3, likely due to disruption of band 3–protein 4.2 interactions.

Erythrocyte Abnormalities

The molecular basis of HS is heterogeneous, thus it is likely that the loss of membrane surface area is a consequence of several molecular mechanisms (Fig. 27.6). The common denominator

TABLE 27.2

CLASSIFICATION OF HEREDITARY SPHEROCYTOSIS

	Carrier	Mild Spherocytosis	Moderate Spherocytosis	Moderately Severe Spherocytosis[a]	Severe Spherocytosis[b]
Hemoglobin (g/dl)	Normal	11–15	8–12	6–8	<6
Reticulocytes (%)	1–3	3–8	8	10	10
Bilirubin (mg/dl)	0–1	1–2	2	2–3	3
Spectrin content (% of normal)[c]	100	80–100	50–80	40–80[d]	20–50
Peripheral smear	Normal	Mild spherocytosis	Spherocytosis	Spherocytosis	Spherocytosis and poikilocytosis
Osmotic fragility: Fresh blood	Normal	Normal or slightly increased	Distinctly increased	Distinctly increased	Distinctly increased
Incubated blood	Slightly increased	Distinctly increased	Distinctly increased	Distinctly increased	Markedly increased

[a]Values in untransfused patients.
[b]By definition, patients with severe spherocytosis are transfusion-dependent.
[c]Normal (±SD) = 245 ± 27 × 10^5 spectrin dimers per erythrocyte. In most patients, ankyrin content is decreased to a comparable degree. A minority of hereditary spherocytosis patients lack band 3 or protein 4.2 and may have mild to moderate spherocytosis with normal amounts of spectrin and ankyrin.
[d]The spectrin content is variable in this group of patients, presumably reflecting heterogeneity of the underlying pathophysiology.

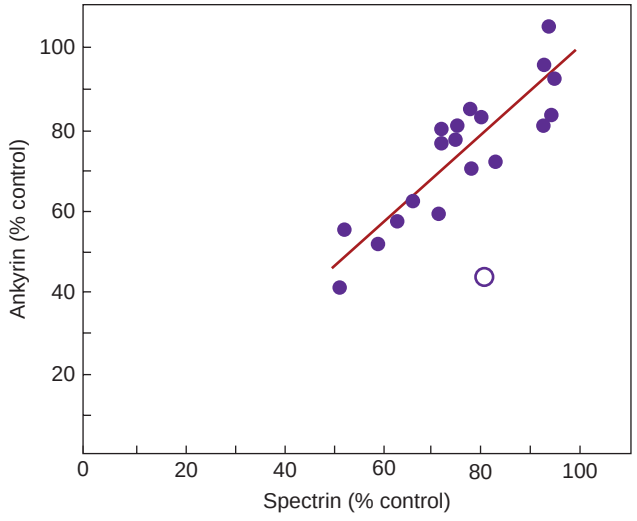

FIGURE 27.5. Role of spectrin and ankyrin in hereditary spherocytosis. The relationship between spectrin and ankyrin content in erythrocytes of patients with dominant hereditary spherocytosis. Each point, expressed as a percentage of control (100%), represents the mean value for a kindred for both spectrin and ankyrin levels. The line represents a computer-generated fitting of the data for 19 of the 20 kindreds. The degree of spectrin and ankyrin deficiencies is essentially identical in these kindreds with one exception (*open circle*), an otherwise typical family in which erythrocytes are primarily ankyrin-deficient. (Reprinted with permission from Savvides P, Shalev O, John KM, et al. Combined spectrin and ankyrin deficiency is common in autosomal dominant hereditary spherocytosis. Blood 1993;82:2953.)

is a weakening of protein–protein interactions that link the membrane skeleton to the lipid bilayer, leading to microvesiculation, loss of membrane surface area, decreased surface/volume ratio, and spherocytosis. In cases associated with spectrin deficiency, the membrane skeleton is unable to provide adequate support for the lipid bilayer, causing destabilization of the lipid bilayer with the resultant loss of band 3–containing membrane microvesicles. In cases associated with band 3 deficiency, the lipid-stabilizing effect of band 3 is lost, releasing band 3–free microvesicles from the membrane. The loss of membrane surface area transforms red cells from biconcave discs to spherocytes with decreased cellular deformability, limiting their ability to pass through the sinusoids of the spleen and predisposing them to splenic entrapment, conditioning, and destruction.

The membrane defect in HS leads to a variety of secondary metabolic changes. These include increased sodium and potassium flux across the HS membrane, which leads to increased membrane sodium-potassium adenosine triphosphatase activation; accelerated adenosine triphosphate (ATP) breakdown; increased glycolytic rate; decreased 2,3-diphosphoglycerate (2,3-DPG) concentration, and lower intracellular pH. HS erythrocytes are slightly dehydrated, although the reason for decreased RBC water content is not known. Possibilities include activation of K-Cl cotransport, a pathway that leads to dehydration and is activated by acid pH, possibly in the acid environment of the splenic cords, or increased Na^+/K^+ pump activity stimulated in response to increased passive cation leaks, leading to decreased total cation content, water efflux from the red cell, and cellular dehydration. Dehydration of HS red cells is important because it can further impair their deformability.

Role of the Spleen

The spleen plays a critical role in the pathobiology of HS, as destruction of spherocytes in the spleen is the primary cause of hemolysis in HS patients.[65] The survival of infused HS red cells into normal recipients is reduced, whereas the survival of normal red cells in HS subjects is normal. Despite the persistence of spherocytosis after splenectomy, red cell survival is normal or only slightly reduced. Taken together, these observations demonstrate that an intrinsic red cell defect leads to RBC destruction, but only in the presence of an extrinsic factor—an intact spleen.

Splenic Entrapment

The unique anatomy of the splenic vasculature leads to sequestration of spherocytes selectively in the spleen. Arterial blood enters directly into the splenic cords, a network of channels formed by reticulum cells and lined by macrophages. Most of the blood that enters the splenic cords passes rapidly through direct channels, which reenter the venous system after traversing fenestrations between the lining endothelial cells. A small fraction of blood in the splenic cords percolates more slowly through this maze before reaching the venous sinuses. The hematocrit of blood from the splenic cords is high, the environment is acidic, and red cells are exposed to macrophages that line these channels. The size of fenestrations in the venous sinuses is small relative to the RBC size, and to pass through requires significant deformability of the red cell and its membrane.[66] This, however, is a major problem for spherocytes, which have lost surface area and are dehydrated. Spleens removed from HS patients reveal congested cords, relatively empty venous sinuses, and few spherocytes traversing sinus walls. The most severely damaged spherocytes, cells unable to negotiate the fenestrations in the venous sinus, are removed from the circulation by macrophages. However, impaired deformability of HS red cells is only significant for the passage of these cells through the spleen. After splenectomy, red cell survival normalizes, even though spherocytes persist and sometimes are increased. Splenectomy has no effect on surface area loss by HS reticulocytes or mature red cells, because surface area loss is due to the intrinsic membrane lesion in these cells. The intrinsic membrane lesion is an independent event that continues even after splenectomy.

Splenic Conditioning

In addition to trapping HS red cells, the spleen also "conditions" these cells in a way that accelerates membrane loss and spherocyte formation. Some conditioned red cells reenter the systemic circulation, gradually shifting from osmotically normal to osmotically fragile cells during their circulation. Osmotically fragile microspherocytes are concentrated in and emanate from the splenic pulp. The more conditioned or spheroidal cells are responsible for the most fragile portion, or "the tail" of the fresh OF curve. The conditioning effect of the spleen is a cumulative injury, thought to result from several passages through the organ. The mechanism(s) of splenic conditioning is not clear. It may be the result of hemoconcentration and erythrostasis with macrophage-induced membrane injury, possibly related to the lower pH in the spleen. The calculated transit time for spherocytes is short relative to the time required for severe metabolic compromise, thus it is unlikely that metabolic depletion is important, and the ATP content of HS cells in the spleen is normal.

Clinical Features

Anemia, jaundice, and splenomegaly are the clinical features of HS most commonly encountered. However, signs and symptoms are highly variable, both with respect to the age of onset and severity.[24,25] For example, anemia or hyperbilirubinemia may be of such magnitude as to require exchange transfusion in the neonatal period or cases may escape clinical recognition altogether, presenting very late in life.[67] Anemia usually is mild to moderate, but it may be absent, mild, moderate, or severe requiring transfusion. Beyond the neonatal period, jaundice is intermittent and is associated with fatigue, cold exposure, emotional distress, or pregnancy. An increase in scleral icterus and a darker urine color is commonly seen in children with nonspecific viral infections. Even when patients have no detectable jaundice, there is usually laboratory evidence of ongoing hemolysis. Splenomegaly is the rule, and in large family studies, palpable spleens

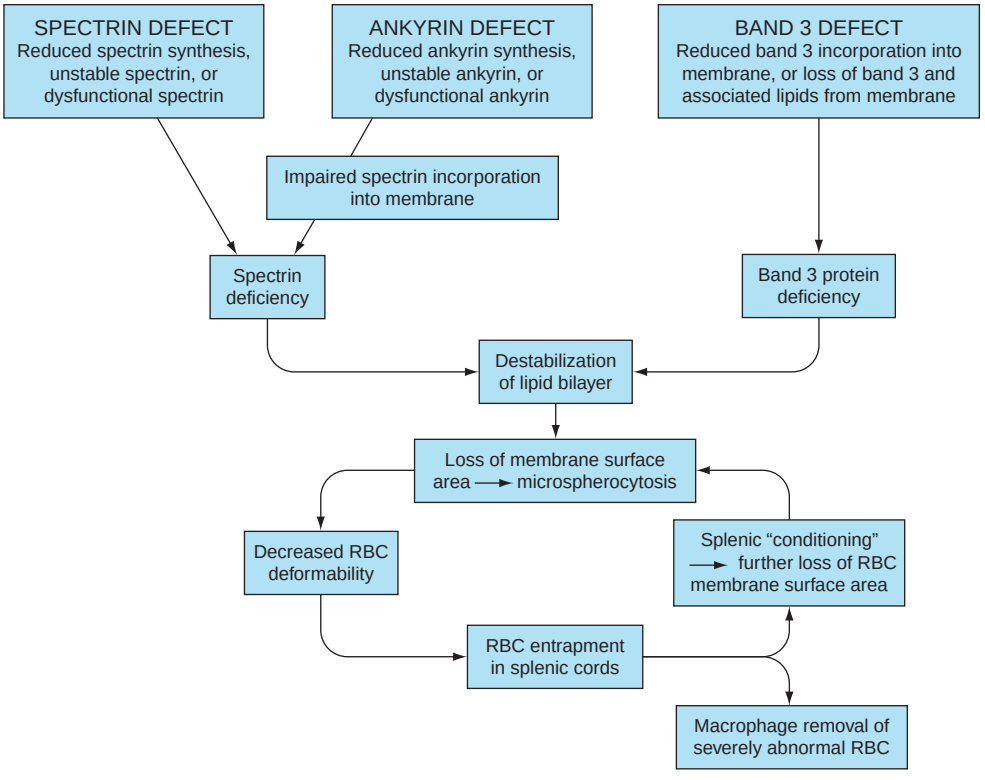

FIGURE 27.6. Pathophysiology of hereditary spherocytosis (HS). The primary defect in HS is a deficiency of membrane surface area, leading to the formation of spherocytes. Decreased surface area may be produced by different mechanisms: defects of spectrin and ankyrin lead to reduced density of the spectrin–actin membrane skeleton, destabilizing the overlying lipid bilayer and releasing band 3–containing microvesicles; or defects of band 3 and protein 4.2 lead to band 3 deficiency and loss of its lipid-stabilizing effect, resulting in the loss of band 3–free microvesicles. Both pathways result in loss of membrane surface area, spherocyte formation, and decreased deformability. These deformed erythrocytes become trapped in the hostile environment of the spleen cords, where splenic conditioning inflicts further membrane damage or they are removed by splenic macrophages. RBC, red blood cell.

have been detected in more than 75% of affected members. No apparent correlation has been shown between spleen size and disease severity, but it may exist. The liver is normal in size and function.

From a clinical perspective, it has been useful to classify HS according to the severity of disease (Table 27.2).[24,25] Moderate HS is the most common presentation, recognized as a chronic hemolytic disorder with characteristic spherocytes on peripheral blood smear and an autosomal dominant pattern of inheritance.

Mild HS occurs in 20% to 30% of cases of HS. Anemia is absent, as the bone marrow is able to fully compensate for the persistent destruction of red cells, and there is little or no splenomegaly.[68,69] Because patients in this group usually are asymptomatic, they often are not diagnosed until later in life. Sometimes, they are identified as a result of hemolytic or aplastic episodes triggered by infection. Occasionally, the condition is identified through family surveys performed to document the hereditary nature of hemolytic disease in a relative.

Moderate HS accounts for 60% to 75% of all HS cases. It is associated with mild to moderate anemia, modest splenomegaly, and intermittent jaundice.[68,69] The reticulocyte count and serum bilirubin levels are elevated. Patients may require transfusion during intercurrent illness.

Severe HS occurs in ~5% of cases of HS. It is characterized by severe hemolytic anemia, the need for red cell transfusion particularly during infancy and early childhood, and usually an incomplete response to splenectomy. The pattern of inheritance is frequently nondominant.[32,33,35]

The silent carrier of HS exists in families with autosomal recessive HS. In most cases, carriers have no signs of HS or minimal signs of HS, e.g., a slightly increased reticulocyte count, a few spherocytes on peripheral blood smear, a minimally abnormal incubated OF, or abnormal erythrocyte spectrin content detected when using sensitive techniques.[32] Using a conservative estimate of 1:5,000 HS incidence in the United States, combined with the observation that ~25% of cases are autosomal recessive, it has been calculated that the HS silent carrier state might exist in 1.4% of the U.S. population.

Hereditary Spherocytosis in Infancy

In the neonatal period, jaundice is likely to be the most prominent feature of HS. Thirty percent to 50% of adult HS patients report a history of neonatal jaundice and the diagnosis of HS is prominent in etiologic studies of severe neonatal hyperbilirubinemia.[70,71] The magnitude of hyperbilirubinemia may be severe, requiring phototherapy or exchange transfusion.[72] Virtually all HS infants who are homozygous for the mutation responsible for Gilbert syndrome are jaundiced enough to require phototherapy.[72] In contrast to jaundice, most newborns with HS are not anemic. Spherocytosis on the peripheral blood smear and reticulocytosis are frequently minimal or absent. However, anemia develops rapidly over the first few weeks of life in many infants and may require transfusion.[72] Maturation of splenic filtering and development of the splenic circulation appear to increase the rate of hemolysis after birth; at the same time, the erythropoietic response to anemia is blunted. Within a few months, erythropoiesis increases, anemia improves, and the need for red cell transfusions disappears in all but the most severely affected infants.

Complications

The two major complications seen in HS are episodes of worsening anemia and the development of gall bladder disease.

Exacerbations of anemia occur in almost all HS patients, even in the large majority of HS patients who have mild or clinically silent disease, associated with various stresses such as infection, major surgery, trauma, pregnancy, etc. For example, previously mild anemia can become much more severe during pregnancy, usually because of the increased plasma volume, but occasionally as a consequence of accelerated hemolysis.[73] As with other chronic hemolytic states, some anemic crises are preceded by a febrile illness and may be observed concurrently in more than one affected member of a single family. In some cases, there may be increased hemolysis (decreased hemoglobin, increased reticulocytes, and increased bilirubin concentration) associated with nonspecific viral infections.[74]

Aplastic/hypoplastic crises resulting from parvovirus B19 infection may occur, just as is seen in individuals with other chronic hemolytic disorders.[75] Parvovirus B19 selectively infects erythroid precursors and inhibits their growth. Erythropoietic arrest leads to a sudden decrease in hemoglobin concentration and reticulocytopenia. Recovery occurs within 7 to 10 days and is heralded by reticulocytosis and thrombocytosis. Parvovirus infection may be the first manifestation of HS, and multiple HS family members infected with parvovirus have developed aplastic crises at the same time, leading to descriptions of "epidemics" of HS.[76] Infection with parvovirus is a particular threat to susceptible pregnant women, because it can infect the fetus, leading to severe anemia, hydrops fetalis, and fetal death.

Less commonly, exaggeration of anemia is the result of exhaustion of folate reserves by the sustained increase in net DNA synthesis.[77] Megaloblastic arrest of erythropoiesis has been observed most commonly during pregnancy, in association with liver disease, or in patients recovering from an aplastic crisis.

Cholelithiasis is common in HS just as in other chronic hemolytic disorders. Bilirubin pigment gallstones may be found in infants and young children,[78] but the incidence of gallstones increases markedly with age, and they are present in 40% to 80% of adults. The history of family members with cholelithiasis in the second or third decade of life is a clue to the possibility of HS or another inherited hemolytic disorder. In patients with mild HS, cholelithiasis may be the initial presentation of the disease. The development of gallstones is increased approximately fivefold in HS patients who are homozygotes for the uridine diphosphate-glucurono-syltransferase mutation responsible for Gilbert syndrome.[79,80] Because of their high incidence, HS patients should be periodically examined by ultrasound for the presence of gallstones, beginning early in childhood.

A few other unusual complications have been noted in HS patients. Heterotopia of the bone marrow has been noted rarely in the renal pelvis or along the vertebral column.[81] These extramedullary masses of marrow may be mistaken for malignant tumors. After the spleen is removed, they undergo fatty metamorphosis. Hemosiderosis and multiple endocrine disorders resulting from transfusion-induced iron overload have been described. Interestingly, symptomatic iron overload also has been reported in some untransfused HS patients who are heterozygous for the hemochromatosis gene. Cases of HS and hematologic malignancy, including multiple myeloma, leukemia, and myeloproliferative disorders, have been reported, suggested to be linked to the persistent hematopoietic stress of HS; but the relationship with HS, if more than coincidental, remains to be determined. Gout and chronic leg ulcers/dermatitis are unusual complications in adults with HS.[82,83] Other rare complications include thrombosis, spinocerebellar degenerative syndromes, movement disorder with myopathy, and hypertrophic cardiomyopathy.[84]

Laboratory Features

The classic laboratory features of HS include anemia, reticulocytosis, increased mean corpuscular hemoglobin concentration (MCHC), spherocytes on the peripheral blood smear, hyperbilirubinemia, and an abnormal OF test.

Anemia is typically mild, accompanied by reticulocytosis with values of 5% to 20%. This compensation is associated with increased erythropoiesis and elevated levels of erythropoietin.[68,69] Erythrocyte indices demonstrate a normal or borderline low mean corpuscular volume (MCV) despite increased numbers of reticulocytes, reflecting the membrane loss and dehydration. The MCHC is usually increased (≥35%) due to mild cellular dehydration.[85,86] Examination of indices obtained by automated cell counters can be used as a screening test for HS. In unsplenectomized children, an MCHC >35.4/dl and a red cell distribution (RDW) width >14 had a sensitivity of 63% and a specificity of 100%[86] for the diagnosis of HS. Histograms of hyperdense erythrocytes (MCHC > 40 g/dl) obtained from laser-based cell counters have been used as a screening test for HS, and when combined with an elevated MCHC, have been claimed to identify nearly all cases of HS.

RBC morphology is distinctive but not diagnostic. Typical HS patients have obvious spherocytes on peripheral blood smear. Spherocytes lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinized. Spherocytes are a feature of many hemolytic anemias, thus their identification alone does not establish a diagnosis of HS. The number of spherocytes and microspherocytes varies considerably from patient to patient; as few as 1 to 3/hpf in mild HS to as many as 20 to 30/hpf in moderate HS (Fig. 27.7). In severe HS, many poikilocytes also are present in addition to the spherocytosis. Unlike the spherocytes associated with immune hemolytic disease and thermal injury, most HS spherocytes are fairly uniform in size and density. Varying degrees of polychromatophilia and anisocytosis are noted. Because the degree of spherocytosis or "conditioning" is a function of cell age, reticulocytes and young red cells are morphologically normal. Specific morphologic findings, including pincered erythrocytes (band 3), spherocytic acanthocytes (β-spectrin), or spherostomatocytes (protein 4.2) have been correlated with specific membrane defects.[24,25]

Osmotic Fragility

Red cells behave as perfect osmometers when suspended in varying concentrations of hypotonic salt solutions, and OF of red cells is a measure of their spheroidicity. With a decreased membrane surface area relative to volume, spherocytes are unable to withstand

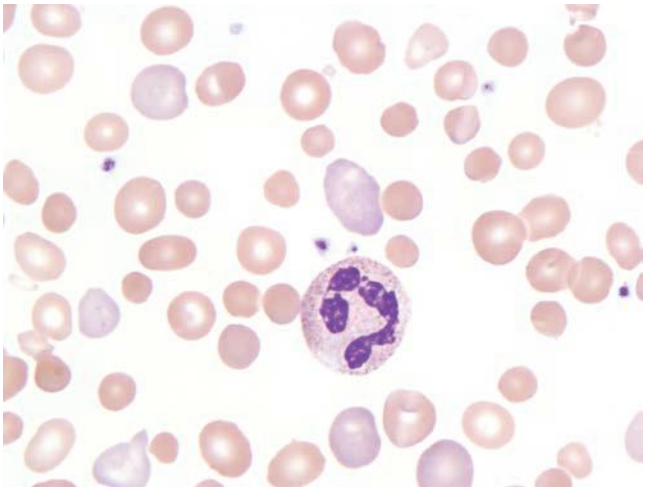

FIGURE 27.7. Hereditary spherocytosis. A typical Wright-stained peripheral blood smear from a patient with autosomal dominant hereditary spherocytosis is shown. Small, dense, round, conditioned spherocytes that lack central pallor are visible throughout.

the introduction of small amounts of free water that occurs when they are placed in progressively more hypotonic solutions. As a consequence, spherocytes hemolyze more than discoid RBCs at any salt concentration (Fig. 27.8). Hemolysis is determined by measuring the fraction of total hemoglobin released from red cells into the extracellular fluid at progressively more dilute salt concentrations. The fresh OF test detects circulating spherocytes, cells that have been conditioned by the spleen. This appears as a "tail" produced by a small population of abnormal cells that undergo hemolysis at salt concentrations that do not affect normal red cells. The most sensitive test to detect spherocytes is the incubated OF test performed after incubating RBCs 18 to 24 hours under sterile conditions at 37°C. This procedure takes advantage of the observation that all erythrocytes lose membrane under these incubation conditions; however, the process is markedly accelerated in HS red cells. Hemolysis of HS cells may be complete at solute concentrations that cause little or no lysis of normal cells. HS individuals may have a normal fresh OF if reduced surface area is balanced by a reduction in volume (due to cell dehydration), but the OF after prolonged incubation at 37°C is usually abnormal. Although OF correlates well with the magnitude of spherocytosis, no correlation is observed between OF and hemoglobin concentration. The sensitivity of the incubated OF test may be outweighed by a loss of its specificity, i.e., spherocytes due to any cause exhibit abnormal incubated OF. A normal OF does not exclude the diagnosis of HS, as 10% to 20% of HS patients, i.e., those with mild HS, lack circulating spherocytes.

Osmotic gradient ektacytometry is more sensitive and specific than the OF test for the diagnosis of HS but is not widely available.

Other laboratory tests used to diagnose HS include the autohemolysis test, the spontaneous hemolysis of red cells incubated under sterile conditions without glucose, the glycerol lysis test, and the pink test; but these rarely are used nowadays, and they offer no advantage over the OF test. The cryohemolysis test and eosin-5-maleimide (EMA) binding to erythrocytes, a flow cytometry-based method reflecting relative amounts of band 3 and Rh-related proteins, have been utilized for use as screening tests in HS.[87] These have been advocated over the incubated OF test as they are claimed to have a higher predictive value. These claims are based on the observation that there have been no reports of positive results in immune-mediated or non–membrane-associated hemolytic disease. However, these tests are not specific, detecting other erythrocyte abnormalities, especially those associated with abnormal band 3, including congenital dyserythropoietic anemia, and abnormalities of erythrocyte hydration and viscosity, including sickle cell disease and cryohydrocytosis.[88,89] The EMA binding test has gained wide popularity because of its ease in execution and relatively low cost of performance. Similar to OF testing, its predictive value is enhanced if family history, clinical information, and additional laboratory data are also available.[89]

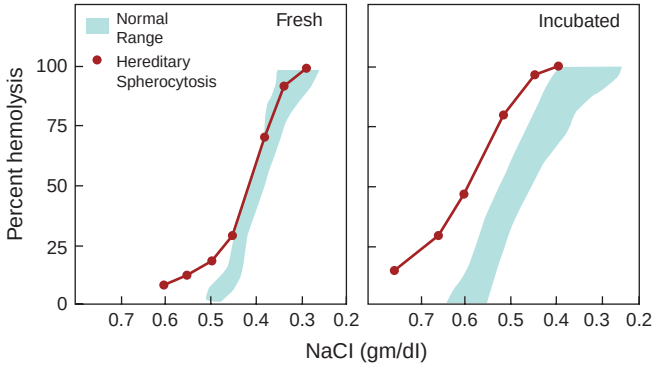

FIGURE 27.8. Osmotic fragility curves in hereditary spherocytosis. Diagrams of the osmotic fragility (OF) test, as manifested by percent hemolysis, of normal and hereditary spherocytosis (HS) erythrocytes after dilution in salt solutions of varying tonicity. (*Left*) In the fresh OF, a "tail" of osmotically sensitive HS erythrocytes produced by splenic conditioning is seen prior to splenectomy. (*Right*) In the incubated OF, the entire population of HS erythrocytes is more osmotically sensitive. (Reprinted with permission from Glader B, Other Hereditary Red Blood Cell Disorders. In: Emery and Rimoin's Principles and Practice of Medical Genetics. Rimoin DL, Connor JM, Pyeritz RE, Korf BR, Eds. Fifth Edition, Churchill Livingstone, New York 2007, pp1675–1698.)

In the past, doubt existed whether HS could be diagnosed in the newborn period because many HS infants have few circulating spherocytes. Moreover, fresh red cells from normal neonates are relatively resistant to OF, whereas incubated infant erythrocytes are osmotically more fragile. However, OF detects HS in many but not all infants if appropriate normal neonatal RBC controls are used. Osmotic gradient ektacytometry reliably detects HS in newborns.[90]

The bone marrow is characterized by erythroid hyperplasia. Normoblasts may constitute 25% to 60% of all nucleated cells. When complicated by folate deficiency, megaloblastic features of both myeloid and erythroid precursors are prominent. Examination of the bone marrow is not needed to diagnose HS.

Molecular Studies

Once the diagnosis of HS is made, it is possible to further characterize the specific membrane lesion. Studies using polyacrylamide gel electrophoresis separation or specific radioimmunoassays allow quantification of major membrane proteins, looking for abnormalities in spectrin, ankyrin, band 3, protein 4.2, or other proteins. Detection of the specific genetic abnormality is accomplished via mutation screening or direct DNA sequence analyses. However, these studies are cumbersome, expensive, and available only in select research laboratories. Detailed molecular studies, which have proven to be highly informative for our understanding of both the pathogenesis of HS and normal membrane structure and function, are indicated for studying difficult or particularly interesting and informative cases.

Diagnosis

The diagnosis of HS generally is straightforward. Often, there is a family history of HS or a family history of anemia, splenectomy, or cholecystectomy. The signs and symptoms of HS are nonspecific and associated with many chronic hemolytic states (mild pallor, intermittent jaundice, and splenomegaly). Typical laboratory features include mild anemia, reticulocytosis, increased MCHC and RDW, normal MCV despite reticulocytosis, spherocytes on the peripheral blood smear, hyperbilirubinemia, and an abnormal incubated OF test. Other disorders, such as immune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, certain syndromes of red cell fragmentation, and thermal and chemical injury of red cells, also are associated with spherocytosis. In most of these conditions, spherocytes are but one of several types of abnormal RBCs present, whereas in HS, there are few abnormal forms other than spherocytes. Additional historical data, such as onset later in life, temporal relationship to prescription of various medications such as methyldopa, or symptoms attributable to malignancy or connective tissue disease, as well as additional laboratory data, such as a positive direct antiglobulin reaction in immune hemolytic disease, may help differentiate other disorders from HS.

Treatment

For practical purposes, the treatment of HS revolves around supportive care, splenectomy, and management of postsplenectomy complications.[91,92]

Neonates with severe hyperbilirubinemia caused by HS are at risk for kernicterus,[71] and such infants should be treated with phototherapy or exchange transfusion, or both, as clinically indicated.[93] Red cell transfusions are sometimes needed during

hemolytic or aplastic crises. Erythropoietin therapy for the first few months of life has been suggested to diminish the need for red cell transfusions until erythropoiesis reaches its full postnatal expression,[94,95] but this therapy is not well studied.

Folic acid is required to sustain erythropoiesis, and normal dietary folate may be inadequate for children and some adults with chronic hemolytic anemia. For this reason, HS patients are instructed to take supplementary folic acid to prevent the rare megaloblastic crises, although in mild cases, this is probably unnecessary.

HS is unique among the congenital hemolytic anemias in that splenectomy is permanently curative except in some severe, autosomal recessive cases[96,97]; and even these severe cases exhibit significant clinical improvement.[65,98] Within days of splenectomy, jaundice fades, the hemoglobin concentration rises, and red cell survival is dramatically improved. Transfusion requirements are decreased or eliminated, and the risk of cholelithiasis is reduced. Spherocytosis and increased OF persist, but the tail of the fresh OF curve, created by splenic conditioning, disappears. The MCV may fall but the MCHC does not change significantly.

For many years, splenectomy was recommended for all patients with HS without regard to clinical severity. The rationale was that splenectomy eliminated the need for transfusion therapy, ensured freedom from aplastic crises, and minimized the risk of gall bladder disease. This position has been tempered in recent years because it is now known that the spleen has a critical immunologic role in protecting against certain types of infections, and overwhelming postsplenectomy infection with encapsulated bacteria, especially *Streptococcus pneumonia,* may occur. The emergence of penicillin-resistant pneumococci has heightened concerns, as has growing recognition of the increased risk of postsplenectomy cardiovascular disease, particularly thrombosis and pulmonary hypertension.[99–103] Finally, the important role of the spleen in protection of individuals living in geographic regions where parasitic diseases such as malaria or babesiosis occur has re-emerged as international travel has become more common.

The risk of postsplenectomy sepsis is greatest in children younger than 5 years of age, but even older children and adults are at increased risk. Death from sepsis may occur decades after splenectomy.[104,105] In one comprehensive review, postsplenectomy infection was assessed in 850 HS patients, 786 of whom were children.[106] Most patients had undergone surgery during the first 5 years of life. Thirty cases of septicemia (3.52%) and 19 septic deaths (2.23%) were identified. The estimated rate of mortality from sepsis was approximately 200 times greater than that expected in the general population. Although most septic episodes were observed in children whose spleens were removed in the first years of life, older children and adults were also susceptible. Another report of 226 patients splenectomized for HS estimated the mortality from overwhelming sepsis to be 0.73/1,000 years. Mortality rates for 35 children who underwent splenectomy prior to 6 years of age and for 191 individuals who were older than 6 at the time of splenectomy were 1.12/1,000 and 0.66/1,000 years of life postsplenectomy, respectively, far beyond that of the general population. Rates for both these studies may overestimate the risk of postsplenectomy, as some of the participants underwent splenectomy prior to introduction of the pneumococcal vaccine.

The rationale that splenectomy prevents development of gallstones and symptomatic biliary tract disease, and also obviates the need for major gallbladder surgery, is not as valid today as it was in the past. Development of laparoscopic cholecystectomy has had a significant impact on the management of nonanemic patients with mild HS who have gallstones. In these patients, if they have no signs or symptoms related to their hemolytic anemia, it is reasonable to follow them without splenectomy. If surveillance ultrasound examinations reveal gallstones, laparoscopic cholecystectomy can be performed, preventing biliary tract disease.

The benefits of splenectomy must be balanced against the immediate and long-term risks of the procedure.[107,108] Recently published HS management guidelines recognize these concerns and recommend discussion between health care providers, patient, and family when splenectomy is entertained.[91] It seems reasonable to splenectomize HS patients with severe hemolytic anemia, and patients suffering from significant complications of anemia including growth failure, skeletal changes, extramedullary hematopoietic tumors, and leg ulcers/dermatitis. Splenectomy for patients with moderate HS and compensated, asymptomatic anemia is controversial, and should be undertaken on a case-by-case basis. Patients with mild HS and compensated hemolysis can be managed expectantly and referred for splenectomy if clinically indicated. The higher risk of overwhelming sepsis in young children who undergo splenectomy makes it important to defer the operation until at least age 6 in all but the most severe patients. Prior to splenectomy, patients should receive immunization with pneumococcal, *Haemophilus influenzae*, and meningococcal vaccines.

Laparoscopic splenectomy, associated with less postoperative discomfort, quicker recovery, shorter hospitalization, and decreased cost, is now the preferred method for splenectomy.[109,110] Operative complications of splenectomy, which include local infection, bleeding, and pancreatitis, are uncommon.[111] Partial splenectomy has been explored for infants and very young children with severe HS.[112–116] The purpose of partial splenectomy is to preserve splenic immunologic function, reducing splenic destruction of spherocytes and thereby palliating hemolysis and anemia. Although long-term data for this procedure are lacking, intermediate follow-up demonstrates that there is sustained and clinically significant improvement in laboratory parameters and clinical signs and symptoms in most patients.[117] In nonresponders, there was rapid regrowth of the spleen. A second (complete) splenectomy may eventually be required, but hopefully at a time when the patients are considerably older and the risk of sepsis is less. The role of radiologic imaging as part of the preoperative evaluation prior to partial splenectomy has been emphasized.[118] Proponents of this procedure note that splenic function is preserved in young children when the risk of overwhelming sepsis is highest and that chronic transfusions and iron overload are decreased. Opponents note that patients who can be well managed with judicious transfusion therapy may be subjected to two operative procedures, possibly both with general anesthesia.

Postsplenectomy care includes counseling of patients or parents to seek prompt medical care during febrile illness. Use of early antibiotic therapy for splenectomized febrile children has led to a decrease in the incidence of severe postsplenectomy infection, leading some to propose having antibiotics available at home for immediate treatment of febrile illness. The emergence of penicillin-resistant pneumococci requires consideration when selecting antibiotic therapy in splenectomized patients.

The role of prophylactic antibiotics postsplenectomy is a matter of current controversy, and few data exist to provide recommendations. Some recommend that all splenectomized children (and adults) receive penicillin prophylactically for life. Others recommend prophylaxis up to 6 years of age, while others prescribe antibiotics for 10 years postsplenectomy. There are even fewer data regarding the prescription of prophylactic antibiotics in adults postsplenectomy.

There have been several reports of major thrombotic events postsplenectomy for HS.[99,100,119] Some of these cases have actually been variants of stomatocytosis, where postsplenectomy risk of thrombosis is well known. Anticoagulants have not been evaluated in this setting.

HEREDITARY ELLIPTOCYTOSIS SYNDROMES

The HE syndromes are a family of genetically determined erythrocyte disorders characterized by elliptical red cells on the peripheral blood smear (Fig. 27.9).[120] Some HE syndromes are associated with symptomatic hemolytic disease, although most are clinically silent and are discovered incidentally when a blood smear is reviewed. The varied clinical and hematologic manifestations of HE are an expression of the numerous molecular defects that give rise to an elliptocytic-shaped erythrocyte.

The HE syndromes are classified into several groups (Table 27.3).[121] *Common HE* is a dominantly inherited condition characterized by many elliptocytes in the peripheral blood smear. The clinical severity of common HE is extremely variable, ranging from an incidental asymptomatic condition, most commonly observed, to a mild to moderate hemolytic anemia. The clinical expression of *hemolytic HE* ranges from a moderate hemolytic anemia to severe, near-fatal, or fatal hemolytic anemia. *Hereditary pyropoikilocytosis* (HPP) is a severe hemolytic anemia, with red cell fragments, poikilocytes, and microspherocytes seen on a peripheral blood smear. From a clinical perspective, it is difficult to distinguish severe hemolytic HE from HPP. Once regarded as a separate condition, HPP is now recognized to be a variant of the HE disorders. *Spherocytic HE* is a rare condition in which both ovalocytes and spherocytes are present on the blood smear. *Southeast Asian ovalocytosis* (SAO), also known as stomatocytic elliptocytosis, is an HE variant prevalent in the malaria-infested belt of Southeast Asia and the South Pacific, and it is characterized by rigid spoon-shaped cells that have either a longitudinal slit or a transverse ridge.

Prevalence of Hereditary Elliptocytosis Variants

When considered together, the HE variants occur with an estimated frequency of 1:1,000 to 5,000. The distribution of HE is worldwide, and no racial or ethnic group appears to be spared.[121] In the U.S. population, the prevalence of HE is approximately 3 to 5/10,000, and it appears to be much more common among patients of African ancestry. In areas where malaria is endemic, HE occurs considerably more frequently. In one study from equatorial Africa, common HE had a prevalence of 0.6%. Resistance of hereditary elliptocytes to invasion by malaria parasites may explain the high prevalence.[122]

Pathogenesis of Hereditary Elliptocytosis Disorders

The HE disorders are caused by intrinsic membrane protein abnormalities, which lead to an alteration in RBC membrane function, changes in RBC shape, and, in some cases, hemolysis.

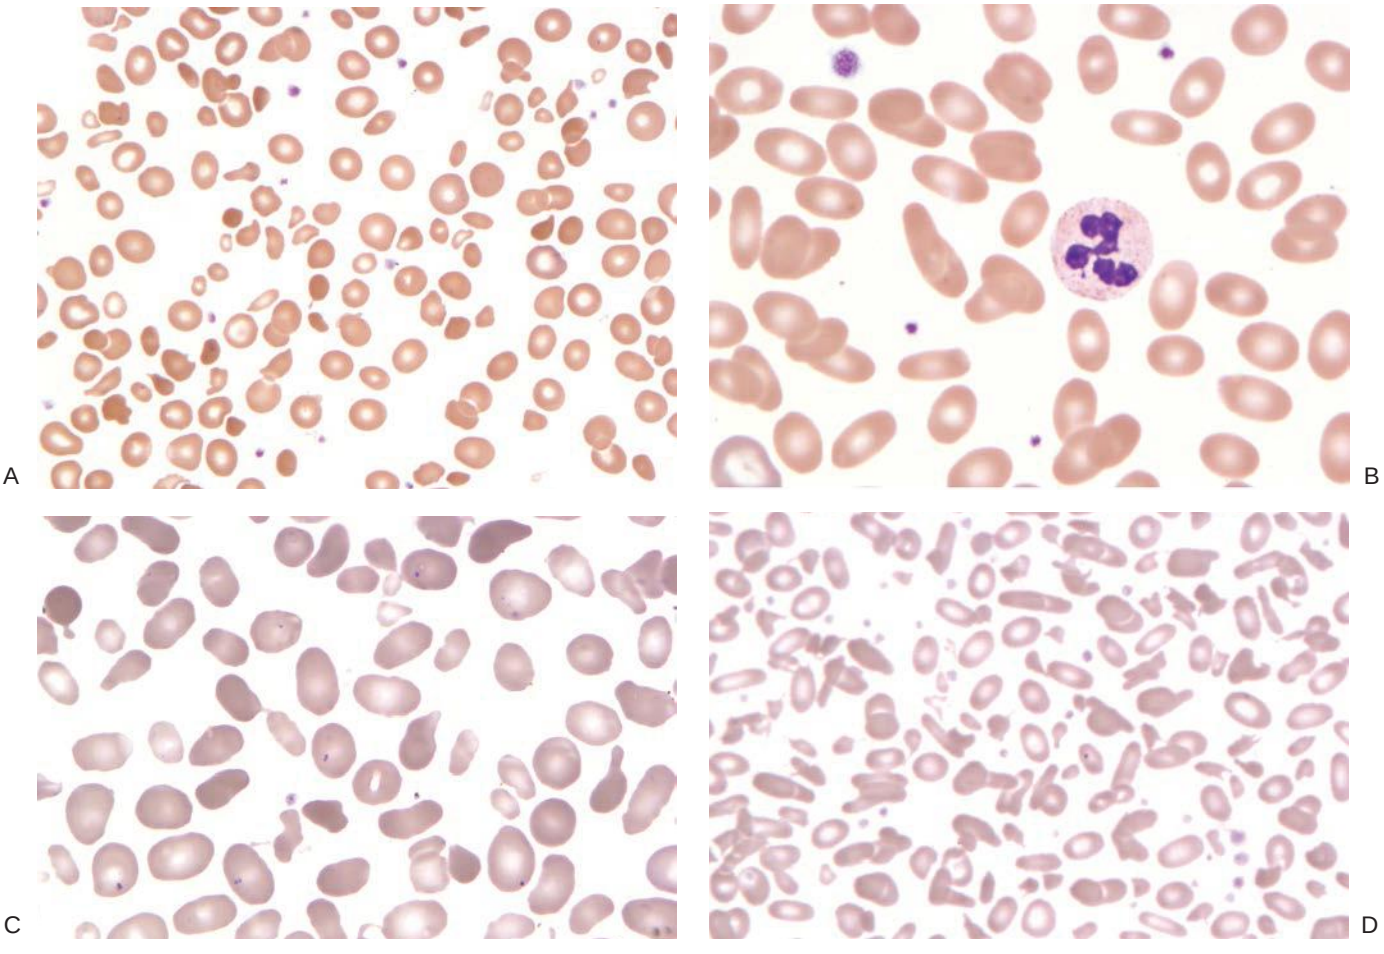

FIGURE 27.9. Hereditary elliptocytosis. Peripheral blood smears representative of different hereditary elliptocytosis syndromes are shown. A: Micropoikilocytes and elliptocytes in a neonate with transient poikilocytosis and an α-spectrin gene mutation. **B:** Same child at 7 months of age, now exhibiting morphology of common hereditary elliptocytosis. **C:** Compound heterozygous hereditary elliptocytosis due to two α-spectrin self-association–site structural mutations. Note distorted red cell shapes, elliptocytes, and fragments. **D:** Hereditary pyropoikilocytosis. Red cell abnormalities are similar to those in **(A)** and **(C)** with prominent budding and fragmentation. (Courtesy of Irma Pereira MT [ASCP]SH.)

TABLE 27.3

CLASSIFICATION OF HEREDITARY ELLIPTOCYTOSIS SYNDROMES

	Common HE	Hemolytic HE	Hereditary Pyropoikilocytosis	Spherocytic Elliptocytes	Southeast Asian Ovalocytosis
Anemia	None	Moderate-severe	Severe	Mild to moderate	None
Hemolysis	None-mild	Moderate-severe	Severe	Mild to moderate	None
Splenomegaly	None	Present	Present	Present	None
Peripheral blood smear	15–90% elliptocytes	Elliptocytes; poikilocytes; fragments	Poikilocytosis; RBC budding with fragments; elliptocytes; microspherocytes	Rounded elliptocytes; spherocytes	Rounded elliptocytes, some having a transverse bar dividing cell
Osmotic fragility	Normal	Normal/increased	Increased	Increased	Normal to decreased
Inheritance	Dominant	Recessive	Recessive	Dominant	Dominant
Other	Poikilocytosis with severe hemolysis, seen transiently in some infants	Normal/low mean corpuscular volume	Low/very low mean corpuscular volume		Rigid erythrocytes

HE, hereditary elliptocytosis; RBC, red blood cell.

Membrane Protein Defects

A primary defect of the membrane skeleton leading to the HE phenotype was suggested by the retention of an elliptical shape by membrane ghosts and skeletons prepared from hereditary elliptocytes, uniform instability of HE membrane ghosts and skeletons to mechanical stress, and abnormal heat sensitivity of spectrin prepared from the red cells of some patients with HE. Subsequent studies have shown that the principal defect in HE is mechanical weakness or fragility of the erythrocyte membrane skeleton, due to qualitative and/or quantitative defects in several membrane skeleton proteins, α- and β-spectrin, protein 4.1R, or glycophorin C.[121]

The majority of HE-associated defects occur in spectrin, the principal structural protein of the membrane skeleton. Spectrin is composed of α- and β-spectrin, two structurally similar, nonidentical proteins encoded by separate genes. The majority of spectrin is triple helical repeats connected by nonhelical segments. The "spectrin repeat," originally defined in erythroid cells, is a conserved triple helical, coiled-coil bundle of amino acids found in a diverse array of proteins that participate in protein–protein interactions and complex formations, with functions as diverse as membrane assembly and signal transduction.[9,14] In the erythrocyte, α- and β-spectrin assemble side to side in an antiparallel position, forming a flexible rod in which the NH_2-terminus of α-spectrin and the COOH-terminus of β-spectrin form an α-β heterodimer. These heterodimers self-associate to form an atypical triple helical repeat in which one helix is contributed by the NH_2-terminus of α-spectrin and two helices are contributed by the COOH-terminus of β-spectrin to form tetramers, the form of spectrin critical for membrane stability as well as erythrocyte shape and function. Spectrin tetramers are connected into a highly ordered two-dimensional lattice through binding, at their tail ends, to actin oligomers at the junctional complex, facilitated by protein 4.1R, into a uniform hexagonal lattice.[16,20] Recent studies have shown that local dissociation of tetramers and reassociation of dimers provide the membrane the ability to accommodate the distortions required for passage through the microvasculature.[17]

Disruption of erythrocyte membrane skeleton protein interactions by mutations that alter protein structure, function, or amount leads to diminished membrane mechanical stability and in severe cases, to hemolysis. Most cases of HE are caused by spectrin mutations that perturb the interactions between αβ-spectrin heterodimers, impairing spectrin tetramer formation, and, consequently, disrupting the integrity and mechanical stability of the membrane skeleton.[15] Mutation of protein 4.1R likely perturbs formation of the spectrin–actin–protein 4.1R–glycophorin C junctional complex and attachment of this complex to the membrane. In 4.1R-deficient erythrocytes, abnormalities in membrane stability and cellular deformability are proportional to levels of protein 4.1R.

Spectrin Abnormalities

Most elliptogenic spectrin mutations are located in the region of spectrin self-association, impairing tetramer formation (Fig. 27.10). These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin. Abnormal tryptic digests of spectrin extracted from HE erythrocytes were first used to identify HE mutations, followed by identification of the precise genetic defects after cloning of the α-and β-spectrin genes. In α-spectrin, the majority of reported mutations are amino acid substitutions. In β-spectrin, mutations are amino acid substitutions and truncations of the COOH-terminus of the β-spectrin chain. When inherited in the heterozygous state, these mutations lead to typical HE. When inherited in trans to modifier alleles that worsen clinical severity, mild to moderate hemolytic HE is seen. Homozygosity and compound heterozygosity are associated with hemolytic HE and/or HPP. Several cases of homozygous β-spectrin self-association site mutations have been associated with fatal or near-fatal fetal and neonatal anemia.[123]

Although most HE mutations are located in the region of spectrin self-association sites, a few spectrin mutations distant from this region have been described. In the heterozygous state, these mutations are asymptomatic, but may be associated with hemolytic HE or HPP in the homozygous state.

Functionally, HE-associated self-association contact site missense mutations likely disrupt predicted conformational rearrangements in the predicted protein structure (Fig. 27.11).[124] Mutations outside the self-association region likely disrupt long range protein–protein interactions, disrupting positively coupled, cooperative interactions of spectrin self-association, spectrin–ankyrin binding, and ankyrin-band 3 binding.[23] Thus, these mutations may act to block repeat-to-repeat transfer of conformational information, decrease the ability of spectrin to transregulate ankyrin binding, and disrupt the register of spectrin repeats and perturb binding of other proteins, e.g., ankyrin, to spectrin.[23,125]

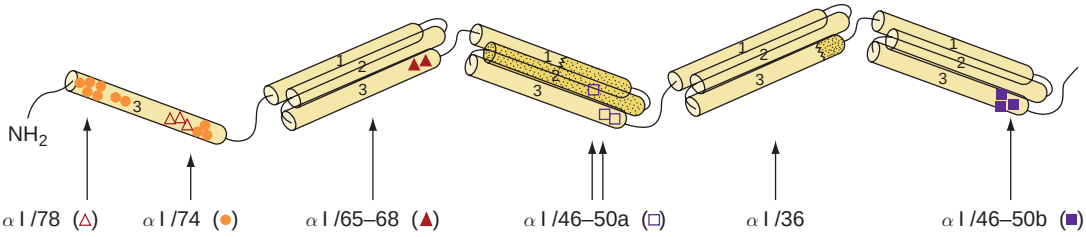

FIGURE 27.10. Defects of the $\alpha\beta$-spectrin self-association site in hereditary elliptocytosis (HE) and hereditary pyropoikilocytosis (HPP). A model of the triple helical spectrin repeats that constitute the $\alpha\beta$-spectrin self-association site is shown. Limited tryptic digestion of spectrin, followed by two-dimensional gel electrophoresis, identifies abnormal cleavage sites (*arrows*) in spectrin associated with various mutations. Symbols denote positions of various genetic defects identified in patients with HE or HPP. In most cases, the mutation found is adjacent to the abnormal cleavage site, either in the same helical coil or in helical coils juxtaposed next to each other in the triple helical model. The hashed lines denote the location of spectrin chain truncations. (Reprinted and modified with permission from Gallagher PG, Tse WT, Forget BG. Clinical and molecular aspects of disorders of the erythrocyte membrane skeleton. Semin Perinatol 14:351,1990.)

Clinically, the most severe clinical phenotypes are associated with mutation of the $\alpha\beta$-spectrin self-association contact site, the atypical hybrid repeat created by 2 helices of β-spectrin and one of α-spectrin. Modifier alleles also influence clinical severity.[126] The most common of these is the low-expression allele, spectrin α^{LELY} (LELY: low-expression allele from Lyon).[127,128] In α^{LELY}, a mutation in intron 45 leads to variable splicing and loss of exon 46 in about half of the α-spectrin mRNA synthesized. Spectrin proteins lacking exon 46 have a reduced ability to participate in dimer and tetramer assembly and are degraded. When α^{LELY} is present as the only variant, it is clinically silent because normal α-spectrin is synthesized in large excess. However, when α^{LELY} is present in trans to an α-spectrin HE mutant, incorporation of the latter into heterodimers is favored, thereby leading to increased proportion of the elliptocytogenic spectrin in red cells and worsening clinical severity. Conversely, when co-inherited in cis to an HE α-spectrin mutation, it reduces the amount of the mutation incorporated into heterodimers and ameliorates clinical severity. α^{LELY} is a common allele, affecting ~30% of α-spectrin alleles of Europeans and 20% of Japanese and West Africans.[129]

Protein 4.1R Defects

Protein 4.1R abnormalities associated with HE are much less common than spectrin mutations. One site on protein 4.1R binds to the distal end of the spectrin $\alpha\beta$-heterodimer, increasing the

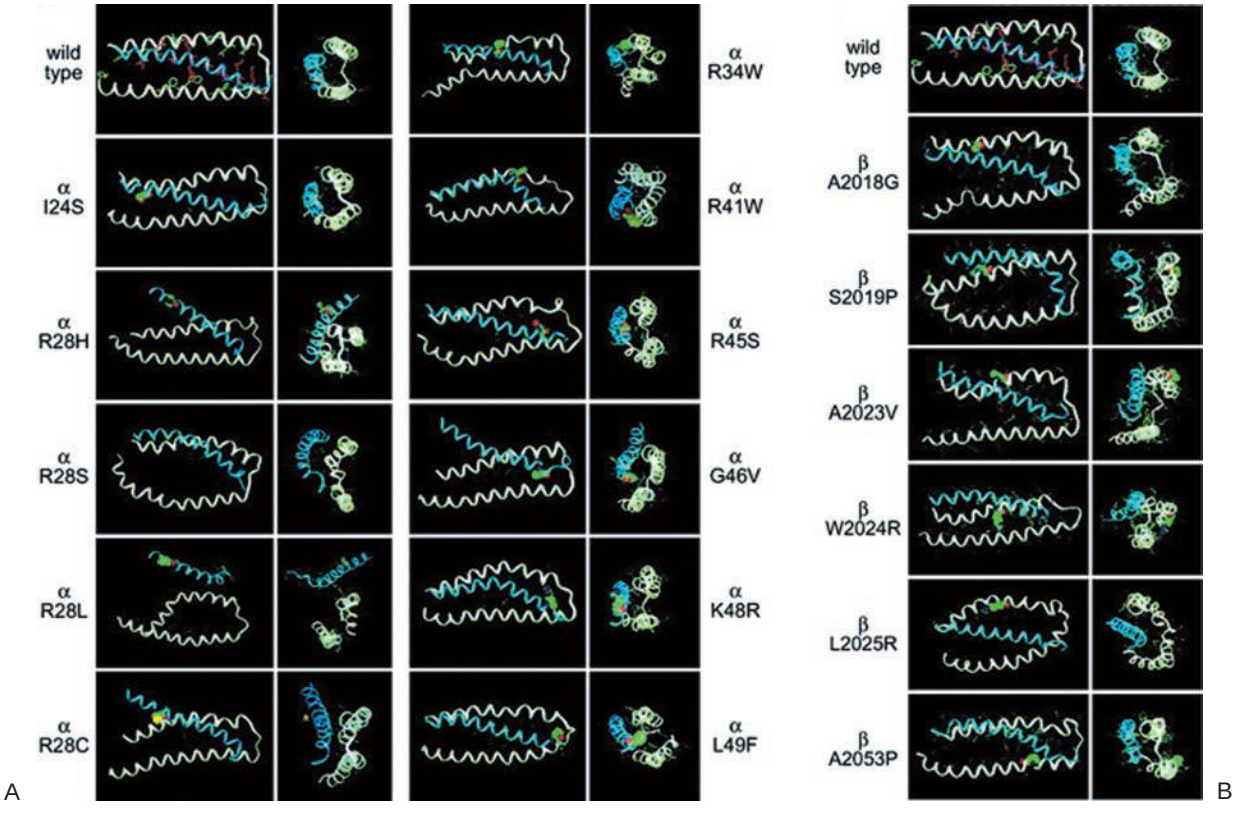

FIGURE 27.11. Molecular modeling of mutations of the $\alpha\beta$-spectrin self-association site. Using dynamic modeling and energy minimization, the three-dimensional structure of the $\alpha\beta$-self-association contact site was determined and the structural consequences of elliptocytosis-associated mutations determined. **A:** Mutations involving α-spectrin. **B:** Mutations involving β-spectrin. Longitudinal and end-on views are shown for each mutation. The mutated residue is depicted using a solid-filled representation. Every pathologic point mutation, including seemingly conservative substitutions such as G for A, A for V, or K for R (single-letter amino acid codes), led to conformational rearrangements in the predicted structure. The degree of structural disruption, as measured by root-mean-square deviation of the predicted backbone structure, correlated strongly with the severity of clinical disease associated with each mutation. (Reprinted with permission from Zhang Z, Weed SA, Gallagher PG, Morrow JS. Dynamic molecular modeling of pathogenic mutations in the spectrin self-association site. Blood 2001;98:1645.)

binding of spectrin to oligomeric actin. The NH_2-terminal domain of 4.1R interacts with glycophorin C, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of the spectrin to the membrane. Complex patterns of alternate splicing lead to the production of various tissue and developmental-stage–specific isoforms of 4.1R, including an erythropoiesis stage-specific splicing event that generates the 80 kDa mature erythroid protein 4.1R isoform.[130]

Deficiency of protein 4.1R has been described in several kindreds from southern France and northern Africa.[121] Partial deficiency of protein 4.1R is associated with mild dominantly inherited HE. Heterozygotes have approximately 50% of the normal amount of protein 4.1R and have mild hemolytic anemia. Homozygotes have no detectable protein 4.1R and a severe transfusion-dependent hemolytic anemia with prominent elliptocytosis and spherocytosis. Homozygous 4.1R-deficient erythrocytes are deficient in p55 and glycophorin C, fragment more rapidly than normal at moderate sheer stresses, and display a dramatically disrupted skeletal network.

Structural abnormalities of protein 4.1R associated with HE have also been found, including deletions and duplications of the exons encoding the spectrin-binding domain.[131,132]

Glycophorin C Deficiency

The Leach phenotype, typically associated with a 7 kb deletion of genomic DNA that removes exons 3 and 4 from the GPC/GPD locus, is characterized by GPC deficiency with elliptocytosis. GPC-deficient erythrocytes are also partially deficient in 4.1R, speculated to be the basis for the elliptocytosis, and lack p55. These abnormalities are presumed to be caused by disruption of a multiprotein complex that recruits, assembles, or stabilizes itself on the membrane. In contrast to other forms of HE, heterozygous carriers of glycophorin C deficiency are asymptomatic with normal RBC morphology. Homozygous-deficient individuals have mild elliptocytosis but no anemia.

Membrane Abnormalities Leading to Elliptocyte Formation

Disruption of erythrocyte membrane skeleton protein interactions by mutations that alter protein structure, function, or amount leads to diminished membrane mechanical stability and in severe cases, to hemolysis. The mechanism by which these protein defects result in elliptocyte formation is not clear. Elliptocytes acquire their shape after release from the marrow and as they age in vivo. Normal erythrocytes assume an elliptical shape in capillaries and in vitro when exposed to shear stress. They resume a normal biconcave shape after passage through the microcirculation and in vitro after removal of shear stress. If mechanical distortion is maintained for long periods, even normal red cells remain misshapen, suggesting that the membrane skeleton is altered as a consequence of sustained shape change. In HE, it is possible that altered membrane protein interactions lead to skeletal reorganization after less extensive deformation or shear stress. With repeated distortions imposed by passage through small capillaries, cells with unstable membrane skeletons gradually elongate to form irreversible elliptocytes. Erythrocytes with more severe skeletal defects presumably are unable to withstand normal circulatory shear stress and undergo fragmentation. This may explain the poikilocytosis seen in homozygous HE and HPP. In all hemolytic HE and HPP syndromes, more severely distorted cells are retained in splenic cords, thus splenectomy markedly ameliorates the associated anemia. Despite alterations in membrane mechanical fragility and stability, intravascular hemolysis has little role in the destruction of HE erythrocytes because hemoglobinuria, hemoglobinemia, and hemosiderinuria are not features of the hemolytic HE syndromes.

Clinical Features

The HE syndrome variants are clinically and hematologically heterogeneous, sharing the features of elliptocytes on a peripheral smear (Table 27.3). There is much overlap when these disorders are classified on a clinical, biochemical, or molecular basis.

Common Hereditary Elliptocytosis

Individuals with common HE are typically discovered accidentally when elliptocytes are identified during routine evaluation of the peripheral blood film.[121] These individuals usually are not anemic, their red cell survival is normal, and there is no splenomegaly. In contrast to the clinical picture, the peripheral blood smear is striking, containing 15% to 100% elliptocytes (Fig. 27.8). Episodic hemolytic anemia may occur during acute or chronic illnesses. Other common HE cases involve mild compensated hemolysis without anemia.

Hemolytic anemia with prominent elliptocytosis and poikilocytosis, termed by some infantile poikilocytosis or infantile pyknocytosis, may be observed in the first few months of life. It is most common in patients of African ancestry. Affected infants have moderately severe hemolytic anemia and hyperbilirubinemia in the newborn period, the latter often necessitating exchange transfusion. The blood smear is characterized by elliptocytosis, marked red cell fragmentation, and poikilocytosis (Fig. 27.9B). These morphologic changes are indistinguishable from those noted in patients with HPP. In contrast to HPP, the hemolysis and anemia abate, evolving to asymptomatic typical common HE throughout childhood (Fig. 27.9C). The basis for this phenomenon is unknown, but increased concentrations of free 2,3-DPG observed in the neonatal period may contribute to membrane instability by perturbing protein 4.1R–actin interactions.[133]

Hemolytic Hereditary Elliptocytosis

In some cases of HE, the hemolytic process is incompletely compensated and patients have a chronic hemolytic anemia of variable severity.[121] Morphologic characteristics may include poikilocytosis, microelliptocytosis, and red cell fragmentation. The spleen may be enlarged, and gallstones occur with increased frequency. As in other hemolytic states, abrupt episodes of more severe anemia may occur in association with viral infection or other intercurrent illnesses, and hemolytic, aplastic, and megaloblastic crises may occur. There is overlap between the findings in patients with hemolytic HE and HPP (see below).

In some families, hemolytic HE has been transmitted through several generations. In other families, not all individuals with HE manifest chronic hemolysis, but instead exhibit asymptomatic common HE or, at the other end of the spectrum, severe HPP. This variation reflects the genetic heterogeneity of the HE syndromes. Some α-spectrin mutations, such as mutations of codon 28, disrupt numerous critical protein–protein interactions, leading to severe membrane dysfunction, and are associated with greater clinical severity. Thus, homozygous or compound heterozygous patients with different spectrin mutations manifest variable clinical severity.[134] In some cases, inheritance of modifier alleles, such as the common α^{LELY} allele, that alter α-spectrin expression may worsen or ameliorate the clinical course. Even patients with mutations of different HE genes, such as patients with both α- and β-spectrin self-association site mutations, have been described. Given the vast combination of mutant alleles and modifier alleles, it is not surprising that there is great clinical, laboratory, and biochemical variability in the HE syndromes.

Hereditary Pyropoikilocytosis

This severe congenital hemolytic anemia, which overlaps with severe hemolytic HE, is characterized by a peripheral blood smear

that resembles those seen in patients with thermal burns.[135] Affected individuals, typically of African ancestry, present in infancy or early childhood with moderate-to-severe hemolytic anemia; and, unlike common HE, the hemolytic anemia is lifelong rather than transient. Complications of chronic hemolysis, including splenomegaly, cholelithiasis, and growth retardation, have been described. Intermittent transfusions may be required. Splenectomy improves or ameliorates the anemia. Most impressive are changes in red cell morphology, which include extreme poikilocytosis, microspherocytosis, microelliptocytosis, membrane budding, and cell fragments. The MCV may be extremely low, 30 to 50 fl, the MCHC is normal, and OF is increased. Thermal instability of HPP erythrocytes, susceptibility to budding and fragmentation upon heating to 46°C, once thought to be diagnostic of HPP, is not unique, as it is also found in some HE erythrocytes. Unlike HE red cells, HPP erythrocytes are also partially deficient in spectrin.

Studies of the genetics of HPP have revealed that many HPP probands have inherited structural mutations on both α-spectrin alleles from HE parents in a homozygous or compound heterozygous manner. In others, the HPP proband has inherited a structural mutation of spectrin from an HE parent on one allele and a null allele of α-spectrin from an asymptomatic parent whose red cells have no detectable biochemical abnormality.[136] This null or "thalassemia-like" allele synthesizes little or no normal spectrin, enhancing the relative expression of the structural spectrin mutant and contributing to a superimposed spectrin deficiency.

Spherocytic Elliptocytosis

This syndrome is characterized morphologically by two populations of cells: red cells that are more rounded than typical hereditary elliptocytes, and a variable number of microspherocytes.[121] In contrast to other HE syndromes with hemolysis, no poikilocytes or fragments are seen. The disorder has been seen primarily in families of European descent and may account for as many as 15% to 25% of cases of HE in whites. Affected individuals have an incompletely compensated hemolytic process with mild anemia and a predisposition to aplastic crises. The relative numbers of spherocytes and elliptocytes vary considerably, even within families. As in HS, the osmotic fragility and mechanical fragility may be increased. Splenectomy is curative.

Southeast Asian Ovalocytosis

This interesting variant, also known as *stomatocytic elliptocytosis,* is characterized morphologically by plump, rounded elliptocytes (ovalocytes), many of which have one or two transverse ridges. These red cells are found in people from Malaysia, New Guinea, Indonesia, and the Philippines. Outside the neonatal period, their presence is not associated with shortened RBC life span, anemia, or hemolysis.[137,138] SAO RBCs demonstrate increased red cell rigidity, increased thermal stability, and decreased OF.[139]

The molecular defect in SAO results from an abnormal band 3 protein lacking codons 400 to 408 at the cytoplasmic and membrane-spanning domains.[140] All individuals with the SAO phenotype are heterozygotes, with one normal band 3 allele and one mutant band 3 allele. The homozygous state has never been observed and is thought to be lethal in utero.[141] There is tight binding of band 3 protein to ankyrin in SAO red cells, restricting the lateral mobility of band 3. Because band 3 protein is a receptor for malarial parasites, its reduced mobility may limit invagination and penetration by the parasite. In vitro, SAO erythrocytes are resistant to invasion by several strains of malaria. Studies of children in Papua New Guinea indicate that SAO does not actually reduce the incidence of infection with *Plasmodium falciparum,* but it does provide remarkable protection against cerebral malaria. This effect is likely due to reduced cytoadherence of SAO red cells to the cerebral vasculature, but the exact mechanism is not yet known.[121] In populations in which SAO is prevalent, its frequency is increased in older individuals, suggesting a favorable effect on longevity.

Laboratory Evaluation

Initial laboratory studies in a patient with a suspected HE syndrome should assess whether the patient is anemic (hemoglobin concentration/hematocrit), whether the anemia is well compensated (reticulocyte count), and whether the anemia is caused by accelerated RBC destruction (increased serum lactate dehydrogenase and bilirubin concentration). The mean cell volume (MCV) is also important because some hemolytic HE and HPP variants with RBC fragmentation often demonstrate severe microcytosis as a result of RBC fragmentation.

Careful evaluation of the blood smear is essential both for the diagnosis of HE and the classification of the disorder into major subtypes. At least 15% and often as many as 50% to 90% of red cells are elliptical, whereas smears from normal subjects contain fewer than 15% elliptocytes. In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is usually minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of "fat" ovalocytes is associated with accelerated red cell destruction. In other patients with hemolytic forms of HE, poikilocytosis almost always is seen on the blood film, and in HPP, many red cells circulate as cell fragments and microspherocytes, producing a marked decrease in mean cell volume. OF is normal in nonhemolytic HE but is increased in hemolytic HE variants with poikilocytosis, HPP, and spherocytic elliptocytosis.

The finding of more than 30% oval red cells on the peripheral blood film, some containing a central slit or a transverse ridge, together with an absence of clinical and laboratory evidence of hemolysis in an individual from Southeast Asia or the South Pacific, is highly suggestive of SAO. A screening test for SAO is the failure of ovalocytes to undergo membrane changes (form spicules) after metabolic depletion or when suspended in hypertonic salt solutions. The mechanism of this resistance to change in shape presumably is because of the extreme rigidity of the red cell membrane. The OF is decreased (i.e., resistant to hemolysis) in SAO red cells.

Once the diagnosis of an HE syndrome is established, it is possible to further characterize the specific membrane lesion. Biochemical studies including studies of membrane protein quality and quantity; functional studies of spectrin, such as analyses of spectrin self-association; and tryptic mapping of spectrin digests to detect mutant spectrin peptides can be performed. Genetic studies to identify specific mutations and associated modifier alleles can also be performed. Like HS, these studies, available in specialized research laboratories, are indicated for studying difficult or particularly interesting and informative cases.

Treatment

In view of the benign nature of typical HE, therapeutic intervention is not indicated in most individuals. Patients with HE variants associated with severe hemolytic anemia should be provided supportive care comparable to that in HS, e.g., supplemental folic acid, periodic screening for cholelithiasis, and transfusion during hemolytic or aplastic crisis. Splenectomy is followed by dramatic improvement or normalization of the hemoglobin concentration and a decrease in the reticulocyte count, despite the persistence of elliptocytes on the peripheral smear.

No therapeutic interventions are required for individuals with SAO.

STOMATOCYTIC DISORDERS

Stomatocytes are erythrocytes with a central slit or mouth-shaped (stoma) area of central pallor when examined on dried smears. In wet preparations, they are uniconcave rather than biconcave, giving them a bowl-like appearance. In vitro, stomatocytes are produced by drugs that intercalate into the inner half of the lipid bilayer, thereby expanding the inner lipid surface area relative to that of the outer half of the bilayer. In contrast, echinocytes (RBCs with numerous fine spicules) are thought to be the result of preferential expansion of the outer lipid bilayer relative to the inner layer. A few stomatocytes may be observed in blood smears prepared from normal individuals.[142] Acquired stomatocytosis has been associated with acute alcoholism and hepatobiliary disease, vinca alkaloid administration, neoplasms, and cardiovascular disease. Stomatocytosis is also sometimes observed as a processing artifact. Stomatocytes are associated with rare hereditary disorders of red cell cation permeability known as the hereditary stomatocytosis syndromes,[143] aberrant Rh blood group antigen expression, sitosterolemia, and familial deficiency of high-density lipoproteins. Each of these stomatocytic disorders is associated with mild to moderate hemolysis.

To appreciate the pathophysiology of the hereditary stomatocytosis syndromes (Table 27.4), an understanding of normal red cell cation and water transport is essential.[144] The RBC membrane, which is freely permeable to water, controls its volume primarily through regulation of the monovalent cation content. Small passive cation leaks (Na^+ in, K^+ out) are normally balanced by the active outward transport of sodium (3 mEq/red cell/hour) and inward transport of potassium (2 mEq/red cell/hour). These cation pumps are linked, require ATP, and are dependent on the membrane enzyme Na^+-K^+-adenosine triphosphatase. If the membrane permeability leak to monovalent cations increases, cation pumps have limited compensatory ability, and, if this capacity is exceeded, red cell volume changes in parallel with the total cation change. Red cells swell when the inward sodium leak exceeds the potassium leak out; red cells shrink when the potassium leak out exceeds the inward sodium leak. These membrane permeability abnormalities are recognized by observing altered RBC hydration (decreased or increased MCHC) and altered red cell sodium, potassium, and total monovalent cation content.

Hereditary Stomatocytosis

Hereditary stomatocytosis (also known as hereditary hydrocytosis, or overhydrated stomatocytosis) refers to a heterogeneous group of autosomal dominant hemolytic anemias caused by altered sodium permeability of the red cell membrane (Table 27.4).[145,146] The major pathophysiologic abnormality is the result of a marked increase in sodium permeability (15 to 40 times normal), leading to increased RBC sodium, a lesser decrease in intracellular potassium, an increase in total monovalent cation content, and, thereby, an increase in cell water. Despite a marked compensatory increase of active sodium and potassium transport, increased pump activity is unable to compensate for the markedly increased inward sodium leak. Treatment of these cells with dimethyl adipimidate (a bifunctional imidoester that cross-links proteins) normalizes membrane permeability, corrects cell

cation and water content, improves membrane deformability, and corrects the abnormal RBC morphology. Moreover, these treated RBCs have an improved survival in vivo. In most patients, excess cation permeability is associated with an absence of red cell membrane protein band 7 on sodium dodecyl sulfate gels. This protein is referred to as band 7.2b or stomatin,[147–149] and its function is currently unknown. No abnormalities in the stomatin gene, which has been isolated and cloned, have been identified in stomatin-deficient individuals with hereditary stomatocytosis. Homozygous knock-out mice that completely lack the murine analog of erythrocyte stomatin exhibit no features of the hereditary stomatocytosis syndrome seen in humans, suggesting that stomatin deficiency is not the proximate cause of the disease in humans, although it may be a marker for another membrane defect that is responsible.[150]

The severity of hemolytic disease is diverse, both between different families and among affected members of the same family. In most patients, symptoms related to intermittent anemia and jaundice are so mild that no therapy is required. Rarely, the anemia is of sufficient severity to require transfusion therapy. Exchange transfusion for severe neonatal hyperbilirubinemia was required in one case. Splenomegaly is an expected corollary of severe anemia. Approximately 10% to 50% of circulating red cells are stomatocytes (Fig. 27.12). The MCV is elevated, often strikingly, the MCHC is normal or low (as a result of increased cell water content), and OF is increased. Red cell sodium content is increased and potassium content is decreased. In most patients, hemolytic anemia is improved after splenectomy, but splenectomy is considered contraindicated in most cases because there is a high risk of postsplenectomy thromboembolic disease and chronic pulmonary hypertension. This has been attributed to increased erythrocyte endothelial cell adhesion due to increased phosphatidylserine exposure of overhydrated erythrocytes.[151] Fortunately, most patients have compensated hemolysis and splenectomy is not required.

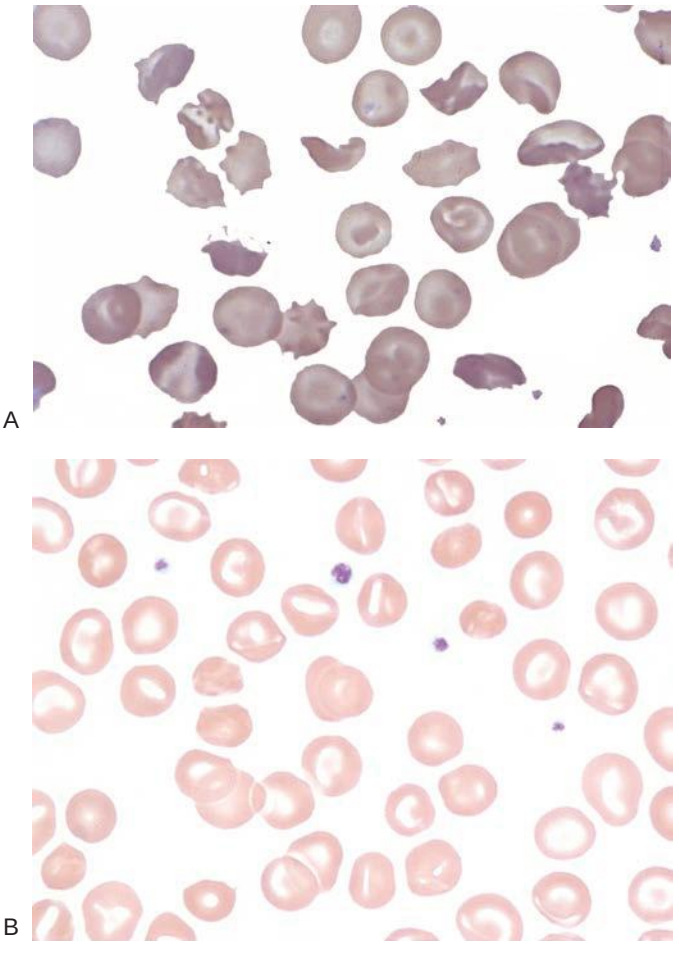

FIGURE 27.12. Hereditary stomatocytosis. A: Wright-stained peripheral blood smear from a patient with hereditary hydrocytosis. Instead of central pallor, characteristic erythrocytes have a central mouth-like or "stoma" appearance, hence the term *stomatocytosis*. **B:** Wright-stained peripheral blood smear from a patient with hereditary xerocytosis, showing dense, abnormal erythrocyte forms where hemoglobin appears puddled at the periphery.

Hereditary Xerocytosis

Hereditary xerocytosis (also known as desiccytosis or dehydrated stomatocytosis) is a rare autosomal dominant hemolytic anemia characterized by red cell dehydration due to net potassium loss from cells that is not accompanied by a proportional gain of sodium (Table 27.4).[145,152] Measurement of RBC cations reveals a slight increase in cell sodium content, a greater decrease in potassium concentration, and, thus, a decrease in the net intracellular cation content and cell dehydration. In some cases, reduced red cell 2,3-DPG has been noted. In several families, an increase in erythrocyte PC content has been observed. Although the total red cell membrane protein content may be elevated, specific abnormalities of stomatin or other membrane proteins have not been observed. The red cells in hereditary xerocytosis are sensitive to shear stress and readily undergo membrane fragmentation.

Xerocytosis patients characteristically have mild to moderate hemolysis. The MCHC is increased, reflecting cellular dehydration, whereas the MCV is slightly increased, reflecting both increased reticulocyte count and artifact from electronic cell counters which, because of alterations in cellular stiffness, estimate the MCV about 10% too high. Peripheral blood film reveals stomatocytes, target cells, spiculated cells, and some cells in which hemoglobin is concentrated ("puddled") in discrete areas on the cell periphery (Fig. 27.12). Peripheral blood smears from mildly affected patients is nearly normal. The OF is decreased. Splenectomy is to be avoided because it has minimal effect on the hemolytic anemia and increases the risk of thrombosis.[153,154] A subset of patients with hereditary xerocytosis also exhibits transient in utero ascites, nonimmune hydrops fetalis, and/or pseudohyperkalemia which are unrelated to the degree of anemia.[155,156,157] The basis for the transient ascites and hydrops is unknown.

Recently, mutations in the mechanotransduction protein PIEZO1 were identified in patients with hereditary xerocytosis.[158] PIEZO1 is encoded by the FAM38A gene on chromosome 16, located in the region previously linked to both hereditary xerocytosis and pseudohyperkalemia (see section "Intermediate Stomatocytic Syndromes").[159–161] This work suggests that PIEZO proteins play a previously unrecognized role in erythrocyte volume regulation, with PIEZO1-mutant erythrocytes gradually becoming dehydrated during their repeated cycles of travel through the microcirculation, associated with changes in oxygenation/deoxygenation. Thus, the PIEZO proteins may participate in the initial calcium-permeable cation conductance pathways involved in sickle cell dehydration.[158,162,163]

Intermediate Stomatocytic Syndromes

Some cases of hereditary RBC cation permeability abnormalities share features of both hereditary stomatocytosis and xerocytosis (Table 27.4).[145,164] Affected individuals have stomatocytes and target cells on the peripheral blood smear. The OF of red cells is either normal or slightly increased. The sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the red cell volume usually are normal or slightly reduced.

Cryohydrocytosis is a variant of hydrocytosis with abnormal cation transport and overhydrated red cells (Table 27.4). Cryohydrocytosis cells exhibit a profound increase in cation permeability in vitro at low temperatures (5°C) compared with 37°C. A similar susceptibility to cold-induced cation permeability in which potassium and water loss predominates and xerocytes instead of hydrocytes are present has also been described. Blood samples left at room temperature for a few hours may manifest pseudohyperkalemia as a result of potassium efflux from red cells into the plasma. Despite the mildly dehydrated red cells, no anemia or hemolysis is associated with this defect. Careful analysis of potassium loss at low temperatures is an excellent way to distinguish between cryohydrocytosis, pseudohyperkalemia, and intermediate forms; at least five different phenotypes can be distinguished. In a group of cryohydrocytosis patients, two different mutations in the Rh-associated glycoprotein (RHAG), Ile61Arg or Phe65Ser, were found.[165] Additional studies support the role of Rh proteins as an ammonia channel in erythrocytes, with the cryohydrocytosis-associated mutations leading to increased cation conductance/permeability.[166,167]

A subgroup of stomatin-deficient cryohydrocytosis patients with hepatosplenomegaly, cataracts, seizures, and movement disorders has been described. In two affected kindreds, mutations in the glucose transporter 1 (GLUT1), encoded by the SLC2A1 gene, have been found.[168]

Study of a group of stomatocytosis, spherocytosis, and spherostomatocytosis patients with large cation leaks at 0°C revealed varying patterns of cation loss over a range of temperatures. Erythrocyte membranes from some of these patients demonstrated band 3 deficiency. Several missense mutations in exon 17, encoding an intramembrane domain of band 3, were discovered in these patients.[119] In vitro studies suggested that these mutations convert band 3 from an anion exchanger to a nonselective cation leak channel.[169]

Rh-Null Disease

Most hematologists are familiar with the Rh antigen because of the immune sensitization that occurs in Rh-negative individuals exposed to Rh-positive red cells. The Rh locus (*RH30*) is composed of two closely linked genes, one encoding the D polypeptide and the other encoding the CE protein.[170] The importance of the Rh locus for membrane integrity was recognized through the discovery of rare individuals whose red cells have absent (Rh_{null}) or markedly decreased (Rh_{mod}) Rh antigen expression.[171] Rh proteins are part of a multiprotein complex that includes 2 Rh proteins and 2 Rh-associated glycoproteins (RhAG).[172] Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2. The Rh-RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer.[173]

Rh_{null} and Rh_{mod} diseases are characterized by mild to moderate normocytic, normochromic hemolytic anemia with stomatocytes and occasional spherocytes on peripheral blood smear. Though the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, with at least two groups defined. The "amorph type" is due to defects involving the *RH30* locus encoding the RhD and RhCE polypeptides. The "regulatory type" of Rh_{null} and Rh_{mod} phenotypes results from suppressor or "modifier" mutations at the *RH50* locus encoding the Rh-associated glycoproteins. When one chain of the Rh-RhAG complex is absent, the entire Rh multiprotein complex is either not transported to or assembled at the membrane.

Sitosterolemia

Sitosterolemia, also known as phytosterolemia, is a recessively inherited disorder associated with elevated plasma levels of plant sterols. Affected patients exhibit early onset xanthomatosis and premature coronary artery disease.[174] Hematologic manifestations include macrothrombocytopenia and stomatocytic hemolytic anemia.[175,176] Mutations in the transporters ABCG5 or ABCG8 lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols as well as altered cholesterol metabolism.[177] Plant sterols are not synthesized endogenously in humans, but are passively absorbed in the intestine.[178] ABCG5 and ABCG8 actively pump plant sterols out of the intestinal cells back into the intestine and out of liver cells into bile ducts. It has been suggested that the stomatocytic phenotype is due to intercalation of plant sterols into the inner leaflet of the lipid bilayer.

Familial Deficiency of High-density Lipoproteins

Familial deficiency of high-density lipoproteins (Tangier disease) is a rare autosomal recessive disorder associated with accumulation of cholesterol esters in many tissues. Affected patients exhibit markedly reduced high-density lipoproteins and mild hypertriglyceridemia. Accretion of cholesterol leads to enlarged yellow- or orange-colored tonsils, hepatosplenomegaly, cloudy corneas, neuropathy, and premature atherosclerosis. Hematologic manifestations include a mild to moderate hemolytic anemia with stomatocytosis. Erythrocyte membranes have low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in PC. Patients with Tangier disease have mutations in ABCA1, a protein involved in the cellular export of cholesterol.

ACANTHOCYTIC DISORDERS

Acanthocytes are dense, contracted red cells with several irregularly spaced "thorny" projections on the surface. Acanthocytes differ from echinocytes in that there are fewer projections, and the width and length of these projections vary considerably. No central pallor is evident. By contrast, echinocytic spicules are similar in dimension and evenly distributed around the cell periphery. Acquired acanthocytosis is encountered in patients with severe liver disease, in malnourished states such as anorexia nervosa [9], in hypothyroidism, and after splenectomy. Acanthocytosis also is seen in hereditary disorders such as abetalipoproteinemia, the McLeod phenotype, and the neuroacanthocytosis syndromes.

Spur Cell Anemia

Acanthocytosis in liver disease (hepatocellular injury) is attributable to a marked increase in the cholesterol content and the cholesterol to phospholipid ratio of red cell membranes (Fig. 27.13).[179] This red cell lipid profile is in contrast to the equal increase in both cholesterol and phospholipid seen in obstructive liver disease. In cirrhotic liver disease, abnormal lipoproteins produced by the liver are loaded with cholesterol; this excess cholesterol is readily transferred to RBCs, resulting in the formation of flat, scalloped cells.[180] These cells, however, are further conditioned by the spleen, resulting in membrane fragmentation, and the evolution of acanthocytes that look like "spurs."

These spur RBCs are cholesterol loaded, with a decreased surface area to volume ratio, and their cellular deformability is decreased. Once formed, spur cells are destroyed over time by the spleen, accounting for the hemolytic anemia associated with severe liver disease. Such patients usually have moderate-to-severe hemolysis, hyperbilirubinemia, splenomegaly, as well as clinical and laboratory evidence of liver disease. This acanthocytic, spur cell anemia can occur in any condition associated with severe hepatocyte injury.

Abetalipoproteinemia

Abetalipoproteinemia is a rare, autosomal recessive disorder characterized by acanthocytosis, malabsorption of fat, hypolipidemia,

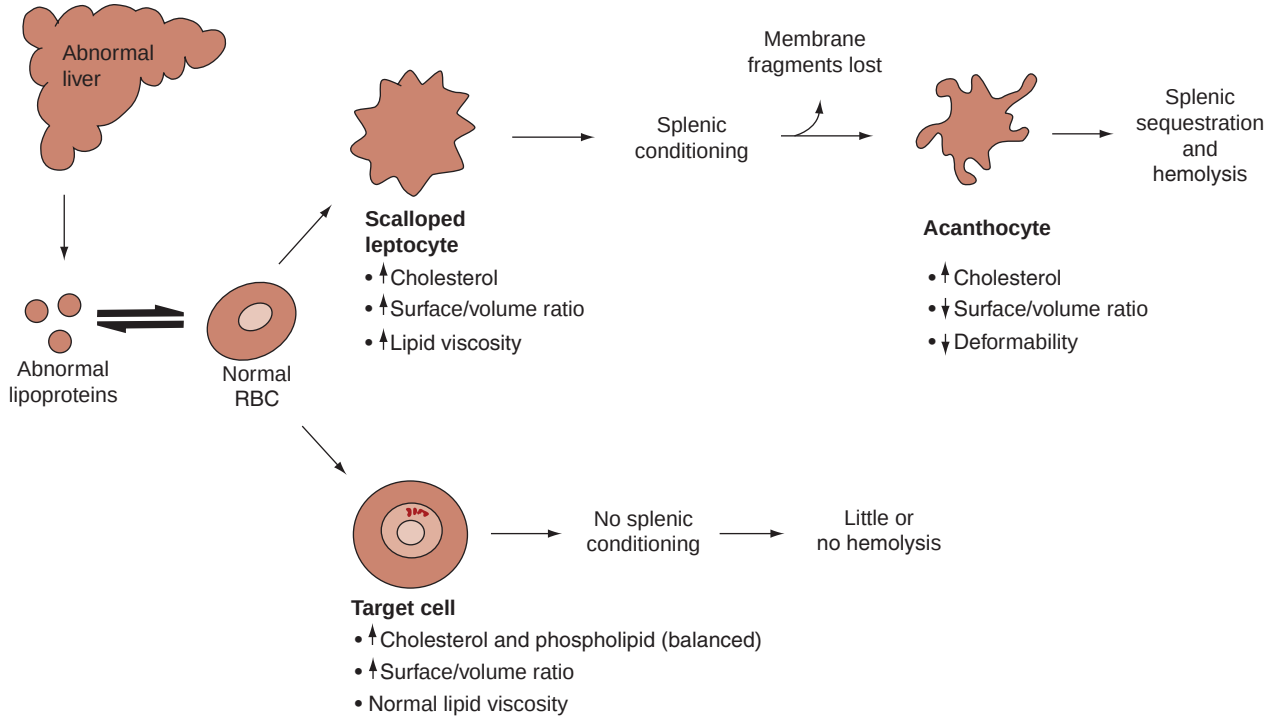

FIGURE 27.13. Alterations of erythrocyte shape in liver disease. N Schematic illustration of the pathophysiology of acanthocyte ("spur cell") and target cell formation in liver disease. RBC, red blood cell. (Reprinted with permission from Gallagher PG, Lux SE, Disorders of the erythrocyte membrane. In: Nathan DG, Orkin SH, Ginsburg D, Look AT, eds. Hematology of infancy and childhood, 6th ed. Philadelphia, PA: WB Saunders, 2003:645.)

retinitis pigmentosa, and progressive ataxia.[181,182] Although affected infants ostensibly are normal at birth, steatorrhea, abdominal distention, and growth failure develop in the first months of life. Retinitis pigmentosa and progressive ataxia are first noted in children between 5 and 10 years of age. Without treatment, neurologic disability is progressive, with death usually occurring during the second or third decade. In some cases, cardiac arrhythmias and heart failure precede death. Many of the clinical abnormalities have been attributed to fat-soluble vitamin deficiency, especially vitamin E, but this has not been well studied. Retinal and neuromuscular abnormalities may be stabilized by the administration of vitamin E.

The primary biochemical defect is failure to synthesize or secrete lipoprotein-containing products of the apolipoprotein B gene, the B apoproteins B100 and B48, or defects in the multifunctional microsomal triglyceride transfer protein,[183] required for production of apoprotein B–containing β-lipoproteins.[184] Absorption of lipids through the intestine is defective, serum cholesterol levels are extremely low, and serum β-lipoprotein is absent. Secondary alterations in CD1 lead to immune defects.[185] The serum appears transparent. Clinical manifestations are variable depending upon the extent to which apolipoprotein B-mediated metabolic processes are affected.

Acanthocyte formation is thought to reflect an increase in the surface area of the outer lipid bilayer relative to the inner bilayer, attributed to increased SM in the outer bilayer mirroring the altered plasma lipid profile of these patients, presumably because of lipid exchange. Normal red cells become acanthocytic when infused into individuals with abetalipoproteinemia. In affected patients, red cell precursors and young erythrocytes are of normal shape, with acanthocyte formation increasing with erythrocyte aging, reaching up to 50% to 90% of erythrocytes on peripheral smear (Fig. 27.14). For unknown reasons, the anemia in abetalipoproteinemia (increased SM) is minimal to mild, whereas in spur cell anemia (increased cholesterol) there is moderate-to-severe hemolysis. Occasionally, severe anemia is observed in patients with abetalipoproteinemia. This is usually the result of broad nutritional deficiencies, including folate deficiency, related to malabsorption.

McLeod Phenotype

The McLeod phenotype, named after the first patient described, is an X-linked abnormality of the Kell blood group system.[186,187] Red cells, leukocytes, or both from affected patients react poorly with Kell antisera. Associated findings in affected males include acanthocytosis ranging from 8% to 85%, a mild, well-compensated hemolytic anemia, and susceptibility to alloimmunization by Kell antigens. Elevated serum creatine phosphokinase levels are seen, often accompanied by myopathy and peripheral neuropathy. Central nervous system abnormalities may appear, particularly after the fourth decade of life. Females have only occasional acanthocytes and minimal to no hemolysis. Because of the susceptibility to alloimmunization, it is important to diagnose affected patients, since if they are transfused, they may develop antibodies compatible only with McLeod red cells.

The McLeod phenotype is the result of mutation in the XK gene located on the X chromosome, which encodes a membrane protein necessary for Kell antigen expression. XK is linked to Kell, a zinc endopeptidase that carries the Kell antigens, by a disulfide bond. McLeod erythrocytes lack XK and Kell proteins. Contiguous X-chromosome gene deletions including the XK gene have led to McLeod individuals with co-inherited chronic granulomatous disease, Duchenne's muscular dystrophy, and/or retinitis pigmentosa.[188]

Neuroacanthocytosis Syndromes

The neuroacanthocytoses are a group of degenerative neurologic disorders marked by great phenotypic and genetic heterogeneity that share the features of acanthocytes on peripheral blood smear.[189,190] These disorders include the X-linked McLeod

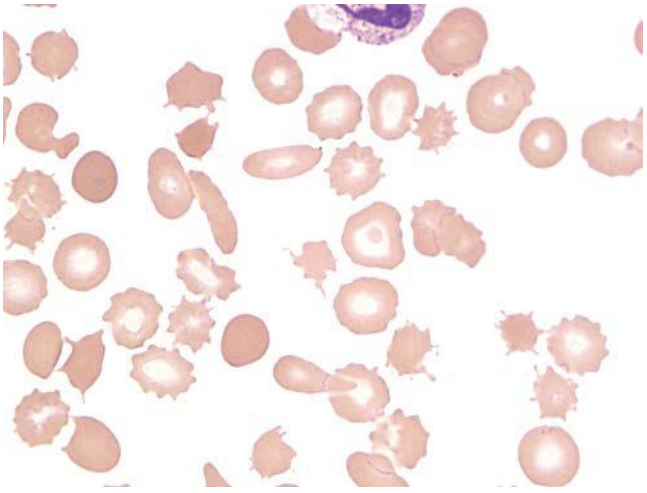

FIGURE 27.14. Acanthocytes. Blood smear from patient with liver disease. Note the numerous erythrocytes with thorny projections, or acanthocytes. (Courtesy of Irma Pereira MT [ASCP]SH.)

syndrome described above; chorea-acanthocytosis (ChAc); and other neurodegenerative disorders such as Huntington's disease like 2 (HDL2), due to mutations in the junctophilin-3 gene; and pantothenate kinase-associated neurodegeneration (formerly known as Hallervorden-Spatz syndrome and its allelic variant HARP syndrome—hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration), due to mutations in the pantothenate kinase 2 (PANK2) gene.[191,192] The etiology of the acanthocytic erythroid phenotype in these disorders is unknown. Further investigation of the pathobiology in erythroid cells may provide important insights into the neurodegenerative processes affecting the brain.

ChAc is an autosomal recessive disorder characterized by acanthocytes, normolipoproteinemia, and progressive neurologic disease, beginning in adolescence or adult life. Neurologic manifestations are variable and may include limb chorea, progressive orofacial dyskinesia, tongue biting, muscle wasting, and hypotonia. Mutations have been identified in the chorein gene (also known as CHAC or VPS13A—vacuolar protein sorting 13 homolog A) in ChAC patients.[193–195,196,197] The role of chorein is unknown, either in erythrocytes or in the brain. In yeast, its homolog is involved in protein sorting and transport. Abnormalities in erythrocyte membrane phosphorylation have been identified, and perturbations in a network of interconnected kinases are suggested to play a role in acanthocyte formation.[198,199]

ECHINOCYTIC DISORDERS

Echinocytes are RBCs with numerous fine uniform spicules distributed equally throughout the cell surface. These cells differ morphologically from acanthocytes, which have fewer projections, and the spicules vary in size. It is thought that echinocytes are the result of preferential expansion of the outer lipid bilayer relative to the inner layer. As mentioned previously, stomatocytes, in contrast, are produced by agents that expand the inner lipid surface area relative to the outer half of the bilayer. The presence of echinocytes on the peripheral blood film often is an artifact caused by interactions of red cells with glass. However, echinocytes also are seen in association with hemolytic anemias in patients with hypophosphatemia, pyruvate kinase deficiency, uremia; and are also seen in some long-distance runners. The mechanism of echinocytosis in these diverse disorders is not clear. In vitro, a variety of factors, such as exposure of red cells to certain drugs, calcium loading, or ATP depletion, can induce echinocyte formation. In echinocytes produced by ATP depletion or calcium loading, it has been suggested that altered phospholipid distribution is a consequence of decreased aminophospholipid translocase activity, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer half of the bilayer to the inner half echinocytes.

TARGET CELL DISORDERS

Target cells are discoid RBCs with a centralized hemoglobinized area in the clear center, resembling a bull's eye or target. Target cells are the morphologic expression of an increase in the ratio of the cell surface area to cell volume. This ratio is influenced by increases in surface area as well as decreases in cell volume. An absolute increase in cell surface area due to net membrane accumulation of phospholipids and cholesterol is the basis of target cell formation in obstructive liver disease and disorders of intrahepatic cholestasis (Fig. 27.13). This accumulation is caused by abnormal low-density lipoproteins that occur in obstructive jaundice. These low-density lipoproteins are laden with cholesterol and lecithin, which is readily transferable to red cell membrane, thereby leading to an expansion of the cell membrane surface. This process explains why HS patients who develop sudden obstructive jaundice due to cholelithiasis have a decrease in hemolysis and normalization of OF; i.e., the increased membrane surface area temporarily normalizes the previously abnormal surface area to volume ratio of spherocytes. Decreased cell volume leading to target cell formation is associated with decreased hemoglobin synthesis (thalassemia or iron deficiency), several structural mutations of hemoglobin (S, C, D, and E), or some primary disorders of cell hydration.

Target cells have decreased OF, as the excess of membrane surface area leads to an increase of the critical hemolytic volume. Typically, an increase in cell surface area does not affect red cell survival, but decreased cell volume associated with cellular dehydration or reduced hemoglobin synthesis may.

Immediately postsplenectomy, target cells appear, reaching levels of 2% to 10%. Like other target cells, membrane lipids are increased, OF is decreased, and the cell surface area to volume ratio is increased.[200] As discussed above, splenic conditioning normally removes excess membrane from erythrocytes. The exact mechanism responsible is not defined, although the reduction in red cell lipid content suggests that lipases may be involved. Postsplenectomy, red cells may eventually lose their excess lipid by conditioning in non-splenic sites, leading to a gradual decrease in target cells.

Familial Lecithin–Cholesterol Acyltransferase Deficiency

Target cells are also observed on peripheral smears of patients with lecithin–cholesterol acyltransferase (LCAT) deficiency. Familial LCAT deficiency is a rare, autosomal recessive disorder due to mutations in LCAT, an enzyme that catalyzes the transfer of fatty acids from PC to cholesterol.[201,202] Manifestations include mild anemia, corneal opacities, hyperlipidemia, renal disease, and premature atherosclerosis.[202,204] In the circulation, LCAT is complexed with high-density lipoproteins. Deficient plasma LCAT activity is responsible for a marked decrease in plasma levels of unesterified cholesterol and an increase in the amount of free cholesterol. The red cell membrane may contain twice the normal amounts of unesterified cholesterol, but PC also is increased, whereas SM and PE are reduced. These RBC lipid changes are reversible when the target cells are incubated with normal plasma. Typically the anemia of LCAT deficiency is mild, with both hemolysis and decreased erythropoiesis due to

renal disease implicated in its etiology. Foam cells and "sea-blue histiocytes" laden with unesterified cholesterol and PC are found in the bone marrow and the spleen of affected patients.

CHAPTER 28

HEREDITARY HEMOLYTIC ANEMIAS DUE TO RED BLOOD CELL ENZYME DISORDERS

Bertil Glader

OVERVIEW OF ERYTHROCYTE METABOLISM

Mature red blood cells (RBCs) are anucleate (thereby incapable of cell division), devoid of ribosomes (thereby incapable of protein synthesis) and lack mitochondria (thereby incapable of oxidative phosphorylation). Despite these limitations RBC survive 100 to 120 days in the circulation, and effectively deliver oxygen to peripheral tissues. Glucose is the main metabolic substrate of red blood cells and it is metabolized by two major pathways: the glycolytic or "energy producing" pathway and the hexose monophosphate (HMP) shunt or "protective" pathway. Under normal conditions approximately 90% of glucose flows through glycolysis, with a much smaller fraction being channeled through the HMP pathway. However, the fraction of glucose entering the pentose phosphate pathway can increase significantly under conditions of increased oxidative stress. The major products of glycolysis are ATP (a source of energy for numerous RBC membrane and metabolic reactions), NADH (a necessary cofactor for methemoglobin reduction by cytochrome b5 reductase), and 2,3-diphosphoglycerate ([2,3-DPG], an important intermediate that modulates hemoglobin-oxygen affinity) (Fig. 28.1). Mature RBC are incapable of de novo purine or pyrimidine synthesis, although many enzymes of nucleotide metabolism are present in erythrocytes. The latter are now known to be important for RBC preservation in vitro; and it also is recognized that abnormalities in purine and pyrimidine metabolism are associated with inherited hemolytic disease.

The consequences of red cell enzymopathies are diverse. Some enzyme variants cause hemolytic disease, with anemia being the sole expression of the enzymopathy. In other enzyme disorders hemolysis is one feature of a multisystem disease affecting many tissues. Also, in some cases erythrocyte enzyme abnormalities have no adverse effects on RBC function, and, if they occur in patients with hemolytic anemia, it is not always clear that the enzyme deficiency and hemolysis are causally related. This chapter focuses on the varied enzyme defects associated with hemolysis. These RBC enzyme disorders are due to abnormalities in the HMP shunt and glutathione metabolism, glycolytic enzyme deficiencies, and abnormalities in purine and pyrimidine metabolism.

DISORDERS OF HEXOSE MONOPHOSPHATE SHUNT AND GLUTATHIONE METABOLISM

The HMP shunt pathway metabolizes 5% to 10% of glucose utilized by red blood cells, and this is critical for protecting red cells against oxidant injury (Fig. 28.2). The HMP pathway is the only RBC source of reduced nicotinamide adenine dinucleotide phosphate (NADPH), a cofactor important in glutathione metabolism. Red blood cells contain relatively high concentrations of reduced glutathione (GSH), a sulfhydryl-containing tripeptide (glutamylcysteinylglycine) which functions as an intracellular reducing agent that protects cells against oxidant injury. Oxidants, such as superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), are produced by exogenous factors (i.e., drugs, infection) and also are formed within red cells as a consequence of reactions of hemoglobin with oxygen. However, when these oxidants accumulate within red cells, hemoglobin and other proteins are oxidized, leading to loss of function and RBC death. Under normal circumstances this does not occur, since GSH, in conjunction with the enzyme glutathione peroxidase (GSH-Px), rapidly inactivates these compounds. During the oxidant detoxification process, however, GSH itself is converted to oxidized glutathione (GSSG), and GSH levels fall. In order to sustain protection against persistent oxidant injury, GSH levels must be maintained, and this is accomplished by glutathione reductase (GSSG-R), which catalyzes reduction of GSSG to GSH. This reaction requires the NADPH generated by glucose-6-phosphate dehydrogenase (G6PD), the first enzymatic reaction of the HMP shunt. Thus, it is the tight coupling of the HMP shunt and glutathione metabolism that is responsible for protecting intracellular proteins from oxidative assault. Almost all hemolytic episodes related to altered HMP shunt and glutathione metabolism are due to G6PD deficiency, and this enzyme deficiency is known to affect millions of people throughout the world.[1–4] Rare cases of hemolysis associated with decreased GSSG-R activity, GSH-Px deficiency, and deficiencies of GSH synthetic enzymes also have been described.

Glucose-6-Phosphate Dehydrogenase Deficiency

The importance of this enzyme for red cell integrity was first recognized following the observation that some African-American soldiers taking the antimalarial drug primaquine would develop acute hemolytic anemia with hemoglobinuria. Initially it was observed that GSH was decreased in the RBC of susceptible individuals during acute hemolytic episodes. Subsequently, the activity of G6PD, one of the enzymes needed to keep adequate GSH levels, was found to be deficient in affected red cells.[5,6] Soon thereafter, the worldwide distribution of G6PD deficiency became apparent, and the variation of clinical expression of enzyme deficiency was discovered. In most individuals with G6PD deficiency, there is no anemia in the steady state, reticulocyte counts are normal, but RBC survival may be slightly decreased. However, episodic exacerbations of hemolysis accompanied by anemia occur in association with the administration of certain drugs, with some infections, and with the eating of fava beans. In a minority of cases G6PD deficiency is associated with a chronic hemolytic process. To date, over 400 G6PD biochemical variants have been recognized.[2,3,7]

Genetics

The gene for G6PD is located on the X chromosome (band X q28),[8–10] The fact that normal males and females have the same enzyme activity in their red cells is explained by the Lyon hypothesis.[1,11] This hypothesis maintains that one of two X chromosomes in each cell of the female embryo is inactivated and remains inactive throughout subsequent cell divisions for the duration of life. In fact, it was studies by Beutler on females with G6PD deficiency which were used in proof of the Lyon hypothesis.[12] Enzyme deficiency is expressed in males carrying a variant gene, whereas heterozygous females usually are clinically normal. However, dependent upon the degree of lyonization, and the degree to which the abnormal G6PD variant is expressed, the mean red blood cell enzyme activity in females may be normal, moderately

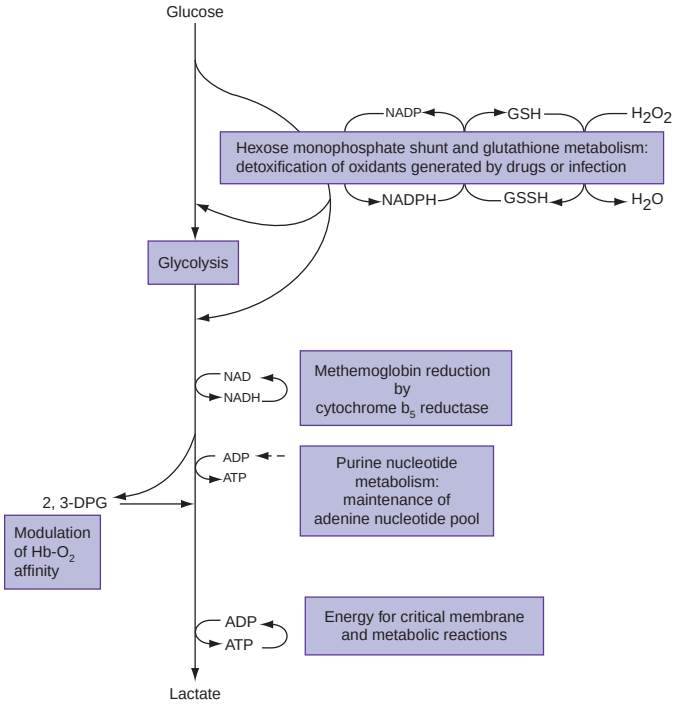

FIGURE 28.1. Summary of overall glycolysis, hexose monophosphate shunt, glutathione metabolism, and red blood cell (RBC) nucleotide metabolism. GSH, reduced glutathione; GSSG, oxidized glutathione; 2,3-DPG, 2,3-diphosphoglycerate NADPH, nicotinamide adenine dinucleotide phosphate.

reduced, or grossly deficient. A female with 50% normal G6PD activity has 50% normal red cells and 50% G6PD-deficient red cells. The G6PD-deficient cells in females, however, are as vulnerable to hemolysis as are enzyme-deficient red blood cells in males.

The concept of X chromosome inactivation and the study of G6PD has been informative in other areas. In particular, it has facilitated our understanding of monoclonal and multiclonal disorders of cell proliferation. Most tumors, both benign and malignant, can be demonstrated to have a clonal origin, being derived from one cell.[13–15] For example, analysis of the G6PD enzyme in uterine myomata of women heterozygous for G6PD A and G6PD B revealed that any given tumor had either G6PD A or enzyme B, but not both.[16] The same principle has been used to demonstrate the clonal origin of the malignant transformation of acute leukemia[17,18] and chronic myelocytic leukemia,[19] and also the clonal nature of polycythemia vera,[20] primary thrombocythemia,[21] and paroxysmal nocturnal hemoglobinuria.[22]

Prevalence and Geographic Distribution

Deficiency of G6PD is the most common metabolic disorder of red blood cells and has been estimated to affect over 400 million people worldwide.[2,3,23] Although global in its distribution, G6PD deficiency is encountered with greatest frequency in the tropical and subtropical zones of the Eastern Hemisphere. The incidence of the deficiency state is approximately 20% among African Bantu males,[24,25] 12% in African-American men,[26] and 8% in Brazilian blacks. As many as 20% of female African-Americans may be heterozygous for G6PD mutants,[27] and as many as 1% are homozygous. In Sardinia, the incidence varies from 35% at low altitudes to 3% in areas above 600 meters.[28] The deficiency state has been reported from most areas of Greece, again with greatest frequency (20% to 32%) in the lowlands.[29] The condition is also prevalent among Sephardic Jews, and as many as 60% to 70% of Kurdish Jews may be affected.[3,30,31] In the male Asian population, the incidence of G6PD deficiency is estimated to be 14% in Cambodia,[32] 5.5% in South China,[33,34] 2.6% in India,[32] and less than 0.1% in Japan.[35] In China the frequency of G6PD deficiency in males ranges from 0% to 17.4%, with the highest prevalence being seen in ethnic groups geographically related to historical malaria. It is rare among Native Americans.[36]

Because of its high incidence among populations in which malaria was once endemic, G6PD deficiency is thought to have conferred a selective advantage against infection by falciparum malaria.[37–39] Partial indirect support for this is that G6PD deficiency in Sardinia is more common at sea level compared to higher elevations, and this also parallels the endemicity of malaria. In addition, it has been observed that parasitized female heterozygotes for G6PD deficiency (who therefore have normal and G6PD-deficient RBC) have more malaria parasites in normal erythrocytes compared to their own G6PD-deficient cells.[40] Moreover, it has been demonstrated that the in vitro growth of malarial parasites is inhibited in G6PD-deficient red cells.[41] The

precise reasons for the observed inhibition of parasite growth in G6PD-deficient red cells are not known. One possibility is that the oxidant stress which causes GSH instability, and destroys the host RBC, also kills the parasite.[2,42–44]

The Enzyme and Its Variants

The monomeric form of G6PD contains 515 amino acids and has a molecular weight of 59 KDa.[45,46] The active form of G6PD in vivo is a dimer which requires NADP for its stability.[47] The G6PD gene has been cloned and sequenced. It is known to contain 13 exons, and is over 18 kb in length.[46,48,49]

The normal or wild-type enzyme is G6PD B, although hundreds of variant enzymes now have been identified. By international agreement, standardized methods have been used to characterize these enzyme variants, which differ on the basis of biochemical properties such as kinetic activity, electrophoretic mobility, the Michaelis constant for its substrate glucose-6-phosphate and cofactor NADP, the ability to utilize different substrate analogues, heat stability, and pH optima. Throughout the years the published list of recognized G6PD biochemical variants has been periodically updated,[50,51] and over 400 biochemical variant forms of G6PD are recognized.[3] However, differences between some variants are subtle, and most likely reflect minor technical differences between laboratories rather than true enzyme differences. Moreover, advances in molecular biology have revealed that many biochemical G6PD variants, in fact, have the same DNA defect (see below).

The World Health Organization (WHO) has classified G6PD variants on the magnitude of the enzyme deficiency and also the severity of hemolysis.[52] **Class I variants** have very severe enzyme deficiency (less than 10% to.20% of normal) and have chronic hemolytic anemia. **Class II variants** also have severe enzyme deficiency (less than 10% of normal), but there is usually only intermittent hemolysis. **Class III variants** have moderate enzyme deficiency (10% to 60% of normal) with intermittent hemolysis usually associated with infection or drugs. **Class IV variants** have no enzyme deficiency or hemolysis. **Class V variants** are those in which enzyme activity is increased. Variants in the last two groups, although of much interest to biologists, geneticists, and anthropologists, are of no major clinical significance.

The normal wild-type enzyme, G6PD B, is found in most Caucasians, Asians, and a majority of blacks. It has normal catalytic activity and is not associated with hemolysis (Class IV). A commonly encountered variant is G6PD A^+ which is found in 20% to 30% of blacks from Africa.[53] It has normal catalytic properties and does not cause hemolysis (Class IV). It differs from G6PD B in that it has a much faster electrophoretic mobility (the letters A and B refer to relative electrophoretic mobilities). The structure of G6PD A^+ differs from that of G6PD B by the substitution of a single amino acid, an asparagine for aspartate at the 126th position of the protein.[54] Another common variant, G6PD A^-, is the enzyme responsible for primaquine sensitivity in blacks, and it is the most common variant associated with mild to moderate hemolysis (Class III). This G6PD variant is found in 10% to 15% of African-Americans, and with similar frequencies in western and central Africa.[55] It has an electrophoretic mobility identical to that of G6PD A^+. However, this is an unstable enzyme and its catalytic activity, although nearly normal in bone marrow cells and reticulocytes,[56] decreases markedly in older RBC.[57] Hence, this variant is designated G6PD A^- compared with G6PD A^+ (the + and − denote enzyme activity). G6PD Mediterranean is a common abnormal variant found in people whose origins are in the Mediterranean area. However, this same variant also is found in the Middle East and India.[2] The electrophoretic mobility of G6PD Mediterranean is identical to that of G6PD B, but its catalytic activity is markedly reduced, and hemolysis can be severe (Class II).[56] G6PD Canton is a common variant enzyme seen in Asians.[58] Its biochemical properties are very similar to those of G6PD Mediterranean.

Advances in molecular biology have further enhanced our understanding of G6PD deficiency, and now over 160 different gene mutations or mutation combinations have been identified.[2,59,60,61] These DNA changes almost all are missense mutations leading to single amino acid substitutions in the enzyme. Large deletions have not been identified, suggesting that complete absence of G6PD might be lethal.[3] The mutations are located throughout the entire coding region of the gene.[62] However, in Class I variants associated with chronic hemolysis, mutations are clustered around exon 10, an area that governs the formation of the active G6PD dimer.[62,63] The correlation between the different biochemical variants, the site of genetic mutation, and the extent of hemolysis is a matter of current investigation.[2]

An interesting example of how molecular biology has enhanced our understanding relates to G6PD A^-, once thought to be a single unstable variant found in blacks throughout the world. However, molecular analysis now has demonstrated that G6PD A^- may have more than one genotype. In all cases there is a mutation at nucleotide 376 (A→G), which also is the nucleotide substitution characteristic of G6PD A^+. In addition, the G6PD A^- variants have a second mutation, and in the majority of cases it is at nucleotide 202 (G→A).[3,64] A smaller fraction of G6PD A^- subjects have the second substitution at nucleotide 680 (G→T) or at nucleotide 968 (T→C).[65] Thus, the G6PD A^- variant, once thought to be a single homogeneous mutation in Africans, now turns out to represent at least three different genotypes.[3] Also, a number of G6PD variants originally described in non-Africans are now found to have one of the known G6PD A^- mutations (Table 28.1). For example, G6PD Betica,[66] a Spanish variant and G6PD Matera,[67] an Italian variant, have demonstrated base substitutions at nucleotides 202 and 376, identical to the common G6PD A^- variant. They are examples, therefore, of G6PD A^-. One subject with G6PD Betica had base substitutions at nucleotides 376 and 968, identical to the less common G6PD A^- variant.[66]

There are several other variants that appear clinically and biochemically heterogeneous but have been found to be genetically more uniform. For example, G6PD Mediterranean involves many different ethnic groups, although most subjects have the same genetic defect, a single base substitution (C→T) at nucleotide 563.[66,67,68] Moreover, just as in the case of G6PD A^-, many of the different biochemical variants have turned out to have the same molecular defect as G6PD Mediterranean (Table 28.1).

In China there are at least 21 variants causing G6PD deficiency. The three most common are G6PD Canton (G→T at nucleotide 1,376), G6PD Kaiping (G→A at nucleotide 1,388), and G6PD Gaohe (A→G at nucleotide 95).[69]

G6PD Canton and G6PD Gaohe are mainly regarded as WHO Class II variants, while G6PD Kaiping is considered a WHO Class III variant.

Because leukocyte and platelet G6PD is regulated by the same gene as that of red cells, documentation of decreased activity in the white blood cells[70,71,72] and platelets[71] of deficient individuals is not surprising. Because of the normally short survival of leukocytes and platelets, however, most individuals with G6PD deficiency do not manifest impairment of phagocytosis or bactericidal activity of granulocytes.[71,72] The exception to this occurs with Class I G6PD deficiency, where some affected individuals may have neutrophil dysfunction and increased susceptibility to infection.[73,74]

Pathophysiology

As red cells age, the activity of G6PD declines. The normal enzyme (G6PD B) has an in vivo half-life of 62 days.[56] Despite this loss of enzyme activity, normal old red blood cells contain sufficient G6PD activity to generate NADPH and thereby sustain GSH levels in the

Data modified from Beutler, E., G6PD deficiency. Blood 1994;84(11):3613–3636; Beutler, E., Glucose-6-phosphate dehydrogenase deficiency. N Engl J Med 1991;324(3):169–174; Miwa, S. and H. Fujii, Molecular basis of erythroenzymopathies associated with hereditary hemolytic anemia: tabulation of mutant enzymes. Am J Hematol 1996;51(2):122–132.

face of oxidant stress. In contrast, the G6PD variants associated with hemolysis are unstable and have much shorter half-lives. The activity of G6PD A⁻ in reticulocytes is normal, but it declines rapidly thereafter with a half-life of only 13 days.[56,75] The instability of G6PD Mediterranean is even more pronounced, with a half-life measured in hours.[56] The clinical correlate of this age-related enzyme instability is that hemolysis in patients with G6PDA⁻ generally is mild and limited to older deficient erythrocytes. In contrast, the enzymatic defect in G6PD Mediterranean is due to much greater enzyme instability, and red blood cells of all ages are grossly deficient. Consequently, the entire red blood cell population of individuals with G6PD Mediterranean is susceptible to oxidant-induced injury, and this can lead to severe hemolytic anemia.

G6PD-deficient erythrocytes exposed to oxidants (infection, drugs, fava beans) become depleted of GSH. This reaction is central to the cell injury in this disorder since once GSH is depleted there is further oxidation of other RBC sulfhydryl-containing proteins. Oxidation of the sulfhydryl groups on hemoglobin leads to the formation of denatured globin or sulfhemoglobin. The latter form insoluble masses which attach to the red cell membrane by disulfide bridges, and these are known as Heinz bodies.[76] Also, with some Class I variants the oxidation of membrane sulfhydryl groups leads to the accumulation of membrane polypeptide aggregates, presumably due to disulfide bond formation between spectrin dimers and other membrane proteins.[77,78–80] The end result of these changes is the production of rigid, non-deformable erythrocytes that are susceptible to stagnation and destruction by reticuloendothelial macrophages in the spleen and liver.[81,82] Both extravascular and intravascular hemolysis occurs in G6PD-deficient individuals, the latter giving rise to hemoglobinemia and hemoglobinuria. Rare patients with unstable hemoglobinopathies also may manifest oxidant injury, since these abnormal hemoglobins are inordinately susceptible to mild oxidant stress (Chapter 35).

Clinical and Hematologic Features

The clinical expression of G6PD variants encompasses a continuous spectrum of hemolytic syndromes. In most affected individuals the deficiency state goes unrecognized, while in some it causes episodic or chronic anemia. The common clinical entities encountered are acute hemolytic anemia, favism, neonatal hyperbilirubinemia, and congenital nonspherocytic hemolytic anemia.

Acute Hemolytic Anemia

With most G6PD variants, hemolysis occurs only after exposure to oxidant stresses. In the steady state there is no anemia, no evidence of increased red cell destruction, nor alteration in blood morphology. Sudden destruction of enzyme-deficient erythrocytes is triggered by drugs having a high redox potential and by selected infectious or metabolic perturbations. The clinical and laboratory features of an acute hemolytic episode are best illustrated in a figure from a classic study with primaquine-induced hemolysis in subjects with G6PD A⁻ (Fig. 28.3)[5,6] After 2 to 4 days of primaquine ingestion, all the signs, symptoms, and

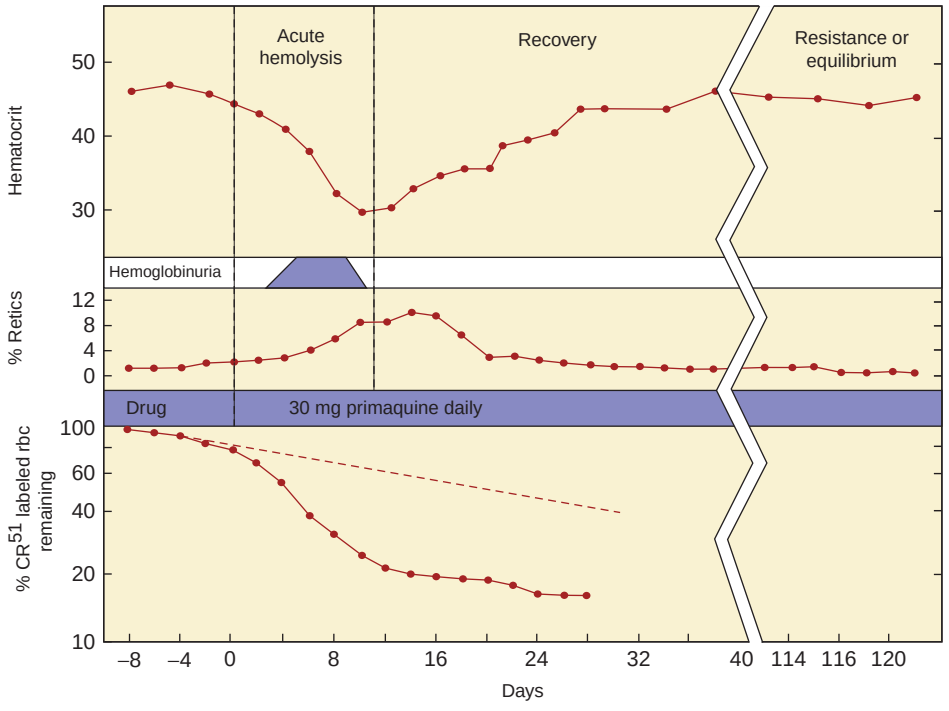

FIGURE 28.3. The course of primaquine-induced hemolysis in the glucose-6-phosphate dehydrogenase (G6PD) A⁻ variant. From Alving A, et al. Mitigation of the haemolytic effect of primaquine and enhancement of its action against exoerythrocytic forms of the Chesson strain of Plasmodium vivax by intermittent regimens of drug administration. Bull WHO 1960;22:621–631.

laboratory results characteristic of an acute hemolytic episode are observed. Jaundice, pallor, and dark urine, with or without abdominal and back pain, are sudden in onset. An abrupt decrement of 3 to 4 g/dl in hemoglobin concentration occurs. The peripheral blood smear contains spherocytes and eccentrocytes or "blister" cells. In response to anemia, red cell production increases; an increase in reticulocytes is apparent within 5 days and is maximal by 7 to 10 days after onset of hemolysis. Despite continued drug exposure, the acute hemolytic process ends spontaneously after about 1 week, and the hemoglobin concentration thereafter returns to normal levels. The anemia is self-limited because the old susceptible population of erythrocytes is replaced by younger RBC with sufficient G6PD activity to withstand an oxidative assault. Although red cell survival remains shortened as long as use of the drug continues, compensation by the erythroid marrow effectively abolishes the anemia in subjects with G6PD A⁻. In contrast, hemolysis occurring with the G6PD Mediterranean variant is more severe because a larger population of circulating erythrocytes is vulnerable to injury.[83] Hemolytic crises occur in heterozygous female subjects, as well as in hemizygous male patients. Of interest, the incidence of clinically significant G6PD deficiency in elderly women reportedly is increased, and this is thought to reflect skewed lyonization that occurs with aging. In a fascinating study from Hong Kong, the incidence of G6PD deficiency in elderly females (80 to 107 years) was increased (1.73%) compared to newborn girls (0.27%).[84] In virtually all cases acute hemolytic episodes are due to administration of drugs, or are associated with infection or fava bean exposure.

Drug-induced Hemolysis. Primaquine is but one of several drugs that can precipitate hemolysis. The common denominator of these drugs is their interaction with hemoglobin and oxygen, thus accelerating the intracellular formation of H_2O_2 and other oxidizing radicals. The published lists of suspect drugs are lengthy; however, many of the putative hemolytic agents were incriminated before it was recognized that infections often mimic the adverse effects of drugs. Consequently, many hemolytic events previously ascribed to drugs may, in fact, have resulted from infections for which drugs were given. Aspirin is such a drug, and it now is recognized that it can safely be given to individuals with Class II and III G6PD variants. Some drugs and chemicals, however, are predictably injurious for all G6PD-deficient subjects,[3,30] and these agents are listed in Table 28.2. Other drugs, although producing a modest shortening of survival of G6PD-deficient red cells, can be given safely in usual therapeutic doses to individuals with Class II and III G6PD variants (Table 28.2). Ascorbic acid is safe in usual therapeutic doses, although large amounts may pose problems.[85] Similarly, acetaminophen (Tylenol), aminopyrine, sulfisoxazole (Gantrisin), sulfamethoxazole, and vitamin K can be given safely in usual therapeutic doses.[30] It also should be noted that other agents that are not drugs also can cause hemolysis in G6PD-deficient individuals. Examples of these include naphthalene (moth balls), henna compounds (used for hair dyes and tattoos), and some Chinese herbs.[86]

Infection-induced Hemolysis. Infection is probably the most common factor inciting hemolysis,[87,88] About 20% of G6PD-deficient subjects with pneumonia experience an abrupt drop in hemoglobin concentration.[87] A variety of infectious agents has been implicated: salmonella,[89–91] *Escherichia coli*,[87] β-hemolytic streptococci,[92] and rickettsiae.[93] Hemolysis is particularly prominent in G6PD-deficient subjects with viral hepatitis.[91,94,95] The accelerated destruction of red cells imposes a bilirubin load on an already damaged liver, resulting in an exaggerated increase in serum bilirubin level. Despite the magnitude of bilirubin retention, however, convalescence is generally complete and uneventful. Although hemolysis triggered by infection characteristically is mild, on rare occasions acute renal failure secondary to massive intravascular hemolysis can occur.[93,94] The mechanism for destruction of G6PD-deficient red cells during infection is not known. One possible explanation for this relationship is that oxidants generated by phagocytosing macrophages may diffuse into the extracellular medium, where they pose an oxidative threat to G6PD-deficient erythrocytes.[96]

TABLE 28.2

DRUGS AND CHEMICALS ASSOCIATED WITH HEMOLYSIS IN G6PD DEFICIENCY

Unsafe (Class I, II, and III G6PD Variants)

Aceteanilide	Thiazolesulfone
Diaminodiphenyl sulfone (Dapsone)	Phenazopyridine (Pyridium)
Furazolidone (Furoxone)	Phenylhydrazine
Glibenclamide	Primaquine
Henna (Lawsone)	Sulfacetamide
Isobutyl nitrate	Sulfanilamide
Methylene blue	Sulfapyridine
Nalidixic acid (Neg—Gram)	Thiazolesulfone
Naphthalene (Mothballs)	Trinitrotoluene (TNT)
Niridazole (Ambilhar)	Urate oxidase (Rasburicase)
Nitrofurantoin (Furadantin)	

Safe in Usual Therapeutic Doses (Class II and III G6PD Variants[a])

Acetaminophen (Tylenol)	Trimethoprim
Acetophenetidin (Phenacetin)	Phenylbutazone
Acetylsalicylic acid (Aspirin)	Phenytoin
Aminopyrine (Pyramidon)	Probenecid (Benemid)
Antazoline (Antistine)	Procainamide hydrochloride (Pronestyl)
Antipyrine	Pyrimethamine (Daraprim)
Ascorbic Acid	Quinine
Benzhexol (Artane)	Streptomycin
Chloramphenicol	Sulfacytine
Chloroguanidine (Proguanil, Paludrine)	Sulfadiazine
Chloroquine	Sulfamethoxazole (Gantanol)
Colchicine	Sulfamethoxypyridazine (Kynex)
Diphenhydramine (Benadryl)	Sulfisoxazole (Gantrisin)
Isoniazid	Tiaprofenic acid
L-Dopa	Trimethoprim
Menadione sodium bisulfate (Hykinone)	Tripelennamine (Pyribenzamine)
p-Aminobenzoic acid	Vitamin K
p-Aminosalicylic acid	

[a]Safety for Class I G6PD variants is not known.
Data modified from Beutler, E. Glucose-6-phosphate dehydrogenase deficiency: a historical perspective. Blood 2008;111(1):16–24.

Hemolysis Associated with Diabetic Acidosis. Diabetic ketoacidosis rarely is associated with triggering destruction of G6PD-deficient red cells.[97] Correction of acidosis and restoration of glucose homeostasis reverses the hemolytic process. Changes in blood pH, glucose,[98] and pyruvate[99] have been proposed as possible mechanisms for hemolysis. Also, occult infection may be a common trigger for inducing both acute hemolysis and diabetic acidosis.

Favism

Exposure to the fava bean (*Vicia fava*, broad bean) is toxic and potentially fatal for some individuals, and this has been known, allegedly, since the time of Pythagoras.[1] Studies several years ago revealed that individuals made ill by the fava bean invariably are deficient in G6PD.[100] Unlike other agents capable of inducing hemolysis, the fava bean is toxic for only some G6PD-deficient individuals. The variant most frequently implicated is G6PD Mediterranean and, as a result, favism is encountered commonly in Italy, Greece, and the Middle East, areas where fava beans are a dietary staple.[3,101] It also occurs in the Asian G6PD variants.[32] Of particular interest, Africans and African-Americans with G6PD deficiency are much less susceptible, although hemolytic episodes have been reported.[102]

Most cases of favism result from ingestion of fresh beans. Consequently, the peak seasonal incidence of this disorder in the Mediterranean is in the spring and coincides with harvesting of the bean.[103] Hemolysis of comparable severity can follow consumption of fried fava beans, a popular Chinese snack. Favism has been observed in nursing infants of mothers who have eaten the beans,[103] as well as in a newborn infant whose mother had eaten fava beans 5 days before delivery.[104] Enzyme deficiency was held responsible for fatal hydrops fetalis in the male infant of a hematologically normal Chinese woman who ingested fava beans during the final month of pregnancy.[105] Moreover, inhalation of pollen from the fava plant has been incriminated.[106]

Favism occurs most commonly in children between the ages of 1 and 5 years. As with other clinical manifestations of G6PD deficiency syndromes, it is seen primarily in males, although it also can occur in females with severe enzyme deficiency. Symptoms of acute intravascular hemolysis occur within 5 to 24 hours of ingestion of the bean. Headache, nausea, back pain, chills, and fever are followed by hemoglobinuria, anemia, and jaundice. The drop in hemoglobin concentration is precipitous, often severe, and may require a red cell transfusion.

Favism does not occur in all susceptible G6PD individuals,[107] and it is thought that additional genetic factors are involved, presumably related to how fava bean oxidants are metabolized. Furthermore, the reaction to the fava bean by the same individual at different times may not be consistent.[103] Clearly, a factor other than enzyme deficiency is operative. Two pyrimidine aglycones, divicine and isouramil, have been implicated as the toxic components of fava beans.[108,109] Both compounds rapidly overwhelm the GSH-generating capacity of G6PD-deficient cells and reproduce many of the metabolic derangements noted during hemolytic episodes.[110] To date, however, there are no convincing data to explain the erratic hemolytic episodes seen in favism.

Neonatal Hyperbilirubinemia

Hyperbilirubinemia and hemolysis resulting from G6PD deficiency are well documented in the newborn period, rarely present at birth but with a peak incidence of clinical onset between days 2 and 3.[111–113] In most cases there is more jaundice than anemia. Close monitoring of serum bilirubin levels in infants known to be G6PD-deficient is warranted.[114,115,116] Neonatal hyperbilirubinemia is seen with G6PD Mediterranean (Class II) variants. An increase in the incidence of neonatal hyperbilirubinemia also is seen in Southeast Asia[32,117] and China[118]; and a significant fraction of the latter are associated with G6PD Canton.[119] African-American infants with G6PD A^- (Class III) once were considered to be at minimal risk, but this is no longer held; and significant hyperbilirubinemia can occur in these neonates.[111,120,121] In Africa, untreated hyperbilirubinemia often leads to kernicterus with severe neurologic injury or death.[122,123] It is of interest that data from the USA Kernicterus Registry from 1992 to 2004 indicate that over 30% of kernicterus cases are associated with G6PD deficiency.[124]

The observation that the incidence of hyperbilirubinemia in G6PD-deficient infants born in Australia to Greek immigrants is lower than that noted in deficient infants in Greece suggests that local environmental variables are probably important.[125] Herbs used in traditional Chinese medicine and clothing impregnated with naphthalene also are examples of covert oxidants to which susceptible infants may be exposed. Lastly, drugs (e.g., sulfonamides) and fava bean ingestion by mothers in late gestation have been implicated as the inciting stimulus of hemolysis in newborns.[105,121,126]

Although the cause of hyperbilirubinemia in G6PD-deficient infants sometimes reflects accelerated red cell breakdown,[112,123,127] often there is no obvious RBC destruction or oxidant exposure. It has been suggested that hyperbilirubinemia may have another etiology, possibly related to impaired liver clearance of bilirubin. In support of this hypothesis are the observations that carboxyhemoglobin production, a marker of hemolysis or RBC breakdown, is the same in G6PD Mediterranean deficient neonates with and without hyperbilirubinemia.[128] It is now thought that the variable degree of hyperbilirubinemia in G6PD-deficient neonates reflects the presence or absence of the variant form of uridine-diphosphoglucuronosyl-transferase responsible for Gilbert's syndrome.[116] The relative importance of the latter is underscored by the observation that most jaundiced G-6-PD neonates are not anemic and that evidence for increased bilirubin production secondary to hemolysis often is lacking.[129]

Congenital Nonspherocytic Hemolytic Anemia

A very small fraction of G6PD-deficient individuals have chronic lifelong hemolysis in the absence of infection or drug exposure. These rare Class I G6PD variants are extremely heterogeneous with respect to biochemical kinetics, but have in common very low in vitro activity and/or marked enzyme instability.[63] Most of these variants have DNA mutations at exon 10, an area which affects monomer-dimer interactions and thereby enzyme activity.[63] The hemolytic anemia associated with Class I variants is indistinguishable from the congenital nonspherocytic hemolytic syndromes related to glycolytic enzyme deficiencies.

Anemia and jaundice often are noted first in the newborn period. Hyperbilirubinemia often necessitates exchange transfusion. Typically, hemolysis occurs in the absence of a recognized triggering factor, although exposure to drugs or chemicals with oxidant potential exaggerates an already established hemolytic process. Beyond infancy, signs and symptoms of the hemolytic disorder are subtle and inconstant. Exaggeration of anemia occurs after exposure to drugs with oxidant properties, even those that are safe for individuals with Class II and III G6PD variants. Hemolysis also can be accelerated with exposure to fava beans.[130]

No hematologic alterations of the Class I variants are distinctive. The hemolytic process may be fully compensated, although mild to moderate anemia is the rule (hemoglobin 8 to 10 g/dl). Under basal conditions the usual reticulocyte count is 10% to 15%. Splenectomy is sometimes of benefit.[131]

In a few instances, leukocyte dysfunction associated with Class I variant G6PD deficiency has been described.[73,74,132] The abnormality is characterized functionally by defective bactericidal activity (but normal chemotaxis and phagocytosis), and clinically by recurrent infections with catalase-positive organisms. Overall, however, clinical infections are not a major problem in G6PD deficiency.

Diagnosis

Because of its prevalence and worldwide distribution, G6PD deficiency should be given serious consideration in the differential diagnosis of any nonimmune hemolytic anemia. Most commonly, anemia is first recognized during or after an infectious illness, after exposure to one of several suspect drugs or chemicals, or following exposure to fava beans. Also, G6PD deficiency should be considered in neonates with excessive and unexplained hyperbilirubinemia. Clinical and hematologic features reflect the severity of hemolysis but are not themselves specifically from G6PD deficiency. Irregularly contracted erythrocytes (eccentrocytes with hemoglobin puddled to one side of the RBC) and "bite" cells are seen in the Wright-stained peripheral blood smear. Previously, these bite cells were considered a consequence of splenic removal of Heinz bodies. Now, however, it is recognized that these RBC contain a coagulum of hemoglobin which has separated from the membrane, often leaving an unstained non-hemoglobin–containing cell membrane (i.e., having the appearance of a bite removed from the cell).[80] These morphologic alterations are a consequence of the oxidative assault on hemoglobin. Brilliant cresyl blue supravital stains of the peripheral blood may reveal Heinz bodies during hemolytic episodes.

The specific diagnosis of G6PD deficiency is made by adding a measured amount of hemolysate to an assay mixture containing substrate (glucose-6-phosphate) and cofactor (NADP) and then spectrophotometrically measuring the rate of NADPH generation.[133] Alternatively, a variety of screening tests which utilize hemolysate as a source of enzyme also can be used. The fluorescent spot test is the simplest, most reliable, and most sensitive of the screening methods.[134] This test is based on the fluorescence of NADPH, after glucose-6-phosphate and NADP are added to a hemolysate of test cells. Other screening methods detect NADPH generation indirectly by measuring the transfer of hydrogen ions from NADPH to an acceptor. In the methemoglobin reduction test,[135] methylene blue is the acceptor used for the transfer of hydrogen from NADPH to methemoglobin, thereby facilitating its reduction. It is important to mention this test because, when combined with a technique for the elution of methemoglobin from intact cells, it can be used to detect relative G6PD sufficiency of individual RBC,[136] thereby detecting the carrier state with approximately 75% reliability. Regardless of the screening test used to detect G6PD deficiency, it should be recognized that false negative reactions occur if the most severe enzyme-deficient red blood cells have been removed by hemolysis. This generally is not critical in testing male Caucasians, but it certainly is a problem in diagnosing some Caucasian females and blacks of both sexes, especially during the reticulocytosis following acute hemolysis. In these cases, family members can be studied. An alternative approach to diagnosis is to wait until the hemolytic crisis is over and reevaluate the patient after the red blood cell mass is repopulated with cells of all ages (approximately 2 to 3 months). False negative tests are less of a problem in diagnosing G6PD deficiency when quantitative spectrophotometric enzyme assays are utilized.

Treatment

Management of the patient with G6PD deficiency is determined by the clinical syndrome with which it is associated. Individuals having variants associated with acute hemolysis may have a significant fall in hemoglobin concentration requiring a RBC transfusion. This is the case more commonly in G6PD Mediterranean (Class II) then in G6PD A^- (Class III). All affected individuals should avoid exposure to drugs known to trigger hemolysis. Pregnant and nursing women known to be heterozygous for the deficiency also should avoid ingestion of drugs with oxidant potential, because some gain access to the fetal circulation and to breast milk. If the indication for its use is sound, however, an offending drug justifiably may be given despite modest shortening of red cell survival. For example, primaquine is safely given to individuals with the G6PD A^- variant, provided it is started cautiously (15 mg/day or 45 mg once or twice weekly) and the blood count is monitored closely.[137] The mild anemia caused by its administration is rapidly corrected by a compensatory erythropoietic effort and does not recur unless the dose of drug is escalated.

Chronic nonspherocytic hemolytic anemia due to Class I G6PD variants may require more active intervention. Exchange transfusion during the first week of life often is required to prevent bilirubin encephalopathy. Beyond the newborn period, anemia rarely is of such severity as to require regular blood transfusions. During aplastic crises, however, transfusions may be lifesaving. As with other syndromes resulting from G6PD deficiency, drugs capable of exaggerating hemolysis should be avoided. Splenectomy, although occasionally bringing about a modest improvement in hemoglobin concentration,[138] is generally without benefit.[131] Because

of its antioxidant properties, vitamin E had been proposed as a therapeutic agent,[139–141] but subsequent evaluation of large doses of the vitamin failed to demonstrate an ameliorative effect on anemia.[142]

Therapy for *hyperbilirubinemia and neonatal hemolysis* resulting from G6PD deficiency includes the following: phototherapy or exchange transfusion to prevent kernicterus; RBC transfusion for symptomatic anemia; removal of potential oxidants that may be contributing to hemolysis, and treatment of associated infections. In infants known to be G6PD-deficient, prevention of severe hyperbilirubinemia by administration of a single IM dose of Sn-mesoporphyrin, an inhibitor of heme oxygenase, is highly effective and appears safe; but this therapy is not yet clinically available.[143,144] A study from Nigeria has reported a much poorer outcome for G6PD-deficient infants born at home, presumably a reflection of delayed identification and treatment of hyperbilirubinemia in these neonates.[123] In the United States, guidelines have been established for following hyperbilirubinemia in babies following discharge from the hospital.[111]

Screening

Aside from the District of Columbia, there is no generalized neonatal screening program for G6PD deficiency in the United States. The approach here has been to recognize that neonatal hyperbilirubinemia may be caused by G6PD deficiency and these children should be tested and monitored closely. In some countries where the predominant G6PD variants are Class II mutations, screening programs have been instituted. Neonatal screening for G6PD deficiency has been very effective in reducing the incidence of favism later in life in Sardinia[145] and other regions where this potentially fatal complication is common.[112] Prenatal diagnosis utilizing molecular techniques is potentially available, but the benign course of most G6PD variants has precluded its development.[146]

Routine blood bank screening has been considered unwarranted and G6PD deficiency is not considered a problem in transfusion medicine. Even in areas where G6PD deficiency is endemic, screening of blood donors is not required. One careful evaluation of the recipients of G6PD-deficient blood uncovered no deleterious consequences.[147] However, patients receiving G6PD Mediterranean blood may have an increased serum bilirubin and lactate dehydrogenase (LDH) concentration following transfusion, and this can be confused with a transfusion reaction.[148] In premature infants, simple transfusions with G6PD-deficient red cells have been associated with hemolysis and severe hyperbilirubinemia requiring exchange transfusion.[149] Also, massive intravascular hemolysis has occurred in an Indian neonate following an exchange transfusion with G6PD-deficient blood.[150] In view of these occurrences, it has been recommended that in areas where G6PD deficiency (presumably Class II variants) is common, donor blood should be screened for the enzyme before transfusing premature infants[149] or using the blood for a neonatal exchange transfusion.[150] This recommendation currently is not standard blood banking practice.

Related Disorders of Hexose Monophosphate Shunt and Glutathione Metabolism

In addition to G6PD, other enzymes of the HMP shunt pathway (6-phosphogluconate dehydrogenase [6PGD]), the closely linked reactions of glutathione metabolism (GSSG-R, GSH-Px), and the glutathione synthetic pathway are important in protecting RBC against oxidant injury. Rare abnormalities in these enzymes have been reported, and in some cases they are associated with hemolysis.

6-Phosphogluconate Dehydrogenase Deficiency

The enzyme 6PGD catalyzes the conversion of 6-phosphogluconate to pentose-5-phosphate (Fig. 28.2), and, in the process, NADPH is generated from NADP. Although deficiency of 6PGD is well documented, it appears to have little or no significance for red cell viability. Presumably this reflects the fact that NADPH is generated by the proximal enzyme, G6PD, suggesting that the second dehydrogenase may not be necessary for cell integrity.

Glutathione Reductase Deficiency

GSSG is reduced in the presence of NADPH by GSSG-R (Fig. 28.2). The enzyme contains flavin adenine dinucleotide (FAD) as a prosthetic component, and as a result, normal enzyme activity is dependent on the dietary availability of riboflavin. Not surprisingly, partial GSSG-R deficiency is a relatively common feature of disorders that are compounded by suboptimal nutrition.[151] GSSG-R levels are restored within days by the administration of physiologic quantities of riboflavin.[152] The association between riboflavin induced GSSG-R deficiency and various disease states is of no hematologic consequence.[152,153]

Genetically determined GSSG-R deficiency has been documented in three siblings who were offspring of a consanguineous marriage.[154] Enzyme activity was not enhanced by incubation of hemolysates with FAD. Despite near absence of erythrocyte GSSG-R activity, the siblings were hematologically normal, except for episodes of hemolysis after the ingestion of fava beans. All three of the siblings acquired cataracts at an early age (24 to 32 years).[155] During the past 35 years, there have been no new reports of hereditary GSSG-R deficiency associated with hemolysis.

Glutathione Peroxidase Deficiency

GSH-Px catalyzes the oxidation of GSH by peroxides, including hydrogen peroxide and organic hydroperoxides (Fig. 28.2). Rare cases of hemolysis in association with moderate deficiency of erythrocyte GSH-Px activity have been described in adults and children.[156–158] Of all the reported cases suggesting a relationship between hemolysis and GSH-Px deficiency, one of the most persuasive was that of a 9-month-old Japanese girl with chronic nonspherocytic hemolytic anemia.[159] This patient's erythrocyte GSH-Px activity was 17% of control activity, while her hematologically normal parents had 51% to 66% control enzyme activity. However, it is not known whether this specific enzyme defect was responsible for the patient's chronic hemolytic anemia. The general consensus today is that GSH-Px deficiency is probably not a cause of hemolysis or other hematologic problems. The reason for this opinion is that many healthy normal individuals, particularly those of Jewish or Mediterranean ancestry, have reduced GSH-Px activity without evidence of hemolysis.[160] Moreover, low GSH-Px activity, in the absence of hemolysis, also is observed in normal people from New Zealand with selenium (Se) deficiency (Se being an integral part of GSH-Px).[161,162] In view of these observations, the role of GSH-Px deficiency as a cause of hemolysis is questioned. Some argue that GSH-Px is only one of the cellular mechanisms available to detoxify peroxides. Under physiologic conditions, catalase and nonenzymatic reduction of oxidants by GSH also may be important factors regulating the rate of H_2O_2 detoxification. From a clinical perspective, because of the questionable role of GSH-Px, any patient with hemolytic anemia and reduced GSH-Px activity should be extensively evaluated for other causes of hemolysis.

Defects in Glutathione Synthesis

Glutathione is actively synthesized in RBC and has an intracellular half-life of only 4 days, in part due to cellular efflux of GSSG. RBC are capable of de novo GSH synthesis, and this is

accomplished by two critical enzymes (Fig. 28.3). γ-Glutamyl-cysteine synthetase (GCS) catalyzes the first step in GSH synthesis, the formation of γ-glutamyl-cysteine from glutamic acid and cysteine. Glutathione synthetase (GS) catalyzes the formation of GSH from glutamyl-cysteine and glycine. In many tissues, but not RBC, these two enzymes are part of the γ-glutamyl cycle, which is involved with the synthesis and degradation of GSH and is also thought to have a role in amino acid transport across cell membranes. Hereditary hemolytic anemia, characterized by reduced GSH content, has been reported in patients with deficiencies of both GCS and GS activity. The clinical effects of these disorders depends on the severity of enzyme deficiency and whether the γ-glutamyl cycle also is affected in non-erythroid tissues.

γ-Glutamyl-cysteine synthetase deficiency is a rare hemolytic anemia which was first described in two adults who were brother and sister.[163] Both of these patients had a lifelong history of mild hemolytic anemia, intermittent jaundice, cholelithiasis, and splenomegaly. They also manifested severe neurologic dysfunction and generalized aminoaciduria.[164] This disorder is an autosomal recessive condition and, in the family studied, presumed carriers had reduced GCS activity, although erythrocyte GSH levels were normal. Hemolytic anemia was seen only in the homozygous state where erythrocyte GSH levels were approximately 5% of normal, and there was markedly reduced GCS activity. A third patient with GCS deficiency, unrelated to the first cases, was a 22-year-old woman with markedly reduced RBC GCS activity, severely reduced erythrocyte GSH concentration, and chronic hemolytic anemia.[165] Family members of this patient had 50% reduced enzyme activity but no decrease in RBC-glutathione content or evidence of hemolysis. Of particular interest, in contrast to the first patients described with GCS deficiency, this patient had no neurologic disease. To date there have been a total of 8 probands reported with GCS deficiency and hemolysis; and 4 of these also have had severe neurologic disease.[166,167,168] The molecular defect in these cases has been associated with different missense mutations. There is no specific therapy for GCS deficiency, although it would seem prudent to obtain periodic gallbladder ultrasound examinations since affected patients have had cholecystectomies.

Glutathione synthetase deficiency has been incriminated as the cause of chronic hemolytic anemia alone (due to isolated RBC enzyme deficiency) and as the cause of a generalized syndrome (due to enzyme deficiency in many tissues) characterized by mild hemolytic disease, severe metabolic acidosis, and mental deterioration. The first syndrome, mild hemolytic anemia and intermittent jaundice, has been described in several families.[164,169,170,171] Exposure to oxidant drugs and to fava beans has occasioned temporary acceleration of hemolysis. Splenomegaly has been noted in approximately one-half of the reported cases. A concurrent deficiency of glutathione-S-transferase is thought to be caused by the instability of this enzyme in the absence of adequate intracellular GSH.[172] The second more generalized syndrome is characterized by mild hemolytic anemia, persistent metabolic acidosis presenting in the newborn period, and progressive cerebral and cerebellar degeneration.[173,174,175,176] Acidosis is caused by the accumulation of 5-oxoproline, a metabolic product of γ-glutamyl-cysteine. Abnormally large quantities of the dipeptide are produced because of the loss of feedback inhibition of γ-GCS by GSH. This disorder is suspected in patients with hemolytic anemia and markedly reduced red blood cell GSH content. Virtually no GS activity is detected in homozygous-deficient individuals.[163,169,177] Rarely, therapy is required for the hematologic consequences of GS deficiency. Exposure to drugs and chemicals with oxidant potential should be avoided by those individuals with chronic hemolytic anemia. In some cases, splenectomy has been efficacious in modifying the anemia, although hemolysis may continue as manifested by persistent reticulocytosis.[170,178] In those individuals with GS deficiency and oxoprolinemia, administration of oral sodium bicarbonate or citrate is necessary to control acidosis.[176]

GLYCOLYTIC ENZYME ABNORMALITIES—GENERAL CONSIDERATIONS

Hemolytic anemias due to glycolytic enzymopathies are relatively rare, affecting a few thousand individuals,[59,179,180] and this is in contrast to G6PD deficiency, which affects millions throughout the world. Abnormalities in virtually every glycolytic enzyme have been described, although over 90% of cases associated with hemolysis are due to pyruvate kinase (PK) deficiency (Fig. 28.4).

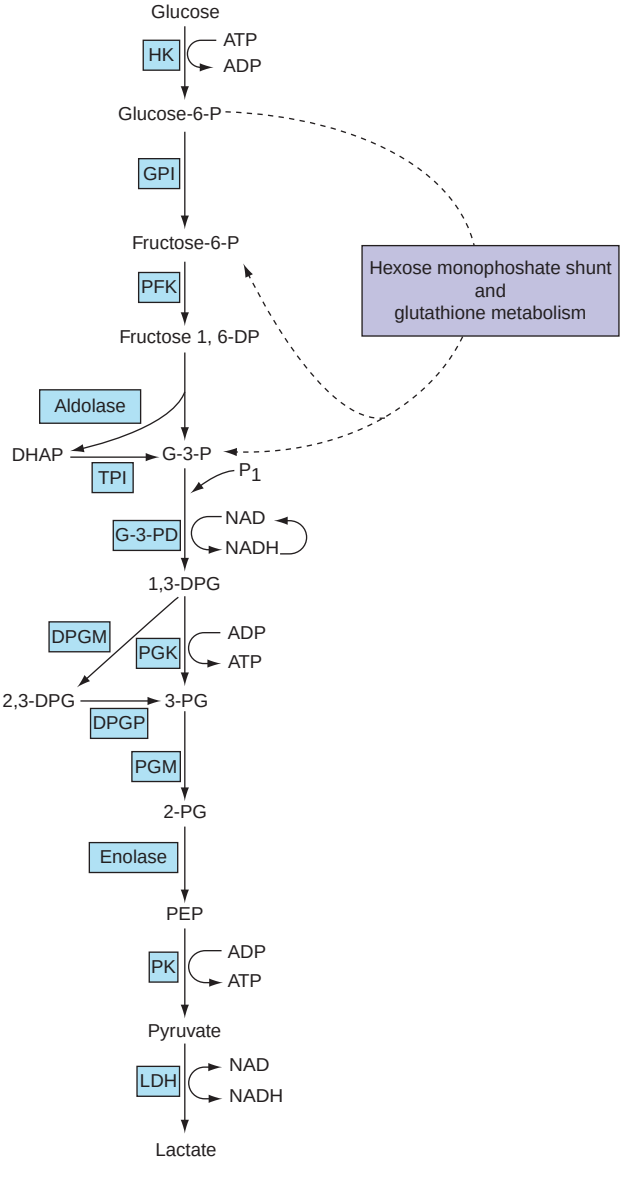

FIGURE 28.4. Overall metabolic pathway of glycolysis in the erythrocyte. Enzyme abbreviations: 2,3 DPGM, 2,3 diphosphoglycerate mutase; 2,3-DPGP, 2,3-diphosphoglycerate phosphatase; GPI, glucosephosphate isomerase; G-3-PD, glyceraldehyde-3-phosphate dehydrogenase; HK, hexokinase; LDH, lactate dehydrogenase; PFK, phosphofructokinase; PGK, phosphoglycerate kinase; PGM, phosphoglycerate mutase; PK, pyruvate kinase; TPI, triosephosphate isomerase. Substrate abbreviations: 1,3-DPG, 1,3-diphosphoglycerate; DHAP, dihydroxyacetone phosphate; G-3-P, glyceraldehyde-3-phosphate; 2-PG, 2-phosphoglycerate; 3-PG, 3- phosphoglycerate; PEP, phosphoenolpyruvate.

Most glycolytic enzymopathies manifest an autosomal recessive pattern of inheritance. Heterozygotes almost always are hematologically normal, although their red blood cells contain less than normal levels of enzyme activity. It once was thought that hemolysis occurred only in those individuals who were homozygous for the enzyme deficiency. However, true homozygosity for a given mutant enzyme now is known to be less common, and usually restricted to consanguineous kindred. The vast majority of cases of hemolytic anemia due to glycolytic enzyme deficiencies are a consequence of double heterozygosity for two different enzyme variants, and this accounts for the diverse biochemical and clinical heterogeneity of the red cell glycolytic enzymopathies. The one exception to this autosomal mode of inheritance for glycolytic enzymopathies is phosphoglycerate kinase (PGK) deficiency, which is an X-linked disorder.

Clinical manifestations of hemolysis due to glycolytic enzymopathies include chronic anemia, reticulocytosis, and some degree of hyperbilirubinemia. In the vast majority of cases the hemolytic process is recognized and diagnosed in childhood. Frequently there is a history of neonatal jaundice, often requiring an exchange transfusion, and rarely causing kernicterus. The magnitude of chronic anemia varies; there may be accelerated hemolysis with some nonspecific infections or transient aplastic crises associated with parvovirus infection. In some enzymopathies, such as PK deficiency, the adverse consequences are restricted to the erythrocyte. In other cases, such as in phosphofructokinase (PFK), aldolase, triosephosphate isomerase (TPI), and PGK deficiencies, hemolytic anemia is but one feature of multisystem disease (see Table 28.3).

The possibility of a glycolytic defect usually is considered when chronic hemolytic anemia cannot be explained by the more common causes (i.e., hereditary spherocytosis or hemoglobinopathies). There are no specific morphologic abnormalities, although anisocytosis and poikilocytosis are common. In virtually all cases a specific assay of RBC enzyme activity is necessary to make the diagnosis. Screening tests are readily available, but these have limited value when there is a partial deficiency or a mixed population of RBC. A particular problem in identifying glycolytic enzymopathies relates to the fact that the most severely deficient cells are removed (i.e., hemolyzed) and the remaining cells may be biochemically less abnormal. Consequently, "false negative" assays can obscure the correct diagnosis. For this reason, it sometimes is helpful to study parents and other family members for the presumed heterozygous state of the enzyme deficiency. In some cases DNA-based molecular diagnostic tests may be available.

Therapy for red blood cell glycolytic defects is similar to that of other chronic hemolytic anemias. RBC transfusions often are needed. Splenectomy usually is beneficial in severely anemic patients since the spleen (along with the liver) participates in the destruction of enzymatically abnormal cells. In most cases, however, the response to splenectomy is only partial, although RBC transfusion requirements may decrease. Cholelithiasis is a common problem, and all patients with glycolytic enzymopathies should have periodic gallbladder ultrasound examinations, even following splenectomy. The biologic and clinical features of specific glycolytic disorders are summarized in the following paragraphs.

Pyruvate Kinase Deficiency

Of the enzymatic deficiencies involving glycolysis, PK deficiency is the most common and the most extensively studied. Over 400 cases have been reported.[181,182] Undoubtedly there are many more cases, since newly diagnosed patients currently are not reported unless there are unusual associated findings.

Geographic Distribution

Most cases of PK deficiency have been reported from Europe, the United States, and Japan; however, the disorder occurs worldwide.[179,183,184] The frequency of the heterozygote state has been estimated on the basis of studies that screened various populations for low enzyme activity. In Germany and in the United States, the prevalence of apparent heterozygosity for PK deficiency has been estimated to be about 1%.[183] In one report from Hong Kong, 3% of newborn infants were noted to be heterozygous for a PK variant.[185] A particularly high frequency exists among the Pennsylvania Amish, in whom the disorder can be traced to a single immigrant couple.[186–188] An increased incidence also has been observed in children from a polygamist community.[189] In studies looking at the most common PK mutations found in a Caucasian

TABLE 28.3

FEATURES OF GLYCOLYTIC AND NUCLEOTIDE ENZYMOPATHIES

Enzymopathy	Approximate Fraction of Enzymopathies[a] (%)	Mode of Inheritance[b]	Effects of Enzymopathy[c]
Hexokinase (HK)	<1	AR	Mild/severe CNSHA
Glucosephosphate Isomerase (GPI)	3–5	AR	Moderate/severe CNSHA; ± neurologic deficits
Phosphofructokinase (PFK)	<1	AR	Mild CNSHA; ± myopathy
Aldolase	<1	AR	Mild/moderate CNSHA; ± myopathy
Triosephosphate Isomerase (TPI)	<1	AR	Moderate/severe CNSHA; neurologic deficits,
Phosphoglycerate Kinase (PGK)	<1	X-linked	Mild/severe CNSHA; ± neurologic deficits; ± myopathy
Pyruvate Kinase (PK)	80–90	AR	Moderate/severe CNSHA
Pyrimidine 5′ Nucleotidase (P5′N)	2–3	AR	Moderate CNSHA
Adenosine Deaminase (ADA) excess	<1	AD	Mild CNSHA
Adenylate Kinase (AK)	<1	AR	CNSHA

population, a prevalence of PK deficiency has been estimated to be 51 per million population.[190]

Biochemical Genetics

PK catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate; and this is one of the two glycolytic reactions resulting in net ATP production (Fig. 28.4). PK is a tetrameric protein with a molecular weight of 230 kDa. There are two different PK genes (PKM2 and PKLR) which encode for 4 distinct PK isozymes.

The PKM2 is on chromosome 15 (15q22)[191]; and it encodes for two isozymes (PK-M2 and PK-M1). PK-M2 is the isozyme present in all tissues during fetal life. As fetal maturation proceeds, other tissue-specific PK isozymes begin to appear. PK-M2 persists as the predominant isoenzyme in mature leukocytes and certain other tissues (platelets, lung, kidney spleen, and adipose tissue). In addition, PK-M2 is the major isozyme in erythroid precursors.[59] PK-M1, which differs from PK-M2 as a result of alternative splicing, is the PK isozyme present in mature muscle and brain tissue.[192]

The PKLR gene is on chromosome 1(1q21)[193]; and it also encodes for two isozymes (PK-L and PK-R). PK-L is the predominant isozyme in hepatocytes.[194] PK-R is the isozyme present in mature erythrocytes.[182,195,196] The hemolytic anemia associated with PK deficiency is due to mutations of the PKLR gene. In some patients with hemolytic anemia, a decrease in the liver PK-L isozyme has also been observed; but this is of no clinical significance since the liver also has residual PK-M2 activity.[197–199] During normal erythroid differentiation, the PK isozyme switches from the M2 to the R-type.[59] Of interest, in one severe form of PK deficiency (PK Beppu), PK-M2-type persists in mature erythrocytes; and it has been proposed that this compensatory PK-M2 production allows affected red cells to survive, analogous to the beneficial effect of persistent fetal hemoglobin production in homozygous β-thalassemia.[59]

Over 200 different mutations of the PKLR gene have been identified as causes of chronic hemolytic anemia. Most of these are missense mutations (approximately 70%), although a few are either nonsense or insertional mutations, deletions, or splicing abnormalities.[59,182,200,201] Most PK mutations are very rare, occurring only once; and the variable phenotypic expression of PK deficiency undoubtedly reflects the heterogeneity of these different PK mutants. A few mutations are seen with some frequency. A significant fraction of affected Caucasians (30% to 40%) have at least one 1529G→A mutation resulting in an amino acid change (510Arg→Gln).[202,203] This particular mutation is common in the United States and in northern Europe. Homozygosity for this 1529G→A mutation was seen in children from a polygamist community in the western United States.[204] A second common mutation, 1456C→T (484Arg→Trp), is observed in Spain, Portugal, and Italy, where it accounts for approximately 30% of all cases. A third common mutation, 1468C→T (Arg490→Trp), is found predominantly in the eastern hemisphere. The PK deficiency seen in the Amish population is associated with a 1436G→A (479Arg→His) mutation.[188] The PK deficiency in Gypsies is due to a deletion of 1,149 bp, resulting in the loss of exon 11.[205]

At one time, PK deficiency was thought to be a consequence of decreased production of a structurally normal enzyme; but it now is recognized that most PK variants are abnormal proteins which differ with respect to their biochemical kinetics and physical properties.[206–208] The heterozygous state for a PK variant is clinically silent with no hemolysis or anemia.

There is little or no relationship between red cell PK activity in vitro and severity of hemolysis.[59,183] In part, this reflects the fact that in vitro assay conditions are very different from what exists in vivo. In addition, the presence of young RBC with elevated enzyme activity can mask the presence of a very unstable PK variant; or there can be persistence of PK-M2 in mature RBC.[59,209,210] Moreover, since most individuals with PK deficiency are doubly heterozygous for two different PKLR mutants,[59] the study of RBC from affected subjects characterizes the mixture of PK variants without providing specific information about the individual enzymes. In the minority of individuals with homozygous disease, a relationship between defective PK enzymes and severity of hemolysis occasionally is apparent.[206,207,211] Ongoing molecular biology studies are focused on determining the relationship of specific mutations (genotype) with hemolysis (phenotype).[182,200]

Pathophysiology

PK deficiency results in impaired glucose utilization and, thereby, decreased pyruvate and lactate production. In addition, glycolytic intermediates proximal to the block accumulate in red cells, and, of particular interest, the levels of 2,3-DPG may increase up to threefold.[212,213] The major impairment due to PK deficiency is a diminished capacity to generate ATP.[214] Paradoxically, however, PK-deficient patients with high reticulocyte counts may have normal or even elevated levels of ATP.[214] This occurs because PK-deficient reticulocytes generate ATP through mitochondrial oxidative phosphorylation, and this is associated with a 6 to 7 fold increase in oxygen consumption compared to normal reticulocytes.[214,215] The advantage of oxidative phosphorylation for PK-deficient reticulocytes is that ATP can be generated requiring minimal flow of pyruvate from glycolysis. When reticulocytes mature, however, mitochondria disappear, oxidative phosphorylation ceases and ATP levels fall. The effects of this will vary because there are marked cellular differences in the enzyme content of PK-deficient red cells. In severely PK-deficient RBC, the fall in ATP leads to cell injury, although the precise ATP-dependent reactions leading to irreversible membrane injury are not known. In some cases this injury is characterized by an increase in membrane calcium, accelerated potassium loss, decreased total monovalent cation content, and cellular dehydration.[215] The end result of these changes is a loss of membrane plasticity, and the formation of rigid RBC marked for premature destruction in the spleen.[216,217]

The reticulocytes most deficient in PK are doomed to almost immediate extinction once they lose their mitochondria. Less severely deficient cells survive to a nearly normal age, their ATP needs satisfied despite marginal metabolic resources.[215] This vulnerability of enzyme-deficient reticulocytes is seen in erythrokinetic studies which demonstrate that reticulocyte-rich fractions of blood from PK-deficient subjects have a shorter survival than do reticulocyte-poor fractions.[215,217] Given the unique metabolic abnormalities of the PK-deficient reticulocyte it is understandable why the spleen poses a problem for them. Because of their greater adhesive tendencies, reticulocytes endure a longer sojourn in the spleen,[216,217] where limited oxygen and glucose restrict effective oxidative phosphorylation.[215] Impaired ATP production then leads to RBC destruction in the spleen or in the liver after escape from the spleen.[216,217] Because severely deficient reticulocytes are metabolically more stable in the absence of the spleen, an exaggerated and sustained reticulocytosis usually follows splenectomy.[183]

As noted previously, the concentration of 2,3-DPG may be up to three times normal.[212] This increase is responsible for a rightward shift in the oxygen dissociation curve of hemoglobin. As a result, PK-deficient subjects have a greater exercise tolerance than would be expected from the degree of anemia.[213]

Clinical Features

The clinical expression of PK deficiency is quite variable, ranging from hydrops fetalis[218,219] to pronounced neonatal jaundice requiring multiple exchange transfusions,[185,220,221] and occasionally complicated by kernicterus[186,222] to a fully compensated hemolytic process detected as an incidental finding in adults.[223]

Unlike hemolysis associated with G6PD deficiency, the jaundice noted in PK-deficient infants invariably is associated with anemia and often with splenomegaly. The PK deficiency observed among the Pennsylvania Amish is particularly severe.[186]

Beyond the neonatal period, anemia of varying degree, jaundice, and splenomegaly characterize erythrocyte PK deficiency. There are no specific or distinguishing clinical characteristics of this disorder; and no tissues are affected besides the red cells. Anemia may be surprisingly well tolerated because of the increased red cell 2,3-DPG content which is responsible for a rightward shift in the oxygen dissociation curve of hemoglobin.

The clinical course may be complicated by aplastic crises, characterized by an abrupt but temporary arrest of erythropoiesis and a precipitous drop in hemoglobin concentration and reticulocyte count. These crises usually are related to infection with parvovirus B19 which is cytotoxic for erythroid progenitors.[224,225] After the first decade of life, gallstones are detected with increased frequency.[183] Bone changes associated with hyperplastic bone marrow, such as those seen in thalassemia, occasionally may result in frontal bossing.[226] Chronic leg ulcers occur rarely.[227,228] Pregnancy has been associated with good maternal and fetal outcomes.[229] However, there also are reports of complications during pregnancy, including preeclampsia and worsening hemolytic anemia.[230] Iron overload is a predictable complication of chronic transfusion therapy, but it may occur also in patients with a limited or no history of transfusions.[231] The rare cases of hemosiderosis occurring in minimally transfused PK-deficient individuals may be due to coexistent inheritance of the more common hereditary hemochromatosis gene.[230,232,233]

Diagnosis

Anemia due to PK deficiency is moderate to severe in degree. The hemoglobin concentration characteristically is 6 to 12 g/dl.[183] The peripheral blood reveals all the morphologic hallmarks of accelerated erythropoiesis: polychromatophilia, anisocytosis, poikilocytosis, and variable numbers of nucleated red cells. Irregularly contracted erythrocytes with surface spicules,[234] tailed poikilocytes,[214] and acanthocytes[222] have been observed in the smears of some affected individuals. Before splenectomy, the reticulocyte count may be increased (5% to 15%); but after splenectomy, reticulocyte counts as high as 70% occasionally are noted.[183,207] The latter is due to the longer survival of PK-deficient reticulocytes following splenectomy.

The hematologic features of PK deficiency are not distinctive. The specific diagnosis rests on laboratory documentation. The once-used autohemolysis test has no current role in the diagnosis of PK deficiency.[235] Simple specific enzyme screening tests are available, but false negative results are common because of the many different variant enzyme kinetics. In cases where PK deficiency is suspected, a direct quantitative assay of the enzyme is essential. Leukocytes must be excluded from the system, because the leukocyte PKM2 gene is not affected in hemolytic variants to PK deficiency, and the PK activity of white blood cells is 300 times that of normal red cells.[236] Most deficient individuals have 5% to 25% of the normal mean activity. Heterozygous carriers of a PK variant have approximately one-half normal activity, although there is considerable overlap with normal. The biochemical heterozygote sometimes is difficult to detect. Recommended methods for the characterization of PK variants have been established by the International Committee for Standardization in Hematology.[206] In patients, usually infants, who are transfused before the enzyme disorder is recognized, the dilution of enzyme-deficient RBC with transfused cells often makes it difficult to make the diagnosis based on chemical enzyme analysis.

In families with a child with PK deficiency, the issue of prenatal diagnosis in subsequent pregnancies is a matter of concern. Most assuredly molecular diagnostic techniques for the prenatal diagnosis of PK deficiency have proven to be useful.[237] In particular, DNA analysis should be helpful in diagnosing those fetuses with the more common mutations described above, thought to account for 45% of cases of PK deficiency in non-Gypsy Caucasians. The large number of cases of PK deficiency in Gypsies are associated with a unique deletional mutation which also could be used for molecular diagnosis.[237]

Treatment

During the first years of life, severe anemia is managed with red cell transfusions. Maintenance of the hemoglobin concentration above 8 g/dl permits normal growth and development. The decision for transfusion therapy must relate to patient tolerance of anemia rather than an arbitrary level of hemoglobin. Because of increased red cell 2,3-DPG content, patients may tolerate moderately severe anemia with little problem.[213]

Splenectomy is useful for long-term control of anemia. However, because of the well-known risk of post-splenectomy sepsis due to *Streptococcus pneumoniae* in young children, surgery should be delayed until 5 years of age whenever possible. Preoperative assessment of red cell survival and splenic sequestration is of no value in selecting patients for splenectomy, and this in part reflects the importance of the liver as a site of red cell destruction. Splenectomy most commonly is followed by improvement but not a complete correction of the hemolytic disorder.[183,214,217] Transfusion requirements, if present before splenectomy, decrease or are eliminated. In almost all patients, an incompletely compensated hemolytic process with reticulocytosis, some degree of hyperbilirubinemia, and an ongoing risk for gallstone formation usually persist.

A severe hemolytic anemia associated with PK deficiency in Basenji dogs has been corrected by bone marrow transplantation.[238] Similarly, marrow transplantation has been shown to be effective in mutant mice with splenomegaly and chronic hemolytic anemia due to PK deficiency.[239] These successes in animal studies clearly indicate a possible role for stem cell transplantation in this therapy in humans. There is one report of a 5-year-old boy with transfusion-dependent hemolytic anemia due to PK deficiency who received an HLA identical bone marrow transplant from his sister; and he is alive several years later without evidence of hemolysis.[240] Despite the success in this one patient, in almost all cases of hemolytic anemia due to PK deficiency, the risk-benefit ratio currently remains weighted in favor of splenectomy over stem cell transplantation. In the future this may change. Moreover, PK deficiency (as a single gene defect, of recessive inheritance, affecting primarily one cell line, and being amenable to hematopoietic stem cell modification) is considered a candidate disease for gene therapy in the future.[241,242]

Other Enzymopathies Affecting Glycolysis

Hexokinase Deficiency

Hexokinase (HK) catalyzes the conversion of glucose to glucose-6 phosphate (Fig. 28.4). As the first enzyme in the glycolytic pathway, HK has a strategic role in the regulation of glucose consumption. The activity of HK declines rapidly as red cells age, and in older cells, HK activity is lower than that of any other glycolytic enzyme. The concentration of 2,3-DPG also may be low, and this has consequences on hemoglobin-oxygen affinity and work performance (see below).

There are four HK isozymes and each one is coded for by a different gene (HK1, HK2, HK3, HK4). The HK1 gene codes for the HK found in erythrocytes, and this gene maps to chromosome 10.[243–245] Type I HK isozyme also is present in lymphocytes and platelets. However, deficiency of type I HK isozyme in lymphocytes is offset by an increase in the amount of type III isozyme.[246] As with PK deficiency, deficient HK activity may result from

quantitative deficiency of an apparently normal enzyme[247,248] from abnormalities that affect substrate affinity,[249–251] or heat stability.[252–254] The molecular defect has been identified in a few cases of HK deficiency.[255,256]

Seventeen different kindred with HK deficiency have been described in families of European, Mediterranean, Scandinavian, and Asian background.[245,247–249,251] The inheritance pattern is consistent with an autosomal recessive mode of transmission. In about 25% of reported cases, neonatal hyperbilirubinemia can occur and may require exchange transfusion.[248,250,257] In many affected individuals, mild anemia or recurrent episodes of jaundice are not noted until after the first decade of life. Splenomegaly is common. Regular RBC transfusions may be required in severely affected patients.[248] Splenectomy ameliorates but does not cure the hemolytic process.[248–250] Symptoms may be out of proportion to the degree of anemia because low levels of erythrocyte 2,3-DPG reduce oxygen release to tissues at any given oxygen tension.[213,258]

There are no unique RBC features associated with HK deficiency. The diagnosis rests on the assay of red cell HK activity. Because HK is among the most age-dependent of red cell enzymes, its activity must be considered in relation to the reticulocyte count or the activity of other age-dependent enzymes.[248]

Glucosephosphate Isomerase Deficiency

Glucosephosphate isomerase (GPI) catalyzes the interconversion of fructose-6-phosphate and glucose-6-phosphate (Fig. 28.4). GPI deficiency is the second most common glycolytic enzymatic defect associated with hemolytic disease.[259] Since the first description of the disorder in 1968,[260] approximately 50 cases have been reported.[59,261–264,265] Just as for the case of PK deficiency, many more cases probably exist but are not published or listed in any rare disease registry. It is estimated that 0.2% of North Americans are heterozygous for a GPI mutant.[266]

The gene for GPI is located on chromosome 19. Several different gene mutations of GPI associated with hemolysis have been identified.[59,265,267,268,269] A single form of GPI is synthesized by all cells of the body; consequently, structural mutations of the enzyme are expressed in all tissues.[263,270] Because most mutations result in enzyme instability,[271] the defect imposes functional compromise mainly in older mature erythrocytes. Both missense mutations and gene deletion have been described.[265,267,272,273] It is inherited in an autosomal recessive manner. Obligate heterozygotes for mutant alleles are hematologically normal but have reduced red cell GPI activity. Symptomatic GPI deficiency results equally from homozygosity for a single mutant gene or compound heterozygosity for two different abnormal alleles.[59,267,272,274]

The severity of hemolytic disease varies considerably. Hydrops fetalis with death in neonates has been reported,[274–276] and anemia and hyperbilirubinemia complicate the postnatal course in many patients.[263,270] Chronic transfusion therapy may be required. As with other chronic hemolytic anemias, the clinical course may be complicated by aplastic and hyperhemolytic crises. Mental retardation and excessive stores of hepatic glycogen were noted in a single patient.[274] Neuromuscular impairment (hypotonia, ataxia, dysarthria, mental retardation) occasionally has been seen, but in only 5 of the known variants.[265] Splenectomy has eliminated or dramatically reduced the transfusion requirement in most patients.[260,262,263,266] Post-splenectomy hemoglobin concentrations are 8 to10 g/dl. Following splenectomy, reticulocyte counts may increase dramatically (50% to 75%).[266]

Red cell morphology is characterized by anisocytosis, poikilocytosis, polychromatophilia, and often the presence of nucleated red cells. Definitive diagnosis requires specific enzyme assay of a RBC hemolysate. Prenatal diagnosis of GPI by enzymatic assay of amniotic fluid cells has been demonstrated in a kindred with unusually severe hemolytic disease.[275] Several abnormal GPI mutations have been identified and molecular diagnostic techniques for prenatal diagnosis are becoming available (P. Gallagher, Yale University, personal communication).

Phosphofructokinase Deficiency

PFK catalyzes the phosphorylation of fructose-6-phosphate to fructose-1,6-diphosphate, and this is one of the rate limiting reactions of glycolysis (Fig. 28.4). The PFK enzyme in RBC is a tetrameric protein made up of varying combinations of muscle or M type subunits, liver or L type subunits, and platelet or P type subunits.[277–279] Three different structural loci encode for these M, L, or P subunits of PFK. The M type subunit is encoded for a gene on chromosome 1,[280] and this gene has been characterized[281] and cloned.[282,283] The L type PFK subunit is encoded by a gene located on chromosome 21,[284] and the structural organization of this gene also has been characterized[285] and cloned.[286] The gene encoding for the P subunit of PFK is located on chromosome 10.[287] The subunits are variably expressed in different tissues. Muscle and liver PFK are composed exclusively of M4 and L4 tetramers, respectively. The red blood cell contains equal amounts of M and L subtypes and all possible tetrameric variations are present (L_4; L_3 M_1; L_2 M_2; L_1 M_3; M_4).[279] Neutrophil PFK is composed primarily of L4 homotetramers, and platelet PFK consists of both P and L subunits. The variable structure of PFK in different tissues provides an explanation for the diversity of syndromes associated with deficiency states. These syndromes include chronic hemolytic disease with myopathy, hemolytic disease alone, and myopathy alone.[288]

The first PFK deficiency syndrome described was characterized by congenital nonspherocytic hemolytic disease and myopathy (Tarui's disease, glycogenosis type VII[289,290]). More than 39 unrelated families have been identified.[291] It is inherited as an autosomal recessive disorder. The myopathy is characterized by muscle fatigue and cramping with exercise and pathologically by increased muscle glycogen.[289] There is a mild compensated hemolytic anemia. The hemoglobin concentration is normal, or even increased. Both myopathy and hemolytic disease result from the total lack of M subunit expression. Biopsies of muscle reveal that PFK activity is completely lacking, while erythrocyte PFK activity is about 50% of normal.[289,290,292] The red cell PFK in these patients is composed exclusively of L4 subunits.[279,289] Glycolytic intermediates proximal to PFK are increased in concentration, and those distal to the block are decreased.[292,293] Of particular interest, 2,3-DPG is decreased,[294] and this presumably leads to an unfavorable shift of the hemoglobin-oxygen affinity, thereby accounting for the mild erythrocytosis in some patients and absence of anemia despite shortened red cell survival in others.

PFK deficiency also has been implicated as the cause of hemolytic disease in the absence of myopathy.[279,293,295,296] Some individuals manifest mild myopathic symptoms during ischemic exercise tolerance tests.[293] This syndrome is attributed to the synthesis of an unstable but catalytically active M subunit. Muscle cells are protected because of continued synthesis of the enzyme, whereas anucleate erythrocytes, incapable of protein synthesis, sustain early loss of enzyme activity.[295] Although myopathy without hemolysis has also been attributed to PFK deficiency, hemolytic disease may have been dismissed because of the absence of anemia.[293] Heterozygosity for L subunit deficiency is associated with about one-half normal red cell PFK activity, but with no myopathic or hemolytic features.[293,297,298]

Aldolase Deficiency

Aldolase catalyzes the conversion of fructose-1,6-diphosphate to dihydroxyacetone and glyceraldehyde-3-phosphate (Fig. 28.4). Aldolase is a tetrameric protein, and three tissue isozymes

(A, B, C) have been identified.[299] Type aldolase, the main isozyme in red blood cells and muscle, has been characterized and cloned.[300,301] The gene which encodes aldolase A is located on chromosome 16.[302]

Aldolase deficiency as a cause of hemolytic anemia is very rare, and has been identified in only four kindred. The first case was documented in a child whose parents were first cousins. In addition to mild hemolytic anemia, the child had hepatomegaly associated with increased glycogen deposition and psychomotor retardation.[303] A second report of aldolase deficiency in a Japanese family described more severe hemolytic anemia (hemoglobin 6 g/dl; 7% to.8% reticulocytes) without attendant hepatomegaly or developmental delay.[304] In a third case, a 4½-year-old boy in Germany was identified with aldolase deficiency.[305] He had a history of neonatal jaundice, recurrent episodes of jaundice beyond the newborn period, and anemia requiring red cell transfusions in the first year of life. In addition, however, he had a myopathy characterized by severe muscle weakness, exercise intolerance, and laboratory evidence of rhabdomyolysis in association with fever and an upper respiratory infection. In a fourth reported case, a young girl of Sicilian extraction had a transfusion-dependent hemolytic anemia requiring splenectomy at 40 months of age.[306] She also had a myopathy with recurrent and progressive episodes of rhabdomyolysis. She died due to hyperkalemia and rhabdomyolysis during a febrile illness associated with gastrointestinal hemorrhage at 54 months of age. Molecular analysis in each of the above cases has identified several different missense or nonsense mutations, each resulting in a thermolabile unstable enzyme.[305,306,308] The mechanism of hemolysis in these cases is uncertain. Deficient red cells accumulate proximal glycolytic intermediates, especially fructose-1,6-diphosphate.

Triosephosphate Isomerase Deficiency

TPI catalyzes the reversible isomerization of glyceraldehyde -3-phosphate and dihydroxyacetone phosphate (Fig. 28.4). TPI is a dimeric enzyme composed of identical subunits. Several electrophoretically distinct bands result from posttranslational modification of a single protein[309] that is encoded by a single structural gene located on the short arm of chromosome 12.[310] Only one isozyme of TPI is produced, and thus enzyme deficiency involves all body tissues. Enzyme activity is greatly reduced in red cells, as well as leukocytes, muscle, and skin fibroblasts.[264] Thirty-five cases of TPI deficiency with hemolytic anemia have been identified. The enzyme abnormality in almost all cases is due to a single amino acid substitution which results in an unstable enzyme.[311] Several different point mutations in the TPI gene have been identified and reviewed.[312,313,314] Most are missense mutations resulting in a single amino acid substitution, and one is due to a deletion. The majority of the mutants result in heat-labile enzymes with residual catalytic activity. All clinically affected patients have been homozygotes or, less commonly, compound heterozygotes. Of the known mutations, one accounts for the molecular defect in most studied families with TPI deficiency; and this variant is due to a 315G→C mutation which results in an amino acid substitution (104 glu→asp).[312,314]

Hemolysis due to TPI deficiency is one aspect of a multiple system disease. A most unique feature of this enzymopathy is an associated severe neurologic disorder characterized by spasticity, motor retardation, and hypotonia.[314,315] It is inherited as an autosomal recessive disorder. Heterozygotes, with half normal erythrocyte TPI activity, are clinically normal. Of interest, the frequency of the heterozygous state for TPI deficiency is relatively high (0.1% to 0.5% in Caucasians, 5.5% in African-Americans).[316] Despite this estimate, less than 40 individuals with symptomatic disease have been identified.[59,288,314] The rare incidence of clinically significant homozygous TPI deficiency suggests incompatibility with fetal life.

TPI deficiency is a progressive, ultimately fatal disease. In most cases, anemia and hyperbilirubinemia have been noted at birth or during the first weeks of life.[314,315,317] The degree of anemia is variable, but most affected infants and children require periodic blood transfusions. Death from hemolytic anemia in the first week of life occurred in a sibling and a cousin of the patient described in the first reported case.[315] Splenectomy appears to have no discernible benefit.[315] Late in the first year of life, spasticity and a delay in the acquisition of motor skills are noted. Neurologic involvement generally is progressive, giving rise to paraparesis, weakness, and hypotonia. Recurrent systemic infections are a problem in most affected children, but it is not known whether these are related to impaired TPI activity in phagocytes. Death, probably from cardiac arrhythmias, usually occurs before the fifth birthday. In the only adult thus far identified as having TPI deficiency,[318] neurologic dysfunction, although profound, was stable. An interesting report of TPI deficiency with chronic hemolytic anemia has been described in a 13-year-old boy and his 23-year-old brother. Noteworthy was the observation that the 13-year-old boy had hyperkinetic torsion dyskinesia, but his 23-year-old brother had no neurologic abnormalities.[319,320]

The diagnosis of TPI deficiency is suspected in young children with chronic hemolytic disease not due to the more common causes of hemolysis. Associated motor neurologic symptoms raise the index of suspicion for TPI deficiency. There are no specific RBC abnormalities. In suspected cases it is necessary to assay for TPI activity in a RBC hemolysate. The large number of cases associated with the codon 104 mutation has allowed the use of chorionic villous biopsy samples and molecular techniques for prenatal diagnosis.[321,322]

Phosphoglycerate Kinase Deficiency

PGK catalyzes the conversion of 1,3- diphosphoglycerate to 3-phosphoglycerate, and this is one of two glycolytic reactions resulting in net ATP generation from ADP (Fig. 28.1). An alternative fate of 1,3-DPG is the formation of 2,3-DPG, a reaction catalyzed by 2,3-diphosphoglyceromutase (DPGM). The product of the latter reaction is 2,3DPG, an important intermediate which is known to enhance oxygen release from hemoglobin. Hereditary deficiency of PGK activity has been recognized as a rare cause of chronic hemolytic anemia for 40 years.[323] Red cells severely deficient in PGK predictably accumulate DHAP,[324] have higher than normal concentrations of 2,3-DPG,[324] and have decreased concentrations of ATP.[323] The altered intermediate profile in PGK-deficient RBC thus reflects an increased flow of triose phosphates through the DPG pathway at the expense of ATP generation.

The genetics of this disorder are unique amongst glycolytic enzymopathies in that it is X-linked.[323] PGK is known to be encoded by a single structural gene on the X chromosome q13.[325] Biochemical variants of PGK with abnormal kinetics and/or enzyme instability have been observed in 26 separate families,[326] and the single amino acid substitutions and genomic structure have been identified in almost all of these variants, most of which are due to missense mutations.[59,291,326]

Similar to G6PD deficiency, male hemizygotes with little or no enzyme activity are symptomatic, with chronic hemolysis that can be severe, often requiring RBC transfusions.[323,327,328] In contrast, females who are mosaics have normal and PGK-deficient red cells, and there may be variable degrees of hemolysis.[323,329] Clinical exacerbations of hemolysis, most of which appear to be triggered by intercurrent infections, are responsible for recurrent episodes of jaundice. Splenectomy obviates transfusion in most patients but does not fully correct the hemolytic process. In deficient male subjects, PGK activity is decreased in leukocytes,[323] platelets, muscle, liver, and brain, as well as in red cells.[330] Although leukocyte PGK activity may also be low, there is no evidence that affected individuals have leukocyte dysfunction or increased infections.

Of far greater consequence is progressive neurologic deterioration. Some deficient male infants experience apparently normal development until 3 to 4 years of age, when motor regression, expressive aphasia, and emotional liability become apparent. Seizures and progressive extrapyramidal disease follow late in the first decade.[323,324,327,331] Most PGK variants manifest both hemolysis and neurologic disease (PGK-Uppsala, PGK-Tokyo, PGK-Matsue, PGK-Michigan); however, there are exceptions. PGK-Shizuoka is characterized by hemolysis and muscle disease,[332] while PGK-San Francisco has only hemolysis without other symptoms.[333] At the other extreme, recurrent exertional rhabdomyolysis producing renal failure but without associated neurologic or hematologic disease has been observed in PGK-Creteil.[334] The absence of hemolysis in this variant is most intriguing, since red cell PGK activity was less than 3% of normal. Also, clinically silent variants producing PGK deficiency have been described, and these variants differ from the normal enzyme with respect to electrophoretic mobility and isoelectric focusing.[325] The reasons for these major phenotypic differences in PGK deficiency remained to be defined.

Glycolytic Enzymopathies of Doubtful Clinical Significance

Hemolysis has been associated with deficiencies of other glycolytic enzymes, but the causal relationship between enzymopathy and reported hematologic disturbances is far from clear.[259]

Glyceraldehyde-3-Phosphate Dehydrogenase Deficiency

The enzyme glyceraldehyde-3-phosphate dehydrogenase (G3PD) catalyzes the reversible conversion of glyceraldehyde-3-phosphate to 1,3- diphosphoglycerate (see Fig. 28.4). This reaction is coupled to the reversible reduction of NAD to NADH. The latter is the major cofactor for methemoglobin reduction by cytochrome b5 reductase. Mild hemolytic anemia attributed to G3PD deficiency was described in two brief reports over 30 years ago.[335,336] The limited content of these reports precludes conclusions regarding the relationship between G3PD deficiency and hemolysis.

2,3-Diphosphoglyceromutase Deficiency

The enzyme 2,3-diphosphoglyceromutase (2,3-DPGM) has more than one metabolic role. Its main function relates to its catalytic role in the conversion of 1,3-DPG to 2,3-DPG (Fig. 28.4). This reaction is of special interest, because 2,3-DPG reduces the affinity of hemoglobin for oxygen, thereby shifting the oxygen hemoglobin dissociation curve to the right (see Chapter 6). A second function of the enzyme relates to its phosphatase activity which catalyzes the degradation of 2,3-DPG to 3-PGA. These two different actions of 2,3-DPGM reflect two different active sites on the same molecule.[337] Deficiency of red cell 2,3-DPGM is associated with deficiency of 2,3-DPG phosphatase of comparable magnitude.[337,338] The third metabolic role of this enzyme is to facilitate the conversion of 3-PGA to 2-PGA. The reports of 2,3-DPGM deficiency are too few and too disparate to permit a unified clinical description. Total deficiency of the mutase and phosphatase activity of DPGM and 2,3-DPG phosphatase activity was described in a 42-year-old man who was well except for ruddy cyanosis and a hemoglobin of 19 g/dl.[338] Erythrocyte 2,3-DPG content was low, as was the p50 determination. Two of his children had approximately 55% normal 2,3-DPGM activity, suggesting they were heterozygous and their father was homozygous, with fully compensated hemolytic anemia.[339,340] Deficiency of 2,3-DPGM imparts no known metabolic lesion having implications for cell survival. Deficient cells consume glucose normally and contain normal or increased amounts of ATP, decreased glutathione concentration and reduced triose phosphates.[338,340] It seems doubtful that 2,3-DPGM deficiency is a cause of significant clinical disease.

Enolase Deficiency

Enolase catalyzes the conversion of 2-PGA to PEP (Fig. 28.4). Chronic hemolytic anemia associated with erythrocyte enolase deficiency was identified in two sisters.[341] Ingestion of nitrofurantoin exacerbated the condition, an occurrence not explained by the enzyme deficiency.

Lactate Dehydrogenase Deficiency

LDH catalyzes the terminal reaction in glycolysis, the conversion of pyruvate to lactate (Fig. 28.4). The enzyme is a tetrameric protein composed of H and M subunits. Severe deficiency of LDH in erythrocytes, leukocytes, platelets, and serum of a 65-year-old Japanese man has been reported.[342] This individual was homozygous for an autosomal recessively transmitted deficiency of the H subunit of LDH. Although no anemia or evidence of hemolysis was noted, red cells contained a marked increase of glyceraldehyde-3-phosphate, dihydroxyacetone phosphate, and fructose-1,6-diphosphate. This severe LDH deficiency was without effect on red cell integrity.

ABNORMALITIES OF PURINE AND PYRIMIDINE NUCLEOTIDE METABOLISM

Mature RBC are incapable of de novo purine or pyrimidine synthesis, although many enzymes of nucleotide metabolism are present in erythrocytes (Fig. 28.5). The latter are now known to be important for RBC preservation in vitro; and it also is recognized that abnormalities in purine and pyrimidine metabolism are associated with inherited hemolytic disease.

Initial interest in RBC nucleotide metabolism was stimulated by blood bank concerns related to ATP and 2,3-DPG loss during storage of red blood cells. Several studies demonstrated that

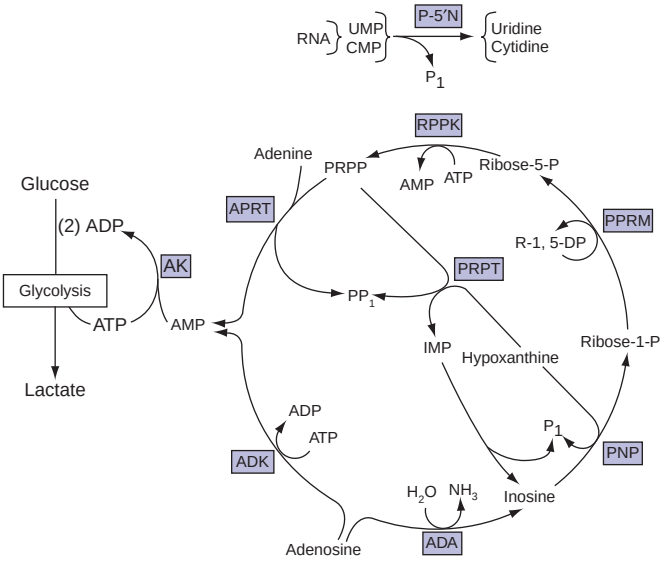

FIGURE 28.5. Schema of purine and pyrimidine metabolism in mature erythrocytes. Enzyme abbreviations: ADA, adenosine deaminase; ADK, adenosine kinase; AK, adenylate kinase; APRT, adenine phosphoribosyltransferase; RPPK, ribopyrophosphoryl kinase; PPRM, pyrophosphoribosyl mutase; PPRT, pyrophosphoribosyl transferase; PNP, purine nucleoside phosphorylase; P5′N pyrimidine 5′ nucleotidase. Substrate abbreviations: AMP, adenosine monophosphate; IMP, inosine monophosphate.

inosine, adenosine, and adenine each could minimize loss of organic phosphates and thereby improve viability of stored blood. These studies defined an important role for purine nucleoside metabolism in maintaining energy pools of stored RBC, and this has had a major impact on the science of transfusion medicine.[343]

In certain immune and metabolic disorders due to inborn errors of purine metabolism, erythrocytes share the same enzymatic deficiency, without any adverse effect on RBC function or viability. The RBC enzyme abnormalities in these cases can serve as a marker of disease in other tissues, and in some cases assay of red cell enzyme activity is used for diagnostic purposes.[344] The two most common disorders for which the red cell is used as a biopsy tool are adenosine deaminase (ADA) deficiency associated with severe combined immune deficiency,[345] and purine nucleoside phosphorylase deficiency associated with impaired T-cell immunity[346] (see below).

Red cell purine and pyrimidine enzyme disorders also have been associated with inherited hemolytic syndromes, and these cases have further identified the important role of nucleotide metabolism in mature erythrocytes. The remainder of this section focuses on the pyrimidine and purine enzyme disorders associated with hemolysis pyrimidine 5′ nucleotidase (P5′N) deficiency, ADA excess, and adenylate kinase (AK) deficiency.

Pyrimidine 5′ Nucleotidase Deficiency

Ribosomal RNA in normal reticulocytes is degraded to 5′ nucleotides. The enzyme P5′N further catalyzes the degradation of cytidine and uridine mononucleotides to inorganic phosphate and the corresponding nucleoside. Whereas the mononucleotides are impermeable to the RBC membrane, after P5′N exposure the nucleosides can passively diffuse from the cell. P5′N thus rids maturing reticulocytes of pyrimidine degradation products of RNA without compromising the purine (adenine) nucleotide pool necessary for energy-dependent reactions. Another enzyme, thymidylate nucleotidase, is thought to catalyze the degradation of thymidine monophosphate in a similar manner. This is supported by the observation that P5′N-deficient cells exhibit brisk nucleotidase activity when thymidine and deoxyuridine monophosphates are used as substrates.[347–349,350]

Reticulocytes deficient in P5′N accumulate large quantities of cytidine and uridine compounds, increasing the total nucleotide pool to more than five times that present in normal red cells.[348,351,352] Cases of P5′N deficiency formerly were classified as "high ATP syndromes" owing to the erroneous assumption that the large amount of nucleotide within deficient cells was adenine phosphate rather than pyrimidine phosphate.[353,354] In addition to the increased nucleotide pool content, elevated levels of GSH [355] and decreased activity of ribosephosphate pyrophosphate (PRPP) synthetase are consistent but unexplained findings of P5′N deficiency.[353,354] As a consequence of impaired ribosomal degradation, intracellular aggregates form in P5′N-deficient cells, and these appear as basophilic stippling on Wright-stained peripheral blood smears.

The gene encoding P5′N is located on chromosome 7p15-p14.[356] Over 20 different mutations in the gene for P5′N have been identified in 30 different families with this enzyme deficiency.[357,358]

P5′N deficiency is a rare RBC defect, yet it is the most common enzyme abnormality affecting nucleotide metabolism.[259,350,357,358] Over 60 patients representing a wide geographic distribution have been reported, with a predisposition for people of Mediterranean, Jewish, and African ancestry.[350,357,358,359] In all families studied, the disorder follows an autosomal recessive mode of transmission. Family members who are biochemical heterozygotes are hematologically normal, whereas homozygotes with less than 5% to 10% normal P5′N activity have lifelong hemolytic anemia associated with splenomegaly and intermittent jaundice. The disorder is characterized by mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. Transfusions usually are not required. Splenectomy is followed by a modest increase in hemoglobin concentration but affords no significant benefit.[354,359,360] There are no associated P5′N abnormalities in platelets or leukocytes. Developmental retardation has been noted.[361]

The possibility of P5′N deficiency as the cause of hemolysis is suggested by the presence of marked basophilic stippling, a unique RBC morphologic feature characteristic of this hemolytic disorder. Definitive diagnosis requires demonstration of decreased RBC nucleotidase activity[359] or increased pyrimidine nucleotides in erythrocytes. Normally, RBC nucleotides are almost entirely adenine nucleotides. However, in P5′N deficiency, up to 80% of nucleotide pool may be pyrimidine nucleotides. The latter is the basis for a simple screening test that utilizes ultraviolet spectroscopy to demonstrate a shift in the absorption spectrum of red cell lysates.[360]

The reason why P5′N deficiency leads to hemolytic anemia is not known, although there have been a variety of proposed mechanisms.[362,363] One curious explanation relates to a concomitant decrease in the G6PD activity of P5′N-deficient cells,[364] which is associated with decreased pentose phosphate shunt activity and increased incubated Heinz body formation. The mechanism whereby P5′N deficiency affects pentose phosphate shunt activity involves both competitive inhibition of glucose-6-phosphate and noncompetitive inhibition of NADP for G6PD by pyrimidine nucleotides.[364] Interestingly, both P5′N and G6PD deficiencies are characterized by hemolytic crises complicating intercurrent infections. Also of interest was the report of a Bangladeshi family which had the genes for both hemoglobin E and P5′N deficiency.[365] One individual homozygous for both conditions had a severe hemolytic anemia, while family members homozygous for Hb E were asymptomatic and those homozygous for P5′N had a mild hemolytic anemia. Globin-chain synthetic studies indicated the interaction between these two genotypes was due to decreased Hgb E stability in P5′N-deficient erythrocytes. Since, as described above, the HMP shunt is impaired in P5′N deficiency, it was postulated that the marked hemoglobin instability in enzyme-deficient cells was due to oxidant stresses exerting their effects on Hb E, which normally is mildly unstable.[365]

P5′N enzyme is readily inactivated by heavy metals such as lead, and it has been proposed that the basophilic stippling in lead poisoning is secondary to acquired P5′N deficiency.[366,367] As blood lead levels approach 200 μg/dl packed red cells, P5′N activity decreases to levels comparable to those associated with the homozygous deficiency state, intracellular pyrimidine nucleotides accumulate, and basophilic stippling can be demonstrated.[348,367] As in congenital P5′N deficiency, pyrimidine nucleotide accumulation inhibits pentose phosphate shunt activity, further compounding a direct inhibitory action of lead on G6PD.[368]

Adenosine Deaminase Excess

Adenosine is a common substrate for two different enzymes, adenosine kinase (ADK) and ADA. The Km (adenosine) is much lower for ADK than for ADA, and thus normally metabolism proceeds through ADK with phosphorylation of adenosine to form AMP (Fig. 28.5). In the presence of plasma adenosine, ADK thereby helps maintain the red cell adenine nucleotide pool.[369,370] The enzyme ADA catalyzes the deamination of adenosine to form inosine.

Hereditary deficiency of ADA is associated with severe combined immunodeficiency,[345] and since the enzyme deficiency also exists in erythrocytes, assay of red cell ADA can be used to diagnose this immune disorder. Red cell adenine nucleotide content is increased in severe ADA deficiency, but this has no adverse effects on RBC, and there is no anemia.[371,372]

Surprisingly, hereditary hemolytic anemia occurs in association with a 60- to 100-fold excess of normal ADA activity,[373] and this has been described in a few families, including a large kindred of English-Irish ancestry and in a Japanese family.[374] In these patients with hemolysis and increased RBC-ADA activity, erythrocyte ATP content is reduced.[373,374] The decrease in adenine nucleotides presumably occurs because elevated ADA activity, despite the higher Km for adenosine, effectively competes with normal levels of ADK, thereby producing a "relative" deficiency of the latter enzyme.[359,370]

In patients with hemolytic anemia and marked ADA excess, the purified enzyme exhibits normal biochemical properties and the defect appears to be due to excess production of a structurally normal enzyme.[375,376,377] The synthesis of this enzyme is directed by a gene on chromosome 20, and posttranslational modifications result in different tissue isozymes. No specific DNA mutation has been identified to account for increased ADA production in patients with hemolytic anemia.

This rare hemolytic enzymopathy is unique because it is associated with an enzyme excess, and also because it is inherited in an autosomal dominant pattern.[373,378] Clinical features include mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. No other tissues share in enzyme excess, and there are no other systemic effects. There are no distinguishing clinical, hematologic, or morphologic features to aid in the diagnosis of this condition. The specific diagnosis can be suspected if red cell ATP levels are low and confirmed by demonstrating increased ADA activity in a hemolysate. Usually no specific therapy is indicated, since most patients have very mild anemia. In contrast to these rare patients with a marked excess of enzyme activity and hemolytic anemia, a much smaller increase in enzyme activity (2- to 4-fold) has been observed in most patients with congenital hypoplastic anemia (Diamond-Blackfan syndrome)[379,380] (see Chapter 43).

Adenylate Kinase Deficiency

AK catalyzes the interconversion of adenine nucleotides (AMP + ATP→2 ADP) (Fig. 28.5). This is thought to be the only enzyme reaction in mature RBC that can lead to ADP synthesis from AMP, and thus AK would appear to have a critical role in salvaging AMP, and protecting the erythrocyte adenine nucleotide pool.[381] In erythrocytes, AMP is formed in two reactions: the ADK-mediated phosphorylation of adenosine and the APRT-mediated phosphorylation of PRPP. There are three isozymes: AK1, AK2, and AK3.[382] AK 1 is the isozyme in red cells, muscle, and brain.

Hereditary nonspherocytic hemolytic anemia in association with AK deficiency has been described in nine different kindred distributed worldwide.[381,383–386,387,388,389,390] This is an autosomal recessive disorder and heterozygote-deficient individuals are not affected. A moderate to severe chronic nonspherocytic hemolytic anemia has been reported in almost all homozygous or compound heterozygous enzyme-deficient individuals. Splenectomy sometimes is beneficial.[387] Mental retardation has been reported in some cases with severe erythrocyte AK deficiency,[384,387,388,389] and this may reflect that AK1 is the isozyme in both RBC and brain.

The causal relationship of this enzyme abnormality to hemolysis is not entirely clear, because some individuals with profound AK deficiency have no evidence of hemolysis.[381] In one sibship, there was congenital hemolytic anemia and less than 1% normal erythrocyte AK activity in an 8-year-old girl, while her brother also had no detectable AK activity, but was hematologically normal.[381] In another family with AK deficiency, a 4-year-old girl had chronic hemolysis with occasional exacerbations during infections, and occasionally she required RBC transfusions.[386] Her RBC had no detectable AK activity, while her parents had half normal activity. In this patient, decreased activity of other phosphotransferases was noted; in particular, PRPP-synthetase activity was reduced, just as in P5′N deficiency. The authors proposed that defects in multiple phosphotransferases may be responsible for the shortened lifespan of AK-deficient RBC.[386] The significance of these observations is unknown.

Molecular analysis has revealed the gene defect in six of the known kindred with chronic hemolysis and AK deficiency. In the first case a single nucleotide substitution resulting in an amino acid change (Arg121→Trp) was detected.[59,382] Analysis of subsequent probands has revealed other missense mutations,[388,390] nonsense mutations,[389] and deletion mutations.[390]

CHAPTER 29

AUTOIMMUNE HEMOLYTIC ANEMIA

Richard C. Friedberg, Vandita P. Johari

CLASSIFICATION

In autoimmune hemolytic anemia (AIHA), pathologic antibodies (autoantibodies) attach to and lead to the destruction (hemolysis) of endogenous erythrocytes (red blood cells, RBCs) resulting in anemia. By definition, both autoantibodies and associated RBC consumption must be identified. AIHA is readily subclassified according to the characteristic temperature activity of the responsible antibodies (Table 29.1). Cold-active antibodies typically have little, if any, activity at body temperature but have greater affinity for RBCs as the temperature decreases toward 0°C. Conversely, warm-active antibodies have their greatest affinity at 37°C. Generally speaking, cold-active antibodies are typically IgM, fix complement, and lead to immediate intravascular RBC destruction or hepatic-mediated clearance. In contrast, warm-active antibodies are typically IgG, may or may not fix complement, and primarily lead to RBC loss by splenic-mediated clearance of sensitized cells. Patients who express both (mixed) cold- and warm-active antibodies are particularly troublesome clinically because of the dual impact from severe RBC destruction and characteristically poor response to therapy.[1] Drug-induced immune hemolytic anemia (DI-IHA) is caused by warm-active antibodies that may be clinically and serologically indistinguishable from the idiopathic warm autoimmune type (α-methyldopa type), or may be dependent on the presence of the drug in serologic studies to demonstrate attachment of the antibody to the RBC. The clinical spectrum of drug-induced antibody attachment to RBCs ranges from asymptomatic positive serologic studies to life-threatening massive hemolysis.[2] Finally, a different type of immune-mediated hemolytic anemia can occur as a complication of organ transplantation. Because the antibodies are generated from donor-derived lymphocytes, the disorder is not truly of "auto"-immune origin, but can be thought of as a graft-versus-host disorder.

Etiology of the Immune Response in Autoimmune Hemolytic Anemia

Immunologic tolerance is a state in which the individual is incapable of developing an immune response to a specific antigen. Self-tolerance refers to lack of responsiveness to an individual's own (self) antigens, which is the normal state. Autoimmunity results from a loss of self-tolerance leading to T-cells or antibodies reacting against self-antigens and the consequent tissue injury. In AIHA, autoantibodies are directed against targets on the individual's own RBCs ("self-antigens"), leading to their enhanced clearance through F_c-receptor–mediated phagocytosis ("extravascular hemolysis") or complement-mediated breakdown ("intravascular hemolysis"). AIHA may be in large part due to self-reactive antibodies against erythrocyte band 3, an anion transporter found in the RBC membrane that is involved in RBC senescence.[3,4]

Central Tolerance

Central tolerance refers to the normal deletion of self-reactive T- and B-lymphocyte clones during their maturation in the central lymphoid organs (thymus for T-cells; bone marrow for B-cells).[5] Central tolerance prevents widespread autoimmunity by preferentially selecting nonautoreactive (i.e., "normal") T-cells for circulation into the periphery ("intrathymic negative selection"). Central tolerance is not complete, and a population of T-cells with intermediate avidity for self-antigens invariably escapes into the circulation. Under certain conditions these cells can become activated and lead to organ-specific or systemic autoimmune disease.[6,7]

Peripheral Tolerance

The mechanisms by which self-reactive T-cells that escape intrathymic negative selection and are deleted in the peripheral tissues constitute peripheral tolerance, including anergy, suppression by regulatory T-cells, and clonal deletion by activation-induced cell death (see Fig. 29.1).

Anergy refers to prolonged or irreversible functional inactivation of lymphocytes. Activation of antigen-specific T-cells requires two signals: (*i*) recognition of peptide antigen in association with self-MHC (major histocompatibility complex) molecules on the surface of antigen-presenting cells and (*ii*) a set of costimulatory signals provided by antigen-presenting cells (the co-stimulators B7-1 and B7-2). In the absence of co-stimulators, a negative signal is delivered, and the T-lymphocyte becomes anergic. Anergic lymphocytes cannot be activated even if the relevant antigen is presented by antigen-presenting cells (e.g., dendritic cells) that can deliver co-stimulation. Anergy also affects B-cells as they encounter antigen in the absence of

  - Drug-induced immune hemolytic anemia (DI-IHA)
    - Drug adsorption type (penicillin)
    - Neoantigen type (quinidine/stibophen)
    - Autoimmune type (α-methyldopa)
    - Nonimmune type (first-generation cephalosporins)
- Transplant-associated hemolytic anemia
  - Hematopoietic stem cell transplant
    - Minor ABO group mismatch
    - Major ABO group mismatch
    - Passive antibody transfer
  - Solid organ transplant
    - Passenger lymphocyte syndrome
    - Passive antibody transfer

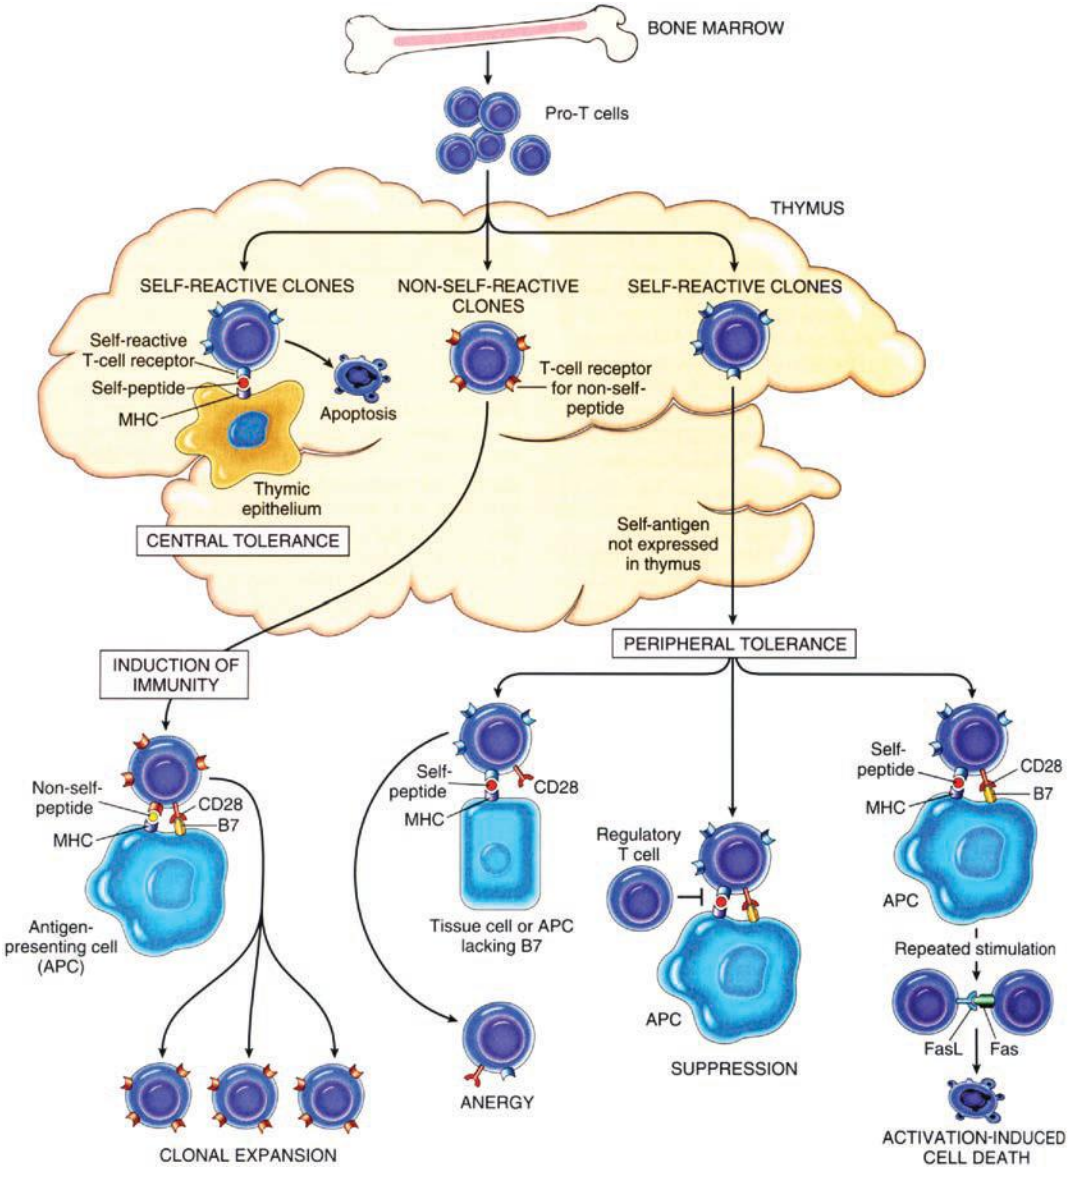

FIGURE 29.1. Schematic illustration of the mechanisms involved in central and peripheral tolerance. The principal mechanisms of tolerance in $CD4^+$ T-cells are shown. APC: antigen-presenting cell. (Used with permission from Abbas AK, Diseases of immunity. In: Kumar V, Abbas A, Fausto N, eds. Robbins and Cotran pathologic basis of disease, 7th ed. Philadelphia, PA: Elsevier Saunders, 2005:223–225.)

specific helper T-cells. They become unable to respond to subsequent antigenic stimulation and may be excluded from lymphoid follicles.[6]

Suppression by regulatory T-cells involves $CD4^+$ cells that co-express CD25, the α chain of the interleukin-2 (IL-2) receptor, but some $CD4^+$ cells that lack CD25 may also induce peripheral tolerance by suppression. These T-cells can suppress (inhibit) lymphocyte activation and effector functions in part by the secretion of cytokines such as interleukin-10 (IL-10) and transforming growth factor-β (TGF-β). However, the precise mechanism of their action is unknown.

Clonal deletion by activation-induced cell death refers to the process by which $CD4^+$ T-cells that are activated by self-antigens may receive signals that cause apoptosis. Lymphocytes express Fas (CD95), a member of the tumor necrosis factor (TNF)-receptor family, and activated lymphocytes express FasL, a membrane protein that is structurally homologous to the cytokine TNF. The engagement of Fas by FasL induces apoptosis of activated autoreactive T-cells. Self-antigens that are abundant in peripheral tissues cause repeated and persistent stimulation of self-antigen–specific T-cells, leading eventually to their elimination via Fas-mediated apoptosis. FasL on T-cells engaging Fas on the B-cells may also delete self-reactive B-cells.[6]

Factors Affecting Initiation of Autoimmunity

Autoimmunity can be affected by a number of different factors, including the nature of the autoantigens, genetic associations, and environmental factors. In AIHA, autoantigenic T-cell epitopes have been mapped for the RhD autoantigen.[8] Although these autoantigenic sites may be a potential target for novel therapeutic interventions, the precise mechanism of disease initiation remains unclear. In addition, MHC class I and class II genes may predispose individuals to certain types of autoimmune disease. For example, the human HLA-DQ-6 molecule has been associated with AIHA. However, the genetic association is multifactorial as with most other autoimmune diseases. Finally, inflammatory stimuli such as viral and bacterial infections have

been implicated as environmental triggers of autoimmunity, possibly because of antigenic mimicry leading to tolerance breakdown, i.e., environmental or infectious agents may have molecular structures similar to self-antigens. Other possible mechanisms involve production of interferon γ during viral infection that causes up-regulation of F_cRI. Alternatively, viral infection may cause a change in the expression pattern of F_c receptors as a result of transcriptional activation or other mechanisms (discussed further under section "IgG-Mediated Red Blood Cell Destruction").[9]

Mechanism of Immune-mediated Red Blood Cell Lysis

The most important features of RBC destruction by IgM and IgG antibodies are summarized in Table 29.2.

IgM-mediated Red Blood Cell Destruction

Destruction of erythrocytes sensitized with IgM antibodies is mediated by the complement system, either directly by cytolysis or indirectly via interaction of RBC-bound activation and degradation fragments of C3 with specific receptors on reticuloendothelial cells, principally liver macrophages (Kupffer cells).

The pentameric structure of IgM enables efficient complement activation. High-titer IgM antibodies can cause direct intravascular hemolysis by generating the cytolytic membrane attack complex (MAC) of complement on the RBC surface. With sufficient antibody density, complement activation may be robust enough to overwhelm the inhibitory activity of the complement-regulatory proteins DAF (CD55) and MIRL (CD59) on the RBC surface and result in hemolysis.[10] However, in most clinical situations, IgM antierythrocyte antibodies are present in sublytic quantities. Under these conditions, DAF (CD55) and MIRL (CD59) are able to prevent direct RBC lysis. Nonetheless, some C3b is deposited on the RBC surface as a consequence of the IgM-induced complement activation, and interactions of C3b and its ligand iC3b with their specific complement receptors (CR) on liver macrophages (Kupffer cells) are ultimately responsible for the immune destruction of RBCs under sublytic conditions. Table 29.3 summarizes the characteristics of various complement receptors.[10,11,12]

Although ligation of erythrocyte-bound C3b to CR1 on Kupffer cells may mediate some of the clearance, interaction between RBC-bound iC3b and macrophage CR3 is probably the principal mediator of extravascular destruction of complement-sensitized erythrocytes. Clearance of the complement-sensitized RBCs is likely mediated by phagocytosis, because the liver lacks the unique anatomy of the spleen and is thus unable to sequester cells. Once RBC-bound iC3b has been converted to C3dg (ligand for CR2), the RBCs are no longer subject to immune destruction because phagocytic cells do not express the specific receptor for C3dg. Thus, erythrocytes bearing only C3dg have a normal life span.[13,14]

IgG-mediated Red Blood Cell Destruction

IgG is a relatively ineffective initiator of activation of the classical complement pathway. Consequently, direct complement-mediated cytolysis of RBCs induced by IgG antibodies is unusual (a notable exception is the D–L antibody of paroxysmal cold hemoglobinuria [PCH]). In the absence of complement activation, clearance of IgG-sensitized erythrocytes is primarily splenic. Two distinct processes appear to be involved. First, binding to F_c receptors expressed by tissue macrophages in the red pulp of the spleen can mediate direct and complete phagocytosis. Second, partial phagocytosis, in which the phagocytes remove a portion of the membrane, results in a decrease in the surface area-to-volume ratio and the consequent generation of spherocytes, the classic morphologic hallmark of immune hemolytic anemia. The loss of deformability as a consequence of spherocyte formation results in sequestration of the abnormal RBCs in the red pulp because the consequent rigidity limits their ability to traverse the splenic cords into the sinuses. The trapped spherocytes are vulnerable to phagocytosis by macrophages that are found in abundance in the splenic cords. In addition, the life span of the sequestered RBCs is shortened by the unfavorable metabolic environment found in the splenic cords (splenic conditioning). Once trapped, RBC destruction is complete within minutes.

The liver clears IgG-coated RBCs less efficiently than the spleen. Nevertheless, the liver plays a clinically significant role in RBC destruction. The quantity of antibody fixed to the RBC roughly correlates with the site of destruction (smaller amounts of antibody lead mainly to splenic sequestration whereas larger amounts of antibody lead to increased sequestration within the liver).[15,16] The more rapid clearance of RBCs sensitized with a higher density of IgG antibodies and the shift in clearance from the spleen to the liver are due to complement activation.[16] Although IgG alone can mediate RBC clearance, the concomitant presence of RBC-bound C3 fragments greatly enhances the rate of immune-mediated destruction.

Phagocytosis of IgG-coated RBCs occurs in the spleen and is mediated by surface receptors for the F_cγ region of the IgG molecule. There are three different classes of F_cγ receptors. F_cγRI mediates in vitro cytotoxic activity. F_cγRII inhibits B-lymphocyte and mast-cell activation. F_cγRIII is responsible for phagocytosis, endocytosis, and antibody-dependent cell-mediated cytotoxicity and therefore plays a key role in hemolysis. The characteristics of F_cγR are summarized in Table 29.4.

Of the four subclasses of IgG, IgG_3 has the highest affinity for the F_cγR and therefore is most efficient at causing extravascular

TABLE 29.2

RED CELL DESTRUCTION BY IgM AND IgG ANTIBODIES

Antibody	Intravascular Clearance	Extravascular Clearance—Liver	Extravascular Clearance—Spleen	Complement Dependency	Hemoglobinuria	Bilirubinemia	Specificity of Antiglobulin Test
IgM Low-titer[a]	+	+	−	+	±	+	Complement
IgM High-titer[a]	+	−	−	+	+	+	Complement
IgG Low-titer[b]	−	−	+	−	−	+	Immunoglobulin
IgG High-titer[b]	−	±	+	−	±	+	Immunoglobulin

[a]Anti-A or anti-B blood group antibodies are examples of IgM antibodies that can be present at low or high concentrations.
[b]Anti-Rh_o(D) is an example of an IgG antibody that can be present at low or high concentration.

TABLE 29.3

CHARACTERISTICS OF COMPLEMENT RECEPTORS

Receptor	Characteristics	Complement Ligand	Cellular Distribution	Function
CR1 (CD35)	210–330 kDa Four allotypes Single-chain glycoprotein 30 SCRs	C3b (high affinity) C4b iC3b (weak affinity)	RBCs; neutrophils; monocytes; macrophages; B- and some T-cells, follicular dendritic cells; Langerhans cells; Kupfer cells	Regulates C3, C4, and C5 convertase of classic and alternative pathways of complements; factor 1 cofactor, RBC CR1, phagocyte CR1
CR2 (CD21)	145 kDa; integral membrane glycoprotein 15 SCRs	C3dg, C3d	B-cells; follicular dendritic cells	Immune modulation; cellular receptor for the Epstein-Barr virus
CR3 (CD11b/CD18)	165 kDa (CD11b); 95 kDa (CD18); heterodimer	iC3b	Neutrophils; monocytes; macrophages; NK cells; cytotoxic T-cells	Adherence and phagocytosis of opsonized RBCs
CR4 (CD11c/CD18)	150 kDa (CD11c); 95 kDa (CD18); heterodimer	iC3b	Neutrophils; monocytes; macrophages; NK cells; cytotoxic T-cells	Undefined

RBCs, red blood cells; SCR, short consensus repeat.

TABLE 29.4

CHARACTERISTICS OF $F_C\gamma$ RECEPTORS

Receptor	Characteristics	Affinity for IgG	Cellular Distribution	Function
$F_c\gamma$RI (CD64)	72 kDa; integral membrane glycoprotein IgG	High ($1–3 \times 10^{-8}$ L/M)	Monocytes; tissue macrophages neutrophils	Binds monomeric IgG interferon-γ stimulated ADCC and resetting of IgG-coated RBCs; not essential for phagocytosis
$F_c\gamma$RII (CDw32)	40 kDa; integral membrane glycoprotein	Low (2×10^{-5} L/M)	Monocytes; tissue macrophages; neutrophils platelets; B-cells	Binds aggregated IgG; mediates ADCC; weak mediator of resetting; important for phagocytosis
$F_c\gamma$RIII (CD16)	50–80 kDa; both integral membrane ($F_c\gamma$RIIIa) and glycosyl phosphatidylinositol-anchored ($F_c\gamma$RIIIb) forms	Low (5×10^{-5} L/M)	Neutrophils ($F_c\gamma$RIIIb); tissue macrophages; NK cells ($F_c\gamma$IIIa)	Binds aggregates IgG; important for clearance of IgG-sensitized RBCs

ADCC, antibody-dependent cell-mediated cytotoxicity; NK, natural killer; RBCs, red blood cells.

hemolysis ($IgG_3 > IgG_1 > IgG_4 >>> IgG_2$).[17,18] The critical role of $F_c\gamma$ receptors in immune destruction in vivo is further demonstrated by the therapeutic approach to management of AIHA and immune thrombocytopenic purpura (ITP). Treatment with corticosteroids, intravenous IgG (IVIG), anti-D, and/or splenectomy is aimed at reducing the capacity of reticuloendothelial cells to mediate immune clearance of IgG-sensitized RBCs.[19] Administration of monoclonal antibody 2.4G2 in mice, which binds to and blocks mouse $F_c\gamma$RII and $F_c\gamma$RIII, allows rapid recovery after induction of AIHA, suggesting that alteration of the balance of stimulatory to inhibitory $F_c\gamma$ receptors has a marked effect on disease progression and susceptibility. Understanding the detailed structure of the $F_c\gamma$ receptors may lead to the development of novel therapeutic strategies. For example, molecules that inhibit the binding of the $F_c\gamma$R to an IgG-coated RBC or those that might inhibit the $F_c\gamma$ receptor signaling at the different steps leading to phagocytosis may be useful therapeutic tools. Treatments that decrease expression of the activating $F_c\gamma$ receptor or increase expression of the inhibitory $F_c\gamma$ receptor may also be effective.[9]

Laboratory Diagnosis

Two criteria must be met to diagnose AIHA: clinical or laboratory evidence of hemolysis and serologic evidence of an autoantibody.

Common Laboratory Features

The basic tests to evaluate hemolysis include a complete blood count (CBC) with peripheral smear, bilirubin, lactate dehydrogenase (LDH, particularly isoenzyme 1), haptoglobin, and urine hemoglobin or hemosiderin. Universal signs of hemolysis include decreased serum hemoglobin and hematocrit, increased serum LDH and unconjugated bilirubin, and polychromasia and reticulocytosis given adequate hematopoietic reserve. Haptoglobin is typically reduced, although sequential levels should be assessed because the protein is an acute-phase reactant and thereby dependent on both hepatic function and systemic stress. Intravascular hemolysis further manifests with increased free hemoglobinemia, increased hemoglobinuria, hemosiderinuria, methemalbuminemia, and decreased serum haptoglobin. Hemoglobinemia is usually evident in the specimen collection tube as a distinctly red- or pink-tinged serum or plasma. Hemolysis in AIHA can be either intravascular or extravascular. Typically, intravascular hemolysis is rapid and aggressive, whereas extravascular hemolysis is milder. The peripheral blood smear may reveal spherocytes in warm AIHA or RBC agglutination in cold AIHA.

Serologic Investigation

The demonstration of RBC surface-bound immunoglobulin or evidence of complement fixation supports the diagnosis of immune-mediated RBC destruction. IgM-coated RBCs may spontaneously agglutinate because the pentameric antibody can directly cross-link RBCs. The capability for IgM antibodies to agglutinate saline-suspended RBCs without additional reagents led to the traditional terminology of "complete" antibodies. In contrast, IgG antibodies typically require antihuman globulin (AHG) as a co-factor to agglutinate saline-suspended RBCs and are thus termed "incomplete" antibodies.

The explanation for this serologic difference lies in the physical properties of the RBCs and the antibody molecules involved. Erythrocytes have a strong net negative surface charge ("zeta potential") produced by the sialoglycoprotein coat, such that the shortest separation attainable between two RBCs is approximately 18 nm. Other factors may also play a role in maintaining the separation distance, such as water that is tightly bound to the surface of the RBCs. IgM molecules, with their large pentameric structure, create a 30-nm distance between adjacent binding sites and can therefore bridge two RBCs. The smaller IgG can accommodate a span of only 12 nm between antigen-recognition sites and thus usually cannot lead to agglutination alone.[20] Exogenous AHG can bridge IgG molecules, which explains the term "incomplete" above. However, some IgG antibodies can indeed agglutinate RBCs (e.g., anti-A, anti-B, and anti-M), revealing the influence on agglutination of the number of antigen sites per RBC[21] and how far the antigenic determinants project from the surface of the RBC. The blood group-defining A and B oligosaccharides extend well beyond the lipid bilayer membrane.[22] In addition to their relative abundance, they are also close together on the RBC surface, potentiating agglutination. The critical number of IgG molecules required to agglutinate RBCs is approximately 7,000 to 20,000 per RBC, whereas the requisite number of IgM molecules is only 25 to 50 per RBC.[23,24] Although serologic tricks such as enzyme treatment, centrifugation, and addition of substances such as albumin, polyvinylpyrrolidone (PVP), and dextran have been used to enhance agglutination by IgG antibodies, the most common way to determine the presence of immune system components on RBCs is with the direct antiglobulin test (DAT, direct Coombs).

Direct Antiglobulin Test (Direct Coombs Test)

In 1908, Moreschi described antiglobulin reactions as an aid to RBC agglutination.[25] This work remained largely unnoticed until 1945, when the investigation of anti-RBC antibodies was revolutionized with the development of the antiglobulin test by Coombs et al.[26] and its role in the identification of maternal IgG on fetal RBCs in hemolytic disease of the newborn (HDN) in 1946.[27] The principle of the DAT is quite simple. In order to ascertain if RBCs carry surface-bound immunoglobulin and/or complement, antisera with reactivity to human immunoglobulin and/or complement molecules is added to a suspension of the RBCs in question, providing the necessary cross-link to elicit agglutination. Figure 29.2 illustrates the principle of the test.[28] An ethylenediaminetetra-acetic acid (EDTA)-collected sample from the patient is used to prevent subsequent complement adherence to the RBC membrane in vitro. The test is performed by first washing the RBCs to remove nonspecifically adhered proteins. Following the addition of AHG, the mixture is centrifuged to enhance agglutination. The result is interpreted by resuspending the RBCs gently and observing carefully for clumps. Magnifying mirrors or low-power microscopy may aid in discerning weak reactions. Negative reactions are further incubated at room temperature, centrifuged, and read again, as this additional incubation promotes positive reactions in the presence of complement.[29] Initial testing is done with polyspecific AHG (antisera), which contain anti-IgG, anti-C3d, and, occasionally, some anti-light–chain activity. Monospecific reagents differentiate between IgG and C3d to further define the specificity. Other monospecific antisera are available for C3b, C4b, C4d, and IgG heavy chain.[30] Specific antiserum for IgM or IgA is rarely used, as IgM is not usually found attached to the RBC surface ex vivo, and IgA is very rarely a cause of immunoglobulin coating by itself.[31,32] The U.S. Food and Drug Administration (FDA) has licensed monoclonal reagents, the most common of which is anti-C3d, which do not cross-react with other complement components.[30]

Early DAT methodology suffered from relative insensitivity. More recent developments have improved the sensitivity for

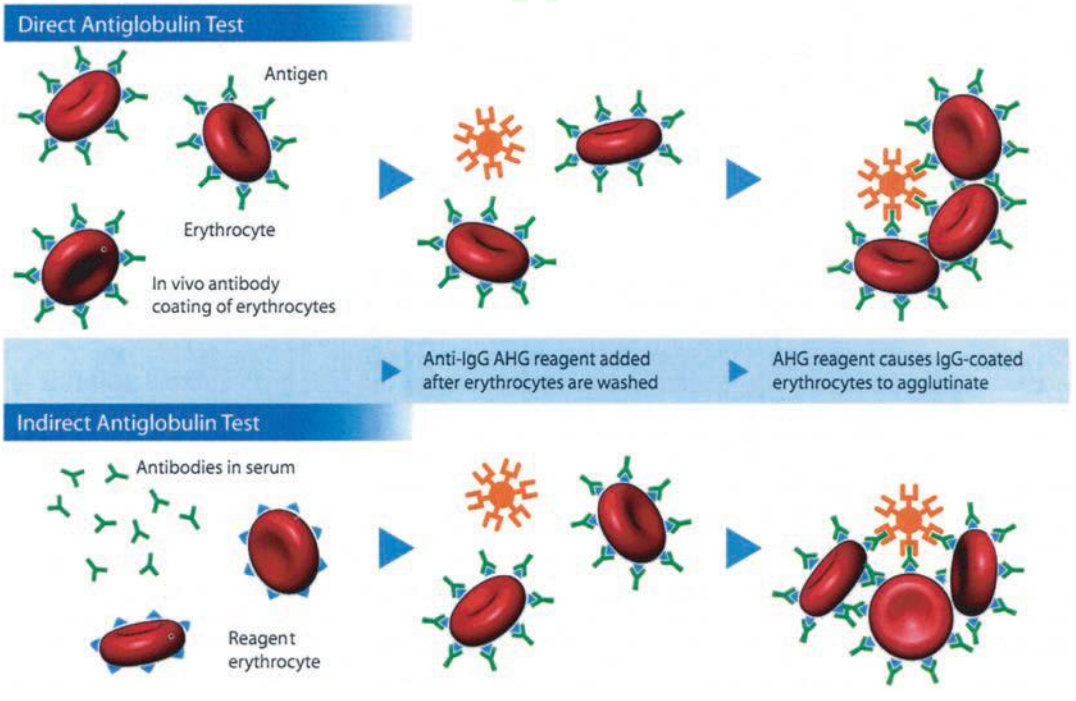

FIGURE 29.2. Direct antiglobulin test (DAT) and indirect antiglobulin test (IAT). The DAT reflects in vivo antibody sensitization of RBCs. Erythrocytes are washed to remove any unbound antibodies, and anti-IgG AHG reagent (AHG: antihuman globulin) is then added. IgG antibodies cannot cause direct RBC agglutination, but IgG-coated RBCs will agglutinate in the presence of AHG containing anti-IgG. This test can also be performed using anticomplement AHG reagent. If it is present, RBC-bound IgG can be eluted for specificity determination. The IAT is used to detect the presence of IgG antibodies in serum (in vitro sensitization). Reagent RBCs are incubated in the presence of serum that may contain antibodies. If they are present, antibodies bind to their target antigens on the reagent RBCs. After incubation, the RBCs are washed to remove unbound antibodies. Anti-IgG AHG reagent is added and will cause IgG-coated erythrocytes to agglutinate. (From Zarandona JM, Yazer MH. Teaching case report. The role of the Coombs test in evaluating hemolysis in adults. Can Med Assoc J 2006;174:305–307.)

RBC-bound immunoglobulin and complement. The traditional tube method described above detects a lower limit of 150 to 200 IgG molecules per RBC.[33] With PVP enhancement and an autoanalyzer, the detection limit decreases to as few as 8 IgG per RBC producing 5% agglutination. If bromelin is added as well, the sensitivity increases even further, with 1 IgG per RBC producing 5% agglutination and 3 IgG per RBC producing 50% agglutination.[34] Additional acceptable techniques include flow cytometry, enzyme-linked antiglobulin tests (ELISA), radioimmunoassays (RIA) using ^{125}I-labeled anti-IgG or staphylococcal protein A, solid-phase techniques using microtiter plates, and gel testing.[35] However, only the tube test, solid-phase test, and gel tests are in common use. Of these, the solid-phase and gel tests are the most standardized and have largely replaced older tube testing technology.

A positive DAT does not always mean decreased RBC survival. Most patients with a positive DAT have no obvious clinical signs of hemolytic anemia. DAT interpretation must consider the context of clinical history and other laboratory findings. Outside of AIHA, a positive DAT may also be seen with (*i*) alloantibodies in a recipient of RBC or plasma transfusion, (*ii*) antibodies from maternal circulation that cross the placenta and coat the fetal RBCs, (*iii*) antibodies directed against certain drugs that bind to the RBC membrane (e.g., penicillin), (*iv*) nonspecifically adsorbed proteins including immunoglobulins and Wharton's jelly, (*v*) RBC-bound complement, and (*vi*) antibodies produced by passenger lymphocytes in transplanted organs or hematopoietic components. Further evaluation of a positive DAT in a patient with clinical and laboratory evidence of hemolysis includes testing for clinically significant antibodies to RBC antigens and testing the eluate. Figure 29.3 illustrates an approach to the evaluation of a positive DAT.[29] A negative DAT, on the other hand, does not exclude AIHA. Possible causes of a negative DAT with clinical evidence of hemolysis include an IgA or IgM autoantibody, insufficient antibody molecules for detection, and low-affinity autoantibodies.[35] Repeat testing, enhancement techniques, and the use of nonroutine reagents may be required when the clinical suspicion is strong.[29]

Indirect Antiglobulin Test (Indirect Coombs Test)

Approximately 80% of patients with AIHA have autoantibodies in their serum as well as on their RBCs.[36] The antibodies in their serum or plasma and the antibodies eluted from their RBCs (the "eluate") are detected by the indirect antiglobulin test (IAT; more commonly known as the antibody screen). Unlike the DAT, which uses patient RBCs with reagent serum, the IAT tests patient serum against reagent RBCs. Immunoglobulin from the patient serum attaches to the reagent RBCs and is detected with antiglobulin sera, which cross-link the RBCs together and produce agglutination, as in the DAT. See Figure 29.2.[28]

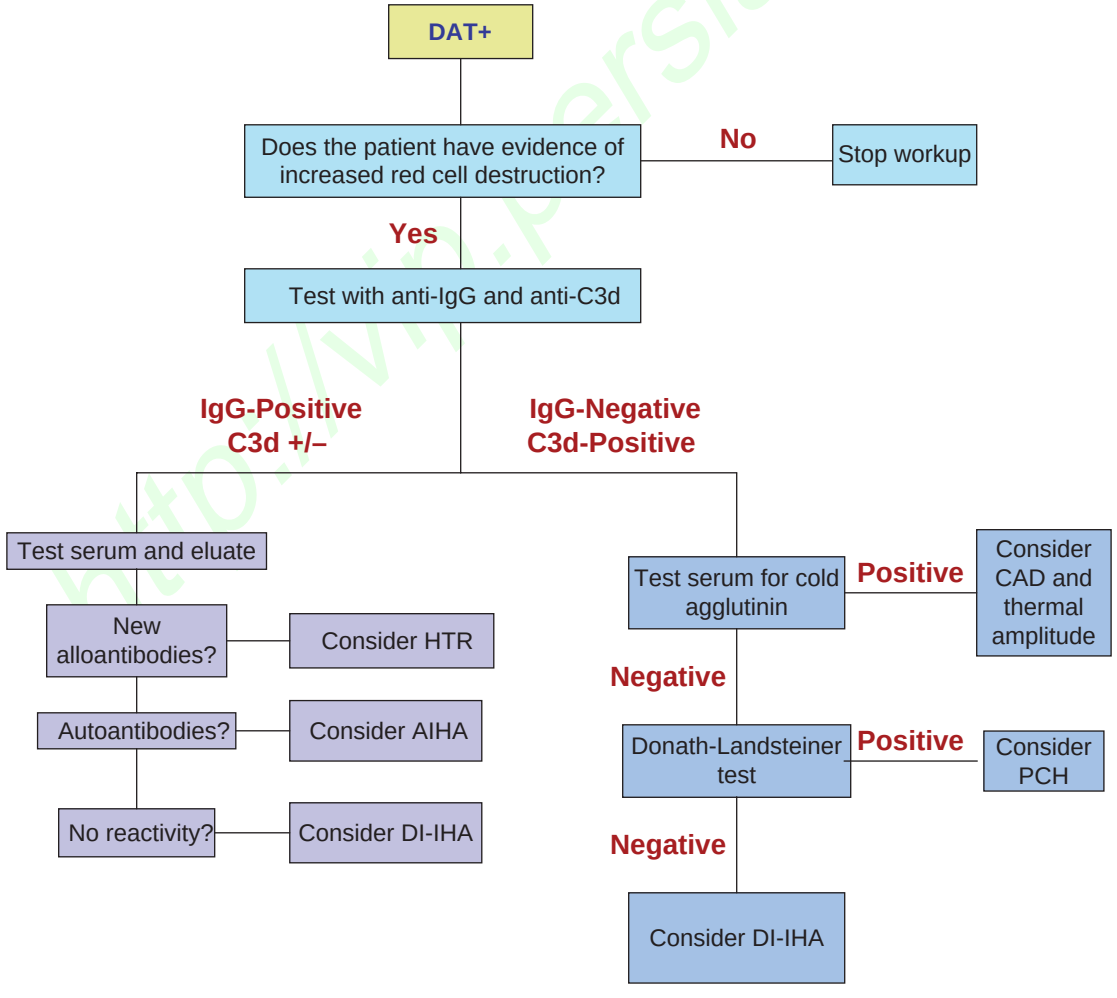

FIGURE 29.3. Flowchart suggesting a rational clinical laboratory approach for investigating a positive DAT. AIHA: autoimmune hemolytic anemia; CAD: cold agglutinin disease; DI-IHA: drug-induced immune hemolytic anemia; HTR: hemolytic transfusion reaction; PCH: paroxysmal cold hemoglobinuria. (Modified from Brecher ME, ed. Technical manual, 15th ed. Bethesda, MD: American Association of Blood Banks, 2005:480.)

Warm autoantibodies are typically panagglutinins, reacting with all cells in the diagnostic RBC panel (i.e., panreactive). Formerly, panagglutinins were believed to react with a basic determinant of the Rh antigen system as they do not react with the very rare Rh_{null} RBCs which do not express Rh antigens.[37] However, as more eluates are studied with a broader population of rare null phenotypes, it has been shown that, in addition to Rh, autoantibodies react to LW antigens, glycophorins A, B, C, and D, and, very rarely, Kidd or Kell blood group system antigens.[38] A small number of case reports exist describing AIHA associated with ABO antigens.[39,40]

Elution

If the DAT is positive for RBC-bound antibody, that antibody can be eluted (removed) from the RBC with the aid of acid or xylene, and any binding specificities can be further investigated with a reagent red cell panel. Elutions are not typically performed on DAT specimens positive only for complement, as these molecules do not exhibit antigen specificity. Occasionally, however, when antibody presence is suspected but perhaps at too low a concentration to be detected on the RBCs, eluates may show reactivity. Elution tends to produce a more concentrated antibody solution, so reactions are often stronger. Once the antibody is in solution, indirect antiglobulin techniques may help define the antibody characteristics.[29]

Other Serologic Techniques

Generally, autoantibodies are panreactive, whereas alloantibodies exhibit antigen specificity, reacting only with specific antigen-positive RBCs. In certain situations an autoantibody may mimic an alloantibody. For example, an alloantibody to a high-incidence antigen in a post-transfusion setting can mimic an autoantibody with a positive DAT (mixed field) and reactions with all panel cells. In addition, autoantibodies may exhibit apparent specificity. Autoadsorption and antigenic phenotyping can help differentiate autoantibodies and alloantibodies, especially if the patient has not been transfused recently. Autoadsorption uses autologous RBCs to adsorb autoantibodies prior to repeating serum testing for alloantibodies. If an antibody exhibits specificity, demonstration that autologous RBCs are negative for the corresponding antigen confirms the alloantibody; in the absence of a recent transfusion, a positive result suggests that it is an autoantibody. Autoadsorption can also be used to cross-match donor RBC units for patients with warm autoantibodies who have not been recently transfused.[29]

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY COLD-ACTIVE ANTIBODIES

Cold-active antibodies exhibit greater titer and RBC-binding activity as the temperature decreases toward 0°C. Two different clinical syndromes are manifested from cold autoimmune antibodies. Cold agglutinin disease (CAD) is associated with IgM antibodies usually directed at the RBC *I* antigen. CAD typically occurs in adult patients and may be primary or secondary to another disease process, usually infectious. In contrast, PCH is caused by an IgG hemolysin, the Donath-Landsteiner (D-L) antibody.[41] Both PCH and CAD are less common than warm AIHA and make up approximately 20% or less of AIHAs. See Tables 29.5 and 29.6.

Cold Agglutinin Disease

Although Landsteiner first described cold agglutinins in 1903,[42] it was not until the late 1940s and early 1950s that the connection between cold autoantibodies and RBC destruction was firmly made. In the 1950s, Schubothe coined the term "CAD," and the disorder became recognized as a separate entity from other acquired hemolytic processes.[43] The responsible pathologic IgM antibodies are distinguished from naturally occurring cold autoantibodies by their titer and *thermal amplitude,* a term describing the range of temperatures over which the antibody is reactive. Natural cold autoantibodies occur with titers less than 1:64 at 4°C and have little to no activity at higher temperatures. However, pathologic cold agglutinins typically have titers well over 1:512 and may react at 28°C to 31°C (peripheral body temperature) or even up to 37°C.[31] See Table 29.6 and Figure 29.4.

TABLE 29.5

COLD AUTOANTIBODIES

	Primary Cold Agglutinin Disease	Secondary Cold Autoantibodies	Paroxysmal Cold Hemoglobinuria
Immunoglobulin	IgM	IgM	IgG
Clonality	Monoclonal	Monoclonal or polyclonal	Polyclonal
Direct antiglobulin test	C3	C3	C3
Hemolysis	Chronic, mild	Self-limited, mild to severe	Episodic, self-limited, mild to severe
Target RBC antigen	*I*	*I, i*	*P*

RBC, red blood cell.

Primary versus Secondary Cold Agglutinin Disease

Primary or idiopathic CAD is typically an affliction of older adults, with a peak incidence around age 70.[43] Both sexes are affected, but women predominate.[44] A monoclonal IgMκ antibody is the usual culprit, and, as with other monoclonal gammopathies of unknown significance, may be a harbinger of future B-cell neoplasms. Most commonly, patients tolerate a relatively benign, waxing and waning hemolytic anemia.

Patients with Waldenstrom macroglobulinemia or other B-cell neoplasms may produce monoclonal anti-RBC antibodies with cold reactivity. As in primary CAD, they are nearly always IgMκ. This type of secondary cold agglutinin may be effectively treated with antineoplastic chemotherapy. A return of hemolysis may herald a tumor relapse. Other non–B-cell tumors reported in association with cold antibody production include squamous cell carcinoma of the lung, metastatic adrenal adenocarcinoma, metastatic adenocarcinoma of the colon, basal cell carcinoma, and a mixed parotid tumor.[45]

Another scenario of secondary cold autoantibody hemolysis occurs after *Mycoplasma pneumoniae* infection or infectious mononucleosis and is more commonly seen in younger adults. This transient, self-limited process is mediated by polyclonal IgM (κ or λ), lasts a few weeks, and seldom requires more than supportive care. In rare cases, massive intravascular hemolysis and acute renal failure may be seen. See Table 29.7.

Antibody Characteristics

Immunochemistry and Origin

As stated earlier, nearly all cold agglutinins are IgM. A few reports of IgG or IgA agglutinins are recorded, and a mixed IgM–IgG has been seen in infectious mononucleosis and angioimmunoblastic lymphadenopathy.[46] Those patients with non-IgM antibodies are more likely to have cold autoantibody hemolysis secondary to another disease and are less likely to display specificity for the *I* antigen.[44,47]

TABLE 29.6

SEROLOGIC OVERVIEW OF HEMOLYTIC ANEMIAS

	Cold Agglutinin Disease	Paroxysmal Cold Hemoglobinuria	Mixed Warm and Cold Autoimmune Hemolytic Anemia	Warm Autoimmune Hemolytic Anemia	Drug-Induced Hemolytic Anemia
Percentage of cases	16–32%	32% (children); rare in adults	7–8%	40–70%	12–18%
Direct antiglobulin test	C3	C3	IgG ± complement	IgG ± C3; rarely C3 alone	IgG or C3; occasionally IgG ± C3
Ig	IgM	IgG	IgG, IgM	IgG, occasionally with IgA or IgM	IgG
RBC eluate	Nonreactive	Nonreactive	IgG	IgG	IgG or nonreactive
Antibody specificity	*I* > *i* >> *Pr*	*P*	Panreactive	Panagglutinin	Rh-related
			Unclear > *I*> others	Rarely Rh	Drug-dependent

RBC, red blood cell.

Anti-idiotypic antibodies and direct nucleotide sequencing of the rearranged immunoglobulin variable-region genes have revealed significant cross-reactivity and homologies among cold autoantibodies with similar specificity.[48,49] For instance, the monoclonal anti-idiotypic antibody 9G4 recognizes an idiotypic determinant present on the heavy chains of both anti-*I* and anti-*i* cold agglutinins as well as the responsible neoplastic B-cells.[50] Essentially all pathologic anti-*I* and anti-*i* cold agglutinins are derived from a distinct subset of heavy-chain variable-region genes called V_H4 family genes, specifically V_H4–21.[51] In ~40% of the patients, a circulating B-cell clone can be identified with a distinctive karyotypic marker (trisomy 3q11-q29; trisomy 12; or 48XX+3+12). The chromosomal abnormalities were associated with chronic idiopathic cold agglutinin syndrome as well as with monoclonal cold agglutinins secondary to a neoplasm.[52,53,54] In addition, the cold agglutinins have the same serologic specificity and isoelectric focusing spectrotype and are therefore likely derived from a pre-neoplastic or neoplastic B-cell clone.[7]

I/*i* Blood Group System Specificity

More than 90% of cold-active antibodies have the *I* antigen as their target on the RBC, and the *i* antigen is the binding site for a significant portion of the remaining 10%.[31] The closely related *I*/*i* antigens are high-frequency carbohydrates similar to the ABO antigens. The RBC surface densities of *I* and *i* are inversely proportional, with neonatal RBCs exclusively expressing large amounts of *i* antigen, usually converting to exclusively *I* antigen by 18 months of age. Consequently, adult RBCs are used to detect anti-*I* agglutinins and cord RBCs are needed to detect anti-*i* agglutinins. Extremely rare adults have been described who never express *I* antigen on the RBCs. Other uncommon but reported antigen

targets include *Pr*. Anti-Pr cold agglutinins tend to be high-titer, with a wide thermal range, and cause symptomatic anemia.[55,56] Other infrequent targets are *Gd*, *Fl*, *Vo*, *Li*, *Sa*, *Lud*, *M*, *N*, *Me*, *Om*, *D*, Sd^x, and *P*.[38,44,57] The fact that *M. pneumoniae* induces anti-*I* antibodies in the majority of patients is potentially related to the finding that sialylated *I/i* antigens serve as specific *Mycoplasma* receptors.[58] Minor modification of this antigen may incite autoantibodies. Another theory suggests that an *I*-like antigen appears on the organism itself, and cross-reacting antibodies lead to RBC lysis.[59] Despite the high rate of antibody production, clinically significant hemolysis occurs in very few patients.[60] Infectious mononucleosis is also associated with CAD, but to a much lesser degree than *Mycoplasma*. Only 0.1% to 3.0% of mononucleosis patients have clinical hemolysis,[61] although anti-i is present in 8% to 69% of sera post-infection.[62–64] Therefore, the majority of patients with antibodies are asymptomatic. Anti-*I* activity is usually noted as well, but not to the same degree. Also, anti-Pr and anti-N have been reported.[65] Both IgM and IgG antibodies as well as IgM rheumatoid-like factors reacting with IgG may act as cold agglutinins after infectious mononucleosis.[66,67] See Table 29.7 for a list of other infectious diseases associated with cold agglutinins, most of which are anti-*I*, although anti-*i* has been seen in cytomegalovirus infections and in lymphomas.[68]

Functional Characteristics

Cold agglutinins attach to the RBC in the cooler peripheral circulation. As the blood returns to the warmer core circulation, the antibody dissociates from the RBC. Antibodies that attach, fix complement, and then dissociate are free to attack another erythrocyte and begin the process again.[69] Complement fixation and activation, which are responsible for the destruction of the RBCs, are far more efficient at the warmer core temperatures. However, with a high antibody titer and a wide thermal amplitude, there may be sufficient temperature overlap to produce hemolysis at 22±10°C.[43] See Figure 29.4. Because of this diversity of temperature requirements for optimal activity of the antibody and complement, RBC destruction is usually not particularly severe with cold autoantibodies. Quite impressive exceptions occur, and these are typically the antibodies with either high titers (>1:1,000) or activity up to 37°C even in the face of modest titers. Thermal amplitude is a better predictor of hemolysis than titer.[46,70] High-titer cold agglutinins with a narrow thermal amplitude may produce a clinical picture with bursts of hemolysis associated with exposure to cold, often manifested as intermittent hemoglobinuria between quiescent periods.[69]

A frequent misconception about cold agglutinins is the assumption that they are cryoglobulins, whereas in fact they are two distinct disease processes. Both may cause cyanosis and Raynaud phenomenon in cooler temperatures. However, cryoglobulins do not fix complement on the RBCs or lead to hemolysis.

Clinical Manifestations

Mild, chronic hemolytic anemia with exacerbations in the winter is the general rule for CAD. Rarely does the hemoglobin drop below 7 g/dl.[71] Pallor and jaundice may occur if the rate of hemolysis is greater than the endogenous capability to metabolize bilirubin.[44] Some patients have intermittent bursts of hemolysis associated with hemoglobinemia and hemoglobinuria on exposure to cold and may be forced to move to warmer climates to minimize attacks. Acrocyanosis can occur from agglutination of RBCs in the cooler vessels of the hands, ears, nose, and feet.[31,44] Digits may become cold, stiff, painful, or numb and may turn purplish. Limbs may manifest *livedo reticularis*, a mottled appearance that is readily reversible upon warming of the affected area. Only rarely does actual gangrene of digits develop, and nearly all of these cases have an associated cryoglobulin.[72] A minority of chronic CAD patients have mild splenomegaly or hepatomegaly. The spleen may be enlarged or more frequently palpable in secondary cold agglutinins due to lymphoma or infectious mononucleosis.[44]

If hemolysis does occur after *Mycoplasma* infections, it typically begins during the post-pneumonia recovery period when cold autoantibody titers are at peaking. The process, even if severe, resolves spontaneously within 1 to 3 weeks.[31] Hemolytic anemia after infectious mononucleosis may begin with the onset of illness or within the next 3 weeks.[44] The self-limited, post-infectious CAD tends to affect younger patients, whereas the chronic idiopathic form is a disease of the elderly, with peak incidence at ~age 70 years.[43]

Laboratory Features

Mild chronic anemia is the rule, but the hemoglobin may fall to 5 to 6 g/dl, especially in the winter months in cold climates. The peripheral smear, if not obtained from a carefully collected prewarmed specimen properly maintained warm until spread on a warm slide, may show significant agglutination and RBC clumping under magnification. Occasionally, clumping is so extensive as to be grossly visible without magnification and may even preclude an adequate smear examination. Agglutinates are frequently visible in the specimen tube and can appear to be a large clot. Dissolution with warming demonstrates that the clumped and clotted appearance is a result of a cold agglutinin rather than Rouleaux formation or fibrin strands. Often, the first suspicion of a cold agglutinin comes from a failed attempt to obtain a valid RBC count and indices on an automated CBC. The initially reported RBC count is often artifactually low and the MCV artifactually high, producing a spuriously high MCHC. The reticulocyte count is modestly elevated except in rare cases of concomitant marrow failure, such as those due to parvovirus B19 infection.[73] Spherocytosis is not pronounced as in warm AIHA. WBC and platelet counts are usually normal, but low levels of both have been reported, as has leukocytosis.[44] Bilirubin is mildly elevated, rarely >3 mg/dl. LDH may be increased (reflecting RBC destruction), and complement and haptoglobin are often low or absent. During brisk hemolysis, hemoglobinuria and hemoglobinemia are manifest. The DAT is positive with polyspecific and anticomplement antisera. As above, IgM has dissociated and is not detectable. In extremely rare cases, the antibody involved is IgG or IgA, either alone or in addition to IgM.[31,44] Mixed warm and cold autoantibodies are not rare (discussed later). Titers measured at 4°C may range from 1:1,000 to 1:1,000,000, although typical values are between 1:1,000 and 1:500,000. Much lower levels can be clinically significant if activity is measurable at 37°C. Post-infectious CAD titers are lower (<1:4,000) than the chronic idiopathic or lymphoma-associated varieties. In patients with monoclonal IgM, evaluation of serum proteins frequently reveals an M spike, shown by serial observations to be stable in the chronic idiopathic disease.[74]

Management

Primary Cold Agglutinin Disease

Because of the mild chronic nature of the anemia, the majority of patients need no specific therapy other than the general principle of avoiding temperatures below those at which their antibody shows activity. In some cases this may necessitate a move to a warmer climate. For patients with more severe anemia and cardiovascular compromise, aggressive therapy is indicated.

Immunosuppressive Therapy: The ideal therapy would only suppress production of the pathologic antibody. Until that becomes an option, a common approach in treating symptomatic CAD is to use cyclophosphamide or chlorambucil. A minority of patients respond, and in these cases transfusions can be avoided. One alternative is chlorambucil, beginning with 2 to 4 mg/day and increasing by 2 mg every 2 months until either a response is

obtained or unacceptable myelotoxicity results. Twice-weekly blood counts plus reticulocyte count should be monitored for toxicity.[31,75] Pulse therapy with cyclophosphamide (250 mg/day) and prednisone (100 mg/day ×4 days) every 2 to 3 weeks, blood counts permitting, or a large dose regimen of cyclophosphamide (1,000 mg), and intravenous methylprednisolone (500 mg) may adequately control hemolysis.[76] In addition, α-interferon has reportedly produced significant remissions.[77] However, recent studies have shown that rituximab is the most effective form of treatment and can be used as first line.

Rituximab: Rituximab, a chimeric human/murine monoclonal CD20 antibody, has been used with success in CAD in several case reports and series. The proposed mechanism of action involves complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity, direct apoptotic effects, and inhibition of B-cell proliferation. The most effective and best-evaluated treatment is rituximab in standard lymphoma dose (375 mg/m^2 each week for 4 weeks). Berentsen et al., in an open, uncontrolled prospective phase 2 study of rituximab in CAD showed that 20 of 27 patients responded with a median duration of response of 11 months.[78] Most relapsed patients responded to retreatment with rituximab. Similar results were obtained by other studies.[79] Some pediatric patients were successful with just two infusions.[80] This evidence suggests that rituximab can be used as first-line treatment in symptomatic CAD.

Plasmapheresis: Given the predominantly intravascular distribution of IgM, a logical conclusion would be that plasmapheresis or plasma exchange should provide rapid relief from hemolysis due to cold autoantibodies. Unfortunately, the results have been somewhat disappointing.[81,82] Simply removing the circulating antibody does not diminish ongoing endogenous antibody production, so improvements are transient at best. In patients with chronic CAD, plasmapheresis should probably be combined with immunosuppressive therapy in an attempt to decrease antibody production.[83] Successful use of plasmapheresis to temporarily decrease cold agglutinin titers in order to permit safe coronary artery bypass surgery has been reported.[84] Other reports of successful cardiac surgery involving warm cardioplegia have circumvented the need for cold exposure and thus the risk of hemolysis.[85,86] Cryofiltration apheresis has been used for acute exacerbations and for surgical procedures requiring hypothermia, such as coronary artery bypass surgery with cardioplegia. In one small study, two of five such patients who received cryofiltration apheresis had a favorable response with a reduction in titer.[87]

Blood Transfusion: Although most patients with CAD have mild anemia and do not need transfusion, RBC support may be required in patients who are clinically symptomatic or severely anemic.88 Patients with high-titer or wide-thermal–amplitude antibodies can pose extremely difficult serologic problems for the blood bank laboratory. Testing needs to be performed carefully at 37°C to minimize the effects of the cold agglutinin so that a search for alloantibodies may be properly performed.[31] This still does not eliminate interference from some particularly pesky autoantibodies. Time-consuming and technically challenging cold autoadsorptions may be necessary to rule out the presence of underlying alloantibodies. Occasionally, incompatible units may need to be issued because of residual agglutination from the cold autoantibody. Most cold agglutinins are directed at the *I* antigen, which is present on nearly all adult donor RBCs. Locating *i* adult RBCs (i.e., *I*-negative) is not practical because of their extreme rarity. Reports have documented *i* adult RBCs effectiveness and lack thereof.[89,90] If transfusion is necessary to treat significant cardiovascular compromise, RBC infusion through an in-line blood warmer at 37°C is recommended.[91] Uncontrolled heating of RBC products is quite dangerous because of the damaging effects of excessive heat and should be avoided. If blood warmers are not available, transfusion may still be accomplished by the slow infusion of room temperature RBCs into a large vein while keeping the patient warm.[31,44]

Steroids: Unlike their effectiveness in treating warm AIHA, steroids have little or no place as monotherapy in the treatment of CAD but are often a component in multidrug regimens. The few reports of a response have been suspect in their serologic evaluations or have required such high maintenance doses of prednisone that side effects of therapy were intolerable.[92]

Splenectomy: Given that most CAD-induced RBC destruction is hepatic, it should be no surprise that splenectomy has been quite ineffective in treating CAD and is therefore not advised. In the rare patient who has the unusual serologic characteristic of hemolysins reactive at 37°C as well as agglutinating activity at cooler temperatures, splenectomy may be of some benefit.[31]

Newer Agents: Because the hemolytic anemia of cold reactive antibodies is mediated by complement, the use of anti-C5 reagents (e.g., eculizumab) and other complement-modifying agents may be of benefit.[93]

Secondary Cold Agglutinin Disease

Hemolysis from infection-associated cold agglutinins lasts for 2 to 3 weeks, and therapy is typically not required. Given the transient nature of the antibody, even in the rare patient with significant hemolysis, supportive measures such as transfusion and plasmapheresis should suffice. Attempts to alter antibody production with immunosuppressives are generally not indicated. Patients with cold agglutinins and malignancies should have their treatment regimens directed at their underlying disease with the addition of supportive measures as the clinical situation dictates.

Paroxysmal Cold Hemoglobinuria

PCH was the first hemolytic anemia to be described because of its dramatic presentation of intermittent attacks of pain, fever, and hemoglobinuria following exposure to cold. In their classic 1904 paper, Donath and Landsteiner[41] described an antibody that produces the characteristic syndrome. The Donath-Landsteiner antibody is a hemolysin that binds to RBCs at low temperatures in the periphery and fixes complement. When the RBCs return to the warm central body core, they are destroyed by complement lysis. The D–L antibody occurs in three clinical syndromes: (*i*) chronic PCH associated with late-stage or congenital syphilis, (*ii*) acute transient PCH occurring after an infectious illness, and (*iii*) chronic idiopathic PCH. The first type was formerly the most common, but because there are now effective treatments for syphilis, it is now quite rare. Chronic idiopathic PCH has always been uncommon. The acute transient variety is believed to be one of the most common causes of acute hemolytic anemia of children.[94,95] See Table 29.6.

Antibody Characteristics

Immunochemistry and Origin

Typically, PCH antibodies are polyclonal IgG.[96] Originally described in patients with advanced or congenital syphilis, the antibody is not cross-reactive in syphilis serology tests in patients with syphilis or in those who manifest the acute transient variety of PCH.[97,98] PCH has been reported in family members, suggesting a genetic predisposition.[44] The origin or stimulus for antibody production is likely micro-organism antigen(s) that induce antibodies that cross-react with the *P* blood group system.[99]

P Antigen Specificity

The antibody in PCH is directed against the *P* antigen, which is a glycosphingolipid globoside found on the RBCs of most

individuals.[100,101] The *P* antigen is similar to the Forssman glycolipids present in many micro-organisms.[99] This similarity suggests that infectious agents may elicit D–L antibodies as a result of cross-reactivity.

Functional Characteristics

The D–L IgG antibody is a potent hemolysin, causing significant RBC destruction even in low titers. The D–L antibody is classically described as a "biphasic" hemolysin. This is based on the test for the antibody originally described by Donath and Landsteiner, whereby the patient's serum is incubated with RBCs at 0°C to 4°C and then warmed to 37°C to produce lysis. The antibody requires the cooler temperatures to bind to the RBC, but complement-mediated lysis does not proceed until the temperature is raised. For optimal lysis, complement C1 should be available when the antibody initially binds.[97,98] Upon warming, C4, C2, and the remainder of the complement cascade bind and disrupt the membrane, producing lysis. Some D–L antibodies have a wider thermal amplitude and bind to the RBC at temperatures compatible with complement activity. These seem to be "monophasic" hemolysins, in that cooling is not necessary to produce binding activity. Some believe that the distinction between biphasic and monophasic activity is unwarranted, representing only differences in thermal amplitude.[44] Also, other cold-active antibodies that vigorously fix complement may produce in vitro hemolysis biphasically but yet not have the distinguishing characteristics (IgG, anti-P specificity) that qualify them as true D–L antibodies.

Clinical Manifestations

Although uncommon, PCH may not be as rare as initial reports suggested. In series of all hemolytic anemias, the incidence has ranged from 1.7% to 10.0%.[31,61,102] PCH may account for more than 40% of immune hemolytic anemias in children <5 years of age.[103] The sudden onset of fever, back or leg pain, and hemoglobinuria after exposure to the cold are the hallmarks of PCH. Cold exposure may be only a few minutes, and symptoms may follow shortly or several hours later. Fever to 40°C is not unusual. Other symptoms may include pain or aching in the back, legs, or abdomen, cramps, headache, nausea, vomiting, and diarrhea. The first urine voided after the onset is dark red-to-black and typically clears in a few hours. Rarely, it persists for a few days. The spleen may be palpable during an attack and shortly thereafter, and mild jaundice may appear.[44] Vasomotor phenomena manifest as cold urticaria, tingling of hands and feet, cyanosis, and Raynaud phenomenon, and even gangrene has been reported.[104,105] Systemic symptoms may appear without the hemoglobinuria and vice versa.

There does not appear to be any racial or gender predilection in PCH. Children are almost exclusively affected by the acute transient syndrome.[31,44] An antecedent upper respiratory infection in children is usually identified, although the responsible organism may not be determined. Attacks have been associated with measles, measles vaccinations, mumps, *Mycoplasma pneumonia*, influenza A, adenovirus, varicella, cytomegalovirus, *Haemophilus influenzae*, and infectious mononucleosis.[106,107,108,109,110,111] Although episodes are typically self-limited and nonrecurring, they can be quite severe and even life-threatening without supportive care.

The original chronic PCH associated with syphilis has all but disappeared. The diagnosis of chronic PCH now should prompt an investigation for occult syphilis infection and, in its absence, should be considered the idiopathic variety.

Laboratory Features

Hematologic findings in PCH are typical for acute, severe intravascular hemolysis. Hemoglobin levels <5 g/dl can be seen.[103,106,107,111] The peripheral smears may show spherocytes, nucleated RBCs, polychromatophilia, anisocytosis, poikilocytosis,[31] and erythrophagocytosis by neutrophils.[107,108,110] The WBC count may be depressed very early in the attack, but is usually normal or high. Platelet counts are usually normal. Reticulocytopenia is quite common early in the episode, and reticulocytosis appears in the recovery phase.[44] Once haptoglobin is exhausted, hemoglobinuria results. The plasma is frequently tinged red, reflecting the free hemoglobin. As in other instances of hemolysis, the LDH and bilirubin (mostly unconjugated) are elevated. Complement levels are depressed.

Urine tests are positive for hemoglobin and methemoglobin, giving it its dark red-to-black appearance. Occasionally, RBCs are found in the sediment, but the discoloration is primarily pigment. Rarely does the patient have renal insufficiency with elevated blood urea nitrogen and creatinine.[112] Hemosiderinuria is found in patients with the chronic variety.

The Donath-Landsteiner test is a simple procedure involving incubating patient serum in melting ice with washed group O, *P*-positive RBCs, and fresh normal serum as a source of complement. Later, the tube is transferred to 37°C for a second incubation. Lysis visible to the naked eye after the warm incubation is a positive test.[29] Appropriate controls should be run simultaneously. Other serologic testing in the blood bank should reveal a positive DAT with anticomplement antisera. The anti-IgG DAT is rarely positive, because of dissociation of the antibody from the RBC at warmer temperatures. If the blood specimen is processed at cold temperatures, RBC surface-bound IgG can occasionally be demonstrated.[31] The D–L antibody may be demonstrated using the IAT. The method of using an ice-cold saline wash to avoid elution of the antibody and then testing with monospecific antisera for IgG is a sensitive indicator for antibody presence.[31] Differentiation between cold agglutinins and the D–L antibody can be made by careful characterization of the antibody involved, including specificity and immunoglobulin class. The classic age discrepancy and the rare occurrence of cold agglutinins in children may lend clinical support to the diagnosis.

Management

Treatment of acute attacks is essentially supportive. Given the transient nature of the syndrome, little else is indicated. In severely anemic children, steroids are usually given, although their benefit has not been documented.[103,108] Blood transfusion may be safely accomplished with standard banked blood even though essentially all donor units are *P*-antigen–positive. Delaying a needed transfusion to locate the rare unit of *pp* blood (i.e., *P*-negative) among 200,000 units[29] may put the patient in far more danger than transfusing readily available units. Warming both the patient and the blood is advisable. The hemoglobin rises the expected amount in most situations. In the rare patient in whom the hemoglobin does not rise, rare-donor files may be able to locate *pp* or Tj(a–) units. When this *pp* unit is available, transfusion results have been excellent.[113] As with other immune hemolytic anemias, critical situations may be ameliorated by plasmapheresis.[114] Chronic PCH is best treated by the avoidance of cold and rarely requires any other therapy. Patients who have documented syphilis should be appropriately treated, and most show response.[115]

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY MIXED COLD- AND WARM-ACTIVE ANTIBODIES

Some patients with warm AIHA also possess a cold agglutinin. Although the majority of these cold agglutinins are not clinically significant, they may occasionally demonstrate sufficient thermal amplitude (>30°C) or high titer (>1:1,000 at 0°C to 4°C) to

indicate CAD. Similar to the separate entities, mixed-type AIHA can be either idiopathic or secondary to lymphoproliferative disorders or systemic lupus erythematosis (SLE). Patients usually have a chronic course interrupted by severe exacerbations, which can result in a hemoglobin level <5 g/dl. These exacerbations do not appear to be associated with cold exposure, and they do not result in acrocyanosis or Raynaud phenomenon.[116]

The laboratory work-up demonstrates a DAT that is positive for both IgG and C3. As with the separate diseases, the mixed-type AIHA produces difficulties with the antibody screen and the cross-match. The RBC eluate typically indicates a panreactive warm IgG autoantibody. The cold autoantibody usually exhibits specificity against the *I* antigen, but reactivity against *i* has been reported.[116,117] Because of technical difficulties associated with performing the cross-match, due to the autoantibody interference, cross-match–incompatible units may have to be transfused in situations where patients are severely symptomatic or severely anemic.[88] Mixed-type AIHA appears to respond to treatment in a similar manner as warm AIHA. Patients generally respond to steroids, and immunosuppressive agents and splenectomy have been employed successfully as well. Associated diseases, if present, also need to be treated to optimize recovery.[116] See Table 29.6.

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY WARM-ACTIVE ANTIBODIES

Autoantibodies with greatest activity at 37°C are responsible for the majority of patients with AIHA. Excluding drug-induced autoantibodies, ~70% of all AIHA patients have the warm-antibody type.[31,61] In general, these autoantibodies are IgG, may or may not fix complement, and typically destroy RBCs by extravascular hemolysis in the spleen (exceptions do occur). They may be secondary to an underlying disease, or in some cases, no underlying process is ever identified, and are labeled *idiopathic*. Certain drugs may induce development of warm-active antibodies, even generating a true autoantibody in the absence of a distinct autoimmune disorder. See Table 29.6.

Primary versus Secondary Autoimmune Hemolytic Anemia

Warm autoantibodies are responsible for 48% to 70% of AIHA cases.[31,118] Primary or idiopathic warm AIHA accounts for less than half of the cases. It can occur in any age group, and females predominate (2:1) in most series.[61,96,119] There is no racial predilection, but a genetic predisposition is suggested by intrafamilial occurrences.[44] No blood group has been consistently shown to be selectively affected. HLA-A1, -B7, and -B8 recur in the literature as being overrepresented in this population, though not all series have reached this conclusion.[120–123] The incidence of AIHA has been reported to be in the range of 1:50,000 to 75,000,[92,118] rising with age, but most of the increase is in the secondary hemolytic anemias as opposed to idiopathic. The immune system abnormality that leads to the production of the pathologic antibody in either primary or secondary hemolytic anemia is still not completely understood.

With an aggressive search and long follow-up, most patients with warm autoantibodies are found to have an underlying associated condition. Lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL), Hodgkin lymphoma, non-Hodgkin lymphoma, and Waldenstrom macroglobulinemia are the leading causes of secondary cases.[124] Other secondary causes include autoimmune disorders (e.g., SLE, rheumatoid arthritis, scleroderma, and ulcerative colitis), nonlymphoid neoplasms (e.g., ovarian dermoid cysts, teratomas, and carcinomas), immunodeficiency disorders (e.g., AIDS, dysglobulinemia, and hypogammaglobulinemia), and childhood viral illnesses.[124] As a result of these secondary causes, the incidence of warm AIHA increases starting around 40 years of age. Children have a peak incidence in the first 4 years of life. See Table 29.8.

Hepatitis C virus
HIV/AIDS
Other
Diphtheria–pertussis–tetanus vaccinations
Pregnancy
Bone marrow transplantation
Congenital immune deficiency states
Hypogammaglobulinemia
Dysglobulinemia

Antibody Characteristics

Immunochemistry and Origin

Most antibodies are IgG with a preponderance of IgG_1 and, to a lesser extent, IgG_3.[125] The subtypes vary in their efficiency at causing hemolysis because of the higher affinities of the macrophage F_c receptors for the IgG_1 and IgG_3 subclasses.[126,127] Various combinations of IgG subclasses may occur together. Although it is uncommon for IgA or IgM to occur in concert with IgG, it is even less common for them to occur singly.[31,32] See Tables 29.4 and 29.6.

Blood Group Specificity

Warm autoantibodies are panagglutinins, reacting with all the RBCs in the diagnostic panel. Of the reported specificities, Rh is by far the most common (70%), including all but the Rh_{null} erythrocytes. Occasionally, the IAT identifies an antibody with relative Rh specificity for a particular Rh antigen such as *e*. It is extremely rare for antibodies of true specificity to occur in the absence of those of broader specificity. Thus, little is to be gained by transfusing antigen-negative blood to these patients. Other blood group specificities that have been reported include Wright (Wr^b), En^a, Duffy (Fy^b), Gerbich (Ge), Kidd (Jk^a), Kell (K), Lutheran (Lu), LW, M, N, S, Pr, A, B, I^T, Sc3, U, Vel, and Xg^a.[38,44]

Clinical Manifestations

Warm AIHA has a highly variable clinical presentation. Typically, patients insidiously develop anemic symptoms such as weakness, dizziness, fatigue, and dyspnea on exertion. Other, less specific symptoms include fever, bleeding, coughing, abdominal pain, and weight loss.[128] Cases with insidious onset generally follow a chronic waxing and waning course. In patients with fulminant hemolysis, the anemic symptoms can be accompanied by jaundice, pallor, edema, and dark urine (hemoglobinuria). Splenomegaly, hepatomegaly, and lymphadenopathy may accompany the anemia. This more acute, potentially life-threatening presentation is usually associated with viral infections, especially in children. Post-infectious acute-onset hemolysis tends to be short-lived.[44] In cases of secondary disease, the symptoms of AIHA may precede the recognition of the underlying illness by months to years, but ultimately the symptoms of the underlying disorder predominate. When presentation includes massive splenomegaly or lymphadenopathy, an underlying lymphoproliferative disorder should be considered. Symptoms can be precipitated by trauma, surgery, infection, pregnancy, and psychologic stress. See Table 29.9.

Pregnancy

The rate of autoantibody formation in pregnant women has been reported at 1:50,000, fivefold greater than in an age-comparable control population.[129] Hemolysis tends to increase during the pregnancy and may remit after delivery of the infant. Maternal hemoglobin levels <5 g/dl have been reported.[130] Infants born to mothers with hemolytic anemia may or may not suffer any hemolysis. Fetal and neonatal IgG are of maternal origin, and diminish post-partum naturally with clearance. Maternal antibody-producing lymphocytes do not typically cross the placenta. Even if difficulties are encountered initially, the infant should normalize in a matter of weeks, as there is no endogenous ongoing neonatal production of pathologic antibodies.[131,132]

Infancy and Childhood

AIHA in infancy and childhood can be quite different from that in adults. The disease onset is more likely to be sudden and severe, usually preceded by a viral prodrome. There is a slight male predominance, and the prognosis is relatively good for a complete and lasting remission within several weeks of the onset. Most children respond well to steroids, and rarely is splenectomy considered.[44] A particular association of childhood vaccines and hemolytic anemia has been documented.[133,134]

Evans Syndrome

Children can have very severe Evans syndrome, the concomitant occurrence of warm AIHA and immune thrombocytopenic purpura (ITP) described in 1949.[135,136,137] The thrombocytopenia may precede, coincide with, or follow the AIHA.[110] This is more common in children and is less likely to respond well to therapy.[138,139] Multiagent protocols have shown some success.[140,141] Recent use of rituximab also has demonstrated clinical utility (see management).

TABLE 29.9

WARM AUTOIMMUNE HEMOLYTIC ANEMIA: PRESENTING SIGNS AND SYMPTOMS

Sign	Frequency (%)	Symptom	Frequency (%)
Splenomegaly	82	Weakness	88
Hepatomegaly	45	Dizziness	50
Lymphadenopathy	34	Fever	37
Jaundice	21	Bleeding	10
Thyromegaly	10	Dyspnea	9
Edema	6	Cough	6
Cardiac failure	5	Weight loss	5
Pallor	4	Gastrointestinal disturbance	5
		Anorexia	4
		Dark urine	3
		Angina	2
		Confusion	2

Modified from Pirofsky B. Clinical aspects of autoimmune hemolytic anemia. Semin Hematol 1976;12:251–265.

Laboratory Features

Hemoglobin and hematocrit values at presentation can vary from essentially normal in the compensated hemolyzing patient to extremely low in the rare patient with fulminant RBC destruction. The MCV is usually elevated, reflecting the increased proportion of young RBCs and perhaps a relative folate deficiency in patients with chronic hemolysis. Reticulocyte counts are usually elevated as well, sometimes remarkably so, but may be depressed early in the course.[142] Reticulocytopenia may have myriad causes, including marrow shutdown from intervening infection, malignancy myelophthisis, parvovirus B19 infection, or the possibility of the autoimmune antibody being directed at antigens in great concentration on the reticulocytes themselves.[44,143,144,145] The bone marrow is usually hyperplastic even in the face of reticulocytopenia.[142] The peripheral smear typically reflects the reticulocytosis with polychromatophilia and macrocytosis, as well as nucleated RBCs. Spontaneous agglutination is uncommon with warm autoantibodies but may occur if the RBCs are strongly sensitized with immunoglobulin. Spherocytes are produced in varying quantity. Albeit unusual, the presence of erythrophagocytosis by monocytes, or rarely neutrophils, on the peripheral smear is an indication of AIHA.[146]

WBC counts are usually slightly elevated but may be depressed. Thrombocytopenia should raise the consideration of Evans syndrome.[142] Both leukopenia and thrombocytopenia may be immune-mediated, as shown in some cases by the presence of antileukocyte and antiplatelet antibodies.[147] Platelet dysfunction may occur as well.[148] Serum bilirubin is elevated but rarely >5 mg/dl in the absence of concomitant liver disease, with the major fraction unconjugated.[149] Hemoglobinemia and depressed or absent haptoglobin can be seen in rapid hemolysis, even if extravascular. Urobilinogens are increased, and hemoglobinuria and hemosiderinuria may follow severe hemolysis. Resultant renal failure has been reported.[150] Stercobilinogens may turn the stool dark. Biologic false-positive syphilis tests are common, and other abnormal antibodies have been reported, including antithyroid antibodies, rheumatoid factors, and anticardiolipin antibodies. Serum immunoglobulin abnormalities have been reported with both elevated or depressed levels, but with no consistent pattern.[151,152]

The hallmark of immune-mediated hemolytic anemia is the presence of immunoglobulin, complement, or both on the surface of the RBCs. In >95% of warm AIHA cases, the DAT is positive. Series vary in their DAT results. Between 20% and 66% have only IgG on the surface, 24% to 63% have IgG and C3, 7% to 14% have only C3, and 1% to 4% are DAT-negative.[31,118,153] Patients with SLE are particularly prone to positive tests for complement on their RBCs. IgG_1predominates, either alone or in combination with other subclasses, and IgG_4 is uncommon. In rare cases of warm hemolysins, IgM antibodies that fix complement and are associated with severe, life-threatening hemolysis have been reported.[154] It is even more uncommon for IgG antibodies to act as hemolysins.[155] The severity of hemolysis is loosely correlated with the quantity of antibody bound to the RBC and the strength of

the DAT.[156,157] However, other factors play a large role in the significance of the clinical picture, such as the immunoglobulin subclass, with IgG_3 being the most efficient at binding to F_c receptors.

Still other characteristics remain undefined to explain why immune hemolysis occurs in DAT-negative patients, and why some other patients with RBC-bound immunoglobulin have no increase in RBC turnover. If standard techniques do not demonstrate a positive DAT, other, more sensitive techniques may be successful. The antibody screen reveals the presence of the panagglutinin in the serum in 80% of cases. Specificity for other antigens can be sought as described earlier but is difficult to obtain accurately without a large selection of rare, antigen-negative RBCs and is of marginal clinical benefit.

Management

General principles of treatment are guided by the severity of hemolysis. Those patients with a positive DAT, mild reticulocytosis, and normal hematocrit are not routinely subjected to steroid therapy. Folate deficiency can be prevented with daily supplements, which probably should be given to any patient with hemolysis. When the RBC life span shortens beyond the point of marrow compensation and a consequent anemia appears, intervention is indicated. Given the high proportion of secondary hemolytic anemias, a search for an underlying disorder that requires specific therapy, such as a lymphoproliferative disorder, is indicated. See Table 29.8. Treatment of the secondary disorder may also bring the AIHA under control. However, in some situations, each disorder must be addressed separately. Many treatment options exist for these patients, who can have vast differences in the severity of their disease.[158,159,160]

First-Line Treatment

Steroids: Glucocorticoids are the initial therapy of choice for warm AIHA, usually on the order of 1.0 to 1.5 mg/kg or 40 mg/m^2/day of prednisone or its equivalent. Higher daily doses or high-dose pulsed therapy may be efficacious.[159,161] Response may not be evident for 3 to 4 days but should be noticeable by 7 days. Reticulocyte counts may increase, and the hemoglobin should rise 2 to 3 g/dl per week. Once the hemoglobin reaches 10 g/dl, weaning of the steroid can begin, at a rate to parallel the response. Rapid responders can reduce their dose by 50% over 4 to 6 weeks. Beyond this point, tapering should proceed more slowly over 3 to 4 months. Some even continue a low dose for prolonged periods thereafter to prevent relapse, although no data exist to support this practice fully. This schedule should be adjusted for the individual response to the treatment and for any significant side effects that result. Side effects include increased susceptibility to infection, hypertension, fluid retention, diabetes, myopathy, peptic ulceration, osteoporosis, and even reversible facial cosmetic changes, and may be intolerable. Alternate-day steroid therapy decreases some of the side effects and may still be effective. Consideration should be given to concomitant prophylactic antacids, bisphosphonates, vitamin D, and calcium according to the recommendation of the American College of Rheumatology. Careful monitoring of blood glucose and aggressive treatment of diabetes is recommended because diabetes is a major risk factor for treatment-related deaths from infections.[162]

The mechanism of action of steroids is multifactorial. Initially, steroids act through tissue macrophages delaying the reticuloendothelial clearance of IgG- and C3-coated RBCs.[163] Steroids may act by reducing antibody avidity,[164] and eventually may actually decrease antibody production.[165] Initial responses to steroids are generally excellent, with >80% of patients having a prompt reduction in hemolysis. In one series, only 7% took longer than 2 weeks, and even fewer more than 3 weeks. Therefore, if there has been no improvement after 3 weeks of therapy, the patient may be considered a steroid treatment failure. Recurrence of hemolysis after remission is usually gradual, especially if the steroids were weaned over a prolonged period.

Relapse of warm AIHA occurs in the vast majority of patients. Approximately 40% to 50% of patients require maintenance doses of prednisone (5 to 20 mg/day).[166] If the maintenance prednisone dose is >15 mg/day, other measures should be considered. Free autoantibody in the serum (positive IAT or antibody screen) may disappear, but the DAT remains positive in most patients, although perhaps weaker.[44] Complete and lasting remission rates from steroids alone are reported as occurring in only 16% to 35% of patients,[167,168] so the majority of patients with warm AIHA require additional therapy.

Second-Line Treatment

Second-line treatment is indicated in those surgical candidates who have not responded to prednisone, require prednisone doses >10 to 20 mg/day to maintain remission, or have suffered intolerable side effects.

Splenectomy: The rationale for splenectomy is twofold. The spleen is the major site of RBC sequestration and destruction in warm AIHA, resulting from the interaction of IgG antibodies with the macrophage F_c receptors. Splenectomy has little effect on the clearance of IgM-coated RBCs and therefore would not be indicated in the unusual patient with a warm-active IgM antibody. The spleen is also believed to be a major producer of IgG antibodies.[31,32] Overall responses are probably ~60% to 75%, but many of these patients relapse or remain on steroids, albeit at lower, more tolerable doses.[31,169,170] The likelihood of response to splenectomy may be higher in idiopathic AIHA than in secondary AIHA.[171] The complications of splenectomy are those inherent in major abdominal surgery and also include subdiaphragmatic abscess, pulmonary embolism, and increased susceptibility to infections, especially in children.[44,172] Pneumococcal, meningococcal, and *Haemophilus influenzae* vaccinations should be given, preferably administered preoperatively.[173] Subsequent to splenectomy, patients should be given antibiotics promptly with any febrile illness.

Rituximab: Rituximab may be used as a second-line treatment option in patients who refuse splenectomy or are at high surgical risk. Rituximab is a chimeric human/murine monoclonal anti-CD20 antibody approved for use in lymphoma. Successful rituximab use in refractory warm AIHA and Evans syndrome has been documented in several case reports and series.[174,175-177,178] Regimens identical to the lymphoma treatment (375 mg/m^2/week × 4 weeks) have produced remissions in some patients who were refractory to other therapeutic regimens. A response rate of 87% was reported for one series of refractory pediatric patients. Twenty-three percent of the responders relapsed, but subsequent courses of rituximab induced additional remissions.[178] Thus far, few side effects have been reported, but rare reactions to the infusion have been documented.[179] B-cell counts remain low for months after treatment, raising the risk of infections due to poor immune response.[180] The efficacy and toxicity of rituximab monotherapy was tested in additional retrospective studies in a mixed population of refractory primary or secondary AIHA. These studies have been summarized in a review by Lechner et al.[181] Overall response rate was 82%. Safety data available are limited and adverse events include two patients with severe infections and one patient with myocardial infarction.[182] The most severe potential long-term complication of rituximab treatment was progressive multifocal leukoencephalopathy (PML), which, however, has been observed in only two patients with AIHA.[181] If remissions remain durable and potential side effects are less harmful than other treatments for warm AIHA, such as prolonged steroid use or splenectomy, rituximab may become accepted second-line therapy.

Immunosuppressive Therapy

Immunosuppressive therapy is indicated for patients who have failed to respond to splenectomy and/or rituximab therapy.[181]

Cyclophosphamide is an effective immunosuppressive agent with capability to suppress the immune response, even if administered after antigen presentation.[183] This is particularly desirable for administration after the onset of immune hemolysis. Beneficial effects of cyclophosphamide therapy are reported in reviews.[166,168,169] Blood counts should be followed closely. Other significant side effects from the antimetabolites and cyclophosphamide include hemorrhagic cystitis, bladder fibrosis, secondary malignancies, sterility, and alopecia.[31,166,184,185] No properly controlled trial exists from which to draw conclusions, but the reviews and case reports suggest a response rate of approximately 40% to 60% in those patients who did not respond to steroids and splenectomy.[168,169,170] A reasonable immunosuppressive regimen might include azathioprine (80 mg/m^2/day) or cyclophosphamide (60 mg/m^2/day), concomitantly with prednisone (40 mg/m^2/day). Prednisone may be tapered over 3 months or so, and the cytotoxic agent continued for 6 months before reducing the dose gradually.[166] Bone marrow suppression may dictate minor dose adjustments. Rapid withdrawal has led to rebound immune response.[186] Alternatively, high-dose cyclophosphamide (50 mg/kg/day ×4 days) has produced a complete remission in 66% of patients who were refractory to other therapies. Severe myelotoxicity and its attendant potential for complications are expected.[173]

Mycophenolate mofetil, an inhibitor of inosine 5′-monophosphate dehydrogenase, is an immunosuppressant initially employed to treat allograft rejection. It has been shown to induce complete or partial remission of hemolysis in case reports. Doses begin at 1 g/day and are then increased to 2 g/day. In cases of partial remission, reduction in doses of other immunosuppressives was possible without sacrificing efficacy. Long-term side effects are not fully established. Short-term side effects consist primarily of gastrointestinal intolerance and mild myelosuppression.[176,177,187,188]

Cyclosporine A has been used both successfully and unsuccessfully in refractory hemolytic anemia patients, as were many of the other immunosuppressive medications previously described. Doses of 3 mg/kg/day with target serum levels of 200 to 400 ng/ml produced remissions.[178,189] It has also been used in combination with other remedies with some success, including danazol and prednisone.[141,179,180,190,191]

Transfusion

As with CAD, red cell transfusion support may be required in patients who are clinically symptomatic or severely anemic. Patients with WAIHA should be tested for the presence of coexisting alloantibodies, which may have developed following pregnancies or prior transfusions. Alloantibodies, rather than autoantibodies, may cause major transfusion reactions in such patients if not discovered. However, identifying an alloantibody in the presence of an autoantibody takes additional time. Thus, if the patient needs to be transfused emergently, transfusion should be given prior to the availability of the results. Most patients will tolerate even serologically incompatible blood. Blood bank personnel should be involved early in the decision to transfuse to minimize delays and possible confusion.[192]

Other Therapies

Intravenous immunoglobulin (IVIG) has not enjoyed the success in AIHA that it has in immune thrombocytopenia (ITP). Case reports of success[193–195] and failure[196,197] have appeared. Escalating the dose from the standard 0.4 to 1.0 g/kg/day (×5 days) may be helpful. In one refractory patient, weekly maintenance infusions of 800 mg/kg/week helped to control transfusion requirements.[198] The mechanism of action of IVIG is not completely clear. Recent evidence suggests that IVIG exerts inhibitory effects on dendritic cells by down-regulating costimulatory molecules, blocking maturation, and modifying their interactions with lipopolysaccharide and cytokines.[199] Other postulated mechanisms include modulating expression and function of F_c receptors, interfering with the activation of complement, modulating immune response through anti-idiotype antibodies, and effects on B- and T-cells.[200]

Plasmapheresis has been used with limited success in attempts to remove the antibody.[31,201,202] However, in some patients fulminant hemolysis proceeds unchecked and plasmapheresis may serve as a temporizing measure until other immunosuppressive therapies can take effect. Selective removal of IgG with staphylococcal protein A columns has also been reported with some benefit.[203]

Stem cell transplantation (SCT) has been described for many severe, life-threatening autoimmune syndromes, including hemolytic anemia and Evans syndrome. Sources of the stem cells have been autologous, HLA-matched sibling, and cord blood.[204,205] Relapses and the expected range of complications, including death, have occurred. For very severe and refractory cases of Evans syndrome, SCT offers the only chance of long-term cure. Available data suggest that allogeneic SCT may be superior to autologous SCT, but both carry risks of severe morbidity and of transplant-related mortality. As more refractory patients are seen, stem cell reconstitution after high-dose immune suppressive regimens will no doubt expand. Cure of Evans syndrome following reduced-intensity conditioning has been reported and should be considered for younger patients in the context of controlled clinical trials.[206]

Alemtuzumab is a humanized anti-CD52 monoclonal antibody that is an effective therapy for B-CLL, mycosis fungoides, and T-cell prolymphocytic leukemia. There have been recent case reports that suggest alemtuzumab may be useful for the treatment of AIHA in B-CLL patients who have failed other treatments.[207,208]

Complications

Hoffmann suggests that venous thromboembolism is an underrecognized complication of AIHA and may in some instances be related to co-existent antiphospholipid antibodies.[209] Although it is premature to recommend anticoagulant prophylaxis in general for patients with AIHA hemolytic episodes, consideration might be given to those at particularly high risk, such as those with evidence of co-existing antiphospholipid antibodies.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Drugs can produce hemolysis by both immune and nonimmune mechanisms. In the 1970s and 1980s, α-methyldopa and high-dose penicillin were responsible for the majority of cases of drug-induced immune hemolytic anemia (DI-IHA). In recent years there has been a significant decline in DI-IHA due to α-methyldopa and high-dose penicillin because of declining use of those medications. More recent estimates of the incidence of DI-IHA are approximately 1 per million.[210] Second- and third-generation cephalosporins, especially cefotetan and ceftriaxone, have been associated increasingly with cases of immune hemolytic anemia, accounting for ~80% of the DI-IHA.[211] Rarely, these cases of cephalosporin-induced immune hemolytic anemia are fatal. Other antibiotic agents associated with immune hemolytic anemia include β-lactamase inhibitors (clavulanate, sulbactam, and tazobactam) found in combination with β-lactam antibiotics in Timentin (ticarcillin/clavulanate), Unasyn (ampicillin/sulbactam), Zosyn (piperacillin/tazobactam), and piperacillin.[211] AIHA has been noted with increased incidence in patients receiving purine nucleoside analogs such as fludarabine, cladribine, and pentostatin for hematologic malignancies.[209] The mechanism by which these drugs cause AIHA is unclear. See Figure 29.4 and Tables 29.6 and 29.10.

TABLE 29.10

DRUGS ASSOCIATED WITH IMMUNE HEMOLYSIS OR AUTOANTIBODIES

Acetaminophen	Doxepin	Omeprazole
Aminopyrine	"Ecstasy"	Oxaliplatin
Amphotericin B	Elliptinium acetate	*p*-Aminosalicylic acid
Ampicillin	Erythromycin	Penicillin G
Antazoline	Etodolac	Phenacetin
Apazone (azapropazone)	Fenfluramine	Podophyllotoxin
Buthiazide (butazide)	Fenoprofen	Probenecid
Carbenicillin	Fludarabine	Procainamide
Carbimazole	Fluorescein	Propyphenazone
Carboplatin	5-Fluorouracil	Pyramidon
Catergen	Glafenine	Quinidine
Cefotaxime	Hydralazine	Quinine
Cefotetan	Hydrochlorothiazide	Ranitidine
Cefoxitin	Ibuprofen	Rifampin (rifampicin)
Ceftazidime	Insecticides	Sodium pentothal
Ceftriaxone	Insulin	Stibophen
Cephaloridine	Interferon-α	Streptomycin
Cephalothin	Intravenous contrast media	Sulfonamides
Chaparral	Isoniazid	Sulfonylurea derivative
Chlorambucil	Latamoxef	Sulindac
Chlorinated hydrocarbons	Levodopa	Suprofen
2-Chlorodeoxyadenosine	Mefenamic acid	Suramin
Chlorpromazine	Mefloquine	Teniposide
Chlorpropamide	Melphalan	Tetracycline
Cianidanol	6-Mercaptopurine	Thiazides
Ciproflaxin	Mephenytoin	Thiopental
Cisplatin	Methadone	Thioridazine
Cladribine	Methicillin	Tolbutamide
Cyclofenil	Methotrexate	Tolmetin
Diclofenac	Methyldopa	Triamterene
Diethylstilbestrol	Nafcillin	Trimellitic anhydride
Diglycoaldehyde	Nalidixic acid	Zomepirac
Dipyrone	Nomifensine	

Modified from Arndt PA, Garratty G. The changing spectrum of drug-induced hemolytic anemia. Semin Hematol 2005;42:137–144.

Mechanisms

Drug-induced antibodies can be divided into two main groupings based on the requirement for the drug in detection. Drug-dependent antibodies (penicillin type or immune complex type) require the presence of the drug in the test system, whereas drug-independent antibodies (autoantibodies) do not. See Table 29.11 and Figure 29.5.

Drug-dependent antibodies may be true autoantibodies with serology that is identical to warm AIHA. There are three major mechanisms by which drugs can cause immune hemolysis in vivo[212] (see Fig. 29.5):

1. The drug adsorption mechanism, in which the antibody reacts with a drug tightly bound to the RBC membrane
2. The neoantigen or immune complex mechanism, in which the drug combines loosely with the RBC membrane and the antibody reacts with new antigenic site(s) created by the combination of drug and membrane
3. The autoimmune mechanism, which is indistinguishable from true AIHA without drug exposure

Some medications may produce hemolysis by more than one mechanism, and differentiating among them is not always possible. Nonimmunologic adsorption of proteins to the RBC membrane can also cause a positive DAT, but is not associated with increased RBC destruction.

Drug Adsorption Mechanism (Penicillin Type)

Ina penicillin-type drug absorption mechanism, the drug binds tightly to the RBC membrane and the antibody attaches to the drug without direct interaction with the erythrocyte. Penicillin binds to the RBC membrane covalently and can be demonstrated on the RBC in most patients receiving high doses of the drug, even in the absence of antibody.[213] Attachment of only the drug does not harm the erythrocyte. However, when the drug is given in large doses (>10 million units/day), it can induce production of IgG antibody, which attaches to the membrane-bound drug, thus producing a positive DAT with AHG sera.[213] Eluates from these RBCs do not react with RBC panels, in stark contrast to the previously discussed true autoimmune antibodies, which display panagglutinin activity. The explanation lies in the fact that penicillin-induced antibodies are attached to the drug alone and not to membrane components of the erythrocyte. If reagent cell suspensions are first coated with penicillin, agglutination occurs with all RBCs, thus providing a diagnostic testing strategy when drug-induced hemolysis is suspected.[31]

The benzylpenicilloyl determinant is the primary antigen-binding site. High-titered IgG antibenzylpenicilloyl antibodies are responsible for the positive DAT and appear in ~3% of patients receiving high doses of the drug.[214] Only some of these patients develop hemolysis.[31] Rare exceptions of complement fixation to the RBCs exist in patients on penicillin. These have been associated with IgG attachment, and the DAT is positive with both anti-IgG and anti-C3 sera.[215,216]

RBC destruction in the drug adsorption mechanism of hemolysis is through sequestration by splenic macrophages of the IgG-coated RBCs.[217,218] Rarely, when associated with complement fixation, the RBCs may be lysed (intravascular hemolysis).[219] Anemia develops gradually over ~7 to 10 days and can be life-threatening if not recognized and the drug discontinued. Once the medication is stopped, the hemolysis resolves over the ensuing couple of weeks. However, the DAT may remain positive for several weeks. Of clinical importance is the observation that other signs of penicillin hypersensitivity, such as urticaria and airway reactivity, are usually absent.[31]

Other drugs can also cause hemolysis by this mechanism. Cephalosporins,[220–224] tetracycline,[225,226] tolbutamide,[227] and semisynthetic penicillins[228,229] can cause DI-IHA by this mechanism.

Neoantigen Mechanism (Quinidine/Stibophen Type)

The neoantigen mechanism is also known as the immune complex mechanism. The antibody is specific for a combination antigen, or neoantigen, created jointly by the drug and RBCs. Investigations with rare antigen-negative RBCs revealed that 2 antibodies have specific sites on the RBC membrane to which they attach along with the drug.[230,231]

The neoantigen mechanism differs from the drug adsorption mechanism in a few key areas. Unlike the penicillin model, these drugs bind very loosely to the RBC membrane. Only a small dose of the medication is required for hemolysis to occur, as opposed to the very large doses of penicillin required. Hemolysis is usually sudden, severe, and accompanied by hemoglobinuria[2] instead of the subacute anemia typically seen with the drug adsorption type. Renal failure is a frequent occurrence in the neoantigen mechanism.[232,233] The effector phase is mediated predominantly by complement

TABLE 29.11

MECHANISMS OF DRUG-INDUCED HEMOLYSIS OR POSITIVE DIRECT ANTIGLOBULIN TEST

	Drug Adsorption	Neoantigen	Autoimmune	Nonimmune Adsorption
Prototype drug	Penicillin	Quinidine/stibophen	α-Methyldopa	First-generation cephalosporins
Role of drug	Cell-bound hapten	Antibody binds drug + RBC	Induces drug-independent RBC antibody	Modifies RBC membrane; adsorbs proteins nonspecifically
Typical direct antiglobulin test	IgG	Complement	IgG	Non-Ig
Antibody reactions	Reacts only with drug-coated cells	Reacts only with drug present	Drug-independent panagglutinin	No antibody present
Typical clinical presentation	Subacute onset; mild to severe hemolysis	Acute onset; severe hemolysis	Insidious onset; chronic mild hemolysis	No hemolysis

fixation and subsequent intravascular hemolysis. Some sequestration of RBCs occurs in splenic macrophages or the liver via complement receptors. The DAT is positive only for the presence of complement, and IgM or IgG are rarely still attached to the RBC.[31] Therefore, eluates are nonreactive primarily because there is no immunoglobulin to elute. In vitro, serum reacts with RBCs only in the presence of the drug or a reactive metabolite.[31] These drugs may also induce thrombocytopenia by similar mechanisms.[234,235]

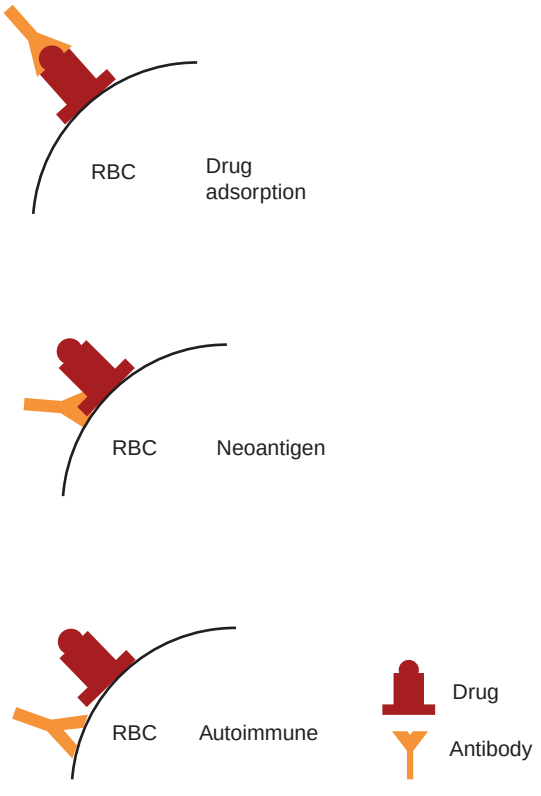

FIGURE 29.5. A proposed theory of drug-induced antibody reactions. A: The antibody attaches only to the drug, which is tightly bound to the red blood cell (RBC) membrane (penicillin type). **B:** The antibody attaches to a neoantigen created by components of both the drug and the RBC membrane (quinidine/stibophen type). **C:** The antibody attaches mainly to the membrane, not requiring the presence of the drug (α-methyldopa type). (Adapted from Habibi B. Drug induced red blood cell autoantibodies co-developed with drug specific antibodies causing haemolytic anaemias. Br J Haematol 1985;61:139–143.)

Autoimmune Mechanism (α-Methyldopa Type)

Unlike the previous two mechanisms, which require the presence of the offending drug for antibody reaction with the RBC membrane, hemolysis induced by α-methyldopa is truly autoimmune in nature. Antibodies bind to erythrocyte membrane antigens in a manner indistinguishable from the sporadic AIHA discussed earlier. With declining use of α-methyldopa, these antibodies are now seen in association with cladribine, fludarabine, levodopa, mefenamic acid, and procainamide.[211] The etiology of these antibodies is unknown, but the drugs likely directly stimulate the immune system to mimic an autoimmune disease. The DAT is positive with anti-IgG and is usually negative with anti-C3. The eluate shows a panreactive antibody. The characteristics of the IgG antibody eluted from the RBCs are strikingly similar to those in idiopathic warm AIHA. They are polyclonal[236] and bind as a panagglutinin to reagent cells even in the absence of the drug. As in warm AIHA, these antibodies have a predilection for Rh antigens, with some specific anti-c and anti-e documented.[236,237]

Despite a high incidence of immunoglobulin coating of RBCs, only a minority of patients actually develop clinical hemolysis.[2] Explanations of this phenomenon have been unsatisfactory. The amount of antibody on the RBC correlates poorly with in vivo hemolysis, and no threshold has been well established.[61,238]

Nonimmunologic Protein Adsorption Mechanism

Proteins other than immunoglobulins may attach nonspecifically to the RBC membrane and cause positive antiglobulin reactions. These do not cause increased RBC destruction and are of importance only because of the need to differentiate them from those of clinical significance. This is most commonly seen in patients on cephalosporins, which produce a positive DAT in ~3% of patients.[239,240] Other drugs that have been associated with this mechanism include cefotetan, cisplatin, diglycoaldehyde, oxaliplatin, suramin, and the β-lactamase inhibitors clavulanate, sulbactam, and tazobactam.[211] Many different RBC-bound proteins have been detected within a few days of instituting the medication, including fibrinogen, albumin, complement, immunoglobulins, and α_2-macroglobulin.[240] Clinical distinction between this benign finding and other, potentially significant ones involves the demonstration of a nonreactive eluate with cephalosporin-treated RBCs and the absence or low titer of antidrug antibodies in the serum.[31] In the absence of hemolysis, a positive DAT is not a cause for discontinuing the medication.

Multiple Mechanisms—Unifying Hypothesis

Many medications have been implicated in producing hemolysis by more than one mechanism, sometimes simultaneously in the

same patient. Arndt and Garratty have referred to a unifying hypothesis in their review.[211] The drug or its metabolites interact with the constituents of the RBC membrane, resulting in production of different populations of antibodies. Of these antibodies, some react with drug epitopes alone (drug adsorption). Other antibodies may react with drug and membrane components (neoantigen mechanism), and others with RBC membrane components (autoantibody mimickers). See Figure 29.6.

Clinical Manifestations

The clinical features of DI-IHA are similar to those found in idiopathic AIHA, including pallor, jaundice, and easy fatigability. Splenomegaly is not uncommon, but lymphadenopathy and hepatomegaly should not be attributed to drug-related hemolysis.[241] The severity of these symptoms depends on the rate of hemolysis, which is, in part, dependent on the mechanism involved. Those patients with the neoantigen mechanism are at the greatest risk for plummeting hemoglobins, hemoglobinuria, and renal failure.[2,232,242] Cefotetan has been implicated in many severe hemolytic reactions.[243–245] Fatal reactions are rare but may occur.[224,246] Cefotetan, ceftriaxone, and fludarabine have been associated with fatalities.[211,247] The drug adsorption and autoimmune varieties are typically characterized by insidious onset of hemolysis over days to weeks. A careful medication history is necessary to evaluate the possibility of a culprit drug in all patients with AIHA.

Laboratory Features

Just as with idiopathic AIHA, anemia with reticulocytosis and a positive DAT are hallmarks of the condition. Elevated indirect bilirubin and LDH are common findings. Rampant RBC destruction leads to hemoglobinemia, hemoglobinuria, and elevated creatinine levels. Distinguishing the mechanisms involved can be accomplished by the serologic results. One can differentiate the neoantigen mechanism from cold autoantibodies by the absence of high-titer cold agglutinins or D–L antibodies in the drug-induced cases. Drug-induced antibodies also do not react in the absence of the drug or a metabolite in IATs. Only a careful history and resolution of the hemolysis after discontinuation of the drug can separate the α-methyldopa variety from true autoimmune antibodies. Antibodies to cefotetan react to very high titers against drug-treated RBCs and at lower titers with untreated RBCs with or without drug present. Antibodies to ceftriaxone are the immune complex type.[211] The positive DAT may persist for a few weeks to months after stopping the medication responsible, especially with the autoimmune mechanism.[31]

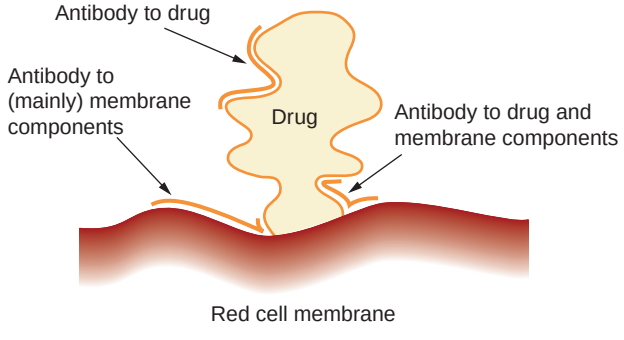

FIGURE 29.6. Proposed unifying hypothesis for drug-induced antibody reactions. The thicker darker lines represent antigen-binding sites on the F_{ab} region of the drug-induced antibody. Drugs (haptens) bind loosely (or firmly) to cell membranes, and antibodies can be made to (a) the drug (producing in vitro reactions typical of a drug adsorption [penicillin-type] reaction); (b) membrane components, or mainly membrane components (producing in vitro reactions typical of autoantibody); or (c) part-drug, part-membrane components (producing an in vitro reaction typical of the so-called immune complex mechanism). (From Garratty G. Target antigens for red-cell bound autoantibodies. In: Nance SJ, ed. Clinical and basic science aspects of immunohematology. Arlington, VA: American Association of Blood Banks, 1991:33–72.)

Management

A careful drug history, including over-the-counter medications, nutritional or dietary supplements, and illicit drugs, is imperative. Discontinuing the implicated medication is usually all that is necessary in management of drug-induced hemolytic anemia. Problems may arise when a positive DAT occurs and uncertainty exists as to whether significant RBC destruction is occurring. As previously described, many medications may be associated with a positive DAT test and yet not cause hemolysis. The drug need not be stopped in these patients.

In cases of brisk hemolysis associated with the neoantigen mechanism, stopping the offending agent can be life-saving. Although the helpfulness of prednisone therapy is questionable,[248] it has been used with some success in fludarabine-associated DI-IHA.[247] Transfusion can be accomplished, usually without difficulty in cross-matching, as the antibodies in the drug adsorption and neoantigen mechanisms are drug-dependent. However, patients with the autoimmune mechanism may encounter the same difficulties as previously discussed in the section on warm AIHA. It is important to keep in mind that transfused RBCs may be destroyed at the same rate as endogenous RBCs if drug or active metabolites are still circulating. Prognosis is typically excellent for these patients after discontinuation of the drug. With the variety of choices of pharmaceuticals available, alternative therapies are nearly always accessible to treat the underlying condition adequately.

TRANSPLANT-ASSOCIATED IMMUNE HEMOLYTIC ANEMIAS

Although it is not technically an autoimmune hemolytic process, the immune hemolysis associated with transplantation is analogous in many ways. In both cases, antibodies are generated against endogenous self-antigens; the key distinction lies in the source of the antibody-producing lymphocytes. That source can be either the lymphocytes and their precursors contained in a stem cell product being utilized for hematopoietic reconstitution, or they can be lymphocytes that are merely passengers contained in the vascular and perivascular regions of a solid organ being transplanted.[249] See Table 29.12.

Hematopoietic Stem Cell Transplants

Hematopoietic stem cell transplants can be ABO-compatible or ABO-mismatched. The mismatch can include major, minor, or both major and minor ABO incompatibilities.[250] ABO-compatible stem cell transplants have the same ABO type for the donor and recipient. A *major ABO mismatch* implies the introduction of a foreign ABO antigen, as would be seen with a group O recipient of a group A, B, or AB donor stem cell product. A *minor ABO mismatch* implies the introduction of a foreign ABO antibody(isohemagglutinin), as would be seen with a group A, B, or AB recipient of a group O donor stem cell product. Both major and minor incompatibilities would be seen with a group A recipient of a group B donor product or a group B recipient of a group A donor product. Appropriate selection of RBC- and plasma-containing blood products can help minimize the complications of passive antibody transfer.[250] The acute impact of a minor incompatible stem cell transplant is ameliorated with a simple washing of the donor product to prevent passive transfer of pre-existing antibodies. However, when there is a minor incompatibility, the novel hematopoietic stem cells will eventually produce lymphocytes that generate antibodies against the recipient's original remaining RBCs. This immune hemolysis

TABLE 29.12

TIMING OF POST-TRANSPLANT IMMUNE HEMOLYTIC ANEMIA

Immediate	Days-Weeks-Months
Hemolysis of original RBCs due to ABO antibodies in the donor stem cell product (minor ABO group mismatch)	Passenger lymphocyte syndrome
Passive transfer of ABO antibodies: infusion of plasma, platelets, IVIG, intravenous anti-D, and antilymphocyte globulin	Passive transfer of ABO antibodies: infusion of plasma, platelets, IVIG, intravenous anti-D, and antilymphocyte globulin
Hemolysis of donor RBCs contained in stem cell product by original pre-existing ABO antibodies (major ABO group mismatch)	Hemolysis of donor RBCs produced by the newly engrafted marrow caused by residual ABO antibodies (major ABO group mismatch)
	Alloantibodies produced by residual cells of the original immune system
	Alloantibodies produced by engrafted cells of the donor's immune system (weeks-months)
Autoimmune hemolytic anemia	Autoimmune hemolytic anemia

IVIG, Intravenous immunoglobulin; RBC, red blood cell.

may begin 7 to 10 days post-transplant and can be abrupt and severe. As the patient's original—but now incompatible—RBCs are destroyed, they are replaced by a combination of transfused cells and post-engraftment novel donor-type RBCs. Consequently, the immune-mediated RBC destruction is limited by the residual original-type RBCs remaining.

Solid Organ Transplants and the Passenger Lymphocyte Syndrome

The immune hemolysis associated with solid organ transplantation is typically due to a *passenger lymphocyte syndrome*. This situation can be seen with just about any solid organ being transplanted, as long as the donor and recipient share an RBC incompatibility. The classic example involves a group O organ transplanted into a group A recipient. Donor lymphocytes that are merely passengers in the transplanted organ react to recipient (endogenous) RBCs and generate antirecipient RBC antibodies. The consequent hemolytic anemia is more frequent with transplanted organs containing significant lymphoid mass. The incidence is lowest in kidney transplant recipients (9% to 17%), intermediate among liver transplant recipients (29% to 40%), and highest in heart–lung transplant recipients (70%).[250,251–253] Extensive perfusion of transplanted organs does not necessarily prevent this passenger lymphocyte syndrome, implying extravascular lymphocyte sequestration. Unlike the hemolysis associated with minor ABO-incompatible hematopoietic stem cell transplants, the target RBCs are not replaced by transfusion and a novel engrafted marrow. Consequently, the immune-mediated RBC destruction is limited only by the survival of the passenger lymphocytes.

CHAPTER 30

HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

Charles T. Quinn, Anne F. Eder, Catherine S. Manno

Hemolytic disease of the fetus and newborn (HDFN) results from the destruction of red blood cells by maternal immunoglobulin (Ig) G antibodies that gain access to the fetal circulation during pregnancy. These antibodies may be directed against Rhesus (Rh) or other blood group antigens on fetal red blood cells, inherited from the father and not present on the mother's red blood cells. HDFN associated with blood group antibodies has a broad spectrum of effects, ranging from mild anemia and hyperbilirubinemia in an infant to life-threatening complications before birth.[1] Clinical manifestations of severe hemolytic disease before birth include profound fetal anemia, hepatosplenomegaly, generalized edema, massive ascites, and congestive heart failure. The accelerated destruction of fetal red blood cells elicits extramedullary hematopoiesis and release of nucleated and other immature red blood cells into the peripheral circulation (erythroblastosis fetalis). Ongoing hemolysis of red blood cells after birth results in neonatal hyperbilirubinemia that may cause kernicterus and permanent neurologic injury or death.

HISTORICAL BACKGROUND

In the 20th century, HDFN was recognized as a distinct clinical entity, its pathogenesis was delineated, and an effective strategy for preventing its most common form was introduced. Case reports in the early 1900s (and before) described edematous (hydropic) stillborns and anemic infants with marked jaundice who died within days of birth. Not until 1932 were these phenomena realized to be the same hematologic disease process when Diamond et al. described the interrelationship of neonatal anemia, jaundice, and edema as symptoms that occur in varying degrees and combinations in erythroblastosis fetalis.[2]

The precise etiology of the disease remained obscure until seminal observations on blood group antigens and incompatibility in pregnancy were made in the 1940s. Landsteiner and Weiner first used immune sera raised in rabbits against red blood cells from Rhesus monkeys to agglutinate human red blood cells, thus discovering the Rhesus factor.[3] This antigen, now known as the D antigen of the Rhesus blood group in humans, is present exclusively on red blood cells of Rh-positive individuals. In the year before this discovery, Levine and Stetson recognized that a woman could become immunized against paternally inherited red blood cell determinants of the fetus during pregnancy.[4] Using Landsteiner's anti-Rh antisera to investigate cases of erythroblastosis fetalis, Levine et al. subsequently demonstrated that 90% of the mothers were Rh negative, and all the fathers and infants were Rh positive.[5] This statistical association as well as the presence of Rh agglutinins in the blood of mothers with affected infants supported their theory that alloimmunization and transplacental passage of these antibodies caused destruction of fetal red blood cells.[5] The inciting stimulus for red blood cell alloimmunization in pregnancy, the passage of fetal red blood cells into the maternal circulation or fetal–maternal hemorrhage (FMH), was directly demonstrated by Chown in 1954.[6]

Methods to monitor alloimmunized pregnancies and to treat affected fetuses and infants were first introduced in the late 1940s. Neonatal exchange transfusion enabled simultaneous correction of the anemia and reduction of bilirubin concentration in affected infants.[1,7] In 1961, Liley described the relationship between the concentration of bilirubin in amniotic fluid and the degree of destruction of fetal red blood cells, providing a tool to assess the severity of intrauterine hemolytic disease.[8] Two years later, Liley introduced the technique of intraperitoneal transfusion of anemic fetuses, which was used for more than 20 years before it was largely supplanted with intravascular transfusion techniques.[9]

Primary prevention of D alloimmunization became possible with the advent of anti-D immune prophylaxis. The ability of passively transferred antibodies to effectively block active immunization to foreign antigens was first demonstrated by Von Dungern in 1900.[1] Experimental studies in the 1960s applied this approach to D alloimmunization, revealing that Rh-negative men could be protected if administered anti-D immune globulin (RhIG) before transfusion with Rh-positive red blood cells.[10,11] Between 1963 and 1968, clinical trials involving Rh-negative pregnant women demonstrated that administration of RhIG within 72 hours of delivery was successful in reducing the incidence of D alloimmunization from 7% to 15% to 1% to 2%.[12,13,14,15,16,17] Meta-analysis of clinical trials of postpartum RhIG administration confirms a >90% reduction in the alloimmunization rate among treated women compared to untreated women (Table 30.1).[17] The recognition that FMH occurring primarily in the third trimester contributed to residual risk of alloimmunization during pregnancy led to the clinical observation that additional, antenatal RhIG prophylaxis could further reduce the risk of D alloimmunization to <1%.[18,19] Meta-analysis of two randomized controlled trials involving more than 4,500 women confirms the effectiveness of antenatal administration of RhIG at 28 weeks and 32 weeks of pregnancy (Table 30.1).[20,21,22]

By 1971, the administration of RhIG to D-negative women after delivery of a D-positive infant and after abortion was recommended by the World Health Organization and rapidly became widespread practice.[23] Recommendations for antenatal administration of RhIG were more controversial in some countries because of supply concerns and economic cost–benefit arguments, but were introduced in Canada and the United States in 1979 to 1980 and in the United Kingdom in 1998.[24,25,26,27] In the United States, the incidence of HDFN due to anti-D decreased from 40.5 to 10.6 cases per 10,000 total births between 1970 and 1986.[28,29] RhIG accounted for most of this improvement, but the trend toward smaller families and improved quality of perinatal care also contributed to the decline in the incidence of anti-D in pregnant women and related perinatal mortality, respectively.[30]

Despite all preventive efforts, HDFN due to anti-D continues to occur in about 6.7 of 1,000 live births in the United States.[31] Failure to prevent maternal D alloimmunization is usually due to inadvertent failure to administer RhIG, or, less commonly, to production of anti-D antibodies early in pregnancy before an antenatal dose of RhIG. No prophylactic measures are available to prevent sensitization to other blood group antigens in pregnancy, most notably Rhesus (c), Kell (K1), and Duffy (Fy^a), and the corresponding maternal alloantibodies can cause severe HDFN.[32,33]

PATHOPHYSIOLOGY

The risk of maternal alloimmunization to blood group antigens is related to the frequency of blood group alleles in the population, volume of incompatible red blood cell exposure, immunogenicity of the sensitizing red blood cell antigen, and maternal immune responsiveness. The propensity of maternal red blood cell antibodies to cause HDFN and the severity of the disease in individual cases are affected by the inherent characteristics of the red blood cell antibodies and the compensatory physiologic reaction to the anemia in the infant.

TABLE 30.1

META-ANALYSIS OF ANTI-D IMMUNE GLOBULIN (RHIG) CLINICAL TRIALS

	Treatment	Control	Odds Ratio, 95% Confidence Interval
Postpartum RhIG (Treatment) vs. No Treatment (Control)			
Immunization after 6 mo (5 RCTs)	10/4,756 (0.2%)	204/2,824 (7%)	0.08 (0.06, 0.11)
Immunization in a subsequent pregnancy (4 RCTs)	11/682 (1.6%)	57/389 (14.6%)	0.12 (0.70, 0.19)
Postpartum and Antenatal RhIG (Treatment) vs. Postpartum RhIG (Control)			
Immunization in pregnancy after birth of Rh-positive infant (2 RCTs)	5/1,112 (0.4%)	13/1,185 (1.1%)	0.44 (0.18, 1.12)
Immunization at 2–12 mo, primigravidae (1 RCT)	0/362 (0)	4/360 (0.7%)	0.13 (0.02, 0.96)

RCT, randomized controlled trial.

Fetal–Maternal Hemorrhage

Although the fetal circulation is separated from the maternal circulation by placental membranes and fetal capillaries, blood cells pass between the fetal and maternal bloodstreams throughout gestation. FMH occurs in 3% of pregnancies in the first trimester, 12% in the second trimester, 45% in the third trimester, and 64% to 100% after delivery.[34,35] The total volume of fetal cells in the maternal circulation is usually small and does not exceed 0.1 to 0.25 ml in most cases.[36] Large-volume FMH occurs less often, with more than 15 ml of fetal red blood cells (approximately 30 ml whole blood) detected at a rate of 1.6% after cesarean section or complicated vaginal delivery and 0.7% after spontaneous vaginal delivery.[37] Invasive procedures, clinical maneuvers, or other traumatic events during pregnancy may also elicit sufficient FMH to induce or augment the production of alloantibodies against red blood cells in susceptible pregnant women (Table 30.2).[38,39,40]

Maternal Alloimmunization to Blood Group Antigens

The likelihood of a relevant blood group incompatibility occurring in pregnancy depends on the frequency of blood group alleles in the population.[41] Among Caucasians and African Americans in the United States, approximately 15% and 8%, respectively, of women are D negative and lack a functional D gene on both chromosomes.[41] Incompatibility with respect to the D antigen occurs in approximately 10% of pregnancies; among D-negative women, approximately 60% to 70% of pregnancies yield D-positive infants. American Indians and Asians are almost all D positive; consequently, D alloimmunization is extremely rare among these populations.[41] Although virtually all pregnant women are exposed to fetal red blood cells with childbirth, alloimmunization to blood group antigens occurs in only a fraction of incompatible pregnancies. Approximately one in six multiparous D-negative women developed anti-D antibodies without RhIG prophylaxis in incompatible pregnancies. The risk of alloimmunization to the D antigen has been estimated for other obstetric interventions (Table 30.2).[38,39,40]

A primary determinant of the risk of red blood cell alloimmunization is the volume of incompatible red blood cell exposure. Less than 1 ml of D-positive, fetal red blood cells is sufficient to induce anti-D antibody formation in 0.3% to 1.9% of D-negative women before delivery, whereas transfusion of a unit of D-positive red blood cells (300 ml) immunizes approximately 70% of D-negative individuals.[16,41] Host factors also influence the risk of red blood cell alloimmunization. Concomitant ABO and D incompatibility between the mother and fetus (e.g., a type O, D-negative mother with a type A, B, or AB, D-positive fetus) results in an almost ninefold reduction in the risk of alloimmunization to the D antigen in a first pregnancy.[18,42] ABO incompatibility does not prevent a secondary immune response in a sensitized individual in subsequent pregnancies. The D antigen is one of the most potent immunogens among red blood cell antigens, but even after incompatible blood transfusion or multiple D-positive pregnancies, approximately 30% of D-negative individuals do not produce anti-D antibodies and are called "nonresponders."[41] Complex genetic factors regulate immune responses, and the basis of this variability to red blood cell immunization among individuals is not well understood.

The overall frequency of alloimmunization to clinically significant blood group antigens among women ranges from 0.04% to 0.3%.[43–47] The variability in these rates may be due to geographic differences in blood group antigen expression, national blood transfusion practice, and higher-order birth and abortion rates in the population,

as well as the sensitivity of laboratory methods used in prenatal antibody screening.[43–48] Anti-D is still among the most frequently detected antibodies in sensitized pregnancies despite a precipitous decline in its incidence after the introduction of RhIG prophylaxis (Table 30.3).[43,44] In recent decades, other red blood cell alloantibodies have accounted for proportionately more cases of maternal alloimmunization and HDFN. The K1 antigen surpassed the D antigen as the leading cause of alloimmunization among women in a recent series, occurring at a rate of 3.2 in 1,000 compared to 2.7 in 1,000 for anti-D.[43] Women who develop anti-K1 antibodies in pregnancy often have a history of blood transfusion as the immunizing stimulus.[48] In another series of 1,133 Dutch women with positive antibody screens, anti-E was the most common antibody detected (23%) followed by anti-K (18.8%), anti-D (18.7%), and anti-c (10.4%).[47]

ABO Blood Group Isoagglutinins

ABO incompatibility occurs statistically in one of every five pregnancies. ABO isoagglutinins are present in the sera of all individuals whose red blood cells lack the corresponding antigen and are usually of the IgM class. High titers of IgG antibodies are more likely to occur in group O individuals than in group A or B individuals, and increased antibody production after antigenic stimulation can occur.[41] Consequently, group O mothers with potent IgG anti-A, -B, or -A,B are at greatest risk of having affected infants. Among group A or B infants born to group O mothers, 30% to 50% have detectable maternal IgG antibody bound to their red blood cells compared to 5% among all infants.[49] Because ABO IgG antibodies can occur without prior red blood cell exposure, they can result in hemolytic disease of the newborn (HDN) in a first pregnancy. However, ABO antigens are not fully developed on red blood cells at birth, and similar carbohydrate antigens occur on other tissues that effectively neutralize anti-A, anti-B, and anti-A,B antibodies to a large extent, thereby mitigating their effect. At birth, neonatal anemia due to ABO HDN is usually mild. Antibodies directed against other carbohydrate blood group antigens (Lewis, I, P) are naturally occurring IgM antibodies that are inconsequential in pregnancy because IgM is not transported across the placenta.

Fetal and Neonatal Immune-mediated Anemia

In contrast to naturally occurring antibodies against carbohydrate blood group antigens, antibodies against Rhesus, Kell, and other

TABLE 30.3

RED BLOOD CELL ALLOANTIBODIES: OCCURRENCE IN WOMEN AND ASSOCIATION WITH HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN (HDFN)

protein blood group antigens only rarely occur without exposure to incompatible red blood cells.[41] IgM may be detected in the primary immune response after the initial stimulus, but IgG may be the only immunoglobulin found and is typically present 5 to 15 weeks after FMH. Because FMH usually occurs late in the third trimester or at delivery, IgG antibodies against red blood cell alloantigens usually do not reach appreciable concentration to cause significant disease in a first pregnancy. Upon re-exposure to the red blood cell antigen, however, an anamnestic immune response rapidly produces IgG with enhanced avidity for target fetal red blood cells, translating to earlier onset and greater severity of hemolytic disease in subsequent incompatible pregnancies.

Maternal IgG red blood cell antibodies bind to their target red blood cells and cause Fc-receptor–mediated extravascular destruction by splenic macrophages and other cytotoxic effector cells in the reticuloendothelial system. Progressive removal of portions of the red blood cell membrane by macrophages and other phagocytic cells in the spleen can produce spherocytes in the peripheral circulation. Anti-D is usually high-affinity IgG1 and IgG3, which are the typical IgG subclass responses to protein antigens, and involve T-helper (Th) cells for their production.[50] The immunoglobulin subclasses IgG1 and IgG3 have greater affinity for Fc receptors on phagocytic cells than IgG2 and IgG4, which may account for their association with more severe hemolytic disease.[41,50] The concomitant presence of maternal antihuman-leukocyte antigen (HLA) and anti-D is associated with a mild course of HDFN, possibly due to the competitive binding of the HLA antibodies to Fc receptors on cytotoxic effector cells.[51]

Extravascular destruction of red blood cells often cannot account completely for the degree of fetal anemia due to anti-K1, unlike most cases of HDF due to anti-D and other red blood cell alloantibodies. Severe fetal anemia may occur with anti-K1 despite low maternal antibody titers and falsely reassuring concentrations of bilirubin in amniotic fluid.[48,52] In Kell-sensitized pregnancies, affected fetuses often have fewer reticulocytes and normoblasts in their peripheral circulation than infants with comparable anemia caused by anti-D, which suggests impaired production of red blood cells.[53,54] Anti-K1 was shown to inhibit specifically the growth of K1-positive erythroid progenitor cells in vitro, whereas anti-D exhibited no effect with D-positive precursors in the same assay.[55] These observations support the dual action of maternal anti-Kell in eliciting both peripheral red blood cell destruction and erythropoietic suppression to produce fetal anemia.

Most cases of severe fetal anemia are caused by anti-D, anti-c, and anti-K1; rarely, anti-Fy^a or other IgG red blood cell alloantibodies are associated with severe HDFN (Table 30.3). Compensatory hematopoiesis in the bone marrow and extramedullary hematopoiesis primarily in the liver and spleen result in the release of nucleated red blood cells, reticulocytes, normoblasts, and other immature erythrocytes in the fetal circulation. Severely affected fetuses have marked hepatosplenomegaly due to the extramedullary hematopoiesis, which can lead to portal and umbilical venous obstruction, portal hypertension, and hepatocellular damage.[1] Production of albumin and other plasma proteins by the liver is markedly impaired, and hypoproteinemia results. Severe anemia and hepatic dysfunction with hypoproteinemia and portal hypertension may also lead to the development of congestive heart failure. Hydrops fetalis describes the ultimate outcome of these physiologic insults, with the development of generalized edema (anasarca), marked ascites, and pleural and pericardial effusions. Although the pathogenesis of hydrops fetalis is not clearly defined, the extent of hepatic damage rather than the degree of anemia more consistently correlates with the severity of the condition.[1]

Neonatal Immune-mediated Hyperbilirubinemia

Immune-mediated destruction of fetal red blood cells results in increased serum concentration of free heme, which is further metabolized to unconjugated (indirect) bilirubin. During gestation, unconjugated bilirubin and other metabolites are transported across the placenta and eliminated by the mother. When the umbilical cord is severed at birth, unconjugated bilirubin begins to accumulate because infants have immature liver function and are not capable of efficiently metabolizing bilirubin.

Unconjugated bilirubin is transported in the plasma bound to albumin, but when its concentration exceeds the plasma-binding capacity or when it is displaced from carrier proteins, the lipophilic free molecule can cross cell membranes and impair mitochondrial function to cause cell death. Preterm infants are at greater risk for developing bilirubin encephalopathy than are term infants because of the immaturity of their blood–brain barrier as well as their more pronounced hepatic deficiency. Bilirubin toxicity is potentiated by factors that displace bound bilirubin or otherwise increase circulating levels of unbound bilirubin, such as decreased albumin concentration, free heme molecules, acidosis, increased levels of free fatty acids, or drugs such as sulfonamides and sodium benzoate.[1] Infants with severe unconjugated hyperbilirubinemia may develop nerve deafness or the spectrum of kernicterus, leading to severe brain damage, mental retardation, spastic choreoathetosis, or, in many cases, death.

CLINICAL FEATURES

The clinical spectrum of HDFN ranges from the ominous intrauterine development of hydrops fetalis to varying degrees of neonatal hyperbilirubinemia and anemia. Approximately one half of infants with detectable maternal anti-D are unaffected or only mildly affected, whereas 30% have moderate disease in the neonatal period, and approximately 20% are severely affected in utero (Table 30.4).[1,56] The onset of intrauterine disease occurs before 34 weeks' gestation in approximately one half of the cohort of severely affected fetuses, or approximately 9% of affected pregnancies, overall.[56] Similar trends are observed when anti-c, anti-Kl, and anti-Fy^a are detected in pregnancy, in that many fetuses are unaffected, and most of the rest have only mild or moderate disease, but a small number have hydrops fetalis or severe anemia necessitating intrauterine transfusion (Table 30.4).[31,32,33,48,56,57] Maternal IgG antibodies with other specificities have been implicated in cases of severe fetal anemia or life-threatening HDN in rare cases.[31,32,33,57–59]

Severely affected newborn infants have cord blood hemoglobin concentrations <12 g/dl and cord bilirubin concentrations >5 mg/dl. If intrauterine transfusions have been given, the course of hemolytic disease in the neonatal period may be relatively mild and the blood type at birth may reflect the ABO and D-negative type of the transfused red blood cells. Infants transfused before birth are at risk for developing late anemia at several weeks of age because intrauterine transfusion may suppress erythropoiesis and persistent circulating maternal alloantibody may cause ongoing hemolysis for 4 to 8 weeks. Infants with moderate disease have 12 to 14 g/dl hemoglobin in cord blood and 7 to 12 g/dl hemoglobin in the first days of life. The bilirubin level in cord blood rarely exceeds 5 mg/dl due to maternal clearance. After birth, however, jaundice may occur within the first 24 to 36 hours of life, earlier than the "physiologic jaundice" otherwise associated with immature liver function, and the bilirubin concentration peaks between 3 and 5 days of life. Mild HDN is characterized by cord blood hemoglobin of 14 g/dl or greater and only slightly increased bilirubin (<4 mg/dl).

The most common cause of HDN is maternal ABO antibodies, although only a minority of infants with detectable maternal ABO antibodies have clinical signs of hemolysis. Exceedingly rare cases of fetal anemia due to ABO antibodies have been reported, but nonimmune hydrops superimposed on ABO incompatibility could not be excluded.[1] Nonimmune hydrops fetalis may be caused by

intrauterine infection, cardiac disease, or chromosomal disorders (Table 30.5). Because the neonatal anemia is usually mild, the compensatory hematopoietic activity in ABO HDN is not as pronounced as in HDN due to anti-D or anti-K1. Consequently, nucleated red blood cells and erythropoietic progenitors may be evident, but spherocytes predominate in the peripheral blood smear of infants with ABO HDN (Fig. 30.1). The failure to recognize hemolysis due to ABO blood group incompatibility or other risk factors for hyperbilirubinemia resulted in 90 cases of kernicterus in a 17-year period.[60] This contemporary tragedy underscores the ongoing importance of monitoring progressive jaundice in all infants.

TABLE 30.5

DIFFERENTIAL DIAGNOSIS OF HYDROPS FETALIS AND NEONATAL HYPERBILIRUBINEMIA

Hydrops fetalis (fetal edema, anemia)
- Hemolytic disease of the fetus due to maternal anti-D, -c, -K1, -Fy^a, or other blood group antibodies
- Homozygous α-thalassemia
- Twin-to-twin or fetomaternal transfusion
- High-output cardiac failure
- Congenital infection (e.g., parvovirus, cytomegalovirus, toxoplasmosis, syphilis)
- Genetic disorders (e.g., Turner syndrome, 45, X)
- Idiopathic

Neonatal hyperbilirubinemia (nonphysiologic)
- *Unconjugated (indirect) hyperbilirubinemia*
  - Hemolysis
  - Hemolytic disease of the newborn due to maternal ABO isohemagglutinins, anti-D, or other blood group antibodies
  - Hereditary spherocytosis
  - Glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency
  - α-Thalassemia
  - Extravascular blood loss/accumulation (e.g., cephalohematoma)
  - Genetic disorders (e.g., Crigler-Najjar syndrome, Gilbert syndrome)
  - Endocrine disease (e.g., hypothyroidism)
- *Conjugated (direct) hyperbilirubinemia*
  - Infection, sepsis
  - Metabolic disorders (e.g., Dubin-Johnson syndrome, cystic fibrosis)
  - Hepatic disease and anatomic abnormalities (e.g., biliary atresia)
  - Cholestasis from total parenteral nutrition or antibiotics (e.g., ceftriaxone)

LABORATORY EVALUATION

All pregnant women should have their ABO/Rh type and antibody screen determined at the first visit to the obstetrician.[61] These initial tests identify women as candidates for RhIG administration or for additional monitoring during pregnancy. After detection of clinically significant red blood cell alloantibodies, further testing may be required for evaluation of FMH, antenatal assessment of fetal anemia, and detection of neonatal anemia and hyperbilirubinemia. The principles of these laboratory tests and controversies surrounding their use are described below; specific practice recommendations for prevention and treatment of HDFN are described in the subsequent sections entitled "Prevention of Maternal D Alloimmunization with Rh Immune Globulin,"

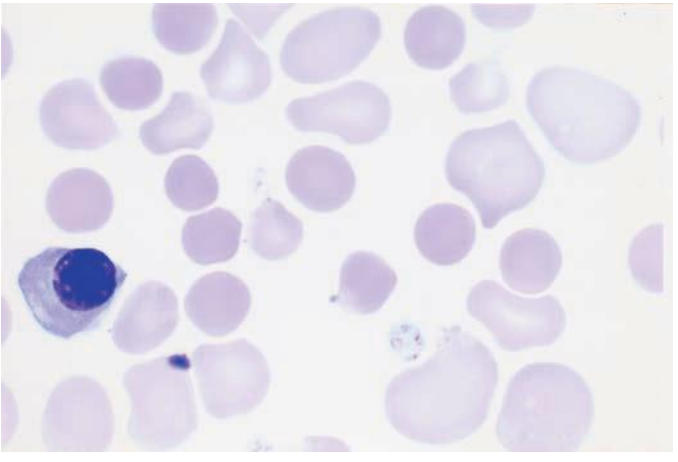

FIGURE 30.1. ABO hemolytic disease of the newborn (HDN). Peripheral blood from an infant with ABO HDN, with numerous spherocytes, occasional nucleated red blood cells, anisocytosis, and polychromasia (Wright-Giemsa stain). (©2002 American Society for Clinical Pathology. Used with permission.)

"Management of Red Blood Cell Alloimmunization in Pregnancy," and "Treatment of the Newborn Infant."

Maternal ABO/Rh Type and Antibody Screen

The red blood cell ABO/Rh type is assigned in the forward group reaction by incubating the patient's red blood cells with specific IgM or IgG antibodies that cause their immediate and visible agglutination if they express the corresponding A, B, or D antigens. The ABO reverse group identifies plasma reactivity due to ABO isoagglutinins and should confirm the forward, red blood cell typing reactions. The forward reaction for the D antigen may include an additional phase with antihuman globulin to enhance red blood cell agglutination and detect weak expression of the D antigen on the red blood cells.

Formerly known as Du, weak D phenotypes are due to quantitative or qualitative alterations in D antigen expression. The need to test D-negative pregnant women for weak expression of D has been controversial. Weak D occurs in as much as 1% to 3% of the general population, but the majority (90%) of weak D individuals (types 1, 2, 3) possess a normal D antigen, only produced in lower quantities on the red blood cell surface, and cannot be immunized to make anti-D.[24,62,63] The remaining 10% of weak D individuals express aberrant D proteins, and are recognized as partial D phenotypes, many of whom will develop anti-D after exposure to D-positive red blood cells.[63,64] Most D-positive individuals with anti-D belong to partial D category D^{VI}, which occurs in 0.02% to 0.05% of Caucasians.[63] The AABB (American Association of Blood Banks) considers testing pregnant women for weak D to be optional, and the American College of Obstetricians and Gynecologists (ACOG) recommends against administration of RhIG to weak-D–positive women.[38,61]

Although severe HDF in women with weak D is rare, women with known partial D phenotypes (e.g., D^{VI}) are at risk of D alloimmunization, and fatal HDF has occurred as a result.[65,66] If pregnant women are tested for weak D, consideration should be given to using a method that accurately distinguishes between those individuals with D variants who are not at risk of anti-D alloimmunization from those who are at risk and may benefit from RhIG prophylaxis.[63,64] The alternative is not to test pregnant women (or transfusion recipients) for weak D, which would result in these individuals being classified as D-negative and candidates for RhIG prophylaxis. This presents a challenge to countries that do not have a sufficient supply of RhIG, and not surprisingly, in a recent survey, international practices on testing for weak D and RhIG administration diverge from practice in the United States.[40] Eight of ten countries reported that they perform further testing for weak D or D variants if the woman types as D negative or if the typing results are anomalous, to limit administration of RhIG to women with partial D at risk of developing anti-D.[40] The relative effectiveness of RhIG in preventing the sensitization of partial D women compared to D-negative women is not yet known.

The antibody screen detects maternal antibody in plasma by hemagglutination in an indirect antiglobulin test, formerly called the indirect Coombs' test. The reaction conditions should allow detection of clinically significant IgG alloantibodies that are reactive at 37°C in the antiglobulin phase. Conditions that permit identification of IgM antibodies are not required in the setting of obstetric testing, because IgM antibodies cannot cross the placenta. If IgM antibodies cause interference in the antibody screen, reducing agents such as dithiothreitol can be used to eliminate their reactivity in the assay and allow for specific detection of IgG antibodies. If the initial antibody screen is negative, the need to repeat testing at 28 weeks' gestation is currently debatable. Arguments for eliminating this testing include the extremely low probability that anti-D or other antibodies are formed during pregnancy.[46,67]

Serologic and Molecular Testing for Paternal/Fetal Blood Group Antigens

If a potentially significant red blood cell alloantibody is detected in a pregnant woman, the blood type of the biologic father may be investigated to assess the risk of HDFN. Three possibilities exist: the father lacks the antigen, and the fetus is not at risk; the father is heterozygous for the antigen, and the fetus may be at risk; or the father is homozygous for the antigen, and the fetus is definitely at risk. Because no antithetic allele for RhD exists, paternal zygosity cannot be definitively determined by serologic testing for the D antigen but RH D inheritance is closely linked to Rh antigens C/c and E/e. The probability that the father is heterozygous for D can be deduced by serologic determination of the extended Rhesus phenotype (D, Cc, Ee) and most probable combination of haplotypes given the gene frequencies in different ethnic populations and the Rh type of previous children.[68] Another indirect approach to determine paternal zygosity involves parallel quantitative amplification of *RHD*- and *RHCE*-specific sequence.[69] The development of direct, D-allele–specific molecular assays is complicated by the genetic diversity of the D locus and the variety of insertions, deletions, and missense and nonsense mutations in the RHD gene that can produce the D-negative phenotype. Recently, a molecular test specifically to detect the most prevalent D-negative allele in white populations, the complete *RHD* deletion, was developed.[70] This approach may be amenable to routine use in most laboratories, but its clinical application will be limited until modification allows for detection of other common D-negative alleles in ethnically and racially heterogeneous donor populations. Determining the paternal genotype of other blood group determinants is more straightforward with the currently available allele-specific assays for other Rh (C/c, E/e), Kell (K1/K2), Duffy (Fy^a/Fy^b), Kidd (Jk^a/Jk^b), and other red blood cell loci.[47,69]

If paternal testing indicates that the father may carry a clinically significant red blood cell antigen, fetal testing should be performed to determine if the allele is present. Considerable genetic diversity underlies aberrant RH alleles associated with the Rh-negative phenotype, which has important implications for fetal testing.[47,69] The most prevalent D-negative genotype in Caucasian populations is the complete deletion of *RHD;* in African blacks and African Americans, other variant RHD genes are more likely to be found.[32] The RHD pseudogene, which contains all ten exons but a stop codon between exons 3 and 4 that blocks transcription of the gene, is found in 69% of South African blacks and 24% of African Americans.[32] Similarly, the variant RHD gene r's (Cde^s) underlies serologic RhD negativity in 22% of African Americans. The presence of one of these genes in the fetus can lead to a false-positive result (i.e., the fetus types as RHD-positive by molecular methods but is found to be D negative by serology after birth) and unnecessary prenatal intervention. A maternal blood sample should be analyzed in parallel with the fetal sample. False-negative results (i.e., the fetus types as RHD negative, but is found to be D positive by serology at birth) have been attributed to erroneous paternity or rearrangement at the paternal RHD gene locus. If no paternal sample is available, an RHD-negative fetal blood type determined by molecular methods should be interpreted with caution, and the pregnancy should be monitored to ensure that maternal anti-D titers do not increase.[32]

The most common method to obtain fetal DNA for molecular testing is still amniocentesis in the United States, because noninvasive alternatives are not yet routinely available.[32,71,72] Amniocentesis is performed at 24 weeks' gestation and is relatively safe, but is associated with a pregnancy loss rate of about 0.3%.[73] This risk is avoided with noninvasive methods to obtain fetal cells or fetal cell-free DNA from the maternal circulation, and maternal blood has been used routinely for RHD fetal typing in Europe.[47,71,72] Fetal DNA can be isolated from maternal plasma as early as 32 days' gestation, and constitutes 3% to 6%

of the plasma DNA pool in the second and third trimesters.[47] Cell-free fetal DNA is rapidly cleared, and does not persist into subsequent pregnancies in contrast to the potential for long-term persistence of fetal leukocytes that can complicate analysis of cell-associated fetal DNA.[74] Several groups have demonstrated 96% to 100% accuracy in predicting the RHD phenotype with over 200 pregnancies tested.[40,47] False positives were due to the presence of a pseudogene or D variant, and false negatives from the failure to isolate sufficient fetal DNA. When negative results are obtained (e.g., no RHD-specific signal is detected), the presence of fetal DNA in the plasma should be confirmed by another fetus-specific DNA sequence from a highly polymorphic paternal antigen or from the Y chromosome for male fetuses (e.g., *SRY*). There are no reported strategies for Kell typing or Rh typing other than *RHD* using a sample of maternal blood, which likely reflects the difficulty of developing a sensitive assay for subtle allelic differences that will still be specific in the presence of an excess of maternal DNA.[40,47]

Maternal Red Blood Cell Alloantibody Titers

If molecular testing suggests the fetus is at risk for HDFN, or if molecular testing cannot be performed, determination of the maternal red blood cell alloantibody concentration may be used as a screening test to guide further clinical management.[75] The concept of a "critical titer" of maternal antibody has been criticized based on the poor predictive accuracy for severe HDN.[76,77] However, critical titers are used not to predict the development of severe hemolytic disease after birth, but rather to predict its absence during gestation, because titers below "critical" thresholds are unlikely to require aggressive intervention in utero. In a classic study almost 50 years ago, Allen et al. followed 174 pregnancies with no history of affected fetuses or infants and with antibody titers of 32 or lower and reported 174 (96%) had live infants at 37 weeks' gestation.[78] The observation that significant intrauterine disease is unlikely to occur when the antiglobulin titer remains low has been substantiated in recent studies and maternal antibody titers are a useful screening tool in a woman's first alloimmunized pregnancy.[75]

Antibody titers are determined with the indirect antiglobulin test by making several dilutions of maternal serum in saline, adding reagent red blood cells and anti-IgG, and observing for macroscopic agglutination in the tubes. The titer is reported as the reciprocal of the highest dilution at which this endpoint is observed; for example, agglutination with a serum dilution of 1:16 but not 1:32 would be reported as an antibody titer of 16. Alternatively, a 12-point scoring system that takes into account the strength of agglutination as well as the dilution factor may be a more specific indication of severe fetal anemia, but it is used less commonly than simple tube titration in current practice.[41,75]

Because serial measurements of maternal antibody titer are necessary, an initial maternal sample should be frozen for comparison in subsequent titers determined with the same method, technique, and reagent red blood cells.[61] A difference of greater than two dilutions or a score increase of more than 10 should be considered a significant change in titer.[61,75] For anti-D, the critical titer is considered by most experts to be 32 (range, 8 to 32).[61] Critical titers for antibodies other than anti-D have been suggested, based on cumulative clinical experience at a center or historical published data. The utility of antibody titers in monitoring Kell-sensitized pregnancies is limited because the severity of intrauterine disease may not correlate with antibody concentration, and severe HDF has occurred with low anti-Kl titers (e.g., 8).[53] In contrast, other antibodies are less likely than anti-D or anti-Kl to cause hemolytic disease at low titers, and higher thresholds have been proposed for anti-Fy^a (titer, 64), anti-M (titer, 32 to 64), and anti-U (titer, 128).[33,75] Anti-M often demonstrates IgG and IgM components that can be distinguished with the use of reducing agents in titration studies, and anti-M–sensitized pregnancies are managed on the basis of the titer of the IgG component.[33]

Investigated as an alternative to maternal antibody titer, antibody functional assays, such as the monocyte monolayer assay, the antibody-dependent cellular cytotoxicity assay, and the chemiluminescence test, examine the behavior of potentially significant red blood cell antibodies in vitro.[77,79] These assays evaluate the ability of the maternal IgG antibody to interact with target red blood cells and effector cells expressing Fc receptors, such as lymphocytes or monocytes, to cause adherence, phagocytosis, or cytotoxic lysis. The antibody-dependent cell-mediated cytotoxicity assay showed a higher specificity than maternal antibody titer for prediction of fetal disease and may be more useful in guiding decisions about invasive testing for D alloimmunization in pregnancy.[77] Antibody functional assays, however, have not been as widely used in the United States as in Europe, primarily because prenatal testing is not centralized in highly specialized laboratories in the United States, and the technical complexities of the tests precludes their use at most American centers.[61]

Tests for Fetal–Maternal Hemorrhage

An assessment of the volume of fetal cells in the peripheral circulation of a D-negative woman is performed to determine the adequacy of the dose of administered RhIG after delivery of a D-positive infant and in other obstetric situations.[38,39,40,80] A common approach to evaluating FMH is the rosette test to screen for the presence of fetal cells followed by the Kleihauer-Betke acid elution method to quantify the magnitude of the bleed. The rosette test is a modified antiglobulin reaction, based on detection of the fetal (D-positive) red blood cells in a maternal (D-negative) blood sample. On reaction with reagent anti-D Ig, fetal (D-positive) red blood cells form small clumps or rosettes around indicator D-positive red blood cells (Fig. 30.2).[41] The presence of rosettes is a sensitive qualitative screen for FMH. A positive test is obtained in 75% of women with FMH of 2.5 ml of D-positive red blood cells (5 ml whole blood) and all women with FMH of 5 ml of D-positive red blood cells (10 ml whole blood) or more.[80,81] If it is determined that an infant has the weak D phenotype, the rosette test is not reliable, and FMH should be evaluated with tests that do not rely on detection of the expression of the D antigen, such as the Kleihauer-Betke acid elution method.[61] Rarely, maternal anti-D is present at such high concentration on the surface of fetal red

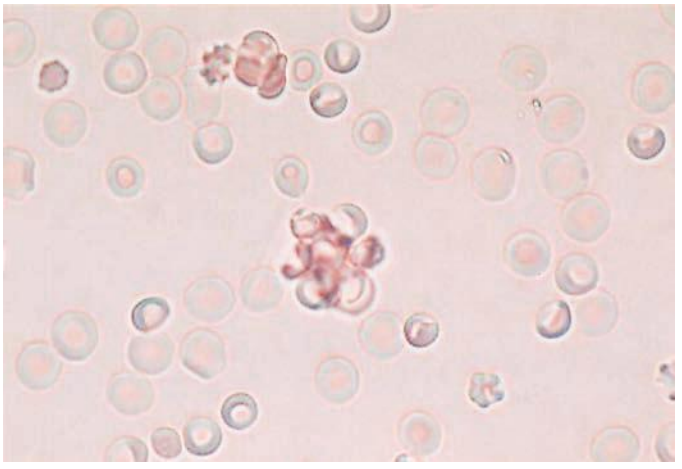

FIGURE 30.2. Rosette assay for fetal–maternal hemorrhage (FMH). D-positive red blood cells are identified in a background of D-negative red blood cells by the formation of rosettes in this screening test for FMH. There are two rosettes in this field: a large one in the center and a smaller one above it; unagglutinated red blood cells appear as refractile biconcave (unstained) disks.

blood cells that interaction with the reagent anti-D is blocked, and the rosette assay produces a false-negative result.

The Kleihauer-Betke acid elution method provides a quantitative estimate of the volume of FMH based on the different solubility properties of fetal hemoglobin (HbF) and adult hemoglobin (HbA). On a peripheral blood smear treated with an acidic solution and counterstained, red blood cells containing acid-soluble HbA appear as pale ghosts compared to the deeply stained red blood cells containing acid-resistant HbF (Fig. 30.3). The Kleihauer-Betke test result is reported as the percentage of HbF-stained fetal cells present on the smear.[80] The corresponding magnitude of FMH is calculated by multiplying the percentage of fetal cells, expressed as a fraction, by the maternal blood volume, which is 70 to 75 ml/kg or approximately 5,000 ml for an average pregnant woman. For example, a Kleihauer-Betke result of 1.4% indicates the presence of 70 ml of fetal whole blood (0.014 × 5,000 ml). The Kleihauer-Betke test is sensitive to bleeds between 0.01% and 0.06% or 0.2 to 1.0 ml, but samples containing at least 0.5% fetal cells are detected more reliably.[81,82] Kleihauer-Betke results that exceed the total predicted fetal blood volume based on gestational age (i.e., 3 ml at 12 weeks; 30 ml at 20 weeks) may reflect the inherent technical imprecision of the method or may reveal precedent maternal conditions associated with increases in HbF-containing red blood cells such as hereditary persistence of HbF. Notably, the levels of HbF often increase during pregnancy in as many as 25% of women.[83] In addition to these false-positives, the Kleihauer-Betke test tends to overestimate the quantity of hemorrhage, resulting in administration of more RhIG than is necessary.[82] This inherent potential for "overdosing" RhIG is not a problem from a medical standpoint given the safety record of the drug, but it is a concern to countries coping with RhIG shortages or those striving for the most cost-effective use of RhIG.[40]

Alternative methods to quantify FMH include flow cytometry and the enzyme-linked antiglobulin test.[84,85] Most flow cytometric assays for FMH are based on detection of the D antigen on fetal red blood cells, but detection of HbF-containing fetal red blood cells is also possible.[84] Flow cytometric methods are sensitive to FMH of 0.1% or 1.8 ml and can be used to detect events as rare as 1 fetal cell in 10,000 maternal cells.[82] The enzyme-linked antiglobulin test is a modified enzyme-linked immunosorbent assay and detects D-positive red blood cells in a maternal D-negative background by successive incubations with anti-D, anti-IgG conjugated with the enzyme alkaline phosphatase, and an enzyme substrate.[85] This test is sensitive to 0.25% or 3 ml FMH.[41,85] Both the enzyme-linked antiglobulin test and flow cytometry are reproducible and reliable but are not as commonly used in practice as the Kleihauer-Betke test for quantifying FMH in the United States.[40]

FIGURE 30.3. Kleihauer-Bethke acid elution for fetal hemoglobin (Hb). Cord blood was mixed with blood from a healthy adult to simulate fetal–maternal hemorrhage, and a Kleihauer-Bethke was performed. Red blood cells containing HbF are deeply stained red; red blood cells containing HbA appear as pale pink ghosts.

Amniotic Fluid Analysis

Amniotic fluid analysis by spectrophotometry, introduced by Liley in 1961 as an indirect marker of fetal red blood cell destruction, is still a cornerstone of obstetric management of alloimmunized pregnancies more than 40 years later.[8] The principle of the test is based on the characteristic light absorbance by amniotic fluid between 365-nm and 535-nm wavelengths in unaffected pregnancies and the observed deviation from this linear baseline in alloimmunized pregnancies when bilirubin or other optically active compounds are present. An increase in optical density at 450 nm (ΔOD_{450}) relative to the normal baseline is proportional to the amount of bilirubin present in the amniotic fluid. Liley correlated the ΔOD_{450} values to clinical outcomes in 101 Rh-sensitized pregnancies from 27 weeks' gestation to term, generating what is commonly referred to as the *Liley curve* (Fig. 30.4).[8] Values in the lowest zone of the Liley curve, zone I, are reassuring because these infants have only a 10% chance of needing treatment after birth.[8] In contrast, readings in zone III predict severe hemolytic disease with the risk of impending hydrops and imminent fetal death (within 7 to 10 days) with 98% accuracy.[8] The presence of contaminating meconium, blood, or the porphyrin-containing breakdown products of red blood cells interferes with the analysis in approximately 10% of cases but can be remedied with chloroform extraction of the amniotic fluid, reducing this rate to 1%.[86] Amniotic fluid analysis may also be affected by fetal conditions other than hemolytic disease, such as congenital hepatitis, and maternal diseases, such as sickle cell anemia.

In most cases, Liley's method accurately reflects the severity of HDF due to anti-D after 27 weeks' gestation. Extrapolating Liley curves for gestation ages earlier than 27 weeks has been used to manage alloimmunized pregnancies in the second trimester, but this approach has been shown to be unreliable in some studies.[86–89] Queenan et al. developed a modified ΔOD_{450} curve for this situation, by evaluating amniotic fluid in 520 unaffected

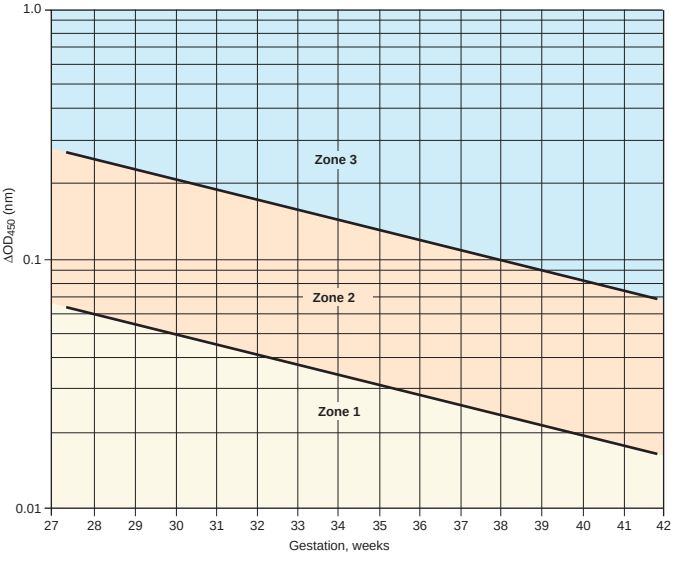

FIGURE 30.4. Liley graph and management zones for alloimmunized pregnancies, based on amniotic fluid increase in optical density at 450 nm (ΔOD_{450}) determination. Patients in zone I or low zone II are allowed to proceed to term, patients in the middle of zone II can progress to 36 to 38 weeks of gestation in most cases; patients in zone III or with a rising value in the upper part of zone II should be delivered or the fetus should receive intrauterine blood transfusion, depending on gestational age. pregnancies from 14 to 40 weeks' gestation and in 75 D-immunized pregnancies to develop four zones to guide management decisions in the second trimester (Fig. 30.5).[89] The upper two zones represent the infants at greatest risk in the Rh-positive (affected) zone and the intrauterine death zone. Analyzing the trends in the four zones was successfully used to manage pregnancies complicated by alloimmunization to the D antigen as well as the simultaneous presence of multiple blood group antibodies.[89,90] The controversy over appropriate management of second-trimester alloimmunized pregnancies spurred development of alternate management strategies that relied solely on fetal blood sampling that was, in turn, met with resistance because of the risks associated with cordocentesis.[91,92] The increasing use of Doppler ultrasonography to monitor alloimmunized pregnancies has largely quenched this debate, and most centers have implemented a less invasive strategy for management of alloimmunized pregnancies, reserving fetal blood sampling for patients with elevated ΔOD_{450} values or elevated peak middle cerebral artery (MCA) Doppler velocities.32

Noninvasive Fetal Monitoring

An important advance in the management of alloimmunized pregnancies has been the use of ultrasonography to predict the severity of anemia. Ultrasonography can accurately establish gestational age and evaluate fetal development, and can detect signs of hydrops fetalis, by the presence of extracellular fluid in two body compartments. Ascites is often the first sign of hydrops, and other sonographic signs of severe or worsening fetal anemia include increases in the size of the fetal liver or spleen, an increase in placental thickness, the presence of effusions or polyhydramnios, visualization of both sides of the fetal bowel, and abnormalities of pulsed Doppler flow velocity waveforms in fetal vessels.[93]

The increase in blood flow velocity that occurs with anemia can be measured by Doppler ultrasonography of the fetal MCA. In the largest prospective, multicenter study of 165 fetuses with maternal red blood cell alloimmunization (anti-D, -c, -E, or -Fy^a), an increase in peak velocity in the MCA expressed as more than 1.5 multiples of the median (MoM) had a sensitivity of 88% and a specificity of 82% for severe fetal anemia.[94] The performance of Doppler ultrasonography was better than amniocentesis using the Liley curve, but similar to amniocentesis with Queenan's method. Doppler ultrasonography has also been used to manage Kell-sensitized pregnancies, and is preferred to amniocentesis, which is often unreliable when HDF is caused by anti-K1, because these antibodies not only cause hemolysis, but also suppress erythropoiesis as reflected by falsely reassuring ΔOD_{450} values in the setting of profound fetal anemia.[33] Fetal blood sampling to measure fetal hematologic parameters directly is generally undertaken after Doppler ultrasonography of the MCA suggests the presence of severe or worsening fetal anemia.

Fetal Blood Sampling

Fetal blood sampling (percutaneous umbilical blood sampling, cordocentesis) provides direct access to the fetal circulation for laboratory measurements and transfusion.[95] With ultrasonographic guidance, a needle (22- or 20-gauge spinal needle) can be introduced into an umbilical vessel as it enters the placenta or, rarely, at other points in its course. Fetal blood sampling permits direct measurement of HbF, hematocrit, reticulocyte count, and bilirubin, and normal values for these variables have been determined for fetuses from 15 weeks' gestational age onward. In addition, the fetal blood cells can be typed for the antigen in question, and, if positive, the presence of the corresponding maternal red blood cell antibody on the surface of fetal red blood cells can be assessed by the direct antiglobulin test.

The risk of fetal loss is generally greater with cordocentesis (1.0% to 2.7%)[95,96,97] than amniocentesis (0.3%),[73] but their comparative risk has not been systematically evaluated. As experience with these invasive procedures increases at an institution, the risk of procedure-related morbidity and mortality decreases. Both amniocentesis and cordocentesis may cause FMH with consequent increases in maternal antibody titers that could potentially accelerate the course of HDF. Other complications of fetal blood sampling include fetal bradycardia, chorioamnionitis, placenta trauma, infection, cord hematoma, thrombosis, bleeding from the puncture site, and rupture of the membranes.[97]

Laboratory Testing of Newborn Infants

Infants born to women with potentially significant red blood cell antibodies or those demonstrating clinical signs of hemolytic disease despite a negative maternal antibody screen should have their ABO and D blood type determined and a direct antiglobulin test (DAT) performed at birth.61 Anti-A and anti-B are not detected in the antibody screen because the reagent red blood cells are type O but can be detected in an indirect antiglobulin test using reagent group A or B red blood cells. The DAT involves mixing cord red blood cells directly with antihuman globulin (anti-IgG) and observing for visible agglutination, which reveals the presence of maternal antibodies on the surface of the newborn's red blood cells.[41] A negative DAT does not exclude the possibility of immune-mediated hemolytic anemia and may reflect a low surface concentration on fetal red blood cells or low avidity of the offending antibody under the reaction conditions. In many cases, maternal antibody may be concentrated by elution from the surface of the fetal cells, facilitating its detection. If HDN is still suspected in the absence of both ABO incompatibility and detectable maternal antibody, the maternal serum or an eluate prepared from the infant's red blood cells can be tested against the biologic father's red blood cells.[41] This procedure may detect a maternal antibody directed against a low-incidence red blood cell antigen that has been associated with severe HDN in rare cases, such as anti-Wr^a (Wright), but is not represented on most red blood cell panels used for antibody identification.[41,61]

AABB does not endorse routine immunohematologic testing of infants in the absence of clinically significant maternal antibodies or without a clinical suspicion of HDN.[61] Despite these

recommendations, some institutions continue to perform ABO/D typing and DATs on all newborn infants; others perform selective testing for infants born to group O mothers. The latter strategy is intended to identify infants at risk of ABO HDN, whose hospital discharge may be planned at <24 hours, but it has been criticized because all newborn infants should be monitored for jaundice during the first weeks of life.[61]

Jaundice is the visible manifestation of increased serum bilirubin concentration, and it becomes apparent when levels exceed 5 mg/dl. Laboratory detection of total, direct (conjugated), and indirect (unconjugated) bilirubin provides important diagnostic information regarding the cause of the jaundice (Table 30.5). In immune-mediated hemolytic disease, the total serum bilirubin concentration may be routinely assayed to guide clinical management, because it is almost entirely unconjugated (indirect) bilirubin. Under investigation are transcutaneous bilirubin measurements as well as measurements of unbound bilirubin, such as the bilirubin-to-albumin ratio, serum-free bilirubin, bilirubin reserve binding capacity, bilirubin saturation index, and other signs of elevated bilirubin production such as the carboxyhemoglobin level and exhaled carbon monoxide levels. These tests may be used in addition to, but not in lieu of, total serum bilirubin in managing infants with immune-mediated hemolytic anemia.

PREVENTION OF MATERNAL D ALLOIMMUNIZATION WITH RH IMMUNE GLOBULIN

RhIG prophylaxis is an international standard in obstetric care.[40] Although the efficacy of RhIG in preventing alloimmunization to the D antigen is unequivocal, the mechanism by which it inhibits the primary immune response is not entirely known. Immune-mediated immunosuppression by passively transferred anti-D antibodies may occur in part by rapid macrophage-mediated clearance of anti-D coated red blood cells in the red pulp of the spleen.[98,99] RhIG, however, does not result in complete clearance of fetal red blood cells but is effective even though fetal red blood cells persist in the maternal circulation.[98] Similarly, the theory that administered RhIG blocks the antigenic stimulus by coating D-positive red blood cells (i.e., epitope masking) is not supported by the fact that immunosuppressive doses of RhIG bind only to a small fraction of the available antigen sites on red blood cells.[98]

RhIG most likely prevents alloimmunization to the D antigen both by rapid clearance of anti-D coated red blood cells by macrophages in the red pulp of the spleen and by down-regulation of immune response, which blocks antibody production by B cells before development of the anti-D response occurs.[99] The two molecular interactions responsible for B-cell inhibition occur between the B-cell receptor (membrane IgG) and the D antigen on the red blood cell and between the B-cell Fcγ receptor and the Fc portion of the bound anti-D on the red blood cell surface. In a primary immune response, naive B cells are stimulated to produce antibody when B-cell receptors alone are activated by antigen (Fig. 30.6A). In the presence of RhIG, this signal is overridden, and apoptosis occurs when Fc receptors are simultaneously aggregated in the complex by their association with the red-blood-cell–bound anti-D antibodies (Fig. 30.6B). Memory B cells differ from naive B cells in that they can be activated to produce antibody even in the presence of pre-existing antibodies. This model is consistent with the observation that RhIG prevents the primary immune response, and is not effective for preventing a secondary or anamnestic immune response in a previously sensitized woman.

Interestingly, immune suppression to the D antigen can be induced not only by anti-D, but also by other passively transferred

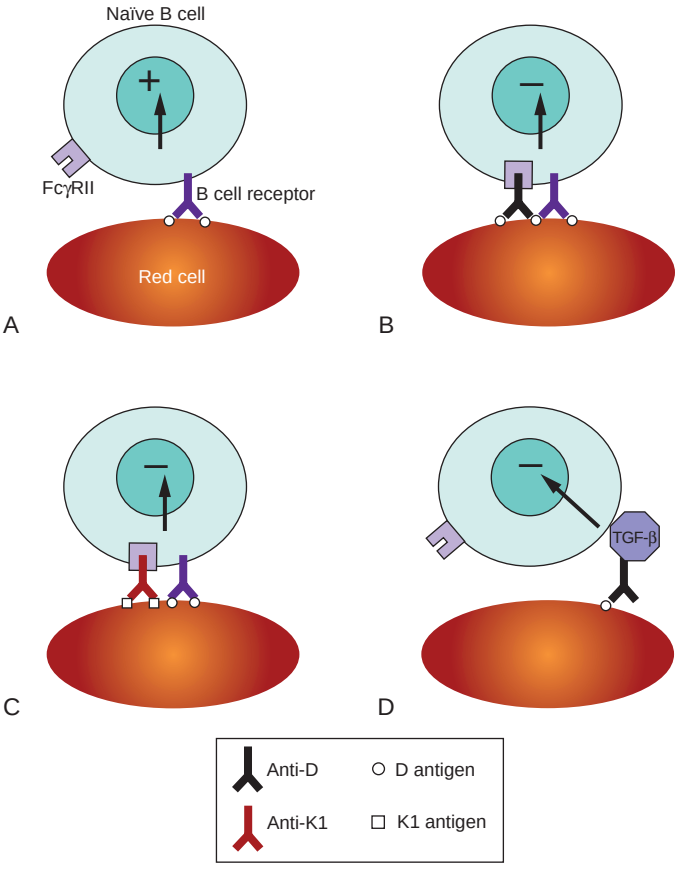

FIGURE 30.6. Mechanisms of anti-D immune globulin (RhIG) immune prophylaxis. A: Alloimmunization. Activation of naive B-cells in a D-negative individual occurs with exposure to D-positive red blood cells through interaction of the B-cell receptor (surface immunoglobulin) and D antigen. **B:** RhIG immune suppression. Inhibition of B-cells is mediated by passively transferred anti-D (RhIG), which cross-links the B-cell receptor and Fcγ receptor (FcγRII). **C:** Specificity of immune suppression. Inhibition of B-cells from a D-negative, K1-negative individual occurs despite exposure to D-positive, K1-positive red blood cells with the administration of anti-K1, in lieu of RhIG, through formation of the same receptor configuration as in (B) (i.e., cross-linking the FcγRII receptor and B-cell receptor for the D antigen). **D:** Fc-receptor–independent pathways for RhIG immune suppression. Inhibition or apoptosis of B cells may occur through interaction between the Fc portion of anti-D antibodies (RhIG) and immune complex formation on the surface of D-positive red blood cells. TGF, transforming growth factor.

antibodies to a co-expressed blood group antigen, as long as the Fcγ receptor is complexed with the B-cell receptor and the antigen (Fig. 30.6C). This phenomenon of co-inhibition was supported by the observation that passively administered anti-K1 IgG antibodies suppressed anti-D antibody formation in D-negative/K1-negative human subjects given D-positive/K1-positive red blood cells.[100] Finally, animal models of antibody-mediated immune suppression suggest the existence of Fc-receptor–independent pathways.[98] For example, RhIG may bind and localize factors to the B cell that inhibit antibody production and induce apoptosis, such as transforming growth factor-β (Fig. 30.6D). The immune response is regulated by cellular (e.g., dendritic cells) and soluble mediators (e.g., cytokines), which affect the potential for immunogenicity or tolerance. Down-regulation of immature dendritic cells may also prevent development of the primary immune response after RhIG administration. A role for immunomodulatory cytokines was suggested by Branch et al., who reported an increased plasma concentration of two anti-inflammatory cytokines, TGF-β and prostaglandin E_2 (PGE_2), in D-negative women after antenatal administration of 300 μg of RhIG.[101] TGF-β is a powerful negative modulator of immune responses, and the finding that the cytokine is elevated after RhIG administration is consistent with a role in the prevention of the primary immune response to D fetal red blood cells.[99,101]

Rh Immune Globulin Viral Safety Record

All commercially available RhIG products approved for clinical use are polyclonal anti-D preparations derived from the plasma of immunized human donors (Table 30.6). Subsequent to the realization in the 1980s that human immunodeficiency virus (HIV) could be transmitted through blood product transfusion was the demonstration that the Cohn-Oncley fractionation process used for producing some of the RhIG formulations (e.g., RhoGAM) effectively partitioned and inactivated HIV. To further improve the safety of plasma derivatives, a serologic test to screen plasma donors for HIV was first implemented in 1985; a serologic test for hepatitis C virus (HCV) was introduced in 1991; and nucleic acid testing for both HIV and HCV was added to the repertoire in 2000. As a further precaution, specific viral removal steps, such as size-exclusion filtration (e.g., RhoGAM), or viral inactivation methods, such as solvent–detergent treatment (e.g., Rhophylac), have been added to the manufacturing process (Table 30.6). Despite these measures, every RhIG product derived from human plasma carries the warning that the potential for disease transmission has not been eliminated.

More than 500,000 doses of RhIG are given to an estimated 350,000 women each year, and no cases of hepatitis or HIV transmission attributed to RhIG have been documented in the United States.[102,103] In Ireland and the former East Germany, however, hepatitis C was transmitted to several hundred women by different batches of contaminated intravenous RhIG in the late 1970s, before the introduction of routine donor screening for anti-HCV antibodies in 1991.[104] In 1994, HCV RNA was also detected in batches of RhIG manufactured in Ireland between 1991 and 1994, and a single donor was implicated in contributing the infectious plasma to the pool.[104] A large-scale retrospective investigation screened more than 19,000 recipients of anti-D in this timeframe and identified 19 women with the same strain of HCV as the implicated donor.[104]

HCV transmission was linked in 1993 and 1994 to two brands of intravenous immune globulin (IVIG) (Gammagard and Polygam), and these infections were the impetus for introducing viral inactivation steps for all plasma derivatives, including RhIG. No cases of viral transmission have been documented in the United States to any plasma derivative since 1995.[105a] Another precautionary step recently taken in the United Kingdom is the importation of all source plasma for anti-D products from the United States, in light of a potential risk of transmission of variant Creutzfeldt-Jacob disease from plasma collected in Europe.[40] Four cases of human variant Creutzfeldt-Jacob disease transmission have been attributed to red blood cell transfusion to date, all in the United Kingdom.[105b] To decrease the reliance on human plasma, monoclonal antibodies directed against D antigen epitopes have been developed with recombinant technology and appear to compare favorably to RhIG in preventing D alloimmunization but are not commercially available.[106a] Rozrolimupab, a mixture of 25 different fully human recombinant anti-D monoclonal antibodies, is currently in clinical testing.[106b]

RhIG Dosage and Administration

The effective dose of RhIG to prevent sensitization (20 μg/ml D-positive red blood cells) was determined experimentally by challenging D-negative male volunteers with incompatible blood.[107] Dosage formulations of different preparations of RhIG are based on this conversion, with the "standard" 300 μg (1,500 IU) sufficient to protect against FMH of 15 ml D-positive red blood cells (30 ml fetal whole blood) (Table 30.6).[80] The intravenous preparation (WinRho) is used more often for treating immune thrombocytopenia (ITP) than for preventing D alloimmunization, but it is effective for both indications. Dosage adjustments must be made for FMH that exceeds the volume covered by a dose of RhIG[41]:

- Multiply the percentage of fetal cells in maternal circulation (expressed as a fraction) by the maternal blood volume (approximately 5,000 ml) to determine the volume (ml) fetal whole blood in the maternal circulation (Kleihauer-Betke result of 1.4%: 0.014 × 5,000 ml = 70 ml fetal whole blood).

TABLE 30.6

ANTI-D IMMUNE GLOBULIN PRODUCTS AVAILABLE IN THE UNITED STATES IN 2012

Route of Administration/ Brand Name	Manufacturer	Fractionation and Viral Inactivation	Dose	Coverage of D-Positive Red Blood Cells (Whole Blood)	Labeled Indications
IM					
RhoGAM MicRhoGAM	Ortho-Clinical Diagnostics, Raritan, NJ	Cold alcohol fractionation; size-exclusion filtration[a]	300 μg (1,500 IU) 50 μg (250 IU)	15 ml (30 ml) 2.5 ml (5 ml)	Pregnancy/obstetric; D-incompatible transfusion
BayRho-D full dose BayRho-D mini dose	Bayer Biological, Elkhart, IN	Cold ethanol fractionation; solvent–detergent and heat treatment[b]	300 μg (1,500 IU) 50 μg (250 IU)	15 ml (30 ml) 2.5 ml (5 ml)	Pregnancy/obstetric; D-incompatible transfusion
IV or IM					
WinRho SDF	Cangene Corporation, Winnipeg, Canada; distributed by Nabi, Boca Raton, FL	Ion exchange chromatography; solvent–detergent and filtration	120 μg (600 IU) 300 μg (1,500 IU) 1,000 μg (5,000 IU)	6 ml (12 ml) 15 ml (30 ml) Not for obstetric use	Pregnancy/obstetric; D-incompatible transfusion; immune thrombocytopenia (ITP)
Rhophylac	CSL Behring LLC, Kankakee, IL	Ion exchange chromatography; solvent–detergent and filtration[c]	300 μg (1,500 IU)	15 ml (30 ml)	Pregnancy/obstetric; D-incompatible transfusion; immune thrombocytopenia (ITP)

[a]Filtration reduces levels of enveloped (e.g., hepatitis C, hepatitis B, human immunodeficiency virus) and non-lipid–enveloped viruses (e.g., parvovirus, hepatitis A).
[b]Solvent–detergent and heat treatment removes and inactivates enveloped and nonenveloped viruses.
[c]Solvent–detergent treatment inactivates enveloped viruses, and filtration removes some non-lipid–enveloped viruses.

- Divide by the volume of D-positive whole blood covered and round off by standard convention to determine required number of 300-μg vials of RhIG (70 ml fetal whole blood ÷ 30 ml whole blood per 300-μg vial = 2.3 vials).

Given the inherent imprecision in calculating FMH with the Kleihauer-Betke test, some American authorities advocate administering one additional vial of RhIG than this calculated dose to ensure administration of sufficient RhIG.[41,80] For example, if the number of vials is calculated to be 2.3, round off to 2.0 vials, but administer 3.0 vials. If the number of vials is calculated to be 2.5, round off to 3.0 vials, but administer 4.0 vials.[41]

RhIG is indicated for antenatal and post-natal prophylaxis as well as any clinical situation in which FMH is demonstrated or suspected in D-negative pregnant women. RhIG may also be administered to D-negative women of childbearing potential who inadvertently or unavoidably receive incompatible D-positive red blood cells or cellular components (e.g., platelets) prepared from D-positive whole blood in an attempt to prevent D alloimmunization.[108] RhIG should *not* be administered to infants or to the following pregnant women[41,80]:

- A D-negative woman whose infant is D-negative
- Any D-positive woman, including women with known weak D phenotype
- A D-negative woman known to be immunized to D

Although the appropriate dose of RhIG to administer was determined experimentally in red blood cell challenge experiments, the dosing interval of <72 hours after exposure was an arbitrary decision in early clinical trials but has been universally adopted. RhIG has been shown to be effective if administered 13 days, and possibly as late as 28 days, after exposure to D-positive red blood cells.[109] Consequently, RhIG should be administered within 72 hours of potentially sensitizing events, but it should still be given if this interval is exceeded, as soon as the oversight is recognized. Depending on the administered dose and sensitivity of the laboratory tests, RhIG is detectable in maternal circulation for up to 6 months, with an average half-life of approximately 24 days. Cases of D alloimmunization in post-date pregnancies have been reported when delivery occurred more than 12 weeks after the antenatal dose of RhIG, although the residual circulating RhIG after the standard antenatal dose of 300 μg should still protect against 1 to 2 ml of D-positive fetal red blood cells at 40 weeks.[24]

Serious adverse reactions to RhIG are extremely rare but include anaphylaxis in IgA-deficient individuals. More commonly, mild to moderate discomfort may occur at the site of intramuscular injection. Products labeled only for intramuscular injection must not be given intravenously, because they may contain immune complexes that could activate circulating complement proteins and subsequently cause a systemic inflammatory response. The anti-D antibodies in RhIG preparations can cross the placenta and bind to fetal cells but do not cause significant hemolysis.[110] Although the possible effects on infants were not consistently examined in previous clinical trials of RhIG, no short-term or long-term detriment to infants whose mothers received RhIG during pregnancy has been demonstrated.[111]

Rh Immune Globulin Immunoprophylaxis Guidelines in Different Countries

ACOG recommends an antenatal RhIG dose of 300 μg at 28 weeks of gestation for nonsensitized, D-negative women and another 300 μg after delivery of a D-positive infant, based primarily on data reviewed at the 1977 McMaster Conference revealing the high success rate associated with this regimen (Table 30.7).[16,38] Current recommendations from the Royal College of Obstetricians and Gynaecologists (United Kingdom) differ from those from ACOG in that antenatal prophylaxis is given as 100-μg (500-IU) doses at both 28 weeks and 34 weeks of gestation, and another 100 μg (500 IU) is given after delivery of a D-positive infant.[39] Compared to the American strategy, the British approach achieves similar low rates of alloimmunization with less RhIG [300 μg (1,500 IU) vs. 600 μg (3,000 IU)].[39,40] This approach also avoids the risk of alloimmunization if delivery occurs more than 12 weeks after administration of the antenatal dose.[24] A potential drawback, however, is the additional clinic visit required for the third injection at 34 weeks of gestation. Routine antenatal prophylaxis has not been implemented in all countries[40]; other differences in practices include indications and methods for testing for FMH, availability of noninvasive pre-natal diagnosis for D, and testing D-negative women for weak D to determine eligibility for RhIG.[40]

All international medical authorities, however, emphasize the importance of recognizing potentially sensitizing events and appropriately administering RhIG after amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling, and obstetric complications, including abdominal trauma, manual removal of placenta, and antepartum vaginal bleeding (Table 30.2).[38,39,40] Smaller doses of anti-D immune globulin can be administered after first-trimester events and procedures, because of the small total red blood cell mass of the fetus before 12 weeks' gestation. Consequently, ACOG recommends 50 μg to protect against sensitization by 2.5 ml of red blood cells in the first trimester (≤13 weeks' gestation) and the standard 300-μg dose after 12 weeks.

Unfortunately, the sensitization rate among D-negative women is higher than theoretically achievable rates, suggesting a failure to follow recommended prophylactic regimens.[29] Although postpartum doses were almost always administered, anti-D immune globulin was less consistently administered after abortion (88% to 94%), antepartum hemorrhage (31%), and amniocentesis (14%) in a 1985 study.[112] Deficiencies were noted as recently as 1994 in a series of more than 900 women in which RhIG administration followed only 60% of invasive procedures or other events associated with FMH.[113] Ongoing vigilance in public health care is required

TABLE 30.7

RECOMMENDATIONS FOR PROPHYLACTIC ANTI-D IMMUNE GLOBULIN (RHIG) ADMINISTRATION TO D-NEGATIVE WOMEN WITHOUT ANTI-D WITHIN 72 HOURS OF DELIVERY, ABORTION, OR EVENT

Antenatal	300 μg RhIG at 28 weeks' gestation unless father of baby is known to be D-negative
Postpartum	300 μg RhIG after the delivery of a D-positive infant. American College of Obstetricians and Gynecologists acknowledges American Association of Blood Banks' recommendation for routine FMH screening in this situation to identify FMH >15 ml D-positive red blood cells requiring larger dose of RhIG.
Abortion	50 μg RhIG in the first trimester; 300 μg RhIG after the first trimester; for induced or spontaneous abortion, ectopic pregnancy
Potentially sensitizing events	50 μg RhIG in the first trimester; 300 μg RhIG after the first trimester. This includes chorionic villus sampling, amniocentesis, and fetal blood sampling. RhIG should be considered in cases of threatened abortion, second- or third-trimester antenatal bleeding, external cephalic version, and abdominal trauma.

FMH, fetal-maternal hemorrhage.

Preventing rhesus isoimmunization: antepartum Rh immune globulin prophylaxis versus a sensitive test for risk identification. Am J Obstet Gynecol 1983;146:749–755.

to ensure effective use of RhIG given the potential severity of HDFN due to D alloimmunization.

MANAGEMENT OF RED BLOOD CELL ALLOIMMUNIZATION IN PREGNANCY

Management of red blood cell alloimmunization depends first on whether the woman has had one or more pregnancies, because HDFN is usually mild in a first pregnancy but likely to increase in severity in subsequent pregnancies. Although an obstetrician may provide routine pre-natal care to an alloimmunized pregnant woman in her first pregnancy and follow antibody titers, perform serial ultrasounds, and initiate amniotic fluid studies (if needed), referral to specialty centers experienced in Doppler ultrasonography and intrauterine transfusion is recommended by fetal–maternal specialists for optimal clinical management.[32,94]

Certain red blood cell antibodies are far more often implicated in cases of alloimmune fetal hydrops (e.g., anti-D, -c, -Kl, and -Fy^a) than others (e.g., anti-E and anti-M).[32,58,114] Other IgG red blood cell antibodies have demonstrated the potential in rare cases to cause severe fetal anemia or life-threatening HDN (Table 30.3), and still more IgG red blood cell antibodies have been reported to cause mild HDN. Although anecdotal reporting introduces bias toward the most severe cases, the previous behavior of non-D antibodies in sensitized pregnancies influences clinical management. If the antibody screen at the initial obstetric visit detects the presence of anti-D or other potentially significant red blood cell alloantibodies, additional monitoring is necessary during the pregnancy, and pre-natal intervention may be required. An algorithm for clinical management of a patient with red blood cell sensitization in a first affected pregnancy contains decision points based on maternal antibody titer, paternal phenotype, and serial fetal MCA Doppler or serial amniocentesis beginning at 24 weeks' gestation[32] (Fig. 30.7). If the fetus is suspected to be antigen positive, and MCA Doppler reaches 1.5 MoM or greater, cordocentesis should be performed at an experienced referral center, and blood should be available for intrauterine transfusion if the fetal hematocrit is found to be <30%.[32] If serial amniocentesis is performed instead of MCA Doppler, ΔOD_{450} values rising into the upper portion of the Rh-positive, affected zone of the Queenan curve (Fig. 30.5) or the 80th percentile of zone 2 of the Liley curve (Fig. 30.4) should trigger fetal blood sampling, with preparation for intrauterine transfusion if necessary.[32] Women with significant red blood cell alloantibodies who have had a prior affected pregnancy, involving either intrauterine transfusion or neonatal exchange transfusion, should be referred to a tertiary care center experienced in the management of severe HDFN. Maternal antibody titers are not indicated because they do not predict the degree of fetal anemia. Amniocentesis can be performed at 15 weeks' gestation to determine fetal antigen status for patients with a history of a severely affected fetus. Serial MCA Doppler assessment has been recommended starting at 18 weeks' gestation with repeated assessments every 1 to 2 weeks.[32] Alternatively, serial amniocentesis for measurement of ΔOD_{450} against the Queenan curves can begin at 18 weeks' gestation. Subsequent management decisions follow the same algorithm for a first affected pregnancy (Fig. 30.7).[32]

Intrauterine Fetal Transfusion

Intrauterine transfusion is performed to alleviate symptoms and extend gestation until the developing infant is mature enough to survive after delivery. Generally indicated if the fetal hematocrit falls below 30%, intrauterine transfusion can be given as early as 17 weeks' gestation by the intraperitoneal route and at approximately 20 weeks by the intravascular route.[114,115] The only access before 17 weeks' gestation, the intracardiac route, is only an option in extreme circumstances, and most transfusions are given after 20 weeks by the intravascular or intraperitoneal routes.[115]

Intraperitoneal transfusions are given by injecting blood into the abdominal cavity of the fetus, which is then absorbed into the fetal circulation by the subdiaphragmatic lymphatic system.[115] The presence of ascites, however, interferes with absorption, limiting the benefit to the most severely affected infants. Intravascular transfusion directly into the fetal circulation has largely supplanted the intraperitoneal method. The obvious advantage of the intravascular approach was the potential benefit offered to infants with hydrops and the ability to directly evaluate hematologic parameters after the transfusion.[115,116,117] A combined approach using both intravascular and intraperitoneal transfusion may produce more stable hematocrits and permit longer intervals between transfusions.[116,117]

The red blood cell volume to administer to a fetus during an intrauterine transfusion depends on the technique, the initial hematocrit, the target hematocrit, and the gestational age.[41] For intraperitoneal transfusion, the volume of red blood cells is calculated by the following equation, which assumes the hematocrit of the donor red blood cell unit is approximately 75%: (gestational age in weeks = 20) × 10 ml.[114] In a nonhydropic fetus, the rate of absorption is approximately 10% to 15% per 24 hours.[114] Intravascular intrauterine transfusions are usually given as simple transfusions of small aliquots of red blood cells ranging in volume from 50 to 100 ml, and not as exchange transfusions, due to the technical complexity of the latter. Several equations have been developed to calculate the dose of red blood cells to transfuse for intravascular transfusion, including the following method[41,118]:

1. Calculate the fetoplacental volume (ml): Ultrasound estimated fetal weight (g) × 0.14.
2. Calculate the volume to transfuse (ml): Fetoplacental volume × [(desired hematocrit — pretransfusion hematocrit) ÷ donor unit hematocrit]

The red blood cells used for intrauterine transfusion should be type O, D-negative, and antigen-negative if other clinically significant maternal alloantibodies are present, and they should be crossmatched against maternal serum. If antigen-negative red blood cells are needed but cannot be located, maternal red blood cells can be transfused to the infant if ABO/Rh compatible and after reducing the amount of antibody-containing plasma.[119] All red blood cell units for intrauterine transfusion should also be collected from cytomegalovirus (CMV)-seronegative donors or leukocyte-reduced to reduce the risk of CMV transmission, should lack hemoglobin S as a precaution against the potential for red blood cell sickling in hypoxic tissue beds, and should be γ-irradiated to prevent transfusion-associated graft-versus-host disease.[41]

Fetal blood is usually aspirated at the conclusion of intravascular transfusions to determine the final hematocrit and adequacy of the treatment. The goal of transfusions is usually to keep the fetal hematocrit around 27% to 30%.[41,114] Based on the association of increased umbilical cord venous pressure and mortality after transfusion, some authors recommend that in a severely anemic fetus, the final hematocrit after intravascular transfusion should not exceed a value of 25% or a fourfold increase from the pre-transfusion value.[120] Repeat transfusions are planned, based on an approximate 1% decline per day in hematocrit after intravascular transfusion.[41] Ongoing brisk hemolysis of fetal cells with severe disease often necessitates a shorter interval between the first and second transfusion, usually 7 to 14 days, compared to subsequent transfusions, usually 21 to 28 days.[114]

Complications of intrauterine transfusions in general include infection, premature rupture of membranes, premature labor, fetal hemorrhage, FMH resulting in increased maternal antibody titers and accelerated course of fetal hemolytic disease, and the risks of allogeneic blood components including virus transmission and graft-versus-host disease.[115] The risk of virus transmission

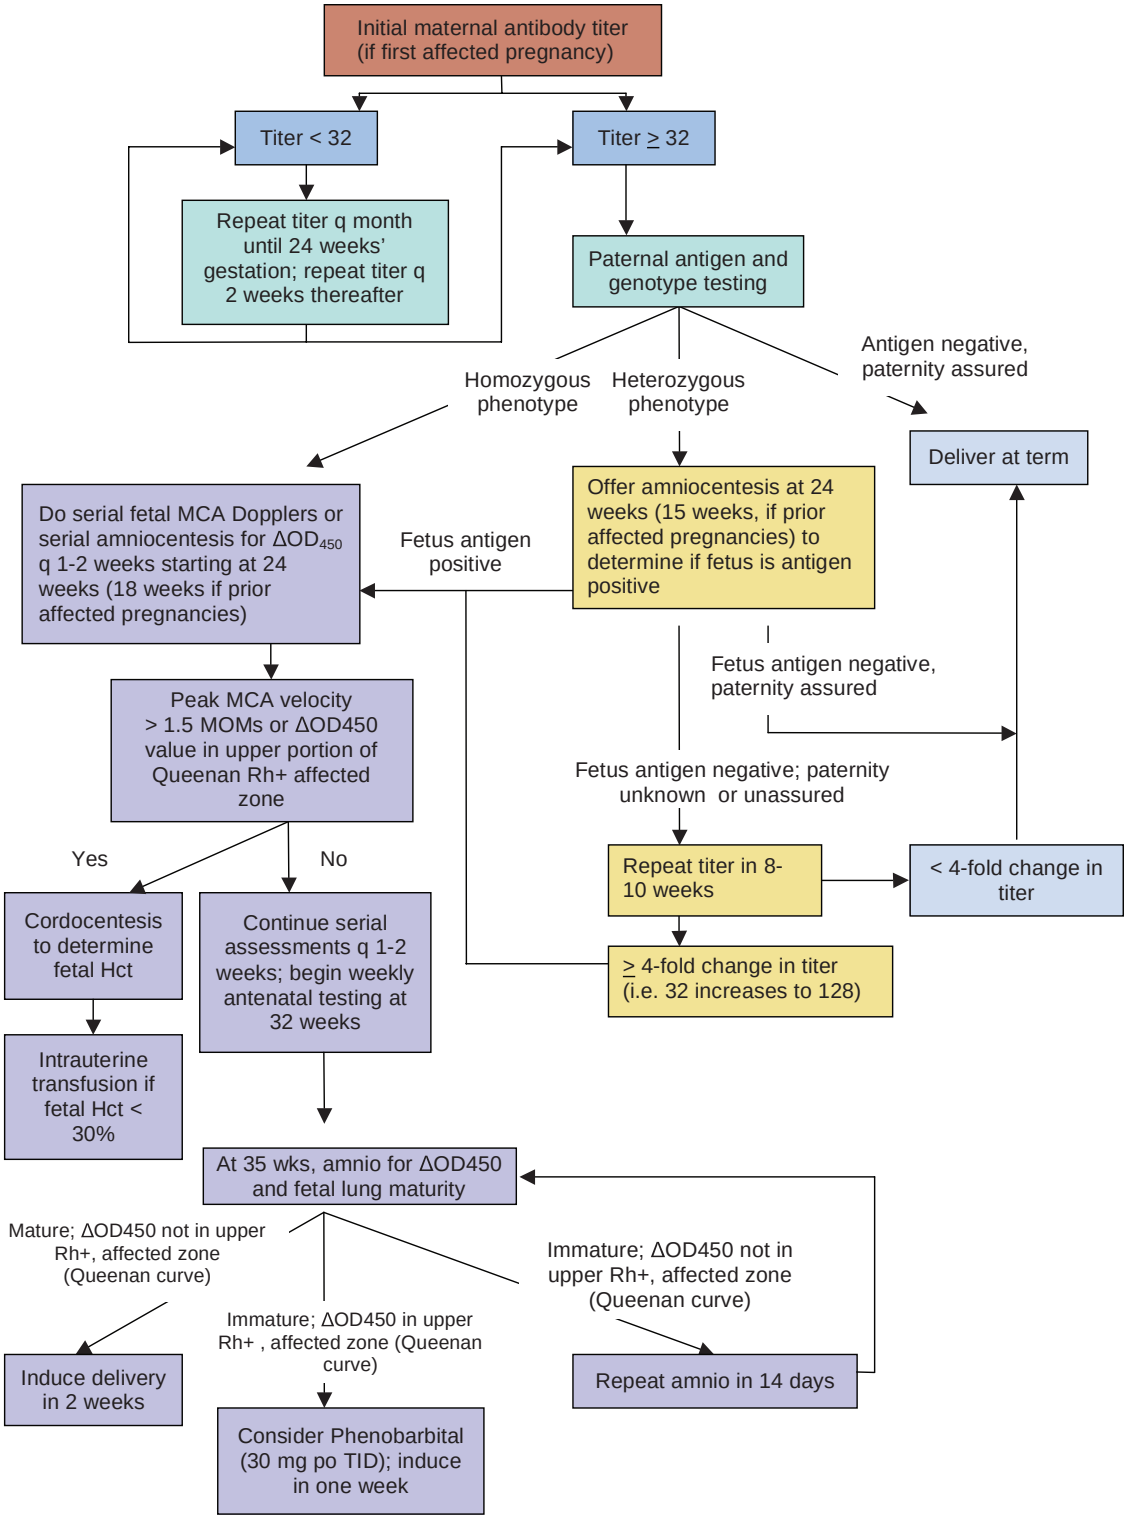

FIGURE 30.7. Algorithm for clinical management of a patient with red blood cell sensitization. Maternal titers are performed for a first affected pregnancy (*shaded boxes*). If a woman has a history of a previously affected fetus or infant, maternal antibody titers are not predictive of degree of fetal anemia and the patient should be referred to a tertiary care center for early intervention to determine fetal antigen status and initiate middle cerebral artery (MCA) Doppler assessment. MoMs, multiples of the median; ΔOD_{450}, optical density at 450 nm. (Modified from Moise KJ. Red blood cell alloimmunization in pregnancy. Semin Hematol 2005;42:169–178, with permission from Elsevier.)

with blood collected from repeat donors in the United States is currently estimated as 1 in 200,000–500,000 units for hepatitis B; 1 in 1,390,000 units for hepatitis C; and <1 in 2,000,000 units for HIV.[121a,121b,121c] The risk of physical injury during intrauterine transfusion, such as damage to fetal viscera with the intraperitoneal approach or umbilical cord damage with the intravascular approach, is minimized with the use of paralytic agents (i.e., vecuronium) to reduce fetal movement during intrauterine transfusions.[114,115] The procedure-related risk of fetal loss with intravascular transfusion is estimated as 4% to

9%.[114] Complications of intravascular transfusion, not previously reported with intraperitoneal transfusion, include umbilical cord hematoma, fetal bradycardia, and porencephalic cysts.[114,115] The procedure-related risks of intrauterine transfusion must be weighed against the risks of pre-term delivery and prematurity, and transfusions are rarely performed after completion of 34 gestational weeks.[114]

Investigational Strategies to Prevent or Treat Hemolytic Disease of the Fetus and Newborn

Investigational treatment strategies for HDF aim to modulate the maternal immune response and delay or avert the need for intrauterine transfusion by administering pre-natal IVIG or performing therapeutic plasma exchange. Results with therapeutic plasma exchange in red blood cell alloimmunized pregnancies are variable, and in many cases, the maternal anti-D titer was not affected or rebounded to even higher levels after treatment.[122] Pre-natal intravenous IVIG administration, to either the mother or fetus, is not efficacious and is not recommended for routine use for management of HDF.[123] For an alloimmunized woman with multiple fetal losses facing her reproduction options with a man heterozygous for the implicated blood group antigen, pre-implantation diagnosis after in vitro fertilization may provide a means to identify antigen-negative embryos.[124] Another investigational approach proposes to immunize these high-risk women against paternal HLA antigens before conception, citing the apparent mitigating effect of HLA antibodies on HDFN caused by anti-D.[51] Research to suppress selectively the maternal B cells that produce red blood cell alloantibodies is ongoing.[114] Finally, recombinant human antibodies directed against D antigen epitopes are being tested to decrease the reliance on human plasma for Rh immunoprophylaxis.[106a,106b]

TREATMENT OF THE NEWBORN INFANT

The therapeutic approach to anemia and jaundice after birth due to HDFN depends on the gestational age at delivery, severity of disease, and other factors.[125,126] Treatment of each affected infant must be individualized after a detailed history, physical examination, and laboratory investigation. An infant born with hydrops requires intensive and immediate supportive care. A thorough physical examination may reveal findings of pallor, tachycardia, and tachypnea, which reflect neonatal anemia. The infant must be monitored for worsening jaundice and neurologic findings of bilirubin toxicity. In contrast to "physiologic" jaundice developing on the second or third day of life, early jaundice appearing in the first 24 hours of life is always pathologic and may signify hemolysis. Initial laboratory assessment should include ABO/D blood typing and a direct antiglobulin test, as well as bilirubin measurement and a complete blood count for assessment of hemoglobin, hematocrit, reticulocyte count, and red blood cell morphology (polychromasia, spherocytes, and nucleated red blood cells). Early erythrocyte precursors and nucleated red blood cells may be prominent in the peripheral blood smear with hemolytic disease due to anti-D, whereas spherocytes predominate in ABO HDN. Serial tests of bilirubin concentration are recommended to follow the rate of the rise in bilirubin and to determine the most appropriate form of treatment.[125] Ongoing hemolysis increases the concentration of unconjugated bilirubin; the concentration of conjugated bilirubin is usually normal or not >0.5 mg/dl and should not be subtracted from the total bilirubin for treatment decisions. Conjugated bilirubin above the upper limit of the normal range in HDN may indicate mild cholestasis or "inspissated" bile.[125] Infants with jaundice due to immune-mediated hemolysis are generally considered at greater risk for bilirubin encephalopathy than infants with jaundice due to other causes, at any given serum unconjugated bilirubin concentration.[125] Acid-base disturbances, asphyxia, free heme groups, and other by-products of hemolysis may potentiate the toxic effects of bilirubin in infants with alloimmune hemolysis.[125,126] The bilirubin-to-albumin ratio is also taken into consideration, because serum bilirubin is transported in the plasma tightly bound to albumin and the portion that is unbound or loosely bound can more readily leave the intravascular space and cross the intact blood–brain barrier.

Phototherapy

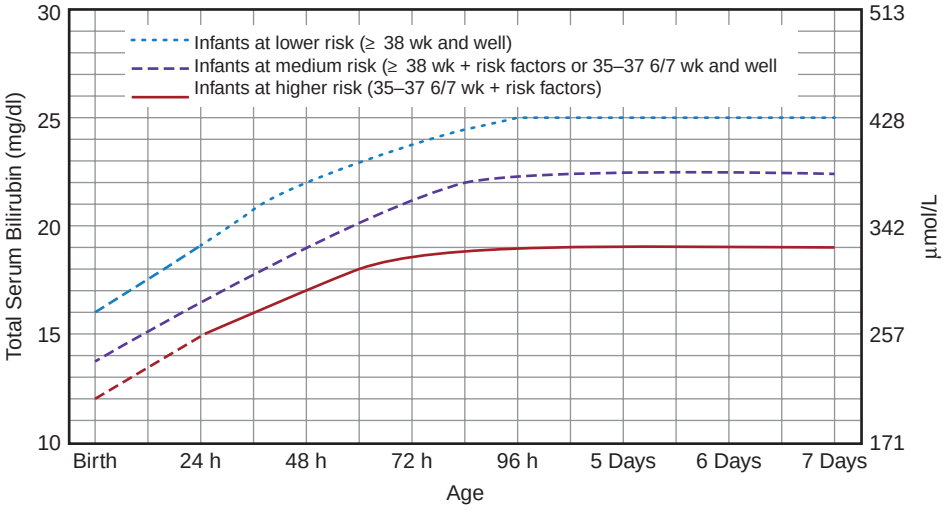
Phototherapy is the first line of treatment for neonatal jaundice and can avert the need for an exchange transfusion in infants with HDN. Light exposure converts insoluble unconjugated bilirubin into a water-soluble photoisomer, permitting more rapid excretion through the urine or bile without conjugation. Factors affecting optimal phototherapy include the dose of light, its spectral emission curve, the infant's exposed surface area, the depth of penetration of the light, and characteristics of the infant's skin and tissues. The effective wavelength of light for transcutaneous degradation of unconjugated bilirubin is in the range of 430 to 490 nm, found at high irradiance in blue light.[127] Conventional phototherapy uses banks of lights, whereas fiberoptic light systems contain optical fibers in a blanket or band that is wrapped around the infant. The fiberoptic light systems expose greater surface area to light, are convenient to use, and are less disruptive to parent–child bonding than conventional phototherapy. Double phototherapy uses both fiberoptic and conventional phototherapy and lowers serum bilirubin faster than conventional phototherapy alone.[125C] Intensive phototherapy implies irradiance in the blue-green spectrum (wavelengths of approximately 430 to 490 nm) of at least 30 $\mu W/cm^2$ per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible.[126]

Clinical practice guidelines from the American Academy of Pediatrics (AAP) treat infants with jaundice caused by immune-mediated hemolysis more aggressively than infants with "physiologic" jaundice, with comparable serum unconjugated bilirubin concentration.[126] Treatment of jaundiced pre-term infants and jaundice on the first day of life in any infant requires individualized treatment decisions. In general, phototherapy should be initiated in term infants if bilirubin increases by 0.5 mg/dl/hour or more, or if total bilirubin exceeds the established parameters, which are determined by gestational age and the presence of risk factors such as hemolysis, sepsis, or acidosis. Premature infants are treated earlier in the course of disease at lower bilirubin concentrations than term infants. Earlier initiation of therapy, at lower bilirubin concentrations, may also be clinically indicated in other scenarios. For example, infants who required extensive pre-natal treatment may be started on optimal phototherapy after birth. High-dose IVIG may block binding of antibody-coated red blood cells to Fc receptors on reticuloendothelial cells, thereby blunting the destruction of red blood cells.[126,128] The AAP recommends administration of IVIG (0.5 to 1 g/kg over 2 hours) if the total serum bilirubin is rising despite intensive phototherapy or the total serum bilirubin level is within 2 to 3 mg/dl (34 to 51 μmol/L) of the exchange level (Fig. 30.8).

Adverse effects of phototherapy include increased insensible water loss, diarrhea, photosensitization, overheating, and hyperpigmentation. Because of the potential for retinal damage with phototherapy, protective eye devices must be used.[127]

Exchange Transfusion

Exchange transfusion is usually needed when phototherapy, IVIG, or both fail to adequately decrease bilirubin concentration



- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clincial circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommeded if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is ≥5mg/dl (85 μmol/L) above these lines.
- Risk factors - isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (See legend)
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

FIGURE 30.8. Guidelines for exchange transfusion in infants 35 weeks or more. B/A, bilirubin to albumin; G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin. (Reproduced with permission from American Academy of Pediatrics, Subcommittee on Hyperbilirubinemia, "Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation." Pediatrics 2004;114:297–316. Copyright ©2004 by the American Academy of Pediatrics.)

or the initial serum bilirubin concentration places the infant at high risk for developing kernicterus. Classical criteria for early exchange transfusion within 12 hours of birth are a cord bilirubin concentration exceeding 3 to 5 mg/dl for pre-term infants and 5 to 7 mg/dl for term infants or a rate of rise of 0.5 mg/dl/hour or greater.[125]

Treatment decisions after the first 24 hours for pre-term infants are guided by weight, bilirubin concentration, the rate of its increase (>0.5 mg/dl/hour), and the presence of comorbid factors such as hemolysis, asphyxia, significant lethargy, temperature instability, sepsis, or acidosis.

For infants at 35 weeks' or more gestation, exchange transfusion is recommended when the total serum bilirubin rises to threshold levels despite intensive phototherapy, based on the gestational age and the presence of risk factors (Fig. 30.8).[126] It is also a clinical option to use the bilirubin-to-albumin ratio together with, but not in lieu of, the total serum bilirubin level as an additional factor in determining the need for exchange transfusion.[126] Immediate exchange transfusion is recommended if infants show signs of acute bilirubin encephalopathy (e.g., hypertonia, arching, fever, high-pitched cry) or if total serum bilirubin is 25 mg/dl (428 μmol/L) or higher.[126]

If exchange transfusion is indicated, a transfusion volume approximately twice the infant's total blood volume (85 ml/kg × 2 for a term infant; 100 ml/kg × 2 for a pre-term infant) is administered incrementally while removing aliquots of the infant's blood over a period of 1 to 2 hours. The procedure either involves a push–pull method with a single vascular access or an isovolemic method that requires two catheters to allow for simultaneous withdrawal and infusion.[1,125] The umbilical artery is usually used for withdrawing blood, and the umbilical vein is usually used for infusion. The isovolemic method may be preferable because mean arterial pressure and cerebral blood volume may be more stable than during the single-catheter, push–pull method.[125] An exchange of approximately two blood volumes removes approximately 85% of red blood cells but only approximately 45% of plasma bilirubin because the latter re-equilibrates between intravascular and extravascular spaces. Consequently, infants with aggressive hemolytic disease may require more than one exchange transfusion before an acceptable bilirubin concentration is achieved.

Red blood cell units chosen for neonatal exchange transfusion should be O, Rh negative, or ABO/Rh type specific; should lack the blood group antigen implicated in hemolytic disease (e.g., ABO hemolytic disease requires the use of type O red blood cells); and should be compatible with maternal serum. Maternal serum or plasma is usually used in crossmatching red blood cells for infants because it contains the implicated antibody in high concentration and is available in large quantity. If a maternal sample is not available, the infant's plasma or serum can be used for compatibility testing; however, the concentration of circulating antibody may be low if most is bound to the infant's red blood cells. In this case, the bound antibody can be eluted from the surface of the infant's red blood cells, and the resulting eluate can be used for crossmatching. Rarely, HDN is due to an antibody to a high-incidence blood group antigen present in almost all persons, and no compatible units can be identified.[41] In this case, maternal blood can be collected and washed to remove incompatible plasma for the infant.

Any blood component collected from biologic relatives must be irradiated as a precaution against transfusion-associated graft-versus-host disease, as well as blood components transfused to infants who received intrauterine transfusion or who are otherwise immunocompromised due to premature birth or severe primary immune deficiency. Because of the difficulty in identifying all high-risk newborn infants, many transfusion services provide γ-irradiated blood for all infants until the age of 4, 6, or 12 months.[129] Another common standard of practice is the use of either leukocyte-reduced cellular components or units selected from CMV-seronegative donors to reduce the risk of CMV transmission to newborn infants.[129] Most blood banks also transfuse only units that lack hemoglobin S to infants to avoid the potential for hypoxia-induced sickling in a critically ill infant and fresh (<5 to 7 days old) or washed red blood cell units to avoid the risk of potassium-mediated cardiac toxicity with large transfusion volumes.[41,129] To prepare a two-blood volume exchange transfusion, red blood cells should be reconstituted with ABO-compatible

plasma to the desired total volume and hematocrit. Albumin infusion before or during exchange in an effort to enhance bilirubin removal is controversial.[125]

Severe reactions related to the neonatal exchange transfusion have been reported in about 5% to 10% of infants, and include citrate-related arrhythmias, bleeding caused by dilutional coagulopathy or thrombocytopenia, catheter-related infection, and bacterial sepsis.[126] The mortality rate among term infants within 6 hours of exchange transfusion was estimated as 3 to 4 per 1,000.[126] Adverse reactions during the transfusion are more often related to the infant's underlying disease rather than the transfusion. In a study involving 331 exchanges given to 190 infants, there was only one death within 6 hours of an exchange transfusion, an infant who was critically ill before the procedure.[130] Procedure-related reactions during exchange transfusion were noted in <10% of infants (22 of 328) and included transient mild bradycardia.[130] Other potential complications of neonatal exchange transfusion include hypervolemia and volume overload, cardiac toxicity due to citrate or hyperkalemia, air emboli or thrombosis in the umbilical vein, necrotizing enterocolitis, bleeding due to dilutional coagulopathy or thrombocytopenia, bacterial sepsis, or viral transmission, as previously described for fetal blood component transfusion.[1]

Transfusion for Late-onset Neonatal Anemia

Infants who respond to phototherapy alone or those who receive intrauterine transfusion may also require straight red blood cell transfusion between 2 and 10 weeks of life due to anemia developing as a result of low-grade hemolysis or erythropoietic suppression. Maternal antibody persists in the infant's circulation for approximately 6 weeks, and resultant hemolysis is usually associated with a marked reticulocytosis. In contrast, the late anemia associated with intrauterine transfusion is characterized by sustained suppression of erythropoiesis and decreased to absent reticulocytes and low erythropoietin concentrations.[131] Erythropoietic suppression also occurs with anti-K1 and anti-D, irrespective of intrauterine transfusion.[125,132] To counter this late hypoproliferative anemia, erythropoietin treatment resulted in increased reticulocyte count and hemoglobin concentration and avoided the need for transfusion in some infants with HDN.[131,132]

Infants with circulating red blood cell antibodies should be closely monitored for at least 8 to 10 weeks to identify the development of late anemia. Hemoglobin concentrations below 7 to 10 g/dl have been proposed as transfusion "triggers." In general, the decision to transfuse should be guided, most importantly, by the infant's condition, such as lethargy, poor feeding, or failure to thrive, rather than the hemoglobin concentration and reticulocyte count in isolation.

Adjunctive and Experimental Treatment

Whereas phototherapy and exchange transfusion effectively eliminate bilirubin in most infants with HDN, experimental strategies are aimed at preventing hyperbilirubinemia by blocking its production. Metalloporphyrins are heme analogs that block the rate-limiting enzyme, heme oxygenase, in the heme metabolic pathway. Tin (Sn)-mesoporphyrin (SnMP) was used to treat two infants with severe immune-mediated hyperbilirubinemia after their parents refused exchange transfusion because of their religious convictions as Jehovah's Witnesses.[133] In both cases, phototherapy failed to achieve adequate control, but SnMP effectively halted the progression of hyperbilirubinemia. Without such extenuating circumstances, however, the use of SnMP is not recommended.[125] Other agents investigated as means to decrease serum bilirubin include phenobarbital, clofibrate, cholestyramine, agar, and charcoal.[125] The clinical effectiveness and the potential toxicity of these various treatments require further study before they can be recommended for treatment of immune-mediated hemolytic disease.

CLINICAL OUTCOMES OF TREATMENT FOR HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

The survival rate among infants who required intrauterine transfusion varies with institution and experience, but infants without signs of hydrops have a relatively favorable prognosis. A survey of 16 institutions in the United States and Canada involving 1,087 intrauterine intravascular transfusions given to 389 fetuses revealed a survival rate of 90% for nonhydropic fetuses and 82% in cases of hydrops.[114] The degree of hydrops, and not merely its presence, is predictive of the outcome of alloimmunized pregnancies.[134] In 2001, Van Kamp et al. reported that 41 of 42 fetuses with mild hydrops (98%) survived, compared to only 21 of 55 fetuses with severe hydrops (55%).[134] Hydrops can be reversed in 60 to 70% of fetuses after intrauterine transfusion, and almost all fetuses with resolved hydrops survived, whereas persistent hydrops was more often associated with an unfavorable outcome.[134] The long-term neurodevelopmental outcome of infants successfully treated in utero with red blood cell transfusion compares favorably to other high-risk, very-low-birthweight infants.[135] The majority of surviving infants who received intrauterine transfusion demonstrate normal development and neurologic function; <10% exhibit mild to severe developmental delays or cerebral palsy (spastic tetraparesis or hemiplegia).[135–137a] The most recent and largest study of neurodevelopmental outcome of children treated with intrauterine transfusion for HDF to date is the LOTUS study, a national cohort study from Leiden University Medical Center, The Netherlands.[137b] The overall incidence of neurodevelopmental impairment was 4.8% (14 of 291 children), and the risk factors for neurodevelopmental impairment were the presence of fetal hydrops, the number of intrauterine transfusions, and severe neonatal morbidity.[137b]

Uncertainties persist regarding the degree and duration of hyperbilirubinemia that place an infant at risk for bilirubin encephalopathy and kernicterus. In the early 1950s before effective treatment was available, approximately one half of infants with bilirubin concentrations >30 mg/dl developed kernicterus. An overall decrease in the incidence of kernicterus has been observed, but evidence for the efficacy of current treatment for neonatal hyperbilirubinemia and the effect of high levels of bilirubin on behavioral and neurodevelopmental outcomes is limited.[125,138] Recently, a prospective blinded study compared 140 term and near-term infants with total serum bilirubin levels of 25 mg/dl (428 μmol/L) or more to 419 control subjects and found no significant differences between the two groups in neurodevelopmental outcomes.[139] However, the subgroup of infants with hyperbilirubinemia resulting from immune-mediated hemolytic disease had lower IQ scores than the control group. This study corroborates previous observations that hemolysis enhances the risk of bilirubin-induced central nervous system injury, and supports the rationale for more aggressive treatment of infants with hyperbilirubinemia associated with HDFN than other infants with physiologic jaundice.

CONCLUSION

Before discovery of RhIG, HDFN from anti-D was a significant cause of perinatal mortality or long-term disability. The incidence of D alloimmunization among D-negative women decreased from 14% to 1 to 2% with the widespread use of postpartum RhIG in the late 1960s, and further decreased to 0.1% with the use of

routine antenatal RhIG prophylaxis after 1979. Smaller family size in recent decades also contributed to the decline in the number of cases, but HDFN due to anti-D continues to occur at a low rate in the United States, which likely reflects inadvertent failure to administer RhIG prophylaxis, inadequate pre-natal care, or antenatal sensitization prior to RhIG administration at 28 weeks' gestation. Maternal alloimmunization to other red blood cell alloantigens in the Rhesus, Kell, or other blood groups currently cannot be routinely prevented and also cause HDFN. Advances in pre-natal care, noninvasive monitoring, and intrauterine transfusion have improved clinical outcomes to the extent that survival rates for nonhydropic fetuses with alloimmune hemolysis currently approach 90%, and those with hydrops fetalis can be effectively treated in most cases.

CHAPTER 31

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Charles J. Parker, Russell E. Ware

INTRODUCTION

Definition

Although usually classified as a hemolytic anemia, paroxysmal nocturnal hemoglobinuria (PNH) is a disease of the hematopoietic stem cell. PNH arises as a result of *nonmalignant* clonal expansion of one or *several* hematopoietic stem cells that have acquired a somatic mutation of *PIGA* (phosphatidylinositol glycan-class A). The *PIGA* gene is located on the X chromosome, and it encodes an enzyme that is an essential component of the complex biosynthetic pathway that generates glycosyl phosphatidylinositol (GPI). The GPI moiety serves as a membrane anchor for more than 20 proteins of diverse function that are normally expressed on hematopoietic cells. As a consequence of somatic mutation of *PIGA*, progeny of affected stem cells are deficient in all GPI-anchored proteins (GPI-APs). Among the GPI-APs normally expressed on hematopoietic cells are the complement regulatory proteins CD55 (decay accelerating factor [DAF]) and CD59 (membrane inhibitor of reactive lysis [MIRL]), and it is the deficiency of these two proteins that accounts for the complement-mediated intravascular hemolysis that is the primary clinical manifestation of the disease. In addition to complement-mediated intravascular hemolysis, an element of bone marrow failure is present in all patients, and PNH frequently arises in association with a defined bone marrow failure process, particularly aplastic anemia and, to a lesser extent, low-grade myelodysplastic syndrome (MDS). Thrombophilia is a major cause of morbidity and mortality in PNH.[1]

PNH is characterized, in the classic case, by macroscopic hemoglobinuria. When intravascular hemolysis occurs at night, while the patient is asleep, hemoglobin accumulates in the bladder, and the patient becomes alarmed the following morning by the startlingly abnormal appearance of the first voided urine. The hemoglobinuria is painless and ranges in color from red to brown to black. Typically the gross hemoglobinuria resolves during the course of the day. In most patients, however, the classic pattern is absent at diagnosis. In these patients, the disease is characterized by symptoms of lethargy, malaise, and asthenia, and by laboratory evidence of chronic, low-grade intravascular hemolysis that may or may not be punctuated by episodes of macroscopic hemoglobinuria, usually occurring in association with infection or unusual stress such as trauma or surgery. Thrombocytopenia, leukopenia, and thrombosis involving unusual sites are other notable clinical characteristics of PNH. As cited above, a close association exists between PNH and certain bone marrow failure syndromes, particularly aplastic anemia, but the basis of this association is incompletely understood.

The history of PNH has been chronicled.[2,3,4,5] Strübling published a remarkable paper on PNH in 1882, clearly recognizing the uniqueness of the disease and providing laboratory support for his prescient hypothesis on the etiology of nocturnal hemoglobinuria (positing that it was caused by the acidosis that resulted from carbon dioxide accumulation associated with sleep-related hypoventilation). Marchiafava and Nazari (1911) and Micheli (1931) subsequently detailed the clinical characteristics of the disease (in some older literature, PNH is called Marchiafava-Micheli syndrome). By 1953, at least 162 cases had been collected. Although the advent of flow cytometry has greatly improved diagnostic sensitivity and specificity, undoubtedly some cases go undiagnosed as the classical signs and symptoms are often absent initially. Even today there may be a significant time lapse between the onset of clinical symptoms and the correct diagnosis. Failure to distinguish hemoglobinuria (when present) from hematuria; the rarity of the disease, which limits familiarity with its protean clinical manifestation; and the absence of gross hemoglobinuria at presentation in many cases are the primary factors that account for the delay in diagnosis.

It can be argued that the term paroxysmal nocturnal hemoglobinuria is imprecise because it describes only one feature of the illness—a feature, moreover, that is found in only one-quarter of affected individuals at presentation. Nonetheless, the term has been established through long, popular use and consequently is part of the essence of the disease.

ETIOLOGY AND PATHOGENESIS

Sensitivity to Complement-mediated Lysis

The chronic intravascular hemolysis that is the clinical hallmark of PNH is due to the abnormal sensitivity of the erythrocytes to complement-mediated lysis. From 1937 to 1939, Ham and Dingle made the seminal observations that connected the hemolysis to complement.[5] Those studies demonstrated that the abnormal cells are hemolyzed when incubated in acidified serum and that the hemolysis is complement-dependent. The lysis of the defective cells in acidified serum (a process that activates the alternative pathway of complement) became the standard technique for the diagnosis of PNH; and appropriately, the assay was called Ham's test. Approximately 10 years after the studies of Ham and Dingle, cross-transfusion studies confirmed that hemolysis in PNH results from an intrinsic abnormality of the red cell. In those studies, Dacie reported that normal erythrocytes survive normally in patients with PNH, whereas the life span of PNH erythrocytes is shortened both in the patient and in a normal recipient. Not all PNH red cells are equally sensitive to complement-mediated lysis, however, and cohorts of relatively long-lived and very short-lived cells can be distinguished in red cell survival studies. Moreover, the proportions of complement-sensitive and complement-insensitive cells vary greatly among patients. Generally, the percentage of abnormal cells remains stable in an individual patient, although there are clearly exceptions. The percentage of markedly complement-sensitive cells correlates with the clinical course of each patient with respect to the hemolytic component of the disease and perhaps to thrombotic propensity.

A defining feature of PNH is *phenotypic mosaicism* based on sensitivity of the erythrocytes to complement-mediated lysis. This remarkable characteristic was first clearly elucidated by Rosse and Dacie in 1966,[6] and Rosse further refined the analysis in 1973.[7] Using an in vitro test that quantitates the sensitivity of erythrocytes to complement-mediated lysis (the complement lysis sensitivity assay), three phenotypes of PNH erythrocytes were identified (Table 31.1; Figs. 31.1 and 31.2). One of the phenotypes (designated PNH I) was characterized by normal or near-normal sensitivity to complement, whereas another phenotype (designated PNH III) was 15 to 25 times more susceptible to lysis. A third phenotype (PNH II) was of intermediate sensitivity, about 3 to 5 times more susceptible than normal cells. Most patients have a mixture of type I and type III cells, but mosaics of type I, type II, and type III, as well as type I and type II, are also observed.

As noted above, the proportion of complement-sensitive and -insensitive cells varies greatly among patients. For example, the

erythrocytes of one patient (hypothetical patient A) may be comprised of 10% PNH III cells and 90% PNH I cells, whereas another patient (hypothetical patient B) may have 75% PNH III cells and 25% PNH I cells. The intensity of the hemolytic component of the disease is related to the size of the PNH III population.[8] The proportions of sensitive and insensitive cells usually remain stable for long periods (years to decades); but population shifts may be observed during the course of the disease, and in some patients, the abnormal clone remits spontaneously.[9,10] The threshold for biochemical evidence of intravascular hemolysis is crossed when the population of GPI-deficient PMNs (as a measure of the PNH clone size) is 20% to 25% or greater.[11] Patients with a clone size of 20% to 25% usually have 3% to 5% PNH erythrocytes (the population of PNH III cells is smaller than the clone size because the complement-sensitive red cells are selectively destroyed intravascularly). As a rule, visible hemoglobinuria is absent when PNH III erythrocytes constitute less than 20% of the red cell population (corresponding to a PNH clone size of 40% to 60%).[8] Paroxysms of gross hemoglobinuria occur when the PNH III population ranges from 20% to 50% of the population (corresponding to a PNH clone size of 60% to 90%), and constant hemoglobinuria is associated with greater than 50% PNH III erythrocytes (PNH clone

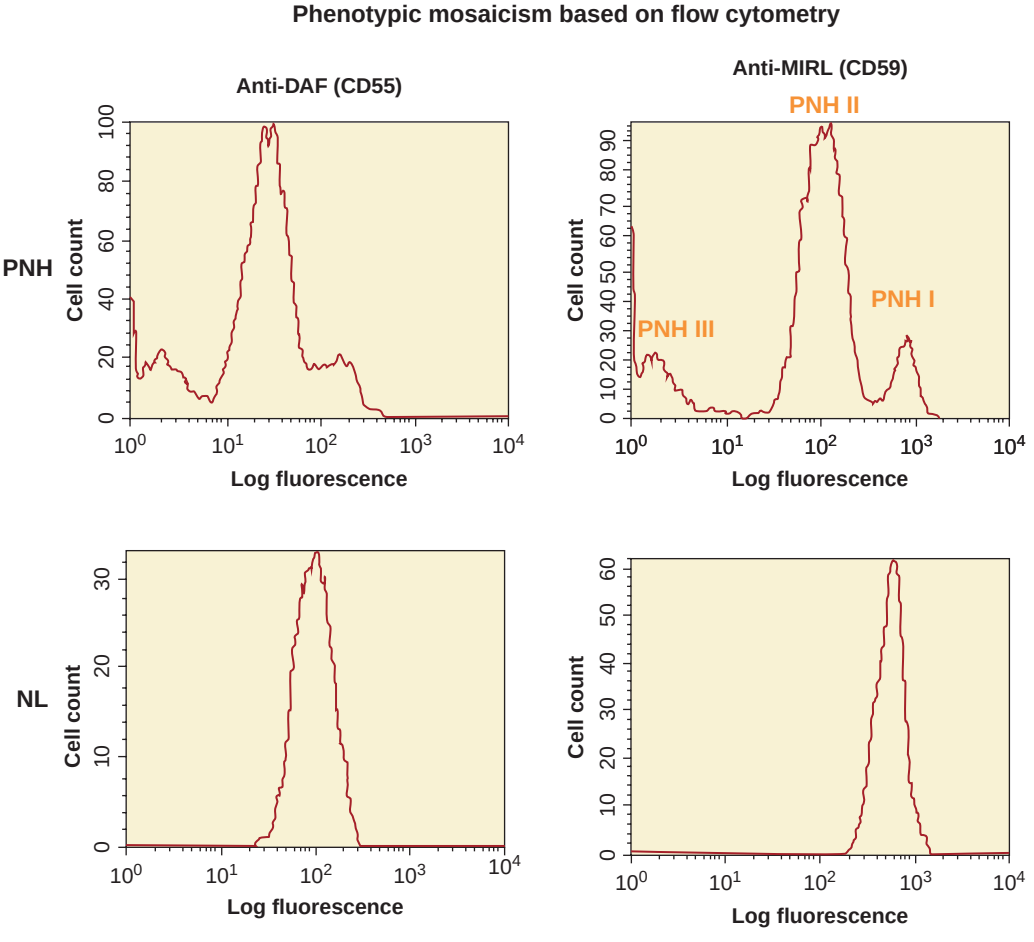

FIGURE 31.1. Phenotypic mosaicism in PNH. Erythrocytes from a patient with PNH and from a normal volunteer donor (NL) were analyzed by flow cytometry using anti-DAF (CD55) and anti-MIRL (CD59) as primary antibodies. The histogram of the erythrocytes from the normal donor shows uniformly positive staining with both antibodies. In contrast, the patient's histogram (PNH) suggests three discrete populations of cells (a negative population [called PNH III], a population with partial expression [called PNH II], and a population with normal expression [called PNH I]). Statistical analysis of the three groups of cells from the patient showed that the negative population contributed 14% to the total, the intermediate population contributed 75%, and the normal population contributed 11%. From Endo M, Ware RE, Vreeke TM, et al. Molecular basis of the heterogeneity of expression of glycosyl phosphatidylinositol-anchored proteins in paroxysmal nocturnal hemoglobinuria. Blood 1996;87:2546–2557.

size >90%). PNH II cells (the erythrocytes of intermediate sensitivity to complement), even when present in high proportions, are associated with no visible hemoglobinuria.

The proportion of abnormal cells is greater in the marrow than in the blood and, among circulating erythrocytes, is greatest in young cell populations (the percentage of GPI-deficient reticulocytes is similar to the percentage of GPI-deficient PMNs).

PNH is not an immune-mediated hemolytic anemia that arises as a consequence of the development of autoantibodies. Rather, the failure to regulate an alternative pathway of complement activation on the erythrocyte surface underlies the hemolysis of PNH (Fig. 31.3). Under physiologic conditions, the alternative pathway is in a state of continuous, low-grade activation. Normal erythrocytes are not hemolyzed as a result of this low-grade alternative pathway activation because specific cell-surface proteins have evolved that inhibit the activity of complement (Fig. 31.3). In contrast, PNH erythrocytes are deficient in the two most important membrane regulators of complement (CD55 and CD59), and consequently, they are subject to chronic, spontaneous hemolysis in vivo (Fig. 31.3). Failure to inhibit alternative pathway activation has a profound effect on red cell survival, as studies have shown that the half-life of complement-sensitive PNH cells is approximately 6 days (compared to 60 days for normal erythrocytes).

Rosse and colleagues reported the first clear evidence of the nature of the aberrant interactions of PNH erythrocytes with complement in 1973 and 1974.[12,13] Those investigators showed that when complement is activated in vitro by either the classical or the alternative pathway, PNH erythrocytes bind much greater amounts of activated C3 than normal erythrocytes. The difference in C3 deposition was particularly striking when acidified serum was used to activate the alternative pathway. Subsequent studies showed that PNH red cells lacked the capacity to regulate the formation and stability of the amplification C3 convertases of complement,[14,15] thus accounting for the greater binding of activated C3. A second defect was suggested by experiments demonstrating that PNH erythrocytes also failed to regulate the activity of the cytolytic membrane attack complex of complement.[16,17] Collectively these observations indicated that PNH erythrocytes had two complement regulatory defects, one that affected regulation of the C3 convertases and a second that affected regulation of the membrane attack complex (Fig. 31.3).

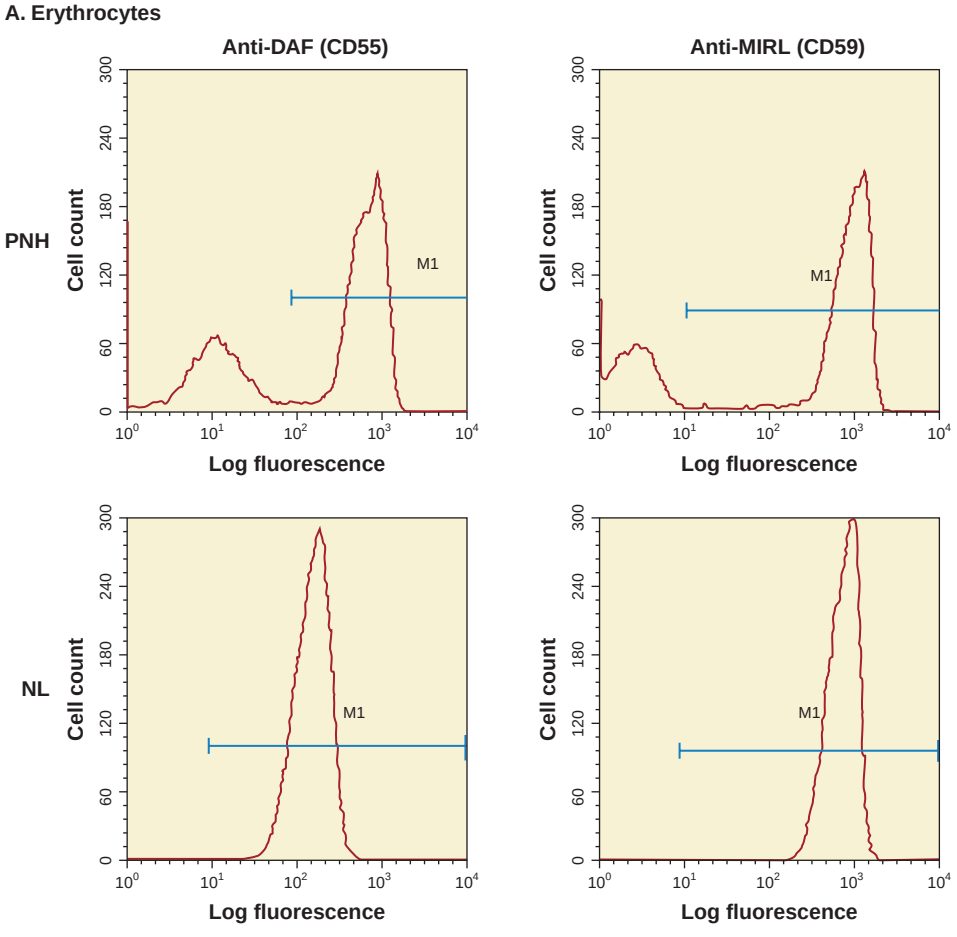

FIGURE 31.2. Analysis of glycosyl phosphatidylinositol-anchored proteins (GPI-AP) on erythrocytes (A) and granulocytes (B) from a patient with PNH. Erythrocytes and isolated granulocytes from a patient with PNH and from a normal volunteer donor (NL) were analyzed by flow cytometry using anti-DAF (CD55), anti-MIRL (CD59), or anti-FcγRIIIb (CD16b) (granulocytes only) as primary antibodies. The histograms of the cells from the normal donor show uniformly positive staining with both antibodies. In contrast, the patient's histograms (PNH) demonstrate two discrete populations of cells. In the case of the erythrocytes **(A)**, 30% of the cells are negative for DAF and MIRL expression, and 70% show normal expression. In the case of the granulocytes **(B)**, 65% are negative for DAF and MIRL expression. The same population of cells shows abnormal expression of FcγRIIIb, but the deficiency is partial rather than absolute. Together, these results demonstrate three characteristic features of PNH: (1) The hematopoietic cells are a mosaic of normal and GPI-AP–deficient cells; (2) the proportion of abnormal granulocytes is greater than the proportion of abnormal erythrocytes; (3) the deficiency of FcγRIIIb is partial rather than absolute.

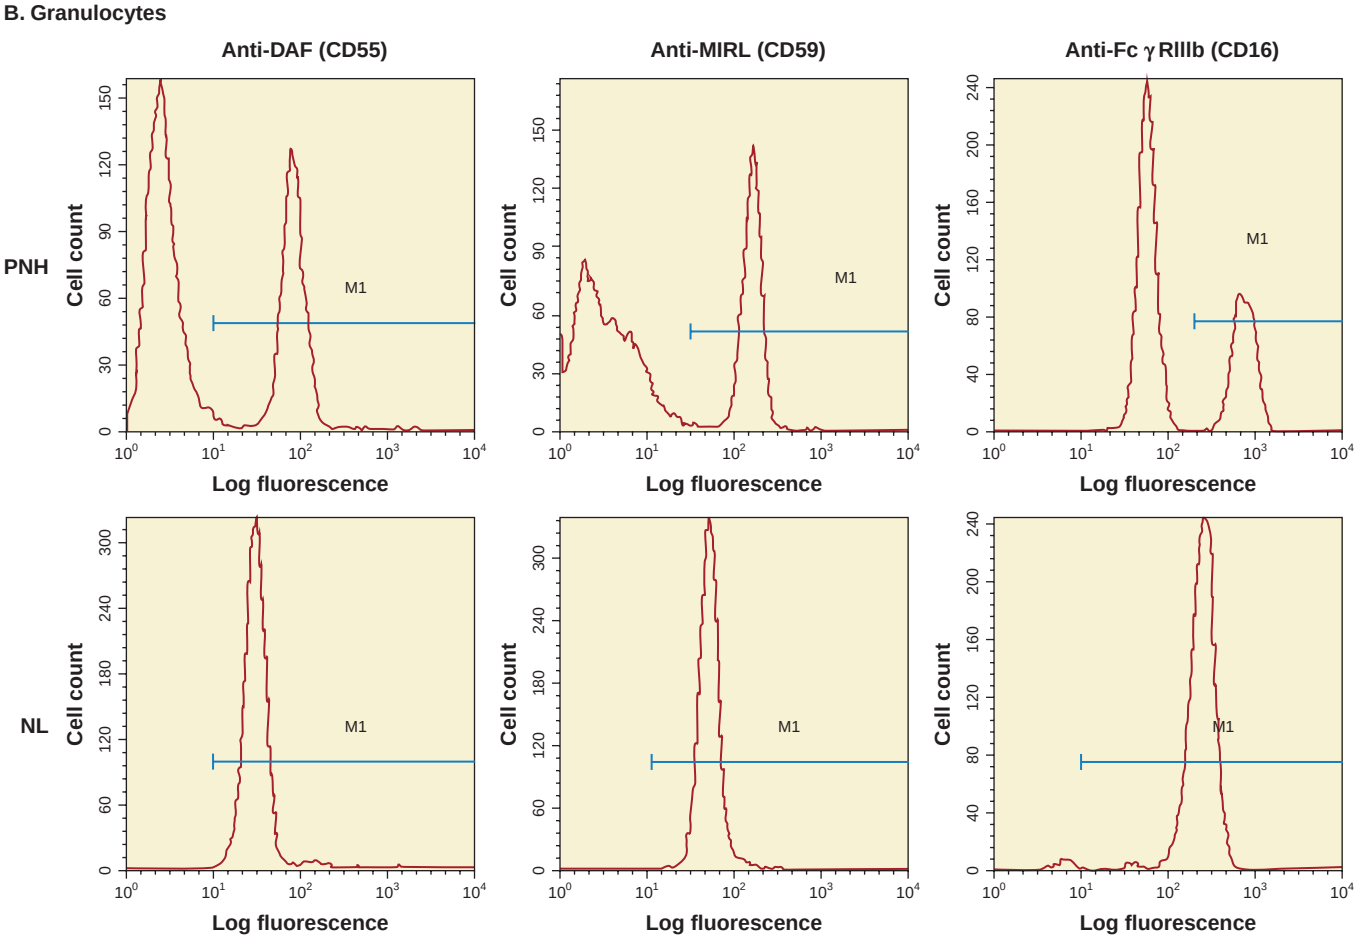

FIGURE 31.2. (continued)

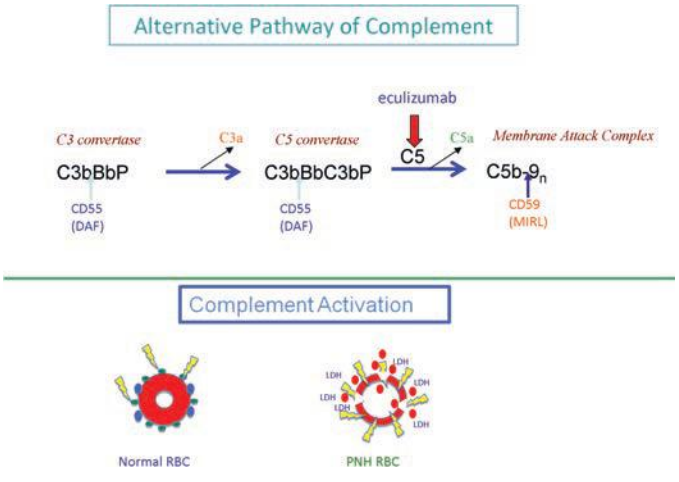

FIGURE 31.3. Complement-mediated lysis of PNH erythrocytes. *Upper panel:* The hemolytic anemia of PNH is Coombs-negative because the process is mediated by the antibody-independent alternative pathway of complement. The GPI-anchored complement regulatory protein CD55 (DAF) restricts formation of both the C3 and the C5 amplification convertases, whereas CD59 (MIRL) blocks formation of the cytolytic membrane attack complex (C5b-9). Inhibition of formation of the cytolytic membrane attack complex of complement (C5b-9) by the humanized monoclonal anti-C5 antibody eculizumab ameliorates the hemolytic anemia in patients with PNH. *Lower panel:* Normal erythrocytes are protected against complement-mediated lysis (lightning bolts) primarily by CD55 (blue filled circles) and CD59 (green filled circles). Deficiency of these GPI-anchored complement regulatory proteins results in complement activation on PNH erythrocytes. The membrane attack complex forms a pore in the red cell membrane resulting in colloid osmotic lysis and release of red cell contents including hemoglobin and LDH into the intravascular space.

Erythrocyte Membrane Protein Deficiencies

Acetylcholinesterase

While Beck and Valentine reported in 1951 that neutrophils from patients with PNH were deficient in leukocyte alkaline phosphatase,[18] the first *erythrocyte* membrane protein that was found to be deficient in PNH was acetylcholinesterase.[19] In 1959, Auditore and Hartmann[19] presented evidence that the extent of the acetylcholinesterase deficiency correlated with the severity of the hemolysis. More detailed studies by others[20] showed that PNH I red cells had a relatively normal amount of acetylcholinesterase, while PNH III erythrocytes were profoundly deficient. Although the deficiency of acetylcholinesterase plays no role in the abnormal susceptibility of PNH red cells to complement-mediated lysis, ultimately the observations that the red cells lack acetylcholinesterase and that the neutrophils lack alkaline phosphatase provided important insights into the fundamental defect that underlies PNH.

Decay Accelerating Factor (CD55)

In 1983, two groups reported that PNH erythrocytes were deficient in DAF (CD55).[21,22] DAF, first identified by Hoffman[23,24] in 1969 and subsequently purified by Nicholson-Weller and colleagues in 1982,[25] is a 70 kD protein that inhibits the formation and stability of the C3 convertases of complement (Fig. 31.3). Thus, the absence of DAF provided a plausible explanation for the greater binding of activated C3 to PNH erythrocytes. Detailed studies, however,

demonstrated that DAF does not regulate the activity of the membrane attack complex of complement. Those results implied that PNH erythrocytes were deficient in a second complement regulatory protein that was functionally distinct from DAF.

Membrane Inhibitor of Reactive Lysis (CD59)

In 1989, Holguin et al.[26] reported the isolation from normal erythrocytes of an 18 kD protein called MIRL (CD59) that protected PNH III red cells against complement-mediated lysis (Fig. 31.3). As anticipated, PNH cells were found to be deficient in MIRL, and additional studies by those investigators and others demonstrated that MIRL inhibits complement-mediated lysis by blocking the assembly of the membrane attack complex[26,27,28,29] (Fig. 31.3).

By comparing expression of DAF and MIRL on PNH I, PNH II, and PNH III erythrocytes, the functional basis of the different complement sensitivity phenotypes was determined.[30] Those studies showed that PNH III cells are completely deficient in both DAF and MIRL, whereas PNH II cells are partially deficient in the two complement regulatory proteins, and PNH I cells have normal expression. Thus, the variability in sensitivity to lysis among the different phenotypes is explained by quantitative differences in expression of DAF and MIRL. Additional experiments demonstrated that the combined deficiency of DAF and MIRL was sufficient to explain the enhanced susceptibility of PNH erythrocytes to hemolysis in acidified serum.[31]

Of the two complement regulatory proteins, MIRL is more important than DAF in protecting cells from complement-mediated lysis in vivo. Antigens of the Cromer-related blood group complex are located on DAF, and rare cases of a null phenotype called Inab have been reported.[32] Like PNH cells, Inab erythrocytes are deficient in DAF, but unlike PNH erythrocytes, MIRL expression is normal on Inab red cells.[33] Although Inab erythrocytes bind more activated C3 when exposed to acidified serum,[33] they undergo little or no hemolysis. Further, subjects with the Inab phenotype have no known hematologic abnormalities, and in particular, they have no clinical evidence of hemolysis.[28,32] These observations show that isolated deficiency of DAF does not produce the PNH syndrome. In contrast, a patient with an inherited, isolated deficiency of MIRL (CD59) had a syndrome that was indistinguishable from PNH.[34,35] Clinically, the patient experienced recurrent episodes of hemoglobinuria, suggesting that MIRL is essential for protecting erythrocytes against complement-mediated lysis in vivo. Recurrent thromboembolic events were also observed in this patient. That patient had normal DAF expression, but in vitro, his cells were susceptible to hemolysis in acidified serum, implying that MIRL deficiency accounts primarily for the positive Ham's test in PNH.[31] While the above studies provide interesting insights into the individual function of DAF and MIRL in vivo, it is important to remember that in PNH, both proteins are deficient (because both are GPI-anchored). Therefore, it is the *combined deficiency of DAF and MIRL that results in the markedly abnormal susceptibility of the red cells of PNH to complement-mediated lysis*.

Basis of the Protein Deficiencies in Paroxysmal Nocturnal Hemoglobinuria

If only DAF or only MIRL were deficient in PNH, it would have been logic to hypothesize that the disease was due to mutations affecting the gene that encodes the particular protein. That PNH cells were deficient in multiple proteins (MIRL, DAF, and acetylcholinesterase on red cells and leukocyte alkaline phosphatase on neutrophils), however, eliminated the possibility that the gene for each protein was mutant. Rather, a more plausible hypothesis was that the PNH defect involved a post-translational modification common to all of the proteins that are deficient in PNH. In 1984, Medof and colleagues[36] reported that isolated DAF spontaneously reincorporated into erythrocyte membranes. This property of DAF had actually been appreciated by Hoffman in 1969.[23,24] Working with the butanol-saturated aqueous phase of a crude extract prepared from normal human erythrocyte stroma, he showed that the sample contained a factor capable of inhibiting complement-mediated lysis by accelerating the decay of the C3 convertase. He further showed that this substance (that he called decay accelerating factor of stroma [DAF-S]) had the capacity to reincorporate into red cells and remain functionally active. In 1980, Low and Zilversmit[37] demonstrated that alkaline phosphatase that had been solubilized from cells by butanol extraction exhibited the capacity to bind to phospholipid vesicles. In this case, the incorporation was thought to be due to the attachment of a phosphatidylinositol moiety to the enzyme. Subsequent experiments demonstrated that isolated acetylcholinesterase also spontaneously reincorporated into cell membranes. Previous studies had shown that alkaline phosphatase, acetylcholinesterase, and 5′-ectonucleotidase (another protein that is deficient in PNH) were released from the cell surface by treatment with phosphatidylinositol-specific phospholipase C (PIPLC). The cumulative work of a number of investigators showed that both the capacity to reincorporate into membranes and susceptibility to cleavage by PIPLC was characteristic of a group of amphipathic membrane proteins that shared the common structural feature of being anchored to the cell surface through a GPI moiety. The structural link between DAF and acetylcholinesterase, alkaline phosphatase, and 5′-ectonucleotidase was made in 1986 by Davitz et al.[38] and Medof et al.,[39] when those investigators presented evidence that DAF is a GPI-anchored protein. Subsequent studies confirmed that MIRL is also a GPI-anchored protein.[40] The results of those studies suggested the following paradigm: *all proteins that are deficient in PNH are GPI-anchored, and all GPI-anchored proteins that are expressed by hematopoietic cells are deficient in PNH*. All data to date are consistent with this postulate.

GPI-anchored proteins are functionally diverse. In addition to the complement regulatory proteins (DAF [CD55] and MIRL [CD59]) and enzymes (acetylcholinesterase, alkaline phosphatase, and 5′-ectonucleotidase [CD73]) discussed above, proteins with a variety of receptor, adhesion, and immune modulatory functions (e.g., FcγRIIIb [CD16b], urokinase receptor [CD87], endotoxin-binding protein receptor [CD14], and LFA-3 [CD58]) are also GPI-anchored. Further, a number of proteins whose function is unknown are GPI-anchored. Over 80 eukaryotic proteins have been shown to be GPI-anchored and approximately 30 of these are found in humans. Currently the list of proteins deficient in PNH numbers at least 23 (Table 31.2). This number is less than the total number of GPI-anchored human proteins because PNH is an acquired disease that affects only hematopoietic cells. Thus, GPI-anchored proteins that are present on somatic tissues other than hematopoietic cells are expressed normally in patients with PNH. Despite the fact that PNH cells lack a number of functionally diverse membrane constituents, the only pathologic component of the disease that is unequivocally causally related to GPI-anchored protein deficiency is the abnormal susceptibility of the erythrocytes to complement-mediated lysis.

Molecular Basis of Paroxysmal Nocturnal Hemoglobinuria

The observation that, based on sensitivity to complement, the peripheral blood of PNH patients is a mosaic comprised of both normal and abnormal cells suggested that the abnormal cells were the progeny of a mutant clone and that they coexisted with the progeny of residual normal stem cells. Further, that PNH is an acquired rather than an inherited disease implied that the abnormal clone arises as a consequence of a somatic mutation. In 1970, Oni et al.[41] analyzed G6PD isoforms in both the complement-sensitive and the complement-insensitive erythrocytes of a female PNH patient who was heterozygous at the G6PD locus.

[a]Deficient on resting platelets, but putative transmembrane form expressed on activated platelets.

The complement-insensitive cells expressed both G6PD isoforms, indicating a polyclonal origin for this cohort. In contrast, the complement-sensitive cells expressed only one isoform, a finding consistent with monoclonality. These studies provided the first experimental evidence in support of the clonal hypothesis of PNH. In 1969, Aster and Enright[42] reported that a portion of both the platelet and granulocyte populations from patients with PNH was abnormally sensitive to complement-mediated cytolysis. This publication represented another watershed event in the understanding of the origins of PNH, because it indicated that the mutation arose in a primitive hematopoietic stem cell that has the capacity to differentiate along myeloid lines. Subsequent studies showed that monocytes are also affected, and, in most patients, affected lymphocytes were demonstrated. Together with the observation that all proteins that are deficient in PNH are GPI-anchored, these studies suggested that PNH arises as a result of a somatic mutation affecting a pluripotent hematopoietic stem cell and that the gene that is mutant is essential for the normal biosynthesis of the GPI anchor.

The GPI anchor is a complex structure with at least 25 proteins being essential for assembly of the moiety.[43,44] Hypothetically, the PNH phenotype would result if any of these proteins were nonfunctional, because if the GPI anchor is not synthesized, GPI-anchored proteins are not expressed. Accordingly, it seemed probable that PNH would be found to be heterogeneous at the molecular level as mutations affecting any one of several genes that encode elements critical for GPI anchor assembly would produce the disease phenotype. In 1992[45] and 1993,[46] however, two groups published the surprising finding that GPI-protein deficient lymphocyte cell lines derived from different patients with PNH all belonged to the same complementation class (Class A) of GPI-AP–deficient cell lines. Additional experiments confirmed that the PNH cell lines had the same biochemical defect as the complementation Class A mutants. Like the Class A mutants, the PNH cell lines failed to synthesize N-acetylglucosaminyl-phosphatidylinositol (GlcNAc-PI), the first intermediate in the pathway of GPI anchor assembly (Fig. 31.4).

A gene that restores normal expression of GPI-anchored proteins in the complementation Class A PNH cell lines was identified by Kinoshita and colleagues in 1993.[47,48] As predicted by the studies cited above, the gene, called *PIGA*, encodes a protein that is essential for the normal synthesis of GlcNAc-PI.[47] Subsequently, Takeda et al.[48] showed that *PIGA* complements the deficient expression of GPI-anchored proteins in PNH lymphoblastoid cell lines and that those cell lines harbored somatic mutations in *PIGA*. Together, those studies defined both the biochemical and the molecular basis of the deficiency of GPI-anchored proteins in PNH (Fig. 31.4).

Additionally, Takeda and colleagues observed that a heterozygous mutation was sufficient to produce the PNH phenotype.[48] As presaged by the studies of Hyman et al.,[49] the dominant expression of the somatic mutation was explained when *PIGA* was mapped to chromosome Xp22.1. As males have a single X chromosome, any functionally significant mutation affecting *PIGA* is expressed. Females are functionally haploid due to X-inactivation. Therefore, somatic mutations in *PIGA* appear dominant when they occur on the active X chromosome. To date, somatic mutations affecting *PIGA* account for the PNH phenotype in all patients in whom the genetic basis has been identified. *PIGA* mutations have not been identified in all patients studied, but this apparent discrepancy is likely a technical artifact rather than a true difference in etiology. The chromosomal location of *PIGA* provides the most logical explanation for the uniformity of the molecular defect in PNH. This interpretation supposes that all other genes that are essential for synthesis of the GPI moiety are autosomal, a supposition supported by available data.

Analysis of *PIGA* has revealed that the same mutation can be identified in isolated neutrophils, monocytes, and lymphocytes from individual patients with PNH, confirming that the disease involves the hematopoietic stem cell.[48,50] More than 150 *PIGA* mutations have been identified in affected cells of patients with PNH. Only three large deletions have been observed[51,52] (Fig. 31.5). The remaining mutations consist of nucleotide substitutions of the missense or nonsense types, or small deletions or insertions that cause frameshifts and introduce premature termination codons (Fig. 31.5). The mutations are distributed randomly over the entire coding region and at splice junctions (Fig. 31.5). At least 19 mutations have been observed in more than one patient. Absence of repetitive mutations indicates that *PIGA* lacks molecular hot spots. The simplest explanation for these observations is that clonal selection and expansion depends on complete or nearly complete inactivation of PIGA such that expression of GPI-AP proteins is below a critical threshold. *Therefore all PIGA mutations in PNH are loss-of-function mutations.*

Studies of *PIGA* mutations have also provided insights into the molecular basis of the phenotypic mosaicism of PNH.[50] Cloned lymphocyte cell lines were established from the peripheral blood of a patient whose erythrocytes were a mixture of PNH I, PNH II, and PNH III cells (Fig. 31.1). Based on expression of GPI-anchored proteins, lymphocyte clones with four different phenotypes were observed. Analysis of clones with normal expression of GPI-AP revealed no somatic *PIGA* mutations. In contrast, among the three phenotypically distinct lymphocyte clones with abnormal GPI-AP expression, four discrete *PIGA* mutations were identified. In the lymphocyte clones with the PNH II phenotype, a missense mutation that changed a highly conserved amino acid was found. This finding suggests that cells with partial expression of GPI-anchored proteins (PNH II) are derived from stem cells with mutations that

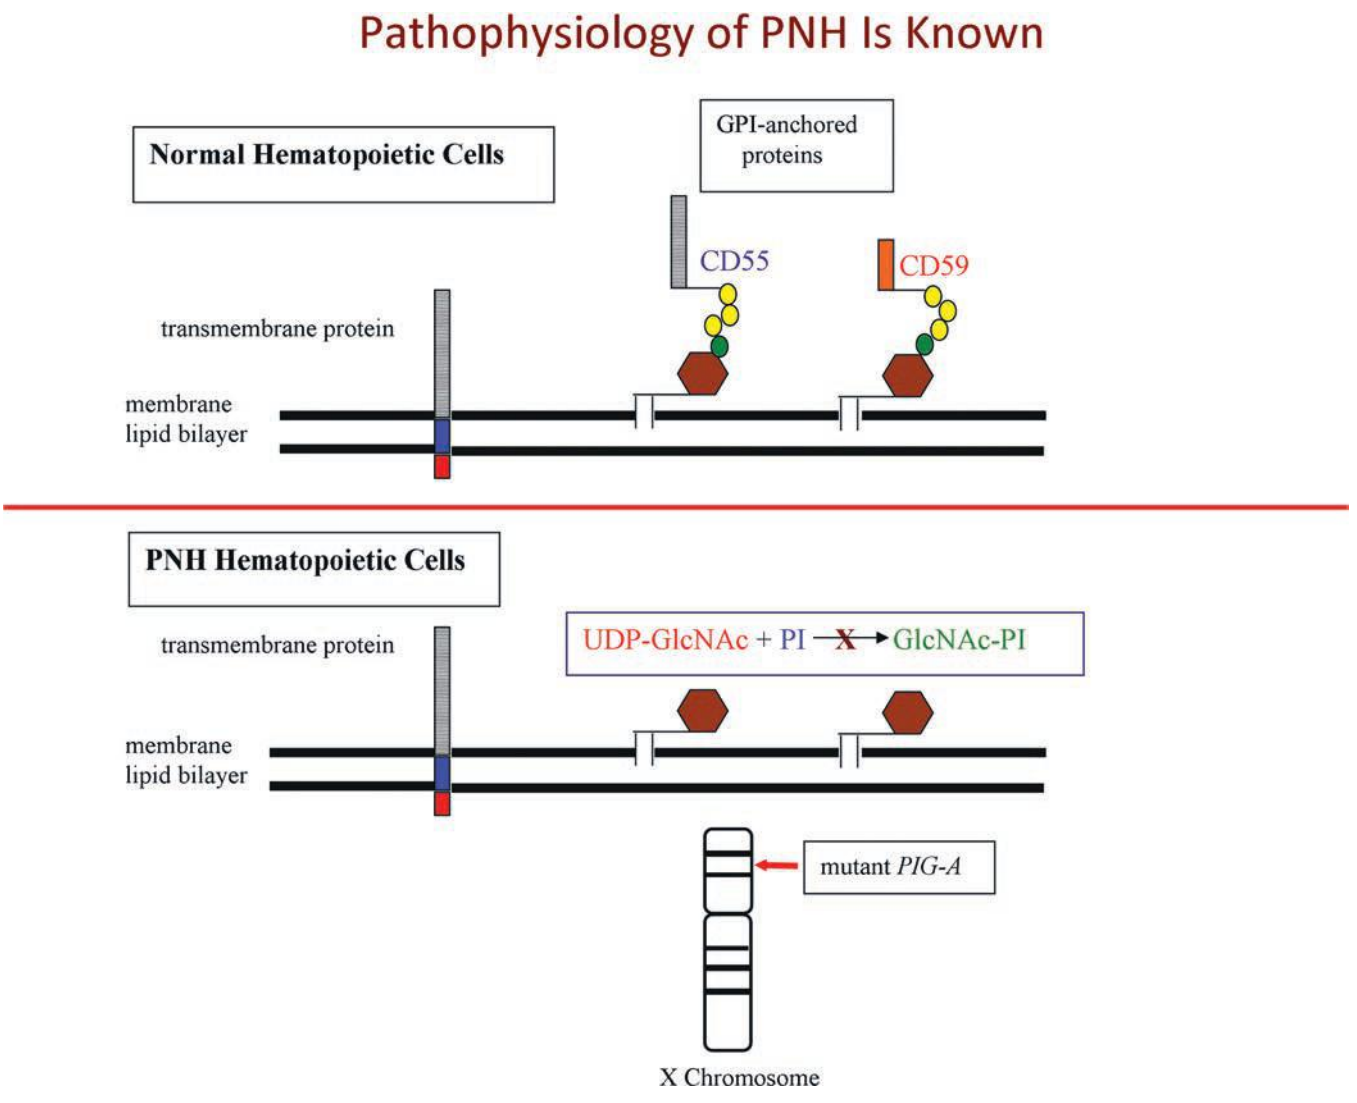

FIGURE 31.4. The PNH defect. Transmembrane proteins have three domains: an ectoplasmic domain (*rectangle with horizontal lines*), a transmembrane domain (*blue rectangle*), and a cytoplasmic domain (*red rectangle*). In contrast, glycosyl phosphatidylinositol (GPI)-anchored proteins lack the cytoplasmic and transmembrane domains. This class of proteins is anchored to the cell by a GPI moiety consisting of phosphatidylinositol (*brown hexagon*), glucosamine (*green circle*), and three mannose (*yellow circles*) residues. The GPI moiety is linked to the COOH-terminus of the protein portion of the molecule by ethanolamine. The *PIGA* gene product is essential for the transfer of the nucleotide sugar uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc) to phosphatidylinositol (PI) to form GlcNAc-PI, the first intermediate in the synthesis of the GPI anchor. PIGA is located on the short arm of the X chromosome. Hematopoietic cells in PNH are deficient in all proteins that are GPI-anchored because a somatic mutation in a hematopoietic stem cell partially or completely inactivates the PIGA gene product. Consequently, the GPI moiety is not synthesized.

incompletely inactivate PIGA. In the case of the lymphocyte clones with the PNH III phenotype, three separate mutations were identified, each of which was expected to inactivate completely the *PIGA* gene product. Collectively, these experiments demonstrate that the phenotypic mosaicism that is characteristic of PNH is a consequence of genotypic mosaicism. Further, because any mutation that completely inactivates PIGA results in PNH III cells, phenotypically identical cells can have different *PIGA* genotypes (Fig. 31.6).

Studies of the pattern of X chromosomal inactivation indicated that, in the female patient with four different *PIGA* mutations, the abnormal clones were not derived from a common ancestor.[50] Further, that each of the mutations was discrete demonstrated that the mutational events occurred independently rather than by clonal evolution. These results demonstrate that PNH is not strictly a monoclonal process and that they have important implications for the origins of the disease.

Studies of mutational frequency in PNH have produced conflicting results. Some of the disparity is almost certainly due to differences in experimental design and interpretation of data. While an abnormally high mutational rate may contribute to generation of multiple *PIGA*-mutant clones, a selective advantage for GPI-AP–deficient stem cells and variable extent of expansion of the mutant clones appears to be necessary to explain the outgrowth of multiple PNH clones, some of which dominate hematopoiesis and some of which persist subclinically.

The Pathophysiology of Paroxysmal Nocturnal Hemoglobinuria Is Unique

Despite the progress that has been made in determining the basis of the abnormal sensitivity of the erythrocytes to complement-mediated lysis and the global absence of GPI-anchored proteins (GPI-AP) from hematopoietic cells, an issue that is fundamental to a more complete understanding of PNH remains largely enigmatic. In order for PNH to become clinically evident, the hematopoietic

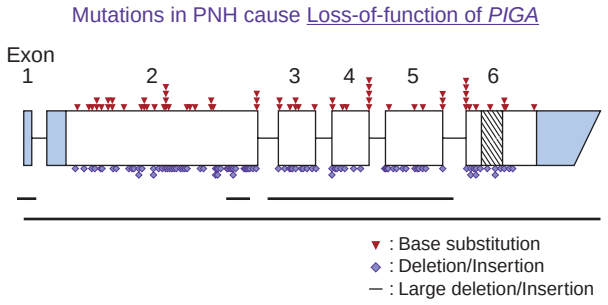

FIGURE 31.5. Diagram of the human *PIGA* gene and the locations of somatic mutations reported in patients with PNH. The boxes represent exons within the *PIGA* gene, and the blackened areas denote noncoding regions. Lines connecting the exons represent introns. The hatched region within exon six indicates the putative *PIGA* transmembrane domain. Single nucleotide substitutions are indicated above the gene as inverted triangles, while small nucleotide deletions and insertions are identified beneath the gene by diamonds. Large DNA deletions and insertions are denoted by horizontal lines below the gene. (From Nishimura J, Murakami Y, Kinoshita T. Paroxysmal nocturnal hemoglobinuria: an acquired genetic disease. Am J Hematol 1999;62:175–182, with permission of Wiley-Liss.)

stem cells bearing the mutant *PIGA* must expand so that progeny sufficient to produce symptoms and signs of the disease are generated. In many instances, GPI-AP–deficient (GPI-AP$^-$) cells dominate hematopoiesis in patients with PNH, suggesting that the mutant stem cell has either a greater proliferative capacity or a survival advantage relative to GPI-AP sufficient (GPI-AP$^+$) stem cells. That *PIGA* mutations are necessary for the development of PNH is incontrovertible. At issue is whether *PIGA* mutations are both necessary *and sufficient* to account for the PNH syndrome and whether the *PIGA* mutation provides an absolute or a conditional growth/survival advantage.

PNH differs from monoclonal hematopoietic stem cell disorders such as chronic myelogenous leukemia in which the t(9;21) that generates the fusion protein BCR–ABL is sufficient to account for the proliferative advantage of the mutant cell, and in which all normal hematopoiesis is progressively and invariably displaced as a consequence of the uncontrolled proliferation of a transformed clone. In PNH, the peripheral blood is a mosaic of normal and abnormal cells and the proportion of GPI-AP$^-$:GPI-AP$^+$ cells varies greatly among patients; that ratio tends to remain fixed over long periods of observations. PNH is, therefore, more aptly characterized as having deregulated cellular proliferation and expansion, rather than cellular transformation.

The oligoclonal nature of PNH[50] suggests that a powerful selection process that is most likely based on phenotype is at work in the bone marrow. According to this hypothesis, stem cells with mutant *PIGA* have an advantage because of some pathological process (perhaps immune-mediated) that involves a GPI-AP. For example, an autoimmune process could arise in which the target antigen is a GPI-AP expressed on hematopoietic stem cells. Under those circumstances, *PIGA*-mutant stem cells (lacking GPI-AP) would escape immune-mediated destruction because the target antigen is absent.

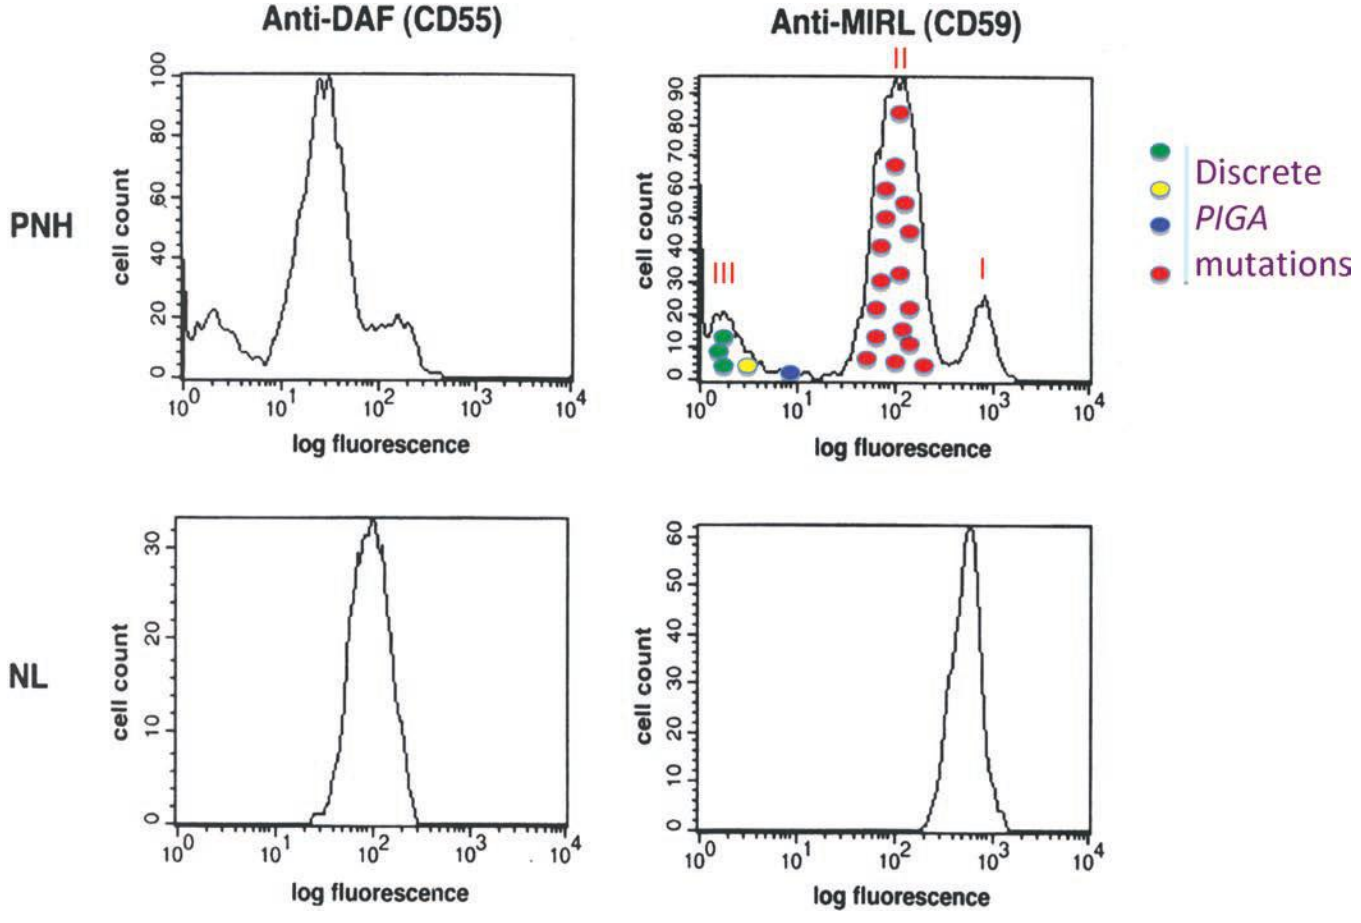

FIGURE 31.6. *PIGA* genotype determines PNH phenotype. A flow cytometry histogram modeled after that of a patient with PNH (Fig. 31.1) is shown. In this case, approximately 75% of the patient's hematopoiesis was derived from a clone (red filled circles) with a *PIGA* missense mutation that produced the PNH II phenotype. Three discrete *PI-A* mutations that produced a null phenotype were found among the PNH III cells (green, yellow, and blue filled circles). These three clones together contributed 11% of the patient's hematopoiesis. In this case, the PNH II clone has expanded much more than any of the PNH III clones.

Hematopoietic cells express a relatively large number of functionally diverse GPI-AP (Table 31.2). Thus, absence of all GPI-AP is probably not required for the clonal selection of the mutant stem cells. Rather, the selective advantage may be dependent on the absence of a single protein that is GPI-anchored, and the reason for the global deficiency of GPI-AP is that *PIGA* is located on the X chromosome. According to this supposition, an autosomal gene encodes the GPI-AP that is conditionally detrimental (e.g., an antigen targeted for immune destruction or a receptor for a negative growth regulator). Inasmuch as two alleles rather than one must be mutated, the probability of inactivating an autosomal gene through somatic mutagenesis is remote compared with the probability of inactivating an X-linked gene. Therefore, stem cells with a deficiency of the detrimental GPI-AP are most likely to arise as a consequence of *PIGA* mutations, as is the case in patients with CLL treated with Campath1H (anti-CD52).[53] Assuming that the GPI-AP complement regulatory proteins are not the targets of the underlying pathologic process, the hemolytic anemia that is the clinical hallmark of PNH may represent an epiphenomenon related to the chromosomal location of *PIGA*.

Although a compelling case can be made in support of the paradigm that the *PIGA* mutation bestows a conditional growth advantage upon the affected stem cell, the hypothesis that the mutant stem cells have an absolute growth or survival advantage must also be considered. Data that both support and challenge this hypothesis can be found.[54,55,56] The most compelling argument against an intrinsic growth or survival advantage for *PIGA*-mutant cells is made by the results of studies using transgenic mice.[57] By using homologous recombination, Kawagoe et al.[58] disrupted *Piga* (the murine homologue of *PIGA*). Only mice with a low degree of chimerism survived. Among those animals, the percentage of GPI-AP$^-$ erythrocytes ranged from ~1% to 5%. During 10 months of observation, the ratio of GPI-AP$^-$:GPI-AP$^+$ peripheral blood cells did not increase. Studies by others using conditional knockout technology have confirmed these observations.[57]

What Is the Origin of the PIGA-Mutant Stem Cells?

Patients with PNH often have more than one *PIGA*-mutant clone.[50,59] A tenet of the Darwinian selection hypothesis as it applies to PNH is that *PIGA*-mutant hematopoietic stem cells are present during the time when the selection pressure is applied to the bone marrow. *PIGA*-mutant hematopoietic elements have been identified in the peripheral blood and bone marrow of normal volunteers, providing experimental support for this concept, although whether the GPI-AP–deficient cells identified in normal individuals originate from hematopoietic stem cells with mutant *PIGA* has been questioned.[60] While there is experimental data that suggest that the mutational frequency of the gene is abnormally high,[60] the fact that *PIGA* is located on the X chromosome (so that only one allele need be mutated for the phenotype to become apparent) likely accounts primarily for the existence of multiple discrete clones in many patients with PNH.

A Two-Step Model of Paroxysmal Nocturnal Hemoglobinuria Pathogenesis

Studies by Inoue and colleagues suggest that a two-step mechanism may account for the unique pathophysiology of PNH.[61] Those investigators identified two patients whose *PIGA*-mutant cells had a concurrent, acquired rearrangement of chromosome 12. Detailed analysis showed that in both cases, the chromosome 12 rearrangement resulted in disruption of the 3′ untranslated region of *HMGA2*. As a consequence, a negative regulatory region of the locus was disrupted, resulting in ectopic expression of the gene. *HMGA2* is a member of the high mobility group of proteins (*HMGA1a*, *HMGA1b*, *HMGA2*) that function as architectural transcription factors. HMG members possess no intrinsic transcriptional activity. Instead, these nonhistone phosphoproteins orchestrate assembly of stereospecific transcriptional regulatory proteins into enhanceosomes. The cellular targets of *HMGA2* are incompletely defined but appear to include cyclin A and E2F1.

Molecular studies established a causal role for *HMGA2* in benign mesenchymal tumors. Rearrangement of 12q13-15 is observed in these neoplasms, but tumorigenesis does not depend on generation of chimeric proteins derived from fusion of *HMGA2* with specific translocation partners. Rather, clonal expansion induced by *HMGA2* appears to result from deregulated expression of the protein. For the two PNH patients, ectopic expression was a consequence of gain-of-function mutational events caused by disruption of the 3′UTR shown to contain elements that negatively regulate *HMGA2* mRNA stability, including the microRNA let-7a.[62,63] Additional studies will be required to determine whether aberrant expression of *HMGA2* underlies clonal expansion in PNH patients without structural abnormalities of 12q13-15, but studies by Murakami and colleagues support this hypothesis.[64]

In contrast to a disorder characterized by cellular transformation and malignant cellular growth, PNH manifests many of the characteristics of a benign tumor, since there is limited expansion of *PIGA*-mutant clones (the peripheral blood of patients is a relatively stable mosaic of normal and abnormal cells); *PIGA*-mutant cells respect tissue boundaries (there is no invasion of non-hematopoietic tissues); *PIGA*-mutant cells respond appropriately to signals that normally regulate hematopoiesis (function is not autonomous); and transformation into acute leukemia occurs rarely (PNH is not a premalignant condition).[65] The studies of Inoue and colleagues[61] suggest the concept of PNH as a benign tumor of the bone marrow with aberrant expression of *HMGA2* acting in concert with mutant *PIGA* (and the consequent deficiency of GPI-APs) to produce the proliferative phenotype that underlies clonal expansion. These studies did not define how the aberrant expression of *HMGA2* works additively or synergistically with mutant *PIGA* to produce the proliferative phenotype.

The findings of Inoue et al. provide new insights into the etiology of the nonmalignant clonal hematopoiesis of PNH. These studies support a two-step process consisting of (i) clonal selection based on phenotype (i.e., GPI-AP deficiency resulting from mutant *PIGA*) and (ii) clonal expansion as a consequence of a second somatic mutation that bestows an additional growth/survival advantage. Clonal selection may induce the exit of *PIGA*-mutant stem cells from a dormant state, thereby favoring acquisition of the second mutation that underlies clonal expansion. The variable expansion of *PIGA*-mutant clones among patients and among mutant clones in the same patient could be explained by heterogeneity involving the second genetic event that partners with mutant *PIGA*. According to this hypothesis, mutant *PIGA* is promiscuous with respect to the second mutant gene with which it partners. But the benign nature of PNH suggests that genes involved in clonal expansion of *PIGA*-mutant stem cells are different from those that underlie malignant clonal diseases such as acute leukemia.

In summary, the basis of the clonal dominance in PNH is incompletely understood; however, available evidence supports a two-step model of pathogenesis. Step 1 of this model is *clonal selection*. In this case, a loss-of-function mutation affecting *PIGA* causes deficiency of GPI-APs on affected stem cells. These mutant stem cells have a relative growth or survival advantage that is likely enhanced in the setting of bone marrow failure (e.g., aplastic

anemia). Thus, principles of Darwinian evolution may apply to development of PNH. *Clonal expansion*, step 2 of the PNH pathogenesis model, is envisioned as a consequence of clonal evolution in which a second somatic (gain-of-function) mutation working in concert with the consequences of mutant *PIGA* bestows upon the double mutant stem cell an absolute proliferative advantage.[61] The extent of expansion of a particular mutant clone and the dominance of one *PIGA*-mutant clone in the presence of other *PIGA* mutants may be mediated by the nature of the second event that may be molecularly heterogeneous. Alternatively, a limited number of second mutations may partner with mutant PIGA, and the extent of clonal expansion may be determined by how the second mutation affects gene function.

Aplastic Anemia and Paroxysmal Nocturnal Hemoglobinuria

Patients with *clinical* PNH can be divided into the following two groups: those without a preceding history of aplastic anemia (classic PNH); and those with an antecedent history of aplastic anemia who subsequently develop PNH (PNH/aplastic anemia).[1] An association between aplastic anemia and PNH has been recognized at least since 1961, and numerous subsequent studies have confirmed the association. The probability is negligible that these two rare diseases would occur together so frequently by chance. Therefore, a pathophysiologic link between PNH and aplastic anemia must exist.

Hillmen et al.[65] reported that 23 of 80 PNH patients (29%) had an antecedent history of aplastic anemia, and in a series of 220 French patients with PNH, Socié and colleagues identified 65 (30%) in whom the diagnosis of aplastic anemia preceded that of PNH.[66] The latter group of investigators also found that 10% of PNH patients with no antecedent history of aplastic anemia developed pancytopenia during the period of observation covered by the study (median follow-up of 2 years). The estimated cumulative incidence of pancytopenia was 8.2% (± 2.4%, SE) at 2 years and 14.2% (± 3.3%, SE) at 4 years.[66] This incidence appears to be somewhat higher than that observed in the study reported by Hillmen et al. in which 5 of 80 patients (6%) with PNH subsequently developed aplasia.[65]

On the other hand, the proportion of patients with aplastic anemia who subsequently develop PNH varies widely among studies, in part because the criteria for diagnosis of PNH are not uniform. In some cases, a positive Ham's test or sucrose lysis test was required for diagnosis, and in other cases, identification by flow cytometry of a population of peripheral blood cells with GPI-AP deficiency was used to classify patients. A recent study reported that PNH cells were found in the BM in 89% of 115 patients with aplastic anemia at some point during the course of their illness.[67] Two other studies reported 38% (11 of 29 patients)[68] and 32% (12 of 37 patients)[69] for the portion of patients with aplastic anemia treated with immunosuppression who developed laboratory evidence of PNH during the course of their disease. In the latter study, 23% of patients had clinical signs and symptoms of PNH. Therefore, in most patients with aplastic anemia, evidence of PNH is subclinical or transient. These results suggest that the selective pressure that favors *PIGA*-mutant cells occurs frequently in the setting of aplastic anemia, but that the clinical syndrome occurs at a significantly lower frequency.

The time between the diagnosis of aplastic anemia and the development of PNH varies from a few months to several years. In the series reported by Socié et al.,[66] the median time between diagnosis of aplastic anemia and laboratory evidence of PNH was 3.1 years (range 0.17 to 15 years). Using an assay with the capacity to detect 0.004% GPI-AP–deficient erythrocytes, Mukhina et al. reported that 61% of patients with aplastic anemia had detectable PNH cells prior to therapy.[70] Similar results were obtained in more recent studies using high-resolution flow cytometry.[71] In most of these cases, the GPI-AP–deficient cells would be undetected by conventional flow cytometry, in which the sensitivity threshold for detecting cells with the PNH phenotype is 1% to 3%. Identification of very small populations of GPI-AP–deficient cells by high-resolution flow cytometry has led to a new class of PNH, termed *subclinical PNH* (PNH-sc).[1] Patients with PNH-sc have no clinical or laboratory evidence of hemolysis. Small populations of GPI-AP–deficient hematopoietic cells (peripheral blood erythrocytes, granulocytes, or both) are detected by very sensitive flow cytometric analysis. PNH-sc is observed in association with bone marrow failure syndromes, particularly aplastic anemia and the refractory anemia variant of MDS.

In summary, while 40% to 60% of patients with aplastic anemia have small, subclinical populations of GPI-AP$^-$ hematopoietic cells at diagnosis,[71] only 10% to 15% subsequently develop clinically apparent PNH.[72,73] In the remainder, GPI-AP$^-$ cells persist subclinically or disappear,[71,74] suggesting that mutant *PIGA* (and the consequent deficiency of GPI-APs) is necessary for clonal selection but is insufficient to account for the clonal expansion required for clinical manifestations of PNH to become apparent. The simplest interpretation of these observations is that factors in addition to mutant *PIGA* contribute to the development of clinical signs and symptoms of PNH by affecting the extent to which the *PIGA*-mutant stem cells expand.

As expansion of the mutant clones occurs later in the course of aplastic anemia, the process could be influenced directly or indirectly by therapy. Although many patients with aplastic anemia who develop PNH are treated with immunosuppressive therapy (e.g., anti-thymocyte globulin and cyclosporin), there is no evidence that immunosuppression causes PNH.[73] Patients with aplastic anemia who respond to androgens appear equally likely to develop PNH.[66]

The basis of the relationship between PNH and aplastic anemia is speculative. Essentially all patients with PNH have some evidence of bone marrow failure (e.g., thrombocytopenia, leukopenia, or both) during the course of their disease. Therefore, bone marrow injury may play a central role in the development of PNH by providing the conditions that favor the growth/survival of *PIGA*-mutant, GPI-AP–deficient stem cells. Currently, there is no evidence that the types of *PIGA* mutations that occur in PNH/aplastic anemia are different from those observed in classic PNH.[75] Further, a distinction between classic PNH and PNH/aplastic anemia may be artificial, as the underlying pathophysiologic process could be the same. According to this hypothesis, in classic PNH, the aplastic or hypoplastic component is subclinical and short-lived, with disease noted only after the *PIGA*-mutant clone has expanded sufficiently to dominate hematopoiesis.

Leukocytes and Platelets

Deficiency of GPI-AP on neutrophils, monocytes, platelets, and lymphocytes has been demonstrated in the peripheral blood of patients with PNH, and identical *PIGA* mutations have been identified in neutrophils, monocytes, and lymphocytes from the same patient.[48,50] Together, these studies indicate that the somatic mutation that gives rise to PNH affects a hematopoietic stem cell. Most PNH patients have pancytopenia or either neutropenia or thrombocytopenia in combination with anemia at some point during the course of their illness. The neutropenia and thrombocytopenia, however, are due to abnormal hematopoiesis rather than to increased peripheral, complement-mediated destruction, as in vivo studies have demonstrated normal survival of neutrophils and platelets in patients with PNH. That absence of GPI-anchored complement regulatory proteins from PNH neutrophils and platelets does not affect their survival implies that these cell types (unlike erythrocytes) have mechanisms in addition to those provided by CD55 and CD59 that protect them from complement-mediated destruction in vivo.

In vitro studies have shown functional abnormalities of PNH leukocytes and platelets. Further, deficiency of some of the GPI-AP from PNH leukocytes and platelets would seem to have important functional consequences (e.g., deficiency of FcγRIIIb from neutrophils, deficiency of urokinase-type plasminogen activator receptor from monocytes and neutrophils, deficiency of LFA-3 from lymphocytes, or deficiency of the folate receptor from hematopoietic stem cells) (Table 31.2). However, evidence that deficiency of GPI-APs other than erythrocyte CD55 and CD59 contributes to the pathophysiologic manifestations of PNH is largely conjectural. At least in some cases, functional redundancy appears to account for the lack of untoward consequences associated with GPI-AP deficiency.

Hematopoietic Stem Cells

The PNH defect can be demonstrated in erythroid and granulocytic precursors grown in vitro (i.e., CFU-E, BFU-E, and CFU-GM).[60] Two populations of colonies can be identified in such studies, and they differ from one another in complement sensitivity and expression of acetylcholinesterase.[76] These latter observations support the concept of a clonal process originating from a mutant hematopoietic stem cell.

Cytogenetic studies on hematopoietic cells of patients with PNH have yielded mixed results. The issue is complicated because patients with aplastic anemia can have karyotypic abnormalities. Araten and colleagues reported karyotypic abnormalities in 11/46 (24%) of PNH patients examined in a retrospective study.[77] In 7 of those patients, there was evidence of clonal regression, and none of the patients developed an excess of blasts or a transformation into acute leukemia. These findings suggest that karyotypic abnormalities in PNH do not predict progression into a malignant phenotype. To date, the only nonrandom chromosomal abnormality specific for PNH involves rearrangement of 12q13-15 that results in ectopic expression of *HMGA2*.[78] A systematic study of a large number of patients is needed to determine if other nonrandom karyotypic abnormalities that contribute to the clonal expansion of *PIGA*-mutant cells exist.

Uncommonly (~1%), patients with PNH develop acute leukemia.[65,66] In some cases, the leukemic clone arises from the PNH clone because the blasts are GPI-AP–deficient.[79] Similar observations have been made in MDS arising in the setting of PNH.[80] However, in other cases, PNH cells disappear following the onset of the leukemia[81] or myelodysplasia.[82] While transformation into acute leukemia or other clonal myelopathies is uncommon in PNH, the incidence is probably higher than in the general population. Therefore, an element of genetic instability may be associated with PNH or the process that underlies PNH.

CLINICAL MANIFESTATIONS

PNH usually begins insidiously with the abrupt onset of clinically apparent hemoglobinuria being the presenting symptom in only 25% of cases.[83,84] The course is chronic with a generally stable clinical pattern in a given individual. The illness ranges in severity from a mild, clinically benign process to a chronically debilitating, potentially lethal disease. The diagnosis is made most frequently in the fourth to fifth decades of life,[65,66,84] but PNH is also encountered in childhood[85] and in old age (age range 16 to 75 years[65] and 6 to 82 years[66] in two large series). Both genders are affected, with perhaps a slight female predominance, and PNH has been described in many racial groups. The disease has no familial tendency. Inherited cases due to global deficiency of GPI-AP have not been reported, suggesting that germ line mutations of *PIGA* are embryonically lethal. This hypothesis is supported by the lack of success in producing a homozygous or hemizygous knockout mouse using a targeted mutation of *Piga*.[58] Observations in humans also support the hypothesis. An X-linked lethal disorder characterized by cleft palate, neonatal seizures, contractures, and central nervous system structural malformations was investigated using whole exome sequencing.[86] In that case, a germ line mutation of *PIGA* was identified, but the PNH phenotype was not observed. In vitro studies indicated that the mutant PIGA had partial function, thereby accounting for the absence of hemolysis. Similarly, two unrelated kindreds with germ line mutations in the promoter of the autosomal gene *PIGM* were identified. Homozygotes were characterized by a propensity toward venous thrombosis and seizures, but clinically significant hemolysis was not observed. The lack of hemolysis was explained by flow cytometric analysis that showed only partial deficiency of GPI-anchored complement regulatory proteins on the red cells.[87] Together, these observations indicate that germ line deficiency of GPI-APs sufficient to produce the PNH phenotype is not compatible with life. As previously noted, a patient with an inherited deficiency of MIRL (CD59) had a syndrome that was clinically indistinguishable from PNH, but other GPI-APs were expressed normally by that patient.[35]

Most commonly, patients with classic PNH complain initially of malaise, lethargy, and asthenia. Yellowish discoloration of the skin (jaundice) and sclera (icterus) may be observed by astute family members.

Hemoglobinuria

Although essentially all patients with classic PNH have episodes of hemoglobinuria sometime during their illness, this defining symptom is reported as part of the initial evaluation in only one-quarter of all patients (Table 31.3). Nocturnal hemoglobinuria appears to result from an increase in the rate of hemolysis that occurs during sleep. It is not related to time of day, however, because the pattern can be reversed if the patient is kept awake at night and allowed to sleep during the day. In patients with nocturnal hemoglobinuria, the urine is usually darkly discolored in the morning and clears gradually over the course of the day. When hemolysis is intense, however, hemoglobinuria persists throughout the day.

The cause of the nocturnal exacerbation is poorly understood. Retention of CO_2 causing a slight fall in plasma pH sufficient to activate the alternative pathway of complement is a possible explanation, but this hypothesis has been challenged.

TABLE 31.3

PRESENTING FEATURES IN 80 PATIENTS WITH PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Signs and Symptoms	Number of Patients (%)
Symptoms of anemia	28 (35)
Hemoglobinuria	21 (26)
Hemorrhagic signs and symptoms	14 (18)
Aplastic anemia	10 (13)
Gastrointestinal symptoms	8 (10)
Hemolytic anemia and jaundice	7 (9)
Iron deficiency anemia	5 (6)
Thrombosis or embolism	5 (6)
Infections	4 (5)
Neurologic signs and symptoms	3 (4)

From Dacie JV, Lewis SM. Paroxysmal nocturnal haemoglobinuria: clinical manifestations, haematology, and nature of the disease. Ser Haematol 1972;5:3–23.

Episodic Hemolysis

In addition to the sleep-related pattern, most patients with classic PNH experience irregular but recurrent exacerbations of hemolysis and hemoglobinuria. Paroxysms may be precipitated by a wide variety of events, including infections (even minor ones), surgery, transfusions, iron supplementation, vaccinations, and menstruation. Attacks of hemoglobinuria are unrelated to cold exposure, thus distinguishing PNH clinically from paroxysmal cold hemoglobinuria.

Mild hemolytic episodes often pass without significant symptoms, but more severe attacks may be associated with substernal, lumbar, or abdominal pain together with drowsiness, malaise, fever, and headaches. The abdominal pain may be colicky and may last for 1 to 2 days. The abdomen may be tender, especially in the left upper quadrant, with guarding and rebound tenderness. The back pain resembles that noted in patients with other types of intravascular hemolysis (such as in an ABO incompatible transfusion reaction) and is most severe in the lumbar region. Headaches may be excruciating and sometimes last for days.

Marrow Hypoplasia

Because many patients with PNH/aplastic anemia have only a small proportion of complement-sensitive cells, few of the changes usually associated with hemolytic anemia are obvious. Therefore, the PNH/aplastic syndrome is probably under-diagnosed. Clinicians need to maintain a high degree of suspicion, and any evidence of hemolysis (e.g., elevated serum lactate dehydrogenase [LDH]) in a patient with aplastic anemia warrants evaluation for PNH. In one series of 80 European patients with PNH, aplastic anemia was the first diagnosis in 23 cases (29%)[65,83]; the same was true of 26 of 85 patients (31%) from Thailand[88] and 65 of 220 French patients (30%).[66] In some instances, the diagnosis of hemolysis is made first, and pancytopenia develops subsequently.

Thromboembolic Complications

PNH is associated with a striking predisposition toward intravascular thromboses, especially within the venous circulation.[65,66,89] Intra-abdominal veins are the most commonly affected. Cerebral vein and superficial dermal vein thrombosis also appear to be represented disproportionately. Thrombotic disease accounts for about 50% of all deaths in patients with PNH. Fatal thromboses usually involve the portal system or the brain.

Recurrent abdominal pain is the dominant clinical manifestation in some patients with PNH (Table 31.3). The cause of the pain is often obscure but may be severe enough to suggest an acute abdomen warranting emergency surgery. The possibility that a thrombosis in the portal or mesenteric veins is the cause of the pain should be considered in this setting. Both transient intestinal ischemia and intestinal infarction due to thrombosis involving the microcirculation are other possible causes.

Hepatic venous thrombosis (Budd-Chiari syndrome) is a serious, potentially fatal complication of PNH.[90,91] In various series, 15% to 30% of patients with PNH had hepatic venous thrombosis, and this complication might be even more common because affected individuals can be asymptomatic when Budd-Chiari syndrome is in its early stage.[92] The clinical manifestations include nausea, abdominal pain, variable degrees of ascites, variceal bleeding, and signs of liver failure. Often the liver increases abruptly in size, but hepatomegaly is not always noted. Three pathophysiologic stages of hepatic venous thrombosis have been defined.[92] In the early or mildest stage, only venules or small hepatic veins are involved. Patients may be asymptomatic and therefore the condition may go unrecognized. Mild, easily controlled ascites is detected in some patients. In the second stage, larger hepatic veins are partially occluded. Ascites is noted in most patients with such abnormalities. Some individuals develop variceal bleeding, and a few become jaundiced. The third or advanced stage is characterized by complete occlusion of large hepatic veins. Ascites is almost always present, jaundice is common, and variceal bleeding occurs in a few patients. This stage is often fatal.

An increase in the level of serum LDH, alanine aminotransferase, and aspartate aminotransferase may be an early clue to the presence of hepatic vein thrombosis. Plasma concentration of conjugated bilirubin also may increase, but other biochemical tests of liver function are of limited value. Ultrasonography is the most effective noninvasive method for early detection of hepatic vein thrombosis, with a sensitivity and specificity of 85% or more.[93,94] Computed tomographic and magnetic resonance imaging (MRI) scans are more sensitive than ultrasound. MRI is better for visualizing the whole length of the vena cava and may permit differentiation of the acute form from the subacute form of the disease.[94] Radioactive isotope scanning demonstrates patchy uptake in most of the liver, except for a normally functioning, hypertrophied caudate lobe that is spared because of its separate venous drainage. Hepatic venography is definitive, but this procedure carries more risk than noninvasive techniques. Biopsy may demonstrate congestion and liver cell loss, but the procedure is hazardous and not always informative.

Small-vessel thromboses may cause severe and refractory headaches or they presage progressive cerebrovascular thrombosis.[95] Isotopic brain scanning and electroencephalography usually are of little help in monitoring PNH patients with headaches.

Renal Abnormalities

Both acute and chronic renal insufficiency occurs in patients with PNH.[96,97] Acute renal insufficiency is associated with hemoglobinuric crises and may resolve without residual damage. In one series of 19 patients with PNH, however, 12 individuals had reduced values for creatinine clearance while their underlying disease was stable. Furthermore, at least three of these patients had progressive renal insufficiency. Patients with PNH may also have hematuria, proteinuria, hypertension, an inability to concentrate their urine, or some combination of these abnormalities. The kidneys usually are enlarged when examined radiographically, and MRI may reveal hemosiderin deposition. The renal abnormalities probably result from repeated thrombotic episodes involving small venules.

Dysphagia and Male Impotence

When closely questioned, many patients with PNH complain of painful or difficult swallowing. The symptom is often worse in the morning and appears to be exacerbated during hemolytic episodes. Studies of peristalsis have shown that the esophageal contractions that occur in this setting have 9 to 10 times the normal force. The pathogenesis of these esophageal complaints is speculative. Inasmuch as hemoglobin binds nitric oxide, it has been proposed that the plasma free hemoglobin that is a consequence of the chronic intravascular hemolysis characteristic of PNH acts as a sump for nitric oxide.[98] Esophageal (and intestinal spasm) may ensue because of consumption by plasma free hemoglobin of the smooth muscle–relaxing activity of nitric oxide. This hypothesis is supported by observations that patients receiving artificial hemoglobin also experience dysphagia and odynophagia.[99]

Male impotence is common in patients with PNH and is worse during hemolytic exacerbations. As is the case with dysphagia, nitric oxide deficiency that is a consequence of the sump effect of plasma free hemoglobin may underlie the erectile dysfunction.

Infections

The apparent increased incidence of infections in patients with PNH may be attributable to leukopenia, to treatment with

corticosteroids, or to functional defects in leukocytes (although compelling experimental support is lacking). Even mild infections may constitute a serious hazard because they may precipitate a hemolytic exacerbation.

Physical Examination

Findings are largely nonspecific (related to anemia, thrombocytopenia, or neutropenia). Jaundice may be observed in patients with brisk hemolysis. Moderate splenomegaly and mild to moderate hepatomegaly are sometimes observed and should raise concerns about hepatic or splenic vein thrombosis.

LABORATORY FINDINGS

Blood

Essentially all patients with PNH are anemic, and in many, the anemia is severe. The red cells are usually macrocytic, as observed in other bone marrow failure syndromes, but the MCV varies considerably among patients. Occasionally, the red cells may appear hypochromic and microcytic because of iron deficiency resulting from chronic and acute hemoglobinuria. Moderate anisocytosis and poikilocytosis are common but spherocytes are not observed in the peripheral blood film. Polychromatophilia, reflecting reticulocytosis, is observed unless bone marrow failure is severe. Relative reticulocytosis may be marked, but the absolute reticulocyte count is often lower than that found in association with other hemolytic disorders at comparable degrees of anemia. This discrepancy reflects underlying marrow dysfunction that is invariably a component of the disease. Normoblasts (nucleated red blood cells) may also be found in the peripheral blood film. The osmotic and mechanical fragility of the erythrocytes is normal, and the reaction to the direct antiglobulin (Coombs') test is negative (although it may become positive in patients treated with eculizumab, see below).

Leukopenia is often observed and may be marked, especially in the setting of PNH/aplastic anemia. The leukopenia is a consequence of bone marrow rather than complement-mediated destruction.[100] Neutrophil alkaline phosphatase (a GPI-AP) expression is low or absent. Functional leukocyte defects have been demonstrated but their clinical relevance is conjectural.

Thrombocytopenia of moderate to severe degree is common, but platelet life span and function generally are normal.[101] Thus, like the leukopenia, the thrombocytopenia of PNH is a consequence of bone marrow failure. Bleeding due to severe thrombocytopenia may contribute to the morbidity and mortality of the disease.

Plasma

The plasma may be golden brown, reflecting the presence of increased levels of unconjugated bilirubin, hemoglobin, and methemalbumin. Predictably, serum haptoglobin concentration is low and LDH concentration is markedly elevated, reflecting intravascular hemolysis.

Urine

When the rate of blood destruction is increased, the urine contains increased amounts of urobilinogen. In addition, intravascular hemolysis leads to depletion of serum haptoglobin, which results in the continuous presence of hemoglobin in the glomerular filtrate of the kidney. The cells of the proximal convoluted tubules that reabsorb much of the hemoglobin become heavily laden with iron. The excretion of this iron in the form of granules gives rise to hemosiderinuria. In addition, spectroscopic examination may reveal variable amounts of free hemoglobin. The continuous loss of relatively large amounts of iron in the urine can result in iron deficiency. Average daily losses of up to 16 mg have been observed, and as much as 4 mg of iron excreted in 24 hours has been demonstrated even in the absence of gross hemoglobinuria. Albuminuria has been detected immediately before and after an episode of hemoglobinuria, and long-term study of PNH patients has shown an unexpectedly high incidence of functional renal abnormalities, such as hematuria, hyposthenuria, tubular malfunction, and declining creatinine clearance.[96,97]

Bone Marrow

In patients with classic PNH, normoblastic hyperplasia is a characteristic finding. As many as 50% of the nucleated cells may be normoblasts, but only occasionally are megaloblastic changes evident. The absence of morphologic changes consistent with megaloblastic anemia suggests that deficiency of the GPI-anchored form of the folate receptor (Table 31.2) does not result in abnormalities in folate metabolism that are clinically significant. The number of megakaryocytes may be decreased. When pancytopenia is evident, a hypoplastic marrow is usually observed, although in some patients, pancytopenia is associated with a cellular marrow, a feature that is more consistent with the ineffective hematopoiesis associated with a myelodysplastic process.

Cytogenetic Studies

Although a number of karyotypic abnormalities have been reported in PNH,[77] the only nonrandom chromosomal aberrations specific for PNH involve rearrangement of the *HMGA2* locus on 12q13-15.[61] Apparently, the presence of karyotypically abnormal bone marrow cells is not a negative prognostic factor in PNH.[77]

Diagnostic Tests

Until the early 1990s, the diagnosis of PNH was based on the results of special tests that exploited the abnormal sensitivity of PNH red cells to lysis by complement. Among the available assays, Ham's test (acidified serum lysis) and the sucrose lysis test (sugar water test of Hartmann) were most commonly used for the clinical diagnosis of PNH. While these tests are sensitive and specific when properly performed, and relatively simple in both theory and practice, their accuracy is strongly operator-dependent. Therefore, in the hands of an inexperienced technician, results are not always reliable. This problem is compounded by the fact that the tests are usually performed on a sporadic basis in most clinical laboratories because the diagnosis of PNH is entertained relatively uncommonly.

The recognition that deficiency of GPI-AP underlies PNH has resulted in the development of a simple, reliable method for diagnosing the disease.[102] By analyzing expression of GPI-AP on hematopoietic cells using monoclonal antibodies and flow cytometry, the abnormal cells can be readily identified (Figs. 31.1 and 31.2). The simplest method is to analyze expression of MIRL (CD59) on erythrocytes (Fig. 31.1). Because it is normally present in relatively high density, red cells with either complete or partial deficiency of MIRL are easily distinguished from normal (Fig. 31.1). Therefore, PNH I (normal expression), PNH II (partial expression), and PNH III (negative expression) erythrocytes can be identified by analyzing the flow cytometry histogram (Fig. 31.1). Analysis of erythrocyte DAF (CD55) expression is also informative. Because erythrocytes express ~6 to 8-fold less DAF (CD55) than MIRL (CD59), however, separation into discrete populations may be less obvious when anti-DAF is used as the primary antibody. By using both antibodies, the diagnosis can be confirmed (Figs. 31.1 and 31.2A).

The size of the PNH clone is best determined by analysis of GPI-AP expression on granulocytes. Unlike the life span of

peripheral blood RBCs that is markedly shortened as a consequence of deficiency of the GPI-anchored complement regulatory proteins CD55 and CD59, the life span of *PIGA*-mutant, GPI-AP–deficient PMNs is normal.[100]

Therefore, the percentage of GPI-AP–deficient PMNs is believed to be an accurate reflection of the contribution of the mutant clone(s) to hematopoiesis. The value of determining the size of the PNH clone is that some of the clinical manifestations of the disease, particularly the risk of thromboembolic complications, appear to be proportional to clone size.[103,104] Analysis of GPI-AP on granulocytes is technically more challenging than on erythrocytes, because of the difficulties associated with shipping, processing, and analyzing these fragile cells. Further, granulocyte expression must be analyzed within 24 to 48 hours after the blood sample is acquired, whereas erythrocytes can be analyzed 1 to 2 weeks after the blood is obtained if the sample is properly stored at 4°C.

GPI-AP–deficient populations that comprise >1% to 3% of the red cells can be identified by standard flow cytometry. Concern that recent red cell transfusion might result in a false-negative result seems unfounded. Because the assay is very sensitive and because the proportion of GPI-AP–deficient cells is greater in the reticulocyte population than in the peripheral blood as a whole, massive transfusion that both replaces essentially all of the patient's blood volume and also completely suppresses hematopoiesis would be required to produce a false-negative result. Transfusion will have an impact on the percentage of GPI-AP–deficient cells that are observed, but the possibility that the diagnosis would be obscured is remote. Conversely, it is unlikely that a recent hemolytic episode would result in a false-negative result because all the abnormal cells are destroyed. However, when documenting the proportion of affected cells and determining the precise erythrocyte phenotype, the analysis is best done when the patient has not been recently transfused, as well as when the patient is not experiencing a hemolytic crisis related to infection or some other cause.

By careful gating and by using triple-antibody staining techniques, the sensitivity of flow cytometry can be enhanced by about three orders of magnitude, such that as few as 0.003% GPI-AP–deficient cells (RBCs and WBCs) can be consistently and reproducibly detected[71] (Fig. 31.7). This high-resolution analysis is used to identify patients with PNH-sc (Fig. 31.7B). Patients with PNH-sc in the setting of aplastic anemia and the refractory anemia variant of MDS appear to have a more benign clinical course than patients without PNH-sc.[71,105,106] In addition, some[71,105,106] but

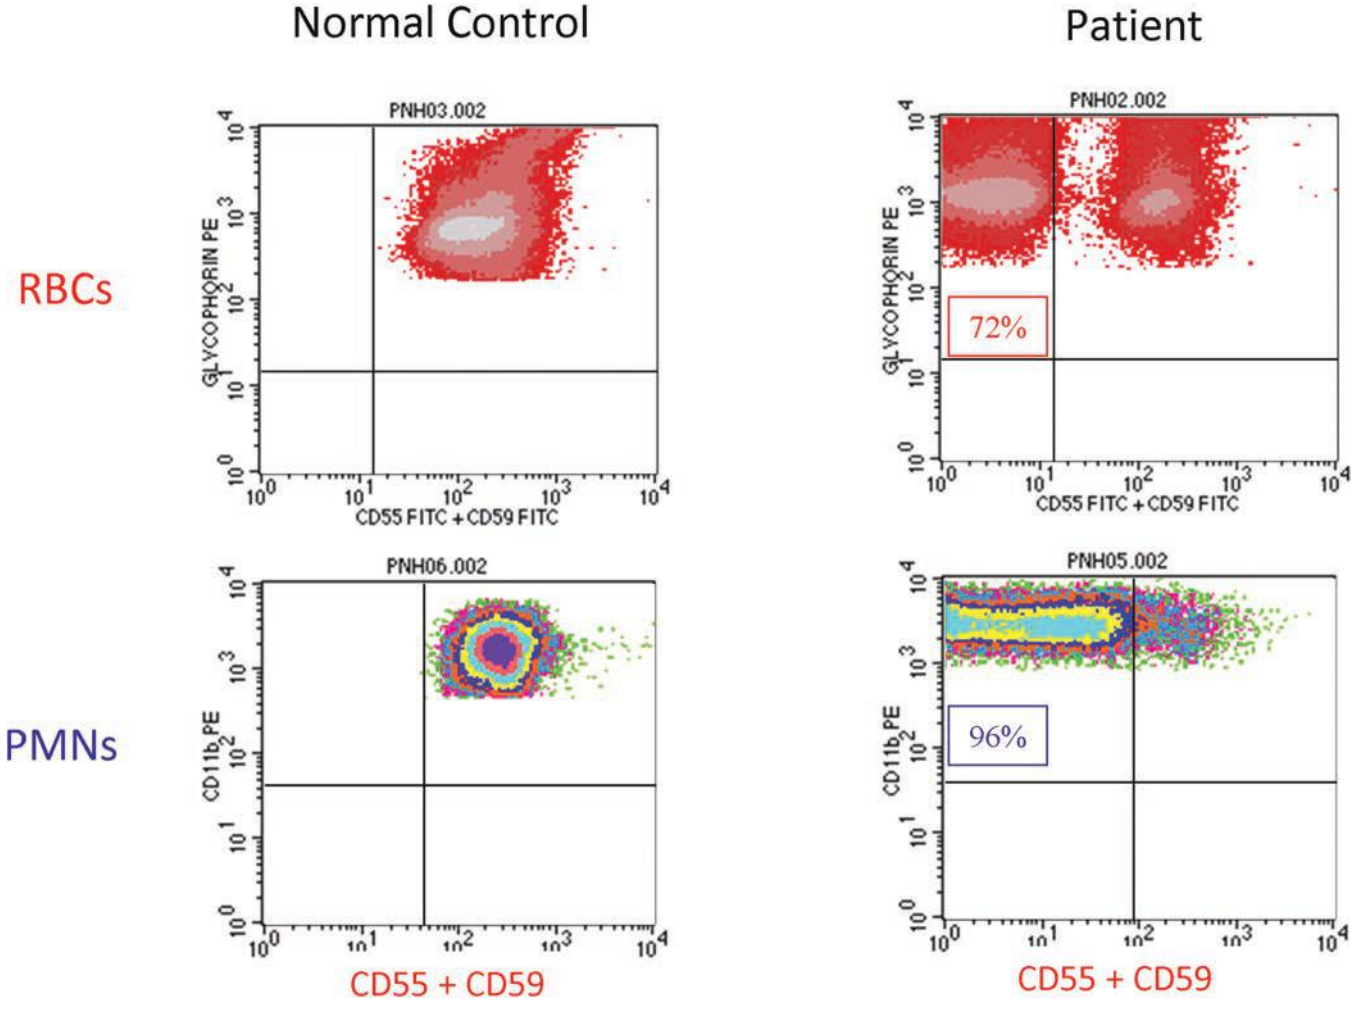

FIGURE 31.7. High sensitivity flow cytometry for diagnosis of PNH. A: Two-color flow cytometry histogram of erythrocytes (*upper panels*) and neutrophils (*lower panels*) from a normal volunteer (*left*) and from a patient with classic PNH (*right*). Erythrocytes were stained with phycoerythrin (PE)-labeled anti-glycophorin A (*vertical axis*) and a combination of fluorescein isothiocyanate (FITC)-labeled anti-CD55 and anti-CD59 (*horizontal axis*). Neutrophils were stained with PE-labeled CD11b (*vertical axis*) and FITC-labeled anti-CD55 and anti-CD59 (*horizontal axis*). No GPI-AP–deficient erythrocytes or neutrophils were among ~100,000 cells counted in this analysis for the normal control, whereas the patient had 72% GPI-AP–deficient erythrocytes and 96% GPI-AP–deficient neutrophils. **B:** Two-color flow cytometry histogram of erythrocytes and neutrophils from two patients with aplastic anemia but with no clinical evidence of PNH. In the example on the left, approximately 0.077% of the erythrocytes and 0.74% of the neutrophils failed to express CD55 and CD59. In the example on the right, 3% of the erythrocytes and 21% of the neutrophils failed to express CD55 and CD59.

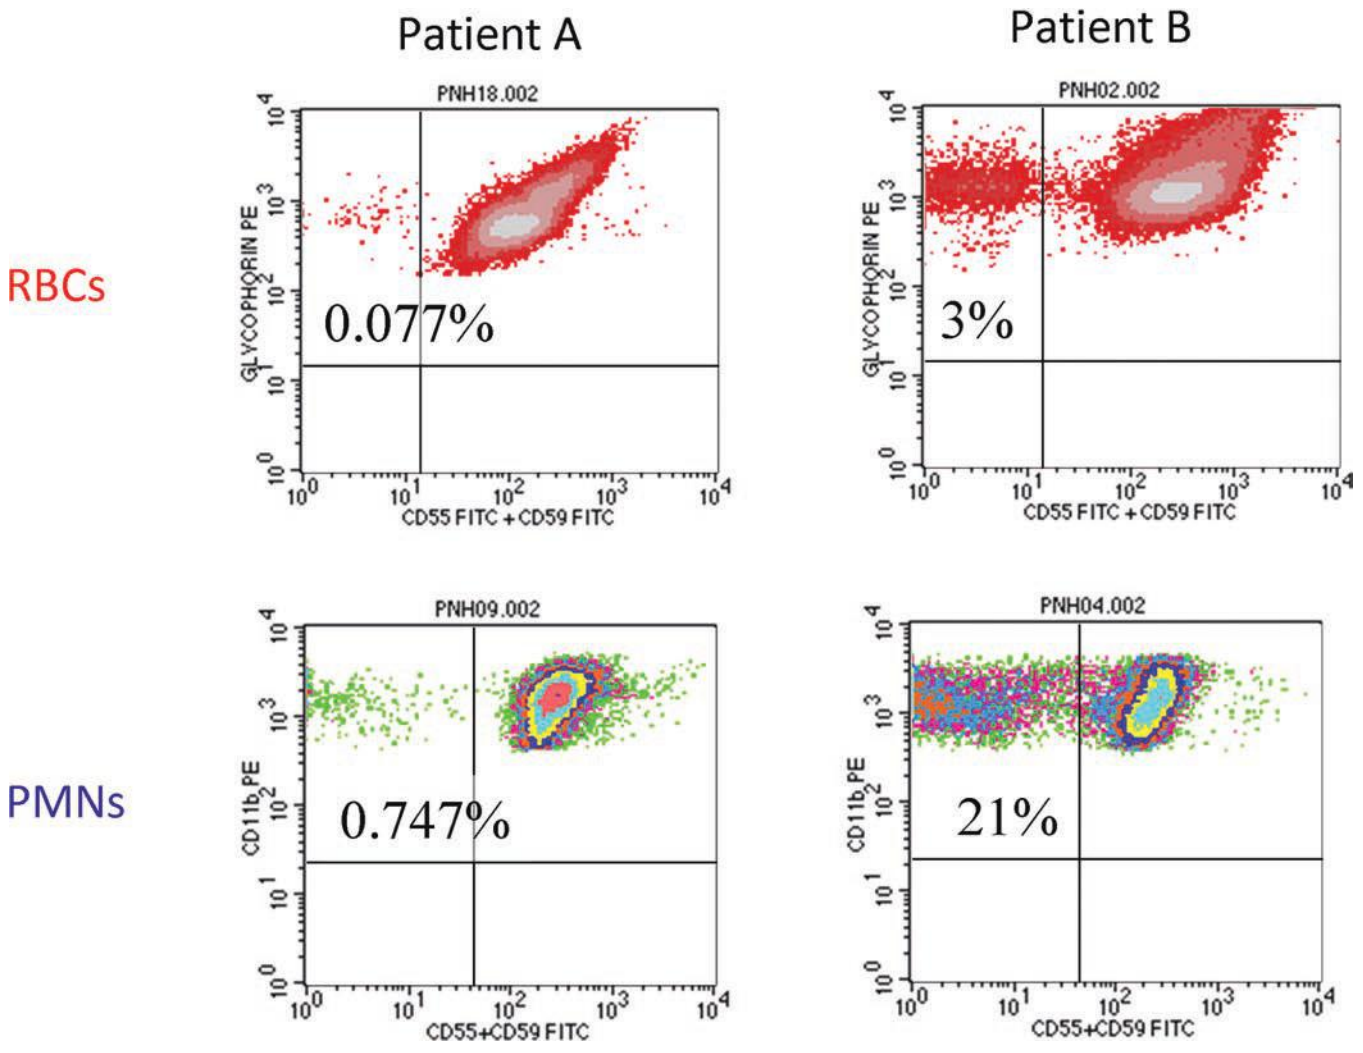

FIGURE 31.7. (continued)

not all[107] studies suggest that patients with PNH-sc respond more favorably to immunosuppressive therapy.

A diagnostic assay for PNH using *fl*uorescent *aer*olysin (FLAER) that exploits the unique properties of the bacterial toxin aerolysin has been developed.[108] This channel-forming protein binds directly to the GPI anchor. By fluorochrome labeling of a modified recombinant form of the protein that does not cause lysis, this reagent can be used to detect leukocytes with the PNH phenotype.[108] The primary advantage of this assay is that because it detects all GPI-APs, it is specific for PNH. The primary disadvantage is that the FLAER reagent does not bind well to RBCs. Thus FLAER cannot be used to characterize GPI-AP expression on erythrocytes.

Analysis of expression of GPI-AP on erythrocytes is a highly specific test for PNH. There is no other known disease in which the erythrocytes include a mosaic of both GPI-AP$^+$ and GPI-AP$^-$ cells. Subjects with isolated deficiency of either DAF (the Inab phenotype) or MIRL (CD59) will be identified by this method (assuming that anti-DAF and anti-MIRL antibodies are used). Such patients are extremely rare, however, and their flow cytometry histograms are readily distinguishable from patients with PNH because 100% of the cells are abnormal and expression of only one GPI-AP is deficient. Patients with inherited abnormalities of GPI-AP synthesis would be distinguished from patients with PNH because in the former case, mosaicism would not be observed.

DIFFERENTIAL DIAGNOSIS

The diagnosis of PNH must be considered in any patient who has the following: (1) signs and symptoms of intravascular hemolysis (manifested by an abnormally high LDH) of undefined cause (i.e., Coombs-negative) with or without macroscopic hemoglobinuria often accompanied by iron deficiency; (2) pancytopenia in association with hemolysis; (3) venous thrombosis affecting unusual sites, especially intra-abdominal, cerebral, or dermal locations accompanied by evidence of hemolysis; (4) unexplained recurrent bouts of abdominal pain, low backache, or headache in the presence of chronic hemolysis; and (5) Budd-Chiari syndrome.

It is important to document evidence of hemolysis before proceeding with tests more specific for clinical PNH. As discussed above, a history of gross hemoglobinuria (nocturnal or otherwise) is not part of the initial clinical presentation in approximately three-fourths of patients with PNH (Table 31.3). However, except for patients with PNH-sc, *laboratory* evidence of hemolysis is a relatively constant feature of the disease. Quantitation of serum LDH is particularly informative because intravascular hemolysis results in markedly elevated values. If LDH concentrations are difficult to interpret because of other comorbid conditions (e.g., liver disease), then alternative evidence for chronic intravascular hemolysis should be sought (e.g., low serum haptoglobin, urine hemosiderin).

Without evidence of hemolysis, more specific tests for clinical PNH are generally unwarranted. PNH must be differentiated from antibody-mediated hemolytic anemias, especially paroxysmal cold hemoglobinuria and the cold agglutinin syndrome, and from HEMPAS (Hereditary Erythroblastic Multinuclearity with a Positive Acidified Serum Lysis Test, or Congenital Dyserythropoietic Anemia type II). The mechanism that underlies the abnormal susceptibility of HEMPAS erythrocytes to acidified serum lysis is different from that of PNH.[109] By using flow cytometry, there is no difficulty distinguishing PNH from other hemolytic diseases because deficiency of GPI-APs affecting a portion of the erythrocytes is diagnostic of PNH.

By definition, patients with PNH-sc have no clinical or laboratory evidence of hemolysis. PNH-sc is diagnosed by using high-resolution flow cytometry. Patients with aplastic anemia and the refractory anemia variant of MDS should undergo screening for PNH-sc at diagnosis and yearly thereafter. Finding PNH-sc appears to have important prognostic and therapeutic implications, as patients with PNH-sc/aplastic anemia or PNH-sc/MDS-RA may have a more benign clinical course and a higher rate of response to immunosuppressive therapy than those without PNH-sc.[71,105,106]

TREATMENT

The size of the PNH clone and the type and severity of the bone marrow failure component of the disease are the main factors that determine the clinical course. Some patients have a relatively benign clinical course with only a moderate degree of anemia and minimal hemolysis, and in such patients, no PNH-specific treatment is required. Other patients have severe anemia punctuated by hemolytic crises and thromboembolic complications; in such patients, treatment of the complement-mediated hemolytic anemia is clearly warranted. In other patients, the disease is dominated by bone marrow failure rather than by hemolysis, and in those patients, the focus of treatment should be on the underlying marrow failure process. By taking into account the size of the PNH clone and the type and severity of the bone marrow failure component of the disease, a classification has been developed that provides a rational basis for management.

Clinical Classification

The basic approach to classifying PNH is straightforward. Flow cytometric analysis of peripheral blood erythrocytes and granulocytes (± monocytes) is needed to determine the phenotype of the red cells and the size of the PNH clone (based on the percentage of GPI-AP–deficient granulocytes (± monocytes). CBC, reticulocyte count, serum concentration of LDH, bilirubin (fractionated), haptoglobin, and iron stores are needed to assess the degree of marrow failure and hemolysis and whether iron deficiency is present. Bone marrow aspirate and biopsy and cytogenetic analysis are needed to characterize the status of the bone marrow. Once the basic evaluation is complete, patients should be classified based on the categories developed by the International PNH Interest Group.[1]

The three categories are as follows (Figure 31.8):

Classic PNH. Patients with classic PNH have clinical evidence of intravascular hemolysis (reticulocytosis, abnormally high concentration of serum LDH and indirect bilirubin, and abnormally low concentration of serum haptoglobin), but have no evidence of another defined bone marrow abnormality. A cellular marrow with erythroid hyperplasia and normal or near-normal morphology, but without nonrandom karyotypic abnormalities, is consistent with classic PNH. The PNH clone is large (>50% and often >90%). Patients with a large population of PNH II erythrocytes, however, will have minimal hemolysis.

PNH in the setting of another specified bone marrow disorder. This subcategory of patients has at least laboratory evidence of hemolysis but also has concomitantly a defined underlying marrow abnormality. Bone marrow analysis and cytogenetics are used to determine if PNH arose in association with aplastic anemia or MDS. Standard criteria are used for diagnosis of the bone marrow abnormality (e.g., aplastic anemia, low-risk MDS). Finding nonrandom karyotypic abnormalities that are associated with a specific bone marrow abnormality may contribute diagnostically (e.g., abnormalities of chromosomes 5q, 7, and 20q are associated with MDS). The large majority of patients with PNH/AA and PNH/MDS have relatively small PNH clones (<50%), and require no specific PNH therapy; and in these cases, treatment should focus on the underlying bone marrow failure syndrome.[73] Approximately half of the patients with clinical PNH in the setting of bone marrow failure will require therapy (eculizumab for hemolysis or anticoagulation for thrombosis).[73]

Subclinical PNH (PNH-sc). Patients with PNH-sc have no clinical or laboratory evidence of hemolysis. Small populations of GPI-AP–deficient hematopoietic cells (peripheral blood erythrocytes, granulocytes, or both) are detected by sensitive flow cytometric analysis.[74] PNH-sc is observed in association with bone marrow failure syndromes, particularly aplastic anemia and refractory anemia-MDS. In approximately 80% of these cases, the proportion of GPI-AP–deficient cells is <1.0%.[74] These patients require no

Classification of PNH*

	Category	Rate of Intravascular Hemolysis†	Bone Marrow	Flow Cytometry	Benefit from Eculizumab
Clinical PNH	Classic	Florid (markedly abnormal LDH often with episodic macroscopic hemoglobinuria)	Hypocellular with erythroid hyperplasia and normal or near-normal morphology††	Large population (>50%) of GPI-AP deficient PMNs¶	Yes
	PNH in the setting of another bone marrow failure syndrome§	Mild (often with minimal abnormalities of biochemical markers of hemolysis)	Evidence of a concomitant bone marrow failure syndrome§	Although variable, the percentage of GPI-AP deficient PMNs is usually relatively small (25%-50%)	Typically no, but some patients have clinically significant hemolysis and benefit from treatment
	Subclinical	No clinical or biochemical evidence of intravascular hemolysis	Evidence of a concomitant bone marrow failure syndrome§	Small (<1%) population of GPI-AP deficient PMNs detected by high-resolution flow cytometry	No

* Based on recommendations of the International PNH Interest Group (*Blood* 2005;106:3699-3709)
† Based on macroscopic hemoglobinuria, serum LDH concentration and reticulocyte count
†† Karyotypic abnormalities are uncommon
§ Aplastic anemia or low risk myelodysplastic syndrome
¶ Analysis of PMNs is more informative than analysis of RBCs due to selective destruction GPI-AP deficient RBCs

FIGURE 31.8. Classification of PNH. This classification is modified based on the recommendations of the International PNH Interest Group.

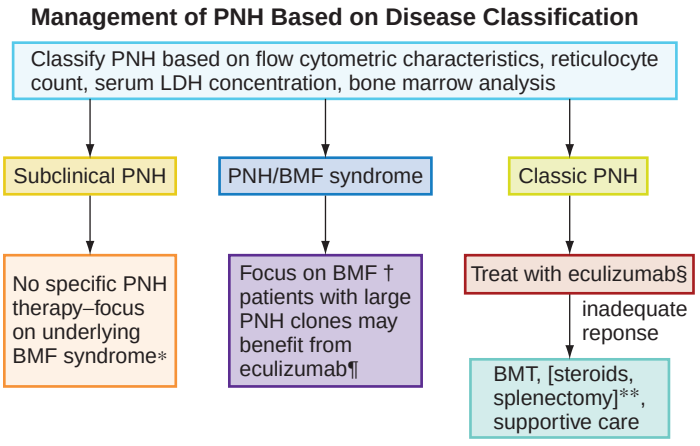

FIGURE 31.9. Algorithm for management of PNH based on disease classification. Disease classification is based on the recommendations of the International PNH Interest Group (Fig 31.8). *Some, but not all, studies suggest a favorable response to immunosuppressive therapy (IST). †BMT eradicates the PNH clone, and typically, treatment with IST does not affect PNH clone size (<10% of patients with PNH/BMF have PNH clone size >50%). §Some patients respond to danazol as first line therapy. **Consider for patients with clinically significant extravascular hemolysis. BMF, bone marrow failure (aplastic anemia and low-risk MDS); BMT, bone marrow transplant. (Reproduced from Parker CJ. Management of paroxysmal nocturnal hemoglobinuria in the era of complement inhibitory therapy. Hematology Am Soc Hematol Educ Program 2011:21–29, with permission of the author).

PNH-specific therapy; however, as noted above, finding a population of GPI-AP–deficient erythrocytes in patients with aplastic anemia may be clinically relevant, as some[71,105,106] but not all[107] studies suggest that these patients have a particularly high probability of responding to immunosuppressive therapy with a more rapid rate of onset of response compared with patients with aplastic anemia without a population of GPI-AP–deficient erythrocytes. Treatment with immunosuppressive therapy appears to have no influence on the size of the PNH clone.[73]

An algorithmic approach to management of PNH based on the above disease classification is shown (Fig. 31.9).

Management of the Anemia of Paroxysmal Nocturnal Hemoglobinuria

Coombs-negative hemolytic anemia is the clinical hallmark of PNH, but because the disease usually arises in the setting of an underlying abnormality of the bone marrow, hemolysis may account for only part of a patient's anemia. Further, the erythrocytes of PNH are a mosaic of normal and abnormal cells, and the portion of GPI-AP–deficient RBCs varies among patients (Figs. 31.1 and 31.2). For example, in hypothetical patient A, only 15% of the circulating RBC may be GPI-AP–deficient while, in hypothetical patient B, 75% GPI-AP–deficient erythrocytes may be observed (Fig. 31.10). In the former, hemolysis would contribute modestly to an observed anemia, while in the latter, a significant hemolytic component would be expected (Fig. 31.10). Another complicating factor is that deficiency of GPI-AP may be partial rather than complete (Figs. 31.1 and 31.10), and partial expression of CD55 and CD59 is sufficient to protect PNH II cells from spontaneous complement-mediated lysis in vivo.[30] Therefore, even if a patient has a high proportion of PNH II cells, only modest evidence of spontaneous hemolysis is usually observed (Fig. 31.10). But brisk hemolysis can occur in patients with predominantly PNH II erythrocytes in situations where complement activation is enhanced (e.g., by infection, trauma, surgery, pregnancy, or unusual stress).

Prior to initiating therapy, an effort should be made to determine how much of the anemia is a consequence of hemolysis and how much is due to impaired erythropoiesis (Table 31.4). Review of the complete blood count is informative because evidence of thrombocytopenia, leukopenia, or both suggests stem cell dysfunction. The capacity of the marrow to respond to the anemia can be inferred from the reticulocyte count. An element of marrow failure is likely a contributing factor in a patient with PNH who has anemia with an inappropriately low reticulocyte count.

Biochemical parameters of hemolysis should be assessed (Table 31.4). Normal or minimal elevation of LDH argues against hemolysis as a major contributing factor to the anemia. The presence of urine hemosiderin suggests chronic intravascular hemolysis but provides no quantitative information, while gross hemoglobinuria indicates clinically significant intravascular hemolysis.

The concentration of erythropoietin should be determined, as renal dysfunction may complicate PNH.[96] Iron deficiency due to hemosiderinuria/hemoglobinuria is common.

Treatment of anemia that is primarily a consequence of bone marrow failure should be aimed at the underlying disease (e.g., aplastic anemia, MDS). Patients with PNH/aplastic anemia or PNH/RA-MDS appear to have a favorable response to immunosuppressive therapy.[71,105,106] If absolute or relative erythropoietin deficiency is thought to contribute to the anemia, replacement with the recombinant protein is warranted, but patients should be closely monitored, as erythropoietin supplementation could exacerbate hemolysis by increasing production of GPI-AP–deficient erythrocytes (patients treated with eculizumab would be protected against such a hemolytic exacerbation). There are also anecdotal reports of patients responding to pharmacologic doses of erythropoietin even when the endogenous concentration is high.[110] Androgens may also be beneficial in patients with PNH who have a hypoproliferative component to their anemia.[111] Complement inhibitory therapy (i.e., eculizumab) would not be expected to have efficacy in the treatment of anemia due to marrow failure.

Complement Inhibitory Therapy

Patients with evidence of clinically significant intravascular hemolysis (markedly elevated LDH, macroscopic hemoglobinuria, reticulocytosis, or transfusion dependence) are candidates for treatment with eculizumab (Soliris, Alexion Pharmaceuticals Inc.). However, patients need not be transfusion-dependent to benefit from eculizumab, as the debilitating symptoms of lethargy, malaise, and asthenia that accompany the chronic, complement-mediated intravascular hemolysis of PNH are ameliorated by treatment with eculizumab. Eculizumab is a humanized monoclonal antibody that binds complement C5, preventing its activation to C5b by the APC C5 convertase and thereby inhibiting MAC formation (Fig. 31.1).[112] In 2007, eculizumab was approved by both the US FDA and the European Union Commission for treatment of the hemolysis of PNH. The drug is now available in countries outside of North American and Europe. Treatment of patients with classic PNH with eculizumab reduces transfusion requirements, ameliorates the anemia of PNH, and improves quality of life.[10,113,114] Following treatment, serum LDH concentration returns to normal or near-normal, with approximately one-half to two-thirds of patients achieving transfusion independence;[84] but mild to moderate anemia, hyperbilirubinemia, and reticulocytosis persist in essentially all treated patients. Eculizumab appears to reduce the risk of thromboembolic complications.[115] For patients being treated with eculizumab who have no prior history of thromboembolic complications, prophylactic anticoagulation may

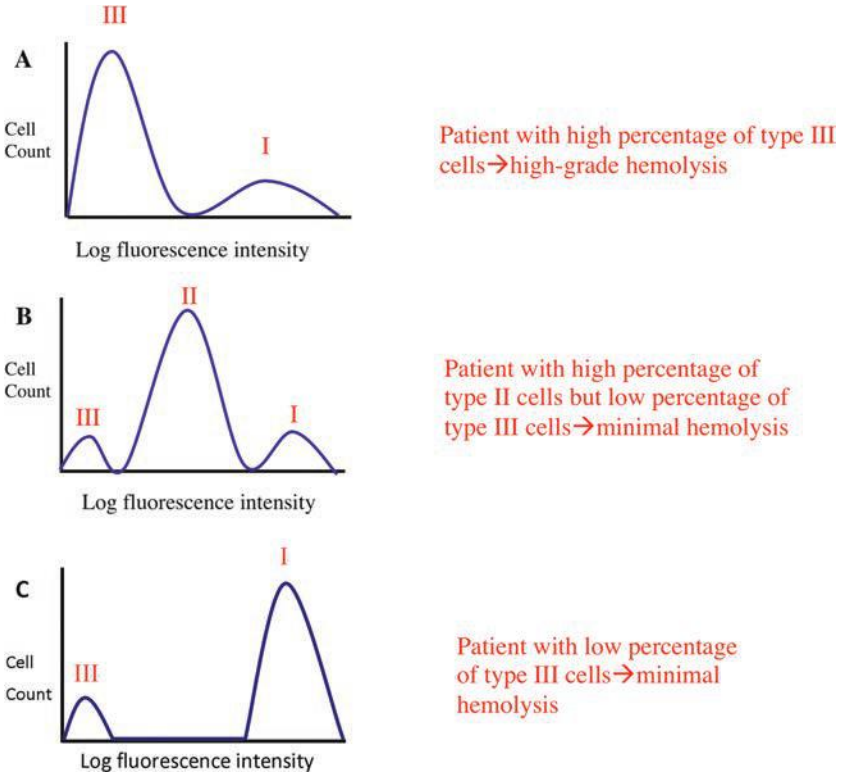

FIGURE 31.10. Impact of phenotype and degree of mosaicism on the hemolytic anemia of PNH. Hypothetical histograms of erythrocytes from patients with PNH stained with anti-CD59 are illustrated. The proportion and type of abnormal erythrocytes varies greatly among patients with PNH and these characteristics are important determinants of clinical manifestations. In general, patients with a high percentage of type III erythrocytes have clinically apparent hemolysis (*panel A*). If the erythrocytes are partially deficient in GPI-AP, hemolysis may be modest even if the percentage of the affected cells is high (*panel B*). A patient may have a diagnosis of PNH, but if the proportion of type III cells is low, only biochemical evidence of hemolysis may be observed (*panel C*). (Modified from Parker C, Omine M, Richards S, et al. Diagnosis and management of paroxysmal nocturnal hemoglobinuria. Blood 2005;106:3699–3709.)

be unnecessary, while it is recommended that anticoagulation continue for those patients who experienced a thromboembolic event prior to initiating therapy with eculizumab.[84] Eculizumab is expensive (~$400,000/year in the United States), and it has no effect either on the underlying stem cell abnormality or on the associated bone marrow failure. Consequently, treatment must continue indefinitely and leukopenia, thrombocytopenia, and reticulocytopenia, if present, persist. Patients treated with eculizumab are at risk for infection with Neisseria organisms, and vaccination against *Neisseria meningitidis* is required prior to initiation of therapy. Nonetheless, deaths from meningococcal sepsis have been observed in patients being treated with eculizumab. Some advocate the use of prophylactic penicillin in patients treated with eculizumab, as the currently available vaccine does not protect against some species of meningococcus.[84] Treatment with eculizumab appears to have a favorable impact on survival, as a recent study of 79 patients treated between 2002 and 2010 showed the same survival as that of age- and sex-matched controls from the general population.[84] However, the contribution of eculizumab to survival in this study cannot be quantified accurately as a control patient group was not included.

TABLE 31.4

INFORMATION USEFUL FOR MANAGING ANEMIA IN PATIENTS WITH PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

- Complete blood count
- Reticulocyte count
- Serum concentration of lactate dehydrogenase (LDH), bilirubin (total and direct fractions), and haptoglobin
- Urine hemosiderin[a]
- Flow cytometric analysis of erythrocytes and granulocytes for expression of glycosyl phosphatidylinositol-anchored proteins (GPI-AP)
- Serum erythropoietin concentration
- Serum concentration of blood urea nitrogen and creatinine
- Serum iron studies (iron concentration, total iron binding capacity, transferrin saturation index, and ferritin concentration

[a]Indicative of chronic hemolysis but provides no quantitative information.
Modified from Parker C, Omine M, Richards S, et al. Diagnosis and management of paroxysmal nocturnal hemoglobinuria. Blood 2005;106:3699–3709.

Reasons for Eculizumab Failure

The recommended maintenance dose of eculizumab is fixed (900 mg every 2 weeks ± 2 days), rather than being based on weight or body surface area. Due to differences in the rate of drug metabolism, some patients may show evidence of breakthrough intravascular hemolysis (i.e., a rise in LDH and development of constitutional symptoms) near the end of a treatment cycle. In these cases, breakthrough hemolysis can be ameliorated by reducing the length of the treatment cycle from 14 days to 13 days or 12 days, and in some instances, the maintenance dose of eculizumab may also have to be increased. All patients with PNH have an element of bone marrow failure, and patients treated with eculizumab who have higher degrees of relative reticulocytopenia may remain anemic or even transfusion-dependent despite excellent control of intravascular hemolysis. Iron stores and serum erythropoietin concentration should be quantified in these patients, and if iron stores are adequate, and serum erythropoietin concentration is inappropriately low, a trial of recombinant erythropoietin is warranted in patients who have symptomatic anemia or who are transfusion-dependent. Following treatment with eculizumab, serum LDH returns to normal or near-normal, but mild to moderate anemia and laboratory evidence of hemolysis persist in essentially all treated patients.[113] A small subgroup of eculizumab-treated patients experiences little or no improvement in either anemia or constitutional symptoms. In these patients, hemolysis is mediated by opsonization of the PNH erythrocytes by activation and degradation products of complement C3, and when tested, they are found to be Coombs'-positive for C3 but not IgG.[116–118,119] The known pathophysiology of PNH predicts that CD55 deficiency would result in ongoing extravascular hemolysis of PNH erythrocytes as a consequence of C3

opsonization (Fig. 31.3), as eculizumab does not block the activity of the APC C3 convertase that is unregulated because of DAF deficiency (Fig. 31.3). Support for this hypothesis is provided by the studies of Risitano and colleagues,[119] who showed that in patients treated with eculizumab, a portion of the PNH erythrocytes (i.e., the CD59-deficient population) had complement C3 bound. Those studies also confirmed the Coombs'-negative designation of PNH, as no C3 was found bound to PNH erythrocytes prior to initiation of treatment with eculizumab, implying that PNH erythrocytes upon which complement has been activated are destroyed directly as a consequence of MAC-mediated cytolysis. Thus, those studies provide a plausible explanation for the persistent hemolytic anemia observed in PNH patients treated with eculizumab. By inhibiting formation of the MAC, eculizumab prevents direct cytolysis of PNH erythrocytes, allowing the manifestations of DAF deficiency to become apparent in the form of aberrant regulation of the APC C3 convertase and the consequent deposition of activated C3 on the cell surface (Fig. 31.3).[120] Covalently bound activation and degradation products of C3 then serve as opsonins that are recognized by specific receptors on reticuloendothelial cells resulting in extravascular hemolysis. The extravascular hemolysis of patients with PNH receiving eculizumab does not require treatment in the absence of constitutional symptoms, symptoms of anemia, or transfusion dependence. As the process is extravascular, splenectomy or corticosteroids may ameliorate the hemolysis in symptomatic or transfusion-dependent patients by removing or inhibiting the function of phagocytic cells. Long-term use of corticosteroids is associated with significant toxicity, however, and concerns about both postoperative and late complications temper enthusiasm for splenectomy. It is also conceivable that the primary site of phagocytosis is hepatic rather than splenic. In such cases, response to splenectomy would likely be inadequate. Based on experience in the treatment of refractory autoimmune hemolytic anemia, a trial of danazol can be considered, however, Rituxan is not indicated, as the process is mediated by C3 opsonization rather than opsonization by IgG antibody.

Androgenic Steroids, Cortical Steroids, and Immunosuppressive Therapy

Although efficacy is controversial,[1] some patients with PNH respond to treatment with androgenic steroids and prednisone.[111]

Approximately one-third of patients appear to respond to androgen therapy with an increase in hemoglobin concentration, a reduction in transfusion requirement, or both; however, attempting to identify the responders in advance is problematic. The mechanism by which androgenic steroids ameliorate the anemia of PNH is not understood, although the rapid onset of action is consistent with complement inhibition.[121] The adverse effects of androgen therapy can be substantial, ranging from virilization in women and acne in both sexes to serious liver disease, including peliosis hepatitis and hepatocellular carcinoma. Although neither of the last two complications has been reported in androgen-treated patients with PNH, some suggest androgens might predispose to an insidious form of hepatic vein thrombosis.[111] These considerations make prudent institution of androgen therapy for 6 to 8 weeks with discontinuation if no clear response is observed. Oral preparations such as fluoxymesterone (5 to 30 mg/day) or oxymetholone (10 to 50 mg/day) have been used most commonly. Because of fewer virilizing adverse effects, the synthetic androgen danazol (400 to 800 mg/day in two divided doses) is an attractive alternative to anabolic steroids. Once hemolysis is controlled, a dose of 200 to 400 mg/day may be sufficient to sustain the response. Monitoring of liver function studies is mandatory, but prolonged use of danazol appears to be safe in most patients.

Corticosteroids have been used as treatment for both chronic hemolysis and acute hemolytic exacerbations. As is the case with androgenic steroids, treatment is empiric, and there is no experimental data that provides a plausible explanation for why steroids should ameliorate the hemolysis of PNH. Nonetheless, some patients appear to respond rapidly and dramatically to glucocorticoids (given in the dosage range of 0.25 to 1.0 mg/kg/d of prednisone). The rapid response (often within 24 hours of initiating therapy) suggests that complement inhibition accounts for the anti-hemolytic activity of glucocorticoid therapy. Such an effect could be direct (the result of inhibition of the activity of some component of the alternative pathway of complement) or indirect (the result of dampening a process, such as inflammation, that stimulates activation of complement).

The main value of corticosteroids may be in attenuating acute hemolytic exacerbations.[1] Under these circumstances, brief pulses of prednisone may reduce the severity and duration of the crisis while avoiding the untoward consequences associated with long-term use. The value of steroids in treating chronic hemolysis is limited by toxicity, and the harm that can accrue from long-term use cannot be overemphasized. An every other day schedule may attenuate some of the adverse effects of chronic steroid use, but patients may note worsening of symptoms on the off day. Careful follow-up is essential and both bacterial prophylaxis and prophylaxis against steroid-induced osteopenia are recommended. Awareness of the potentially debilitating effects of steroid myopathy and sensitivity to the disfiguring consequences of iatrogenic Cushing's syndrome are essential for proper management.

Responses to immunosuppressive therapy with cyclosporin and anti-thymocyte globulin have been reported.[122–124] This approach to management has been applied primarily to patients with PNH/aplastic anemia, and as noted above, immunosuppressive therapy appears to have no effect on the size of the PNH clone.[73] Use of high-dose cyclophosphamide for treatment of PNH and PNH/aplastic anemia has been investigated.[11]

Transfusions

Blood transfusions may be required for treatment of anemia. The recommendation that the blood be given in the form of saline-washed or frozen-thawed, deglycerolized red cells in order to avert a hemolytic episode has been questioned.[125] But hemofiltration is recommended to prevent transfusion reactions resulting from interaction between donor leukocytes and recipient antibodies. Transfused red cells survive normally in patients with PNH, and transfusion to nearly normal hemoglobin levels can produce short-lived "remissions." Clinical improvement may result from a temporary decrease in the production of abnormal cells with a consequent reduction of hemolysis and other disease-associated epiphenomena. Iatrogenic hemochromatosis can occur from chronic transfusions, but may be delayed because of iron loss from hemoglobinuria and hemosiderinuria. In fact, iron overload in patients with classic PNH is rare. But iron overload remains a concern in patients who require chronic transfusion when the anemia is primarily a consequence of marrow failure rather than hemolysis.

Iron

As a result of chronic hemoglobinuria and hemosiderinuria, iron deficiency eventually develops in most patients (even in heavily transfused patients).[126] The amount of iron lost should be replaced, since iron-limited erythropoiesis may contribute to the anemia, and hemolysis appears to be exacerbated by iron deficiency. Most patients tolerate oral iron therapy well, but hemolytic episodes have been precipitated by such treatment. This phenomenon probably results from the outpouring of a cohort of young erythrocytes, a larger proportion of which is more complement-sensitive. Parenteral iron repletion is generally safe. If hemoglobinuria after iron therapy is troublesome, hematopoiesis can be suppressed by a brief period of transfusion during which iron stores are repleted. Alternatively, a short course of high doses

of prednisone given during the early phases of iron replacement therapy may ameliorate the hemolytic exacerbation. For patients treated with eculizumab, a hemolytic exacerbation would not be induced by iron replacement, and iron deficiency should not develop in patients on eculizumab, as inhibition of hemolysis eliminates hemoglobinuria and the consequent iron loss.

Splenectomy

The role of splenectomy in the management of patients with PNH is debatable. Reports of amelioration of hemolysis and improvement in cytopenias following splenectomy are anecdotal. Concerns about lack of proven efficacy and the potential for postoperative complications, particularly thrombosis, limit enthusiasm for splenectomy in the management of PNH.[1]

Folate

Although most normal western diets supply adequate folate, supplemental folate (1 to 5 mg/day) is recommended to ensure compensation for increased utilization associated with heightened erythropoiesis that is a consequence of hemolysis.

Bone Marrow Transplantation

Bone marrow or other forms of stem cell transplantation has been used in the treatment of PNH for nearly 40 years.[127] The unique pathophysiology of PNH should be taken into account when planning a transplant strategy. PNH is a nonmalignant clonal disease, and observation of a patient who underwent a syngeneic stem cell transplant[128] underscores two important differences in response to transplant compared with malignant clonal myelopathies such as acute leukemia. First, cytoreduction of the "tumor" cell burden prior to transplant conditioning is not required, whereas the success of transplant for acute leukemia (and other malignant clonal myelopathies) is dependent on maximum pretransplant tumor debulking. Second, graft vs. tumor effect is not essential for eradication of the PNH clone, whereas graft vs. tumor effect plays a critical role in the outcome of transplant for malignant disorders.

The optimal transplant conditioning regimen for PNH should be made on a case-by-case basis.[1] Clearly some conditioning is essential, as infusion of syngeneic donor marrow without conditioning has limited, transient, efficacy.[129] Using a nonmyeloablative regimen, Childs and colleagues reported that eradication of the PNH clone was incomplete without any graft vs. tumor effect,[130] but as noted above, a myeloablative regimen can completely eradicate the PNH clone without graft vs. tumor effect.[128] Together, these observations can be used in planning a transplant strategy for patients with PNH, depending upon the anticipated or desired role of graft vs. tumor effect in the therapeutic process.

While allogeneic BMT is potentially curative, the benefits must be weighed against the significant morbidity and mortality associated with the procedure. The experience of the International Bone Marrow Transplant Registry (IBMTR) was reviewed in 1999.[131] A total of 57 patients were included in that study, with 48 receiving HLA-identical sibling transplants. The 2-year probability of survival for this group was 56%. Only 1 of 7 patients who underwent unrelated donor transplant was alive after 5 years of follow-up. However, improvements in HLA matching using molecular techniques may improve outcomes with unrelated donors, though unlikely to reach those observed for transplant using stem cells from HLA-identical sibling donors. Successful treatment of patients with PNH using nonmyeloablative stem cell transplantation has been reported.[130,132,133]

When BMT is used to treat patients with PNH/aplastic anemia or PNH-sc/aplastic anemia, the decision on transplantation should be guided primarily by recommendations for management of that particular marrow failure syndrome, typically based on the degree of aplasia and transfusion dependence. For patients with classic PNH, both recurrent life-threatening thrombosis and refractory, transfusion-dependent hemolytic anemia are indications for transplantation. In the pre-eculizumab era PNH patients who had thrombosis at presentation had only a 40% survival rate at 4 years.[66] Progression to pancytopenia was also a risk factor that negatively affected survival,[66] as did development of MDS or acute leukemia, age over 55 at diagnosis, and thrombocytopenia at diagnosis (Table 31.5). Surprisingly, however, an antecedent history of aplastic anemia has been reported to influence favorably survival in a multivariate analysis (Table 31.5).[66] That rarely some patients with PNH undergo spontaneous remission must also be taken into account when deciding on the appropriateness of allogeneic BMT as treatment for PNH.[65,134]

In the unusual circumstance in which the patient has a syngeneic twin, bone marrow transplantation is the most appropriate therapy for classic PNH because absence of graft vs. host disease greatly reduces transplant-associated morbidity and mortality, while graft vs. tumor effect is not necessary for eradiation of the *PIGA*-mutant clone.[128,135] Syngeneic transplantation without preconditioning has been unsuccessful because abnormal hematopoiesis usually returns, suggesting that the residual *PIGA*-mutant stem cells have a survival or proliferative advantage relative to the transplanted GPI-AP$^+$ cells.[129] This same phenomenon may limit the efficacy of gene therapy, as transducing *PIGA*-mutant stem cells with normal *PIGA* would hypothetically eliminate the conditional growth or survival advantage. An attractive alternative approach to gene therapy would take advantage of the fact that the hematopoietic stem cells of patients with PNH are a mosaic. Conceivably, the GPI-AP$^+$ cells can be selected and used for marrow rescue following myeloablation. The success of this approach depends upon developing a method for separating uniformly and efficiently the GPI-AP$^+$ population from the GPI-AP$^-$ population and acquiring GPI-AP$^+$ stem cells sufficient to repopulate the ablated marrow. Fluorescence-activated cell sorting may be useful for this purpose, as CD34$^+$, CD38$^-$ hematopoietic stem cells express both CD55 and CD59.[136]

The question now arises regarding when and how best to perform transplant in the eculizumab era. Short-term treatment with eculizumab may provide an opportunity to reduce hemolysis and

TABLE 31.5

RISK FACTORS AFFECTING SURVIVAL BEFORE THE AVAILABILITY OF ECULIZUMAB

Factor	Relative Risk of Disease-Related Mortality (95% Confidence Interval)	*p* value
Development of thrombosis	10.2 (6.0–17)	<0.0001
Progression to pancytopenia	5.5 (2.8–11)	<0.0001
Myelodysplastic disease or acute leukemia	19.1 (7.3–50)	<0.001
Age over 55	4.0 (2.4–6.9)	<0.0001
More than one treatment	2.1 (1.3–3.6)	<0.003
Thrombocytopenia at diagnosis	2.2 (1.3–3.8)	<0.003
Aplastic anemia antedating paroxysmal nocturnal hemoglobinuria	0.32 (0.14–0.72)	<0.023

stabilize the blood counts, prior to a planned transplant. In one recent report, eculizumab was used until 2 weeks before a highly lymphoablative conditioning regimen, with good success.[137]

Before the availability of eculizumab, the primary indications for transplantation for PNH were bone failure, recurrent life-threatening thrombosis, and uncontrollable hemolysis.[1] The latter process can be eliminated by treatment with eculizumab, and the thrombophilia of PNH may also respond to inhibition of intravascular hemolysis by eculizumab.[138] Nonetheless, transplantation is the only curative therapy for PNH; and the availability of molecularly defined, matched unrelated donors, less toxic conditioning regimens, reductions in transplantation-related morbidity and mortality, and improvements in post-transplantation supportive care make this option a viable alternative to medical management.[138] The decision of who should receive a transplantation and when it should be performed is complex, however, and requires an understanding of the unique pathobiology of PNH and the input of physicians experienced in transplantation and medical management of PNH.[139] The recent studies of Kelly et al.[84] showing normal survival for patients with PNH treated with eculizumab make the decision concerning medical management versus transplantation even more challenging.

Prevention and Treatment of Thrombosis

In contrast to our thorough understanding of the basis of the hemolysis, much less is known about the mechanism that underlies the thrombophilia of PNH[89] (Table 31.6).

A recent review of 13 retrospective studies of PNH in nonpregnant patients revealed considerable variation in the reported rate of thromboembolic disease; however, overall 14.4% (95% confidence interval 7.6 to 25.5) of the patients included in these studies were affected.[140] Thromboembolic complications of PNH appear to be more common among patients from western countries (with the exception of Mexico[141]), with intra-abdominal (hepatic and mesenteric veins) and cerebral veins being the most commonly involved sites (Table 31.6). Nine of these studies described cause of death, with 22% of the mortality being due to venous thrombosis (higher among westerners).

Clinicians should be particularly alert for thrombotic disease in patients with indwelling catheters, after surgical procedures, during prolonged sedentary periods, and during the puerperium (pregnancy and PNH are discussed below). Female patients should avoid the use of estrogen-containing oral contraceptives because these agents increase the risk of serious thrombotic disease.

TABLE 31.6

THROMBOSIS AND PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH)

The pathogenesis of the thrombophilia of PNH is incompletely understood

- Sites of thrombosis that are disproportionately represented in PNH
  - Hepatic vein (Budd-Chiari syndrome)
  - Mesenteric veins
  - Portal vein
  - Cerebral veins
  - Dermal veins
- Propensity toward thrombosis appears roughly proportional to the size of the PNH clone[a]
- The risk of thromboembolic disease appears higher in Caucasian and African-American patients than in patients of Asian/Pacific Island or Hispanic ancestry even when adjusted for clone size
- Caucasian and African-American patients with >50% GPI-AP–deficient granulocytes who have no contraindications are candidates for prophylactic anticoagulation with warfarin[b]
- Patients with PNH who have experienced a thromboembolic event should remain anticoagulated indefinitely[c]

[a]The size of the PNH clone is determined by flow cytometric analysis of expression of GPI-AP on peripheral blood granulocytes.
[b]Standard intensity warfarin therapy (INR 2.0–3.0) is recommended for chronic therapy.
[c]Long-term anticoagulation should be reassessed in any patient who undergoes a spontaneous remission or in whom the PNH clone size falls to below 50%.
Modified from Parker C, Omine M, Richards S, et al. Diagnosis and management of paroxysmal nocturnal hemoglobinuria. Blood 2005;106:3699–3709.

Treatment of thromboembolic complications of Paroxysmal Nocturnal Hemoglobinuria

Anticoagulation is required for treatment of venous thrombosis (including cerebral vein thrombosis) associated with PNH, with thrombolytic therapy being advocated for extensive acute or life-threatening hepatic vein thrombosis (see below). Mild to moderate thrombocytopenia (platelet count between 50,000 and 100,000/μl) is not a contraindication to anticoagulation; however, platelet transfusion may be required for patients with counts < 50,000/μl. Occasional episodes of hemolysis coincident with the administration of heparin have been reported,[111] and this phenomenon has been attributed to activation of the alternative pathway of complement by heparin. This complication is rare, however, and concern for exacerbation of hemolysis by heparin should not deter its use in standard pharmacologic doses in situations where anticoagulation is warranted. Once adequately anticoagulated with heparin, Coumadin therapy should be initiated with a goal of maintaining the international normalized ratio between 2.0 and 2.5. Although data on recurrence rates have not been generated, patients with PNH who experience a thromboembolic episode probably warrant life-long anticoagulation.

For hepatic vein thrombosis or other life-threatening conditions, prompt treatment with heparin or thrombolytic agents is recommended.[91,142] Even with heparin therapy, extensive hepatic vein thrombosis is associated with a poor prognosis.[95,142] Experience with thrombolytic therapy in this setting is limited, but success has been reported with the use of streptokinase, urokinase, and tissue plasminogen activator.[142,143] A recent review of nine patients receiving intravenous tissue plasminogen activator on 15 occasions reported serious hemorrhagic complications in three, so thrombolysis must be considered a high-risk intervention.[144] A PNH patient with chronic hepatic vein thrombosis markedly improved following bone marrow transplantation.[135]

Prophylactic anticoagulation

In the study of Socié et al. that antedated the use of eculizumab,[66] 30% of French patients experienced an episode of thrombosis within 8 years of the diagnosis of PNH, and based on Kaplan-Meier estimates, approximately 50% of patients were predicted to have this complication within 15 years. Because of the relatively high incidence of thrombosis (particularly among westerners) and its associated morbidity and mortality, an argument can be made for prophylactic anticoagulation in patients without contraindications such as severe thrombocytopenia.[104] A nonrandomized study with a relatively short follow-up period suggested a significant reduction in thrombotic events when PNH patients with ≥50% GPI-AP–deficient granulocytes received prophylactic anticoagulation with Coumadin[104] (Table 31.6). A second, more recent retrospective study supports the use of prophylactic anticoagulation for patients with large PNH clones (>50% to 60%).[103] The benefits of prophylactic anticoagulation, however, must be weighed against potential adverse effects of long-term anticoagulation. Patients at risk for cerebral vein thrombosis and portal/hepatic vein thrombosis would likely derive the greatest benefit from prophylactic anticoagulation. A method for identifying that subgroup of patients, however, has not been developed.

Eculizumab appears to reduce the risk of thromboembolic complications.[115] For patients being treated with eculizumab who have no prior history of thromboembolic complications, prophylactic anticoagulation may be unnecessary.[84] Because PNH patients with prior thrombosis are at higher risk for recurrent thrombosis, anticoagulation for eculizumab-treated patients who experienced a prior thromboembolic event should be continued.[84,138]

Pregnancy and Paroxysmal Nocturnal Hemoglobinuria

Pregnancy is often hazardous in PNH;[145–147] however, patients with PNH can have successful, uncomplicated pregnancies[147–150]. De Gramont and colleagues[147] reported that approximately one-third of 38 pregnancies observed in 28 patients with PNH were uncomplicated and that life-threatening complications in mothers are uncommon. Complications experienced by mothers in that series were mainly hemorrhage and acute hemolysis. However, 45% of the pregnancies resulted in either spontaneous miscarriage or elective termination. Other studies[145] have reported a maternal mortality of ~6%, with the major complications being related to thrombosis (particularly Budd-Chiari syndrome). Fetal wastage and prematurity were also reported to be relatively common. Based upon a review of 20 published reports that described the outcome of 33 pregnant women with PNH, Ray and colleagues[140] calculated an all-cause maternal mortality rate of 20.8% (95% confidence intervals 7.3 to 39.0). Approximately half of all infants were delivered preterm. Three deaths were reported among 34 live births (perinatal mortality of 8.8% with 95% confidence intervals of 1.9 to 23.7).

When possible, patients with PNH who are contemplating pregnancy should be counseled about the potential for both maternal and fetal complications. However, in approximately 25% of cases of PNH and pregnancy, PNH is first diagnosed during pregnancy.[140] The care of a pregnant patient with PNH requires the combined expertise of an experienced hematologist and an obstetrician who specializes in the management of high-risk pregnancies.[151]

Unless there is an absolute contraindication, patients should receive therapeutic doses of subcutaneous heparin during pregnancy. Low-molecular-weight heparin may be advantageous because it is associated with a lower incidence of drug-induced thrombocytopenia compared with unfractionated heparin. Nonetheless, the platelet count should be monitored frequently (weekly), as thrombocytopenia frequently complicates PNH during pregnancy. Patients should undergo hepatic ultrasound monthly to monitor the patency of hepatic veins. Anticoagulation should be initiated as soon as the pregnancy is documented and should continue 4 to 6 weeks into the postpartum period.[140] Coumadin should be used for anticoagulation during the postpartum period.

In the eculizumab treatment era, the question has arisen regarding the safety of treating a pregnant woman with PNH. Since eculizumab is a hybrid of IgG2 and IgG4, little antibody is believed to cross the placenta. Two reports have documented the safety of treatment throughout gestation for both mother and baby.[152,153]

Pediatric Paroxysmal Nocturnal Hemoglobinuria

PNH can occur in the young (about 10% of patients are younger than 21),[1,65,66,154] but is often misdiagnosed and mismanaged.[85,155] A retrospective analysis of 26 cases[85] underscored the many similarities between childhood and adult PNH. Signs and symptoms of hemolysis, bone marrow failure, and thrombosis dominate the clinical picture, with hemoglobinuria occurring less often in young patients. A generally good response to immunosuppressive therapy (6 of 9 patients) was observed. However, based on the lack of spontaneous remissions and poor long-term survival (80% at 5 years, 60% at 10 years, and only 28% at 20 years), sibling-matched stem cell transplantation is the recommended treatment for childhood PNH. A recent Dutch study confirmed the common presentation of bone marrow failure in 11 children with PNH,[155] and reported that five patients eventually received BMT (three matched unrelated donors and two matched family donors) of whom four are alive. A recent cohort of 12 children with PNH documented five with myelodysplastic features without excess blasts or malignant transformation.[156] Mortality appears high in young patients with PNH treated with transplantation using unrelated donors, although surviving cases have been reported.[133,155]

Dysphagia, Male Impotence, Abdominal Pain

Many patients with PNH are troubled by dysphagia and odynophagia, especially during hemolytic exacerbations.[1] These symptoms appear to be a consequence of esophageal spasm. The cause of the spasm is speculative, but may be due to acquired deficiency of nitric oxide (NO), a bioactive molecule that mediates smooth muscle relaxation.[99] Males with PNH may experience episodes of impotence, particularly during hemolytic exacerbations. The cause of the impotence may also be a consequence of decreased bioavailability of NO. Sildenafil citrate has shown efficacy in the treatment of hypercontractile motility disorders of the esophagus, including idiopathic achalasia, where the mechanism of disease appears to be impaired NO production similar to that reported for erectile dysfunction.[157–159] Therefore, sildenafil citrate and pharmacologically related compounds are candidate therapies for both the dysphagia/odynophagia and male impotence of PNH. Agents such as oral or dermal nitroglycerine that supply NO pharmacologically have also shown efficacy.

Some patients with PNH are debilitated by recurrent episodes of colicky abdominal pain.[1] The etiology of the abdominal pain is largely speculative, but thrombosis of mesenteric vessels appears to play a role in some cases. Vascular spasm may also contribute to this process. Vigorous hydration and pain control are the mainstays of management, but mesenteric vein thrombosis can result in intestinal infarction necessitating surgical intervention. Still to be determined are the roles of anticoagulation, complement inhibition, and NO supplementation in the management of abdominal pain of PNH.

Geographic/Ethnic Differences

The natural history of PNH appears different for Americans and Europeans compared with Asian/Pacific Islanders and Hispanics.[88,134,141,160,161] In general, the manifestations of bone marrow failure are more common in Asians/Pacific Islanders and Hispanics. In contrast, thrombosis and infection appear more common in American and European patients (Table 31.6). The basis of these phenotypic differences is unknown, but the relationship of ethnicity and geography to the natural history of PNH should be considered when formulating a management plan.

DISEASE COURSE AND PROGNOSIS

PNH is a chronic disease. Retrospective studies that antedated the use of eculizumab suggested a median survival of 10 to 15 years.[65,66] Approximately 25% of patients survive for 25 years or longer after diagnosis.[65] The major causes of morbidity and mortality are thrombosis, bleeding, and infections. The latter two complications are due to thrombocytopenia and neutropenia, respectively, which are consequences of the abnormal hematopoiesis that underlies this stem cell disorder. The salutary effects of eculizumab therapy on both hemolysis and thrombosis should also help reduce the early mortality of PNH, but long-term data have not been reported to date.[84]

In some PNH patients, the severity of the illness lessens with time, and (in one series) approximately one-third of patients who survived 10 years experienced a spontaneous clinical remission.[65] These cases suggest that, in time, the abnormal clone(s) can gradually lose their relative proliferative or survival advantage.

That the disease spontaneously remits in some instances provides a basis for hope for both patient and physician. Additionally, this feature of the disease should enter into management decisions, particularly when the patient is a candidate for allogeneic bone marrow transplantation.[65] Spontaneous remission, however, appears to occur primarily in patients with PNH/aplastic anemia, with such remission being unlikely in patients with classic PNH.

Development of other clonal myelopathies, including myelodysplastic disease and acute leukemia, adversely affect prognosis.[66] The incidence of acute leukemia in association with PNH appears to be in the range of 1%,[66] although higher (7.7% in a study of Japanese patients[160] and lower (0 of 80 patients in a study from England[65]) incidences have been reported. The rate of myelodysplastic disease in association with PNH is on the order of 5%.[66] Other clonal myelopathies that have been reported in association with PNH include myelofibrosis, chronic lymphocytic leukemia, chronic myelocytic leukemia, polycythemia vera, and erythroleukemia. In some instances, the clonal myelopathy arises in the PNH clone,[79,80] whereas in other instances it arises in a GPI-AP+ clone.[81,82] The association of PNH with other stem cell disorders, particularly myelodysplasia and acute leukemia, suggests that genetic instability is a component of the disease.[162] This process may be a consequence of the as yet undefined bone marrow injury that underlies PNH.

Future Directions for Clinical and Basic Research

Among the important issues that need to be addressed through careful clinical studies are the following:

a. Guidelines for management of the thrombophilia of PNH
b. Guidelines for bone marrow and stem cell transplantation
c. Guidelines for how best to use eculizumab
d. Guidelines for management of pregnancy and PNH
e. Clearer definitions of the effects of ethnic/geographic differences on the natural history of PNH

An international observational study designed to generate data on the natural history and treatment of PNH is currently open to enrollment (http/www.pnhregistry.com).

Basic research into the mechanism of the thrombophilia of PNH and the basis of clonal selection and clonal dominance will likely produce new insights into the pathobiology of PNH and the physiology of benign and malignant clonal hematopoiesis.

CHAPTER 32

ACQUIRED NONIMMUNE HEMOLYTIC DISORDERS

Robert T. Means, Jr., Bertil Glader

Hemolysis occurs when red blood cells (RBCs) are exposed to a variety of infectious agents, chemicals, or physical stresses. In some cases these effects are antibody mediated (Chapters 29 and 30). In other patients, such as those with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 28) or those with unstable hemoglobins (Chapter 35), there is an underlying propensity of the RBCs to be more susceptible to injury. In still other cases, such as paroxysmal nocturnal hemoglobinuria (PNH), hemolysis occurs as a consequence of an acquired clonal abnormality in the RBC membrane (Chapter 31). Hemolytic anemia also occurs when otherwise normal red cells are injured directly by infectious agents, chemicals, thermal injury, mechanical stresses, or altered metabolites. These etiologies of hemolysis are the focus of this chapter.

HEMOLYSIS DUE TO INFECTION

A variety of infectious processes can lead to hemolytic destruction of normal RBCs. In some cases, such as in *Mycoplasma pneumoniae* infection or with infections related to paroxysmal cold hemoglobinuria, hemolysis is related to antibody-mediated cell destruction (Chapter 29). With the infections described in this section, hemolysis is largely the result of direct nonimmune effects on erythrocytes. Some of the infections discussed here are not major problems in North America or Europe; however, to the extent that there is significant international travel to and from endemic areas, recognition of these infections is important for medical personnel worldwide.

Malaria

Malaria is an acute, chronic, or recurrent febrile disease caused in humans by four species of *Plasmodia: Plasmodia vivax, Plasmodia falciparum, Plasmodia malariae,* and *Plasmodia ovale.* Infections with *P. falciparum* are the major form of malaria in Africa and Southeast Asia, whereas *P. vivax* is most common in Central America and India. These protozoan microorganisms are capable of parasitizing erythrocytes and other body tissues. Malaria is spread by female mosquitoes of the genus *Anopheles* (Fig. 32.1). The sexual phase of the *Plasmodium* life cycle takes place within the mosquito. The semitropical and tropical endemic distribution of malaria corresponds to the distribution of the vector.

On a worldwide basis, malaria is the most prevalent of all serious diseases; it has been estimated that approximately 2.5 billion people are at risk for malaria, and that approximately 500 million people are infected with *P. falciparum.*[1,2] Ninety percent of the deaths is in African children.[3] Malaria has not been endemic in the United States since the 1940s, but approximately 1,000 cases have been reported each year since 1985, and there has been a steady increase in the number of cases reported annually.[4] Malaria can also be transmitted by blood transfusions[5] or by sharing needles among intravenous drug abusers.[6,7]

Clinical Manifestations

After the initial exposure to malaria, some patients are completely asymptomatic, whereas others have nonspecific flulike symptoms that mimic a viral illness.[8] Classically, the most prominent clinical manifestations are recurrent paroxysms of chills and fever with temperatures as high as 105° to 106°F (40.5° to 41°C) associated with malaise, headache, vomiting, and other systemic symptoms. The paroxysms tend to recur regularly every 36 to 72 hours. They are most prominent with *P. malariae* infections and much less with *P. falciparum.* Splenomegaly is noted in about one half of patients during early stages of disease[8] and becomes more common later. Jaundice and hepatomegaly may develop in later stages of the illness.

Of the various malaria species, *P. falciparum* infection causes the most morbidity and mortality. In the acute stage, it can be associated with increasing parasitemia, hypotension, malignant hyperthermia, and death. In addition, *P. falciparum* malaria is associated with cerebral, pulmonary, and renal complications.[9] The overall mortality from a study of over 1,800 children with malaria in Kenya was 3.5%; in 84% of cases death occurred within 24 hours of admission.[10] The most important prognostic factors for death were impaired consciousness and respiratory distress (Fig. 32.2). Severe anemia alone did not affect prognosis.[3,10]

Anemia is common in malaria.[11–13,14] It is particularly characteristic of *P. falciparum* malaria because of the greater extent of red cell parasitization with this species. With uncomplicated *P. falciparum* malaria, moderately severe anemia is seen in approximately 20% of previously healthy patients during or after the first infection.[15] Complete eradication of malaria parasites from the blood may take months to years, particularly in areas of high transmission; immunity to malaria is slowly acquired. In tropical areas, anemia tends to be most prevalent and most severe in children from 1 to 5 years of age,[16] whereas only moderate anemia is usually noted in adolescents and adults.

In children, the circulating parasite count is inversely proportional to the hematocrit.[17] Leukocyte numbers may be normal, but patients often have leukopenia. Thrombocytopenia has been observed in about two thirds of patients with *P. falciparum* malaria,[9,16] often associated with splenomegaly.[18]

The most serious hematologic complication of malaria is acute intravascular hemolytic anemia (blackwater fever), which occurs as a rare event in the course of infection by *P. falciparum.* The clinical manifestations are fulminating, the intravascular hemolysis being associated with prostration, vomiting, chills, and fever. Hemoglobinemia, hemoglobinuria, and hyperbilirubinemia are consistent features, and in the most severe episodes, acute oliguric renal failure supervenes.

Pathogenesis

After a bite from the female *Anopheles* mosquito, sporozoites introduced into the circulation go to the liver parenchyma where they proliferate into thousands of merozoites (Fig. 32.1). The duration of this liver development stage varies between species. The infected hepatocytes next release merozoites into the bloodstream where they invade erythrocytes.

The ability of various *Plasmodia* to infect red cells is related to their attachment to specific membrane receptors. Of the species that infect humans, *P. vivax* and *P. ovale* invade only reticulocytes. *P. malariae* invades mature red cells, and *P. falciparum* invades erythrocytes of all ages. As a result, the proportion of cells parasitized in *P. vivax* malaria rarely exceeds 1%, whereas as many as 50% of cells may be affected in *P. falciparum* malaria. It is of interest that *P. vivax* invades only Duffy blood-group–positive red cells[19]; in West Africa where the Duffy antigen is missing on red cells, *P. vivax* malaria is nonexistent. *P. falciparum* apparently has two receptors: one that binds to sialic acid groups on the erythrocyte membrane protein glycophorin and another that

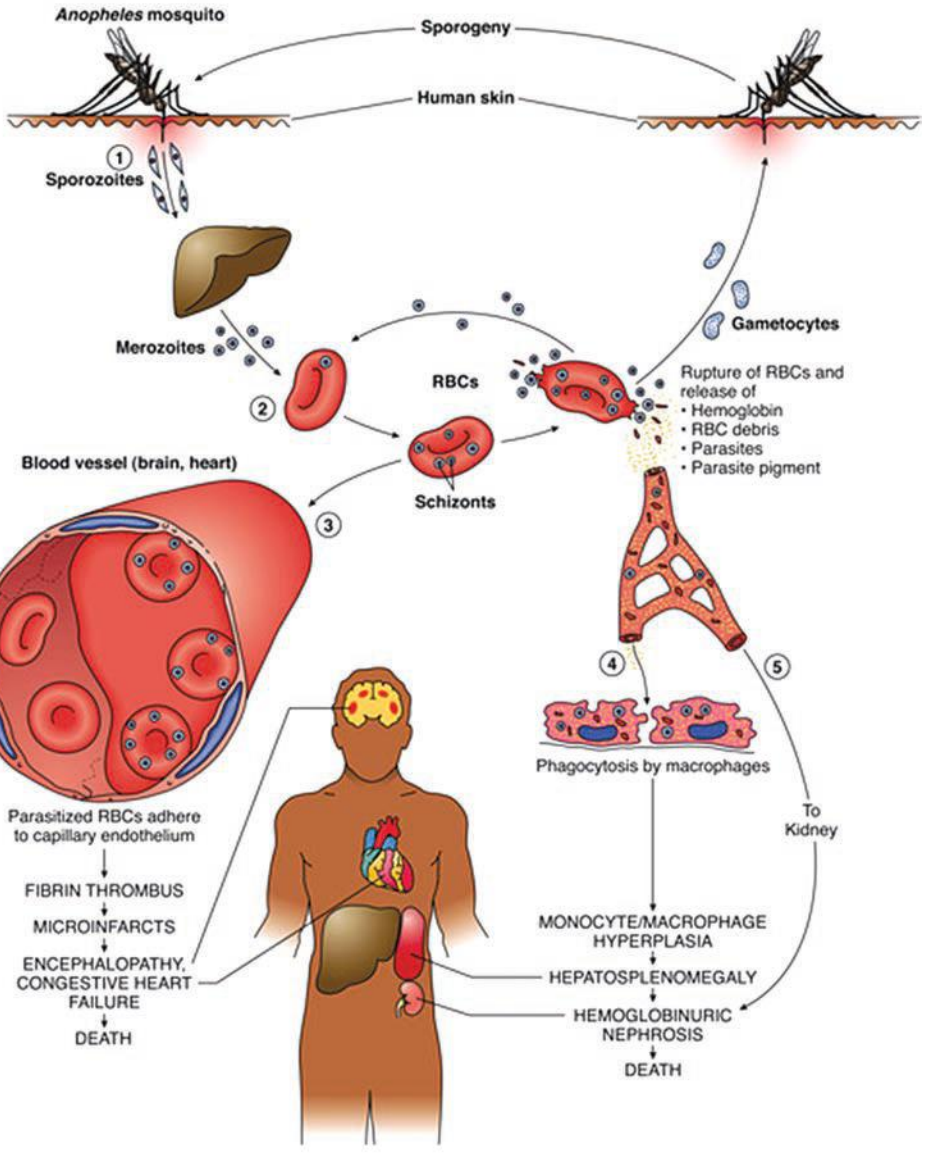

FIGURE 32.1. Life cycle of malaria. An Anopheles mosquito bites an infected person, taking blood that contains micro- and macrogametocytes (sexual forms). In the mosquito, sexual multiplication ("sporogony") produces infective sporozoites in the salivary glands. (1) During the mosquito bite, sporozoites are inoculated into the bloodstream of the vertebrate host. Some sporozoites leave the blood and enter the hepatocytes, where they multiply asexually (exoerythrocytic schizogony), and form thousands of uninucleated merozoites. (2) Rupture of hepatocytes releases merozoites, which penetrate erythrocytes and become trophozoites, which then divide to form numerous schizonts (intraerythrocytic schizogony). Schizonts divide to form more merozoites, which are released on the rupture of erythrocytes and re-enter other erythrocytes to begin a new cycle. After several cycles, subpopulations of merozoites develop into micro- and macrogametocytes, which are taken up by another mosquito to complete the cycle. (3) Parasitized erythrocytes obstruct capillaries of the brain, heart, kidney, and other deep organs. Adherence of parasitized erythrocytes to capillary endothelial cells causes fibrin thrombi, which produce microinfarcts. These result in encephalopathy, congestive heart failure, pulmonary edema, and frequently death. Ruptured erythrocytes release hemoglobin, erythrocyte debris, and malarial pigment. (4) Phagocytosis leads to monocyte/macrophage hyperplasia and hepatosplenomegaly. (5) Released hemoglobin produces hemoglobinuric nephrosis, which may be fatal. (From Rubin E, Farber JL. Pathology, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.)

binds to a trypsin-sensitive, nonsialated ligand.[20,21,22] Other proposed parasite receptors include surface heparinlike molecules[23] and complement receptor type-1.[24]

Further development of the parasite within red cells is along one of two pathways, either asexual or sexual differentiation (Fig. 32.1). Sexual forms, or gametocytes, continue their development within mosquitoes. The asexual differentiation of parasites in red cells proceeds from young ring forms through trophozoites to produce schizonts containing 6 to 32 merozoites (Fig. 32.3). In the process, parasites use 25% to 75% of the hemoglobin of the cell.[25] The intraerythrocytic phase lasts 24 to 72 hours, depending on the species. The schizonts then lyse, the cell ruptures, and the merozoites are released to invade other cells, thereby continuing the erythrocyte cycle. The simultaneous rupture of billions of schizonts from red cells is associated with the classic paroxysms of malarial fever.

Erythrocytes parasitized by certain strains of *P. falciparum* develop electron-dense knobs that mediate the attachment of the infected red cells to venules.[26–28] Such sequestration of parasite-infected RBC creates an obstruction to tissue perfusion. In addition, the sequestration in venules prevents parasitized cells from entering the splenic circulation, thereby evading destruction and enhancing merozoite development; this phenomenon may be a factor in the rapid development of anemia in severe infections.[29]

The anemia in malaria is due to a combination of factors that include parasite-mediated RBC destruction, splenic removal of

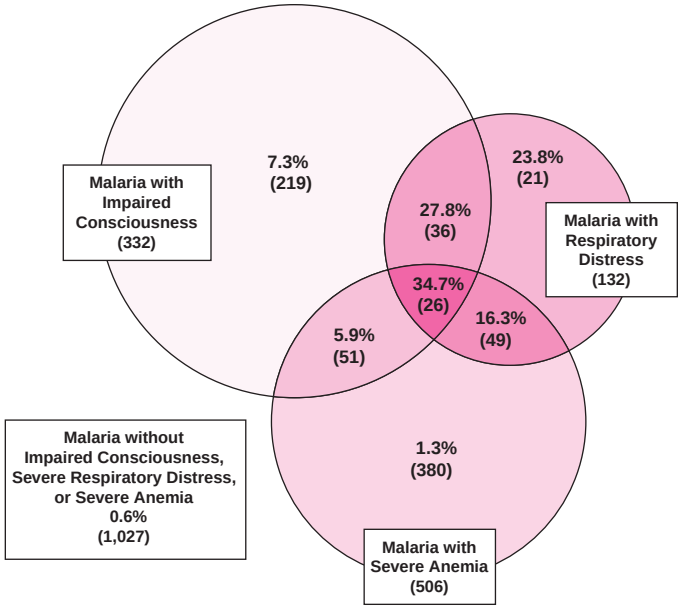

FIGURE 32.2. Prevalence, overlap, and mortality for major clinical subgroups of severe malaria in 1,809 African children. In 1,027 of these children, malaria was present without signs of impaired consciousness, respiratory distress, or severe anemia. In a subset of all children presenting with malaria (782 patients; approximately 40% of total) there was evidence of severe anemia (hemoglobin <5 g/dl), severe respiratory distress, impaired consciousness, and/or some combination of these clinical findings. Almost all deaths occurred in the children who presented with combinations of these clinical abnormalities. Total numbers of patients are given in parentheses. Mortality is given as a percentage. (Modified from Marsh K, Forster D, Waruiru C, et al. Indicators of life-threatening malaria in African children. N Engl J Med 1995;332(21):1399–1404.)

infected RBCs, and decreased red cell production (Table 32.1). Hemoglobin digestion and cell disruption by the parasite are clearly the major causes of hemolysis.[11,12,30] The malarial pigment hemozocin, a product of hemoglobin degradation,[25] also inhibits erythropoiesis.[31,32]

The role of the spleen in red cell destruction is related to the decreased deformability of RBCs infected with *Plasmodia*,[33–35] erythrocyte retention in the red pulp, prolonged exposure to splenic macrophages, and removal of parasitized cells or "pitting" of the parasite, with consequent damage to the cell.[36–38] A similar process of macrophage-mediated destruction of parasitized RBCs occurs in the marrow sinusoids.[39] Moreover, normal nonparasitized RBCs have a shorter survival in malaria, presumably a consequence of hypersplenism and hyperactive macrophages.[40]

Even after complete clearance of the parasites, hemolysis may persist for 4 to 5 weeks.[41] A complement-mediated process may be responsible in part, and the direct antiglobulin test is often positive.[42]

Dyserythropoiesis with characteristic morphologic findings also occurs in malaria. It is thought that this contributes to the slow recovery seen after a single malarial attack and also to the persistence of anemia in individuals with chronic parasitemia.[13,43,44]

Anemia often persists for weeks following treatment of malaria, and this results in part from relative marrow failure, as occurs in association with other forms of infection (see Chapter 41).[12,41] Abnormalities in several of the cytokine mediators of the anemia of chronic disorders (tumor necrosis factor, interferon gamma) have been reported in patients with severe *P. falciparum* malaria.[45,46,47–49]

Serum erythropoietin levels often are inadequate for the degree of anemia.[50,51,52] The bone marrow response to erythropoietin also appears to be impaired.[53] Circulating concentration of the iron regulatory peptide hepcidin, a key mediator of the anemia of chronic disease, is elevated early in the course of malaria.[54,55] This results in impaired iron mobilization.[56,57]

The percentage of reticulocytes tends to be low during active infection and increases transiently after effective treatment. In *P. vivax* malaria, however, the low reticulocyte count may be explained in part by the increased affinity of the organism for immature erythroid precursors and reticulocytes.[58] Infection by *P. vivax* appears to be retricted to reticulocytes.[59]

The pathogenesis of acute intravascular hemolysis (blackwater fever) remains uncertain, and currently this complication is less commonly seen, although it still occurs.[60,61] Blackwater fever does not reflect an unusual degree of parasitemia. In many historical cases, the acute intravascular hemolysis appears to have been precipitated by quinine ingestion[62,63]; quinine, for many years the primary treatment agent for malaria, may act as

TABLE 32.1

FACTORS CONTRIBUTING TO ANEMIA IN MALARIA

Accelerated red blood cell (RBC) destruction
Direct parasite destruction of red cells
Decreased deformability of parasitized RBCs and destruction by splenic macrophages
Macrophage-mediated destruction of parasitized RBCs in marrow and liver sinusoids
Destruction of nonparasitized cells by immune mechanisms
Destruction of nonparasitized cells by hypersplenism and hyperactive macrophages
Hapten (quinine)-induced intravascular hemolysis (blackwater fever)
Decreased RBC production
Bone marrow suppression due to inflammatory cytokines
Inadequate erythropoietin production
Dyserythropoiesis

Modified from Menendez C, Fleming AF, et al. Malaria-related anaemia. Parasitol Today 2000;16(11):469–476.

a hapten, becoming antigenic after interacting with the red cell. However, cases involving untreated individuals also have been reported.[9] Some episodes thought to represent blackwater fever may have resulted from the use of primaquinelike drugs in G6PD-deficient people.

Certain inherited red cell disorders appear to confer resistance to malaria, either by inhibiting parasitic invasion or by slowing intracellular growth. It is thought that these phenomena may contribute to increased prevalence of such inherited diseases because of their effects on survival (balanced polymorphism). These disorders include sickle cell trait,[64–66] G6PD deficiency,[67–69,70] thalassemia,[71,72] hemoglobin E variants,[70] hemoglobin C variants,[73] ovalocytosis of the Melanesian (Malayan) type,[74] and lack of the Duffy blood group antigen.[19]

Diagnosis

Diagnosis of malaria in the United States is often delayed because it is not suspected.[8,75] Such delays are dangerous because the early mortality rate from *P. falciparum* malaria approaches 10%, and these deaths can be prevented with adequate treatment. Malaria should be considered in the differential diagnosis of any febrile patient returning from an endemic zone.

Diagnosis traditionally has required identification of parasites on the blood smear (Fig. 32.3). They can be recognized on ordinary Wright-stained smears, but the chances for detection and identification of species are enhanced by the use of thick smears. Single negative smears do not exclude the disease with certainty in patients with low-grade infections. Parasites may be detected in blood during any phase of the illness, but the chances of detection are greatest during afebrile periods. *P. falciparum* disease is distinguished from that caused by other strains by heavy parasitemia involving all ages of erythrocytes and by the lack of trophozoites and schizonts; usually, only ring forms and the distinctive, banana-shaped gametocytes are apparent (Fig. 32.2).

Simple test strips that take 10 to 15 minutes are available for diagnosis of malaria from a drop of fingerstick blood. The sensitivity of these tests is probably as good as microscopy. Diagnosis by rapid polymerase chain reaction is also available.[76–78] Regardless of the method used, it is important to distinguish *P. falciparum* malaria from other malaria species because of therapeutic considerations, and because only *P. falciparum* infection has the potential for being rapidly fatal.[9]

Management

Therapeutic considerations for malaria include supportive medical care for anemia and other complications. Administration of folate to patients with malaria is controversial; its use is associated with higher hematocrits, but may also prolong parasitemia.[79] Chemoprophylaxis should be recommended to all people traveling to an endemic area.[80,81] Because of the spread of drug-resistant strains of *P. falciparum,* however, no single regimen is completely effective. Knowledge of the characteristics of the malaria strains in the sites to be visited is essential. Because of changes in drug resistance and the development of new agents, before recommending a regimen to a prospective traveler, physicians should become familiar with current guidelines from the U.S. Centers for Disease Control and Prevention (CDC), Atlanta, Georgia. See the CDC website (http://www.cdc.gov/travel/malinfo.htm).

Babesiosis

Infection by tick-borne protozoans of the genus *Babesia* is rare in humans.[82–83,84] The infection has been reported in Nantucket and other islands off the northeastern U.S. shore, as well as in neighboring coastal areas of New England. It also is found in north central states, Washington, and California.[85] Most cases of babesiosis described in Europe have occurred in asplenic individuals.[84,86] In the United States, *Babesia microti* is the causative agent, whereas *Babesia divergens* is the species identified in Europe, and the latter cases are usually more severe.[82,87] Babesiosis also can be transmitted by blood transfusion.[88]

Babesiosis is characterized by an acute febrile illness and hemolytic anemia, very similar to malaria. In most cases it is a mild self-limited disorder that goes undiagnosed, and thus is not reported. It is likely the true incidence of babesiosis in healthy hosts is underrecognized. However, in asplenic individuals it can produce serious, often fatal illness with hemolytic anemia, renal failure, or pulmonary edema.[82,84,89]

Laboratory features include hemoglobinuria, hyperbilirubinemia, normocytic anemia, thrombocytopenia, and sometimes leukopenia.[82] Both *B. microti* and *B. divergens* can be seen in RBCs on the peripheral blood smear and can be confused with malaria.[82] Serologic antibody tests and polymerase chain reaction–based assays are available to aid in diagnosis.[90]

In mild cases of babesiosis no treatment may be necessary. In more severe cases, the combinations of atovaquone and azithramycin or of clindamycin and quinine are useful. The atovaquone/azithramycin is reportedly better tolerated.[90,91] Red cell exchange transfusions have been used also.[90,91,92]

Trypanosomiasis

Moderate to severe hemolytic anemia is a regular feature of African trypanosomiasis (sleeping sickness).[93–95] This often fatal illness is caused by *Trypanosoma brucei gambiense* or *T. brucei rhodesiense*. The diseases induced by the two subspecies are similar except that *T. brucei gambiense* infection follows a more chronic course. The organisms are transmitted to humans and domestic animals by the bite of the tsetse fly.

Normocytic anemia with reticulocytosis is prominent. Red cell survival is shortened and autoagglutination of erythrocytes with accelerated erythrocyte sedimentation characteristically is observed. The results of the direct antiglobulin (Coombs) test may be positive. Erythrophagocytosis by macrophages is seen throughout the reticuloendothelial system.[96]

The toxic effects of the parasite and immunologic mechanisms both are implicated in the destruction of red cells. The intensity of the hemolytic anemia may fluctuate with the degree of parasitemia. Transient hepatosplenomegaly and decreased serum complement levels accompany the episodes. Marrow failure often supervenes during the terminal phases of the illness. Diagnosis

depends on serologic tests or demonstration of the parasite in the blood.[97]

Visceral Leishmaniasis (Kala-Azar)

Leishmaniasis is an infection caused by intracellular protozoan parasites transmitted by sandflies. There are three main forms of *Leishmania* infections in humans: cutaneous, mucocutaneous, and visceral. The major hematologic problems occur with the visceral infection (kala-azar) and involve the lymph nodes, liver, spleen, and bone marrow. The disorder is caused by *Leishmania donovani,* and is found throughout Asia and Africa, affecting individuals of all ages. A variant parasite, *L. donovani infantum* is the form that causes kala-azar in southern Europe and North Africa, and it primarily affects young children and infants. Visceral leishmaniasis mainly occurs in local endemic areas; however, it may be contracted on short-term visits. It has been recognized in Europe in travelers returning from Mediterranean holidays.[98] Both cutaneous and visceral leishmaniasis have been reported in military personnel returning from deployment in the Persian Gulf.[99,100]

Following an incubation period of 1 to 3 months, there is the insidious onset of fever, sweating, malaise, and anorexia, but these acute symptoms gradually abate. Next, hepatosplenomegaly gradually evolves, and this stage of illness is associated with anemia, neutropenia, and thrombocytopenia. In young children with acute visceral leishmaniasis, particularly in Mediterranean populations, the clinical and hematologic features may be more aggressive with a rapid onset of severe hemolytic anemia.[101]

The bone marrow is hyperplastic with dyserythropoietic changes, and the diagnosis can usually be made by finding macrophages containing intracellular parasites (Leishman-Donovan bodies). The overall hematologic picture is typical of hypersplenism. Red cell survival studies indicate that hemolysis is the major cause of anemia in leishmaniasis.[101,102]

In most cases there is no evidence of immune hemolysis, although both immunoglobulin G (IgG) and complement occasionally are found on the red cells. Similar to what is seen in malaria, nonsensitized red cells are destroyed by macrophages recruited to the spleen and liver as part of the inflammatory response to the parasite.

Bartonellosis (Carrion's Disease)

A severe, acute hemolytic anemia is produced in humans by *Bartonella bacilliforms,* a flagellated bacillus.[103] The infection is limited to South America, particularly in the Andean valleys of Peru, Ecuador, and Columbia, at elevations of 500 to 3,000 m.[104–107] The bacillus is transmitted by the sand fly (*Phlebotomus*) and probably by other arthropods. After a 2- to 3-week incubation period, the acute phase of the illness, known as Oroya fever, begins. It is marked by malaise, headache, muscle pains, remittent fever, chills, and rapid onset of severe anemia. The disease has existed in Peru since pre-Incan times.[103,108] The highest rates of infection are in children.[104,107]

The findings in the blood are characteristic of acute extravascular blood destruction.[103,109] As viewed in Wright- or Giemsa-stained blood smears, numerous *Bartonella* organisms are apparent in the erythrocyte.[103] The organisms are rod shaped (1 to 2 m in length and 0.2 to 0.5 m in width) or round (0.3 to 1.0 m in diameter).

In patients who recover from the acute phase, a quiescent period ensues during which the organisms disappear from the blood. A chronic eruptive stage follows, verruca peruviana, a benign condition characterized by hemangiomalike lesions of the skin but without hematologic manifestations.[109]

Bartonella infection can be treated by antibiotic combinations containing chloramphenicol and other antibiotics, often a beta lactam. Verruca peruviana is typically treated with streptomycin-containing regimens. In the era prior to antibiotics, the only available treatment was blood transfusion.[104,110]

Clostridial Sepsis

Clostridium perfringens septicemia occurs after septic abortion or in association with a diseased biliary tree, traumatic wound infections, cancer, leukemia, endocarditis, gastrointestinal arteriovenous malformations, or necrotizing enterocolitis of newborns.[111–117] Sometimes no underlying disease is identified.[118,119,120] Profound, often fatal hemolytic anemia is a regular feature of clostridial sepsis.[118,121] Signs of intravascular red cell destruction are prominent, and many microspherocytes are found in the blood. The hemolysis can be rapid and massive, with hematocrit values falling to very low levels in a matter of hours.[119,120] Hemolysis is thought to result from the elaboration of a clostridial toxin, a phospholipase that attacks erythrocyte membrane lipids to form highly lytic lysolecithins.[122,123] The diagnosis should be suspected when fever, jaundice, and intravascular hemolysis occur together in a patient with a history of previous gastrointestinal or genitourinary surgery, a recent wound, cancer, or other disease. Clostridial infections respond to antibiotic therapy, but in order to affect outcome, treatment must be started quickly, usually before culture results are available.[124]

Other Bacterial Infections

Acute hemolytic anemia with bacterial infection is common, especially in childhood, and has been reported with streptococcal, staphylococcal, or pneumococcal septicemia or endocarditis.[125–128] Intravascular hemolysis with hemoglobinuria has been reported in patients with cholera[129] and with typhoid fever.[130] *Escherichia coli* 0157 gastroenteritis can cause the hemolytic-uremic syndrome, but can also bring about hemolytic anemia with no renal involvement or red cell fragmentation.[131] Severe hemolytic anemia not attributable to autoimmune mechanisms is observed occasionally in patients with miliary tuberculosis.[126,132] Certain spirochetal infections are also associated with hemolytic anemia, including relapsing fever caused by *Borrelia recurrentis*[133] and leptospirosis.[134]

The pathogenesis of hemolysis in most cases cited above is uncertain. In some it is thought that anemia is due to direct action of the infectious agent or its products on erythrocytes. Adsorption of microbial antigens to red cells has been detected by immunofluorescent techniques,[135] and this phenomenon may lead to phagocytosis or complement-mediated erythrocyte destruction. The capsular polysaccharide of *Haemophilus influenzae* type b, polyribosyl ribitol phosphate (PRP), is released from growing organisms during human infection and can be found in body fluids including red cells. It has been proposed that the hemolytic anemia that occurs during *H. influenzae* type b infection may be due to absorption of PRP to red cells and immune destruction of sensitized erythrocytes.[136]

In other cases, serious bacterial infections are associated with disseminated intravascular coagulation and a microangiopathic hemolytic anemia. Also, as discussed above, *C. perfringens* may release phospholipases that can lead to red cell membrane injury and cell destruction. Of interest, some bacteria release neuraminidase, an enzyme that cleaves red cell sialic acid residues, thereby exposing a cryptic "T antigen."[137] These "T-activated" red cells can react with anti-T IgM antibodies present in most human adult plasma, thereby resulting in RBC agglutination and possible hemolysis in vivo.[137] The main bacteria that release neuraminidase are *C. perfringens* and *Streptococcus pneumoniae*; however, *Bacteroides, E. coli, Actinomyces,* and *Vibrio cholerae* also have been implicated.[138]

HEMOLYSIS DUE TO DRUGS AND CHEMICALS

Many drugs and chemicals injure normal red cells to cause hemolytic anemia. Some of the more common occurrences are summarized below. (Drug-induced immune hemolysis is discussed in Chapter 29.)

Oxidant Drugs and Chemicals

Certain chemical agents can bring about the oxidative denaturation of hemoglobin, leading to the sequential formation of methemoglobin, sulfhemoglobin, and Heinz bodies. In some cases, the chemical itself acts as an oxidizing agent; more often, however, it interacts with oxygen to form free radicals or peroxides. These free radicals or peroxides, if produced in quantities too great to be detoxified by the glutathione-dependent reduction system, denature hemoglobin and damage other cellular structures, such as the cell membrane.[139] Individuals deficient in G6PD or other components of glutathione-dependent detoxification processes (Chapter 28) are particularly sensitive to the hemolytic effects of oxidant compounds (Table 32.2). These agents may also unmask otherwise insignificant defects in the metabolic pathways that defend the erythrocyte against oxidative stress.[140] However, some of these agents are powerful enough to overcome the defense mechanisms of otherwise normal erythrocytes, and can cause hemolysis if given to healthy subjects in higher than usual doses or if renal failure leads to unusually high blood levels.

Hemolytic anemia caused by oxidant drugs varies considerably in severity. Usually the anemia is noted within 1 to 2 weeks after drug therapy is initiated with laboratory findings of low hemoglobin, reticulocytosis, hyperbilirubinemia, and low serum haptoglobin. Also, in some cases, hemoglobinemia and hemoglobinuria may be apparent. Cyanosis with methemoglobinemia or sulfhemoglobinemia is sometimes noted. The hemolytic process usually disappears within 1 to 3 weeks after use of the offending drug has been discontinued.

Morphologic findings characteristic of hemolytic anemia caused by oxidant drugs and chemicals include the following: Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes) (Fig. 32.4A); "bite cells" (seen in routine Wright-stained blood smear) as erythrocytes that look as if a semicircular bite has been taken from one edge (Fig. 32.4B)[141,142]; and hemighosts[143] or eccentrocytes,[144] erythrocytes that look as if the hemoglobin has shifted to one side of the cell, leaving the other side clear (Fig. 32.4C). These hemighosts also are referred to as "blister cells" and may appear to contain a large vacuole. These RBCs contain a coagulum of hemoglobin that has separated from the membrane, often leaving an unstained non-hemoglobin–containing cell membrane.[145] Hemighosts appear only when hemolysis is brisk,[141,143] and probably indicate a particularly severe degree of oxidant damage. All of these morphologic alterations are consequences of oxidative assault on hemoglobin.

Although the treatment of drug-induced nonimmune hemolysis is largely supportive, erythropoietin has been used in cases associated with a blunted erythropoietic response, particularly in the hemolytic anemia that is observed in hepatitis C patients treated with ribavirin.[146]

TABLE 32.2

DRUGS AND CHEMICALS THAT CAUSE HEMOLYTIC ANEMIA IN PATIENTS WITH NORMAL ERYTHROCYTES

- Sulfonamides[375]
- Sulfones[376]
- Phenazopyridine (Pyridium)[142]
- Nitrofurantoin (Furadantin)[377]
- Phenacetin[378]
- Acetylsalicylic acid[379]
- Phenol[380]
- Cresol (Lysol, penetrating oil)[381]
- Naphthalene (mothballs)[382]
- Nitrobenzene[383]
- Aniline[384]
- Phenylsemicarbazide[385]
- Phenylhydrazine[143]
- Chlorates[386]
- Nitrates[387]
- Oxygen[388]
- Hydroxylamine[389]
- Methylene blue (in infants)[390]
- Hematin[391]
- Pentachlorophenol[392]
- Cisplatin, Carboplatin[393]

Arsine Poisoning

Arsine (AsH_3) is the most acutely toxic form of arsenic. It is a colorless, nonirritating, highly toxic gas that is produced by the action of water on a metallic arsenide. Arsine poisoning is associated most often with the use of acids in refining, extracting, or otherwise processing crude metals that contain arsenic as an impurity.[147,148] Industrial processes such as galvanizing, soldering, etching, and lead plating can expose workers to this noxious gas.[149] Arsine is also used in the transistor industry to stabilize silicon, and leakage from cylinders in which the gas is transported can lead to accidental poisoning.[150]

Manifestations of poisoning appear 2 to 24 hours after exposure and include abdominal pain, nausea, and vomiting; the passage of dark-red urine; jaundice; anemia; reticulocytosis; leukocytosis; and other signs of acute hemolytic anemia. Hemoglobinemia and hemoglobinuria are found, and acute, oliguric renal failure may ensue. The antiglobulin test result is negative. The mortality rate can approach 20%.[150,151] The mechanism of red cell injury is not known for certain. Interactions between arsine and oxyhemoglobin may be involved.[152,153] Also, arsine-induced membrane injury with altered ion transport has been proposed.[152,154]

The treatment of choice for acute toxicity is exchange transfusion to remove the arsenic-containing erythrocytes and to restore the blood hemoglobin levels.[155,156]

Copper Toxicity

Hemolytic episodes due to copper toxicity have been noted in humans after accidental exposure to toxic amounts of copper sulfate.[157–159] Moreover, copper has been implicated in hemolytic episodes after hemodialysis due to faulty copper tubing and increased levels of the metal in dialysis fluid.[160,161]

When inorganic copper enters the blood in large amounts, much of it accumulates in RBCs.[162,163] Within RBCs it may damage the cell membrane, accelerate oxidation of hemoglobin, and inactivate enzymes of the pentose–phosphate and glycolytic pathways.[163] Which of these abnormalities is responsible for shortened RBC survival is not known.

The release of inorganic copper into the circulation accounts for the hemolytic anemia that is observed in patients with Wilson disease (hepatolenticular degeneration).[164,165,166–171] This inherited illness, characterized by a lifelong tendency to accumulate

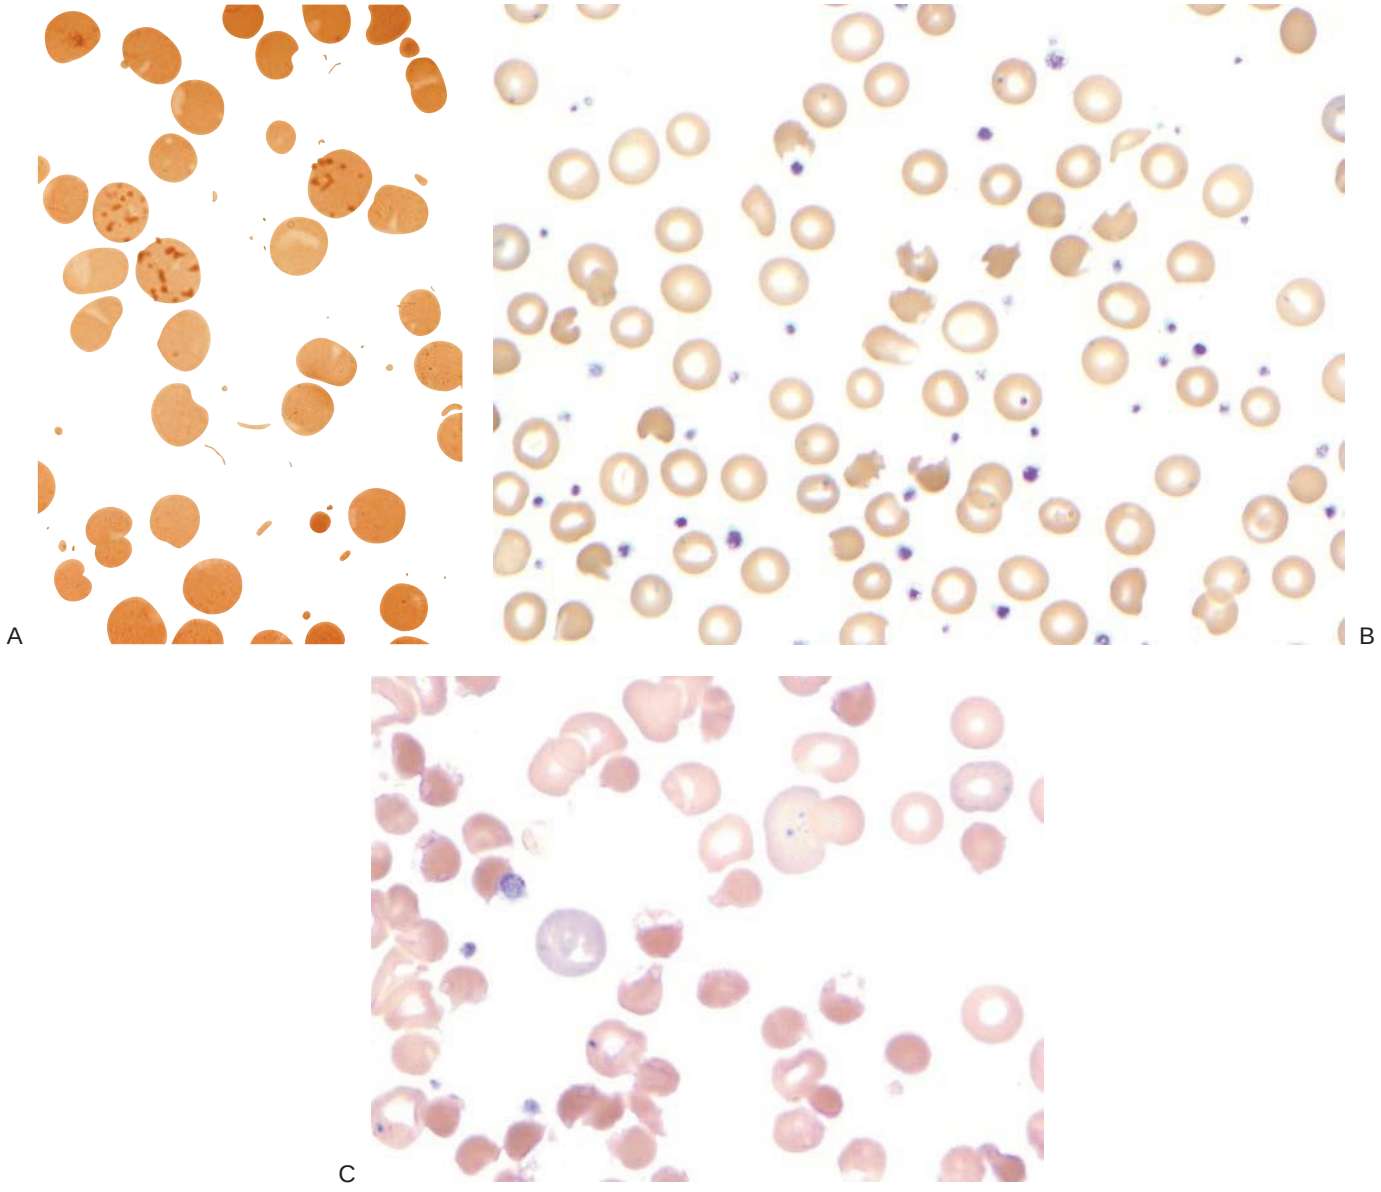

FIGURE 32.4. Morphologic findings characteristic of hemolytic anemia caused by oxidant drugs and chemicals. A: Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes). **B:** "Bite cells" (seen in routine Wright-stained blood smear) as erythrocytes that look as if a semicircular bite has been taken from one edge. **C:** "Blister cells" or hemighosts (seen in routine Wright-stained blood smear) appear as if hemoglobin has shifted to one side of the cell, leaving the other side clear. These blister red blood cells contain a coagulum of hemoglobin that has separated from the membrane, leaving an unstained non-hemoglobin–containing cell membrane. This image is from a patient receiving Pyridium. (Courtesy of Irma Pereira, MT [ASCP]SH.)

copper, is due to defects in the copper transporting intracellular ATPase ATP7B, which leads to a deficiency of ceruloplasmin, the plasma copper transport protein.[172,173] It usually becomes symptomatic in the teens or early 20s, when copper concentration in the liver or nervous system reaches toxic levels.[174] Hemolytic anemia can be associated with the early stages of Wilson disease[175] and occasionally may be the first manifestation of the disorder,[170,171,176–178] or it may be associated with hepatic decompensation.[167] However, it may appear late in the course of the disease if chelation therapy is discontinued.[164,165] The hemolytic episodes in Wilson disease usually are transient and self-limited, but they may be severe and recurrent. When they occur with hepatic decompensation, death from liver failure often follows.[167] The true incidence of copper-induced hemolysis in Wilson disease is not known: reported frequencies range from 2% to 50%.[177–179] Treatment of this complication may require plasma exchange transfusion.[180]

Lead Toxicity

Risk factors for lead toxicity are related to occupational hazards in adults and environmental exposure in children.[181,182,183] Occupational hazards include the manufacturing of batteries, paint or pigments, mining, or smelting; the primary route of assimilation is by inhalation. Environmental exposures in children occur by ingestion of lead from ceramics, paint, gasoline, or water from lead pipes, or having a parent who works in a high-lead environment. Lead poisoning through use of herbal or traditional medicines has also been reported.[184,185]

Acute toxicity occurs when lead accidentally gets into a food or water source. Such acute poisoning leads to lead encephalopathy (headache, confusion, stupor, coma, and seizures) and in addition there is abdominal colic, hypertension, and hemolytic anemia. Chronic exposure over time also is associated with a variety of neurologic, gastrointestinal, reproductive, and hematologic complications.

The peripheral smear shows extensive coarse basophilic stippling and reticulocytosis. Red cell morphology is not otherwise characteristic. The diagnosis of lead-related hemolysis can be made from the history of lead exposure, the physical finding of the gingival lead sulfide line, and the coarse basophilic stippling of red cells. The diagnosis is confirmed by measuring the blood and urine lead levels.

Lead inhibits two steps in heme synthesis: *d*-aminolevulinic acid dehydratase and heme synthetase (or ferrochelatase). The latter enzyme catalyzes the insertion of iron into protoporphyrin IX to form heme. The lead-induced inhibition of ferrochetalase is responsible for the increase in free erythrocyte protoporphyrin seen in this disorder and also is the basis of a simple screening test for lead toxicity.

The explanation for hemolysis in acute lead toxicity is not known for sure, but it is intriguing that the basophilic stippling seen in acute lead poisoning is similar to that found in hereditary deficiency of the enzyme pyrimidine 5′-nucleotidase (P5′N) (Chapter 28). In the enzyme-deficient cells, intracellular aggregates form as a consequence of impaired ribosomal degradation; these aggregates appear as basophilic stippling on Wright-stained peripheral blood smears. Of interest, the P5′N enzyme is readily inactivated by heavy metals such as lead, and it has been proposed that the basophilic stippling in lead poisoning is secondary to acquired P5′N deficiency.[186–189] As blood lead levels approach 200-μg/dl packed red cells, P5′N activity decreases to levels comparable to those associated with the homozygous deficiency state, intracellular pyrimidine nucleotides accumulate, and basophilic stippling can be demonstrated.[187,190]

Water (Osmotic Hemolysis)

There are anecdotal reports of hemolysis following inadvertent injection of water and other hypotonic fluids.[191] Hemoglobinuria, renal failure, and death were observed in association with transurethral resection of the prostate when distilled water was used for irrigation. Apparently, the water entered the bloodstream by way of the lymphatic and venous channels opened during the operation.[192] Hemolysis also has been noted in survivors of near-drowning in fresh water.[193] The entry of more than 0.6 L of water into the circulation produces hemoglobinemia and hemoglobinuria as a result of osmotic hemolysis.

HEMOLYSIS WITH VENOMS

Spider Bites

Certain spider bites produce severe, necrotic, gangrenous lesions ("necrotic arachnidism") that may be associated with hemolytic anemia or disseminated intravascular coagulation, and occasionally renal failure.[194,195–198] In South America and the southwestern part of the United States, the spiders implicated are the brown recluse spider (*Loxosceles reclusa*) and other *Loxosceles* species.[198,199] In the northwestern United States, a similar picture follows the bite of the hobo spider, *Tegenaria agrestis*.[200,201]

The initially painless *Loxosceles* bite develops into a painful, edematous, necrotic lesion that may progress to an extensive, slowly healing, gangrenous process, necrotic arachnidism.[199,202,203] In a few patients, systemic manifestations, including intravascular hemolytic anemia, develop within several hours to 5 days later. Hemoglobinuria and severe anemia are characteristic findings; spherocytes and leukocytosis are found in the blood. Thrombocytopenia also has been observed, sometimes associated with diffuse intravascular coagulation.[204] In some cases, red cells are coated with complement and the direct antiglobulin test is positive.[203,205,206] Most often, the hemolytic episode subsides spontaneously in about 1 week, but occasionally severe reactions occur with renal failure and death.

The spider venom primarily attacks endothelium and secondarily activates granulocytes with adhesion and discharge of their granular contents.[207] Granulocytes are required for the necrotic process to ensue. The spider venom also causes complement-dependent intravascular hemolysis associated with cleavage of glycophorin from the red cell membrane.[202,205,208] These events occur because *Loxosceles* venom contains sphingomyelinase activity that activates a membrane-bound metalloproteinase.[209–211] Recombinant *Loxosceles* neutral sphingomyelinase is the target antigen in an experimental antivenom for brown recluse bite.[212]

Treatment of spider-bite–induced hemolysis is largely supportive.

Snake bites

Snake bites are a significant health problem worldwide, especially in parts of Asia where thousands of people die from them annually.[213] The composition of snake venom varies considerably between species, between the same species living in different geographical locations, and in the same snake at different times of the year. Most venoms contain a mixture of active ingredients.[214,215] The problems resulting from snake venoms include neurotoxicity, myotoxicity, renal failure, edema, bleeding due to activation of clotting proteins, and intravascular hemolysis. Hemolysis is seen following evenomation with most poisonous snakes including cobras,[216,217] Australian king brown snakes,[218] the Tunisian saw-scaled (carpet) viper,[219] North American rattlesnakes,[220] habu snakes[221](191), and the several species of Russell viper (*Dabois russelli*) found throughout India and the rest of Asia.[213–215,222] Much of our information regarding the pathophysiology of envenomization comes from studies of the Russell viper in Asia.[215]

The clinical presentation of intravascular hemolysis from snake bites can be acute and fulminant, or the effects can be delayed for a few hours to days. Hemoglobinemia and hemoglobinuria are present, the severity of which varies with the degree of evenomation and species of snake. There are a variety of components in venom which may be contributing to hemolysis. The best studied of these is phospholipase A_2, which has direct toxicity for many tissues including the red cell membrane.[215,223] Venom from the habu snake contains enzymes that activate complement and cleaves CD55 and CD59 from the red cell membrane, thus leaving the red cell susceptible to complement-induced lysis.[221] Other snake venoms contain protein kinase C inhibitors implicated in hemolysis.[224]

Bee Stings

Africanized honey bees (*Apis mellifera*) were originally a problem in Brazil[225] where these bees were accidentally released in the 1950s. By 1990, they were reported in Texas and are now distributed through the United States as far north as the Canadian border.[226] These bees are aggressive and their attacks are usually massive.[227]

The effects of bee stings can be immediate or delayed. "Immediate" reactions are related to anaphylaxis. "Delayed" reactions refer to patients who are asymptomatic after massive bee evenomation, but 12 to 24 hours later, have evidence of hemolysis, disseminated intravascular coagulation, thrombocytopenia, rhabdomyolysis, liver dysfunction, or renal failure.[228,229] The delayed effects are related to the degree of evenomation, and it is thought that problems in an adult occur after 100 to 500 stings, although as few 30 to 50 stings can be problematic in a child.[230] In one instance, a 3-year-old child stung 200 to 300 times by honeybees died after the development of intravascular hemolysis and oliguric renal failure.[231] The venom contains melittin and phospholipase A_2, which together disrupt the red cell membrane and cause hemolysis.[227] Hemolytic reactions to bee stings appear to be rare. Renal failure is a much more significant problem than hemolytic anemia.

HEMOLYSIS WITH THERMAL INJURY

Burns

Acute hemolytic anemia has been observed after extensive thermal burns.[232–234] Signs of intravascular hemolysis are associated with schistocytes, spherocytes, and echinocytes in the blood along with increased osmotic and mechanical fragility of the erythrocytes.[234,235] The severity of the reaction is related to the area of body surface affected. In one series, hemoglobinuria was found in 11 of 14 patients who were moderately to severely burned with more than 15% of the body surface involved in most cases.[234] In another series, hemolysis was apparent in patients with third-degree burns affecting more than 20% of the body surface.[236]

Hemolysis occurs during the first 24 to 48 hours after the burn[235] and as much as 30% of the circulating red cell mass may be destroyed in this 2-day period.[237] After the acute hemolytic episode, anemia develops and may last for many weeks,[232] although signs of hemolysis disappear. This later stage of the anemia of thermal injury is probably a form of the anemia of chronic disorders (see Chapter 41).[238,239,240,241]

The acute hemolytic reaction in burned patients results from the direct effects of heat on erythrocytes. When red cells are heated to temperatures >47°C, irreversible morphologic and functional abnormalities occur, the severity of which is related to the temperature and the duration of exposure.[242,243] The major alterations are fragmentation of the cells and the development of spherocytes, accompanied by an increase in osmotic and mechanical fragility. These changes result from irreversible denaturation of the cytoskeletal protein spectrin.[244–246] Mildly heat-damaged erythrocytes are removed predominantly by the spleen, and with greater degrees of damage, the red cells also are destroyed in the liver.[243,247]

Heated Fluids and Blood

Overheating of biologic fluids is another clinical circumstance resulting in thermal red cell damage. One reported example of this was the overheating of dialysis solution due to failure of thermostatic controls on the hemodialysis equipment.[248] It is also recognized that direct microwave warming of blood prior to transfusion can damage red cells and cause hemolytic anemia following infusion.[249,250,251] Similarly, the heating of intravenous tubing has resulted in hemolysis.[252]

The U.S. Food and Drug Administration-approved inline blood warmers, equipped with thermometers and alarms, and close adherence to the manufacturer's specific directions should provide a safety level that prevents the accidental overheating of blood.

FRAGMENTATION HEMOLYSIS

When red cells are subjected to excessive physical trauma, they may undergo premature fragmentation and intravascular hemolysis, thereby resulting in hemoglobinemia, hemoglobinuria, and hemosiderinuria. The hallmark of this type of hemolysis is the fragmented red cell or schistocyte, and these cells take the form of crescents, helmets, triangles, and/or microspherocytes (Fig. 32.5). Hemolytic anemias resulting from red cell fragmentation are associated with abnormalities of the heart and great vessels, diseases of small vessels, disseminated intravascular coagulation, and hypertension (Table 32.3). In most of these conditions hemolysis is one of many clinical findings, and usually not the major problem.

Cardiac and Large Vessel Abnormalities

Etiology

Soon after the advent of open-heart surgery came the realization that the postoperative course of some patients was complicated by the development of anemia of varying severity. The discovery of fragmented red cells as a characteristic feature of this type of anemia was made in 1961, when Sayed et al. described these morphologic alterations in a patient who developed severe and persistent intravascular hemolysis after repair of an ostium primum defect with Teflon.[253] It is now well recognized that fragmented erythrocytes with intravascular hemolysis are commonly associated with a wide variety of structural defects of the heart or great vessels (Table 32.3). Surgically inserted prosthetic devices, particularly heart valves, furnish the most striking examples of red cell fragmentation. Most of the prosthetic valves associated with hemolytic disease are of the aortic variety,[254–257] but cases of hemolysis caused by mitral valve replacement[258,259,260,262,263,264,265] unsuccessful mitral valvoplasties,[266,267] and repair of ruptured chordae tendineae[268] also have been reported. The use of bioprostheses has reduced the risk of hemolysis greatly, although red cell fragmentation still occurs after the insertion of porcine xenografts or bioprostheses constructed from bovine tissues.[261,269–273] In these patients, hemolysis usually is associated with a paravalvular leak,[270] a torn cusp,[271] or other manifestations of valvular dysfunction,[269] including infective endocarditis or calcification.[274]

Intracardiac patch repairs of various types also may lead to intravascular hemolysis[253,275,276]; typical cases involve patients with Teflon patches used in the repair of ostium primum defects.

Mechanical ventricular assist devices and other similar pump-based technologies employed as a bridge to cardiac transplantation are also associated with mechanical hemolysis.[277,278]

Last, although red cell fragmentation is associated most strikingly with intracardiac surgical procedures, intravascular

TABLE 32.3

CAUSES OF RED CELL FRAGMENTATION

- Associated with abnormalities of the heart and great vessels
  - Synthetic valvular prostheses
  - Valve homografts
  - Valve xenografts and xenobioprostheses
  - Autograft valvoplasties
  - Ruptured chordae tendineae
  - Intracardiac patch repairs
  - Unoperated valve disease (especially aortic stenosis)
  - Coarctation of the aorta
- Associated with small vessel disease: microangiopathic hemolytic anemia
  - Thrombotic thrombocytopenic purpura (TTP)
  - Hemolytic-uremic syndrome (HUS)
  - HUS/TTP-related disorders
    - Disseminated carcinoma
    - Chemotherapy/drugs
    - Transplant-associated microangiopathy
  - Pregnancy and postpartum period
    - HELLP syndrome
    - TTP/HUS
  - Malignant hypertension
  - Disseminated intravascular coagulation
  - Immune mechanisms
    - Lupus erythematosus
    - Acute glomerulonephritis
    - Scleroderma
    - Wegener granulomatosis
  - Hemangiomas
    - Giant hemangioma (Kasabach-Merritt syndrome)
    - Hemangioendothelioma of the liver
    - Plexiform lesions in pulmonary hypertension
  - March hemoglobinuria

HELLP, hemolysis, elevated liver enzymes, and low platelet counts.

hemolysis occurs in many patients with valvular heart disease who have not had surgery.[279–282] Most often, this red cell fragmentation is noted in patients suffering from severe aortic valve disease, especially aortic stenosis; occasionally, however, patients with mitral valve involvement are affected. Intravascular hemolysis also has been reported in patients with a ruptured aneurysm of the sinus of Valsalva,[283] coarctation of the aorta,[284] coarctation with a bicuspid aortic valve,[285] and a ventricular septal defect in conjunction with a patent ductus arteriosus.[286] The hemolysis accompanying valvular heart disease that has not been treated surgically is usually minor and rarely severe.

Incidence

Clinically significant hemolytic disease is reported in 5% to 25% of patients with various types of valvular prostheses,[254,287,288] usually involving replacement of defective aortic valves, and in about 5% of patients with Teflon repairs of ostium primum defects.[231] The incidence of clinically detectable hemolysis in patients with mitral valve prostheses is considerably lower, although the incidence of hemolysis with ring repair of mitral valve defects was 3.8% in one series.[265] When more sensitive techniques are used to detect red cell destruction, such as red cell survival studies[279,281,289] or haptoglobin levels,[282,290–292] most patients with aortic valvular prostheses have evidence of mild intravascular hemolysis. Undoubtedly, the severity of the valvular disease is an important variable.

Pathogenesis

Several mechanisms may account for the intravascular nature of the hemolysis and the appearance of the characteristic fragmented cells.

Direct mechanical trauma, for instance by the closure of prosthetic valves, has been postulated; it is known also to occur in other conditions, such as march hemoglobinuria.[293] However, it is unlikely that valve closure itself is responsible for RBC fragmentation inasmuch as many patients with prosthetic valves do not have clinically significant hemolysis. It also is unlikely that the presence of prosthetic materials per se contributes to red cell fragmentation,[254,294] although Teflon that is not covered by endothelium[253,276] has been found at reoperation in some patients. In all likelihood, therefore, both hemolysis and the lack of endothelialization depend on the presence of a third factor, such as turbulence.

The most common feature in recorded cases of hemolysis occurring after the insertion of prosthetic devices is the existence of some form of hemodynamic defect, such as regurgitation through or around valvular prostheses[254,263,270] or mitral insufficiency after Teflon patch repair of atrioventricular canal defects.[275] Teflon patch-associated hemolysis has become less common as the use of biomaterial and autologous patches has increased.[295,296] Extreme turbulence is a common factor in all of these patients and can routinely generate shearing stress >3,000 dyn/cm^2,[259,297,298] leading to mechanical hemolysis in vitro[299] and in vivo, such as in the presence of regurgitant defects between the aorta and the left ventricle, when the lumen of the aortic prosthesis is small relative to the stroke volume or when the ball of a ball valve is large relative to the diameter of the aorta.

Clinical Manifestations

No distinctive clinical features are noted, with the exception of those related to pre-existent heart disease or cardiac surgery. The development of hemolysis sometimes coincides with severe deterioration of cardiac function because of the tear of a valve cusp or the loosening of valve attachments. When the hemolysis is clinically significant, jaundice often is obvious, but hemoglobinuria may not be detectable by the naked eye.

Laboratory Findings

The blood findings of these patients vary widely, depending on the severity of the hemolytic process. The hemoglobin level may be normal if the hemolysis is compensated, or it may be extremely low. Most cells are normocytic and normochromic, but there also are variable numbers of fragmented erythrocytes, and these are identical to the schistocytes seen in patients with microangiopathic hemolytic anemia (Fig. 32.5). The number of fragmented cells apparent in the blood smear directly reflects the severity of the hemolytic process.[300] In patients with long-standing hemolysis, iron stores may be depleted because of hemoglobinuria and hemosiderinuria, and the red cells may appear hypochromic due to iron deficiency. Hemosiderinuria is present in many patients when hemoglobinuria is not detectable. The serum bilirubin level is slightly or moderately raised. Serum haptoglobin is reduced or absent. Lactic dehydrogenase (LDH) levels usually are elevated. The reaction to the antiglobulin test is usually, but not always, negative. A positive direct antiglobulin test is observed occasionally in a few patients with prosthetic valves[301–303] and occasionally in patients with severe aortic valve disease in the absence of

surgical intervention.[304] It is possible that mechanical damage may expose subsurface antigens, which then elicit the production of autoantibodies.

Treatment

A marked degree of anemia and elevated LDH often indicate wear or malfunction of a valvular prosthesis,[258,300] and under these circumstances, prompt surgical intervention and valve replacement are usually indicated. Only occasionally does the condition causing hemolysis improve spontaneously.[256] Severity of the hemolytic process increases with physical activity.[305] When iron deficiency has developed because of prolonged hemosiderinuria, iron therapy is indicated. Erythropoietin has been used to reduce the need for blood transfusion.[306] Folate supplementation may also assist in maintaining an adequate erythropoietic response to hemolysis.

Small Vessel Disease (Microangiopathic Hemolytic Anemia)

In 1952, Symmers introduced the term *microangiopathic hemolytic anemia* to describe a clinical syndrome now commonly called thrombotic thrombocytopenic purpura (TTP).[307] Brain et al. subsequently popularized the term,[308] and it is now used to designate any hemolytic anemia related to red cell fragmentation occurring in association with small vessel disease (Table 32.3).

The term *thrombotic microangiopathy* also is used to describe syndromes characterized by hemolytic anemia with red cell fragmentation, thrombocytopenia, and thrombotic lesions in small blood vessels.[309]

TTP and the hemolytic-uremic syndrome (HUS) are similar disorders included in this category. They share many laboratory and clinical features, and the clinical distinction between TTP and HUS is not always clear. There are also TTP/HUS-related conditions seen with pregnancy, cancer, collagen vascular disease, drug therapy, tissue transplantation, and other disorders (Table 32.3). A detailed discussion of TTP, HUS, and related disorders can be found in Chapter 48, and TTP related to pregnancy is discussed in Chapter 42.

Hemolysis due to Malignant Hypertension

An association between red cell fragmentation and malignant hypertension was first recorded in 1954 and has since been confirmed in many other studies.[310,311] The pathogenesis of microangiopathic hemolytic anemia in malignant hypertension is attributed to the presence of fibrinoid necrosis within the arterioles,[308] which in turn appears to depend on the presence of hypertension.

Hemolysis due to Disseminated Intravascular Coagulation

Microangiopathic hemolytic anemia is associated with a variety of disorders characterized by disseminated intravascular coagulation (DIC), including sepsis,[312,313] purpura fulminans,[314] heat stroke,[315] and abruptio placentae.[316] In all of these clinical conditions, red cell fragmentation is thought to result from the deposition of fibrin within the microvasculature. Fortunately, hemolysis often is not severe and may not contribute significantly to the morbidity of the disease. As the underlying disease comes under control with appropriate therapy, the fragmentation of red cells also ceases.

The generation of RBC fragmentation with DIC is supported by classical experimental animal data. When intravascular coagulation is induced in rabbits by the infusion of endotoxin[308] or thrombin,[317] the onset of red cell fragmentation and hemoglobinemia is closely linked to the development of renal glomerular thrombosis. These findings indicate a link between the deposition of platelet and fibrin thrombi and red cell fragmentation, and this is supported by histologic studies that associate hemolysis with a loose fibrin network to which red cells adhere.[318] From in vitro experiments it has been observed that when red cells are forced through a loose fibrin clot within a slide chamber, they attach to fine fibrin threads and fold around these razor-sharp strands (Fig. 32.6).[319] As other cells flow past the attached RBCs, they cause either their release or their fragmentation, often with resealing of the membrane, and thus the formation of red cell fragments described. Similar results are obtained when nylon or glass fibers are used in artificial circuits.[319]

Fragmentation Hemolysis with Immune Disorders

Microangiopathic hemolytic anemia may be a feature of diseases in which the microvasculature is damaged by immune mechanisms. Connective tissue diseases characterized by vasculitis, which occasionally lead to red cell fragmentation, include lupus erythematosus[320] and perhaps rheumatoid arthritis, Sjögren syndrome, and polyarteritis nodosa.[309] Red cell fragmentation also has been observed in association with polymyositis,[309] scleroderma,[321] Wegener granulomatosis,[322,323] giant cell arteritis,[324] and Still disease.[325] The diverse symptomatology of vasculitic disorders, along with the presence of microangiopathic hemolysis, may lead to these disorders being confused with TTP. ADAMTS13 activity levels, although often lower in vaculitic disorders than in healthy patients, are rarely as low as is typical for TTP (discussed in Chapter 48).[326,327]

Circulating immune complexes trigger the coagulation cascade,[328] leading to fibrin deposition, which in turn stimulates the proliferation of endothelial cells. Fibrin deposition and endothelial changes, including immune-complex–mediated damage of endothelial cells, are probably responsible for the red cell fragmentation that occurs in disorders characterized by the presence of circulating immune complexes. Such complexes, together with red cell fragmentation, have been found in patients with a variety of disorders, including TTP, subacute bacterial endocarditis,[329] and glomerulonephritis.[330,331] The significance of this association is unclear, however, because immune complexes are commonly

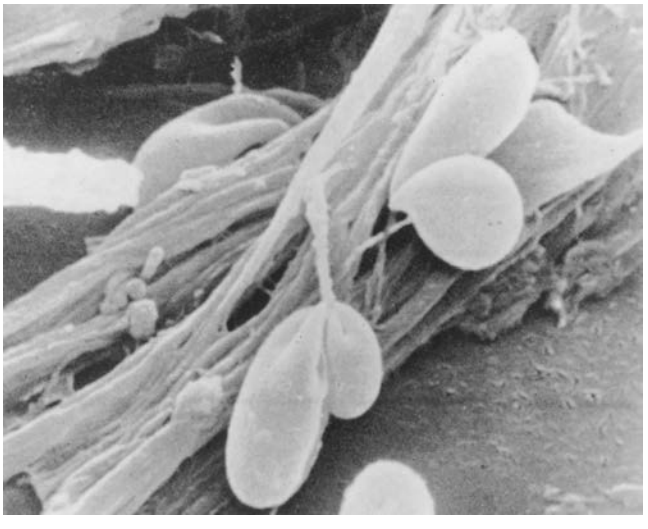

FIGURE 32.6. Scanning electron micrograph. Red cells are "clotheslined" over fine fibrin strands (in vitro model). Other cells, moving past these trapped erythrocytes, may cause their fragmentation. Thicker fibrin strands in background do not cause this injury. (From Bull BS, Kuhn IH. The production of schistocytes by fibrin strands. Blood 1970;35:104.)

found in patients with some of these conditions, whereas red cell fragmentation and other manifestations of thrombotic microangiopathy are much less common.

Giant Hemangiomas and Hemangioendotheliomas

Microangiopathic hemolytic anemia has been identified in patients with giant hemangiomas[332,333,334] and in patients with hemangioendotheliomas of the liver.[335,336] Microangiopathic hemolytic anemia also has been described in the blue rubber–bleb nevus syndrome, a rare disorder characterized by subcutaneous and gastrointestinal hemangiomas.[337] It is thought that local coagulation in the abnormal blood vessels plays a role in red cell fragmentation.[332] Therapeutic resolution of the hemangioma cures the microangiopathic hemolytic anemia and consumption coagulopathy.[333]

March Hemoglobinuria

March hemoglobinuria is an unusual hemolytic disorder in which transient hemoglobinemia and hemoglobinuria develop in susceptible individuals after strenuous exercise that involves forceful contact of the body with a hard surface. Although red cell fragmentation is not always evident, the condition carries all the hallmarks of acute intravascular hemolysis, which presumably results from the mechanical disruption of circulating red cells. Few cases have been reported since Fleischer described the first case in 1881.[293] Clinically inapparent hemoglobinemia may be more common.

March hemoglobinuria primarily affects young males.[293,338] Hemoglobinuria is precipitated by prolonged marches or competitive running, but the syndrome has also been noted in conga drum players[339,340] and people participating in karate exercises.[341] Passage of red or dark urine after physical exertion is often the only complaint. Occasionally, symptoms include nausea; vague abdominal, back, or thigh pain; or a burning feeling in the soles of the feet. Hemoglobinuria characteristically occurs immediately after exercise and lasts for only a few hours. March hemoglobinuria most commonly affects athletes at the beginning of a running career or on resumption of road training.[342]

Laboratory studies show evidence of intravascular hemolysis, specifically hemoglobinemia and a decreased serum haptoglobin concentration. Significant anemia is uncommon. The bilirubin concentration rarely exceeds 2 mg/dl. Serum lactic dehydrogenase levels may be elevated. The urine contains hemoglobin; after recurrences, it also may contain hemosiderin. Long-distance runners may develop iron deficiency attributable to hemosiderinuria, although the possibility of exercise-associated gastrointestinal bleeding in long-distance runners must also be considered.[343] Swimmers, who do not sustain comparable trauma, have a similar situation.[344]

Hemoglobinuria can be prevented by the use of shoes with thicker and more resilient soles than those usually worn. Thus, one postulate was that susceptible individuals destroy red cells in the soles of their feet while running. Confirmation came from the ingenious experiments of Davidson, who inserted polyvinyl tubes containing blood into the running shoes of susceptible individuals and showed that these runners destroyed their own and the control blood at about the same rate, and to a greater degree than control subjects running on the same surface.[345] Whether hemolysis is entirely attributable to the type of exercise and the style of running or whether other factors make the red cells of some people particularly susceptible to hemolysis is not clear.[346]

No specific therapy is usually needed for individuals with march hemoglobinuria. Attacks may be prevented by wearing shoes with more resilient soles and by changing to a less traumatic running style. Banfi and colleagues have reported that immersion of the legs in cold water for several minutes, either before or after training, prevents hemolysis and hemoglinuria in rugby players.[347]

OTHER CAUSES OF HEMOLYSIS

Hemolytic anemia is also seen in association with a number of nonhematologic systemic disorders, and in most cases there are several etiologies to the anemia.

Hypersplenism

Normal functions of the spleen include the monitoring and processing of "old" and "damaged" red cells. These culling and pitting functions are executed by macrophages that line reticuloendothelial sinuses of the spleen, and also the liver and bone marrow (Chapter 65). Macrophages have receptors that recognize immunoglobulin and complement molecules on the RBC surface, and possibly receptors that detect alterations in the outer portion of the phospholipid bilayer. The spleen is considered to be the most stringent of the reticuloendothelial filters, and this is aided by the slow rate of blood flow through the splenic red pulp.

Broadly defined, the term *hypersplenism* refers to sequestration and/or destruction of blood cells occurring in an enlarged spleen, associated with peripheral anemia and/or neutropenia and/or thrombocytopenia. In experimental animals with splenomegaly induced by methyl cellulose injections, there is accelerated destruction of normal erythrocytes.[348] Also, in humans, it is generally held that splenomegaly from any cause can be associated with increased filtering, extended macrophage attack, and increased erythrocyte destruction.[349] Rarely does hypersplenism cause significant hemolysis. However, under conditions where macrophages are activated, there may be increased red cell destruction, and this may explain the accelerated hemolysis commonly seen with infections, in particular with malaria.[36]

Massive splenomegaly often is associated with an increased plasma volume, and in these cases the low hemoglobin or hematocrit gives a falsely low estimate of the true red cell mass.

Liver Disease

Anemia in liver disease has many causes including hemolysis (Chapter 41). One component of this shortened red cell survival relates to portal hypertension and associated splenomegaly. However, the hemolysis occurring under these conditions is usually mild, with varying degrees of a compensatory increase in red cell production.

Another cause of hemolysis in liver disease is associated with the formation of "spur cells," a variant form of acanthocytes. In patients with liver disease, abnormalities in lipid metabolism result in RBCs becoming selectively loaded with excess cholesterol. The cholesterol-loaded RBCs have impaired ability to repair peroxidized membrane lipids,[350] and thus they undergo oxidative damage. As a consequence, they become rigid and nondeformable, and are rapidly cleared by the reticuloendothelial system, in particular the spleen[351,352] (see Chapter 41).

Attempts to correct portal hypertension have utilized angiographic techniques to create a communication between the intrahepatic portal vein and the hepatic vein. The placement of these transjugular intrahepatic portosystemic shunts (TIPS) avoids the anesthetic and surgical risks of other shunting procedures; however, some 10% of patients develop mild intravascular hemolysis.[353] The hemolysis usually is self-limited and rarely requires intervention.

Renal Disease

Hemolytic anemia and renal failure together can occur with the thrombotic microangiopathies (Chapter 48). Anemia also

is a frequent complication of primary renal disease, the most common cause being due to impaired erythropoietin production (Chapter 41). However, in some cases there also is a hemolytic component[354,355] that is thought to be a consequence of uremia. Classic cross-transfusion studies demonstrated that normal erythrocytes have a shortened survival in uremic patients, whereas red cells from uremic patients survive normally when transfused into healthy control individuals.[356,357] RBC survival is decreased in proportion to the blood urea nitrogen concentration,[358] and it improves significantly following intensive hemodialysis.[359] The exact uremic metabolite responsible for red cell injury is not known and the specific uremia-induced RBC injury that causes shortened RBC survival also is not defined. Of interest, it has also been observed that uremic red cells have increased expression of phosphatidylserine (PS) on the outer membrane surface, and incubation of normal RBC in uremic plasma also induces increased expression of PS on the outer cell surface.[360,361] These observations are important because it is now thought that one mechanism for macrophage recognition of damaged RBCs may be the loss of phospholipid asymmetry across the membrane, particularly the appearance of PS on the external side of the membrane[362,363] (Chapter 6).

Hypophosphatemia

Severe hypophosphatemia can occur in patients undergoing prolonged antacid therapy, in those receiving intravenous hyperalimentation without phosphorus supplementation, in debilitated and starved people, and in alcoholics. In addition to confusion, weakness, anorexia, malaise, paresthesias, and electroencephalographic and electromyographic changes, hypophosphatemia also has been noted to cause hemolytic anemia.[364–366,367,368–370,371] The anemia is characterized by reticulocytosis and microspherocytosis seen on the peripheral smear.[365] In affected individuals, the serum phosphorus concentration invariably is very low.

POSTPERFUSION SYNDROME

Cardiopulmonary bypass sometimes is associated with several adverse reactions including acute intravascular hemolysis, leukopenia, a hemostatic deficit, and nonspecific systemic inflammatory reactions, collectively referred to as the postperfusion syndrome. This systemic dysfunction may result in acute respiratory distress syndrome and shock.

After cardiopulmonary bypass, intravascular hemolysis can occur with hemoglobinemia. The mechanism of hemolysis associated with this syndrome was thought to be due to mechanical factors during surgery.[372] However, it now is recognized that complement is activated during the procedure[373] and the terminal C5b-9 complement complexes are deposited on both erythrocytes and polymorphonuclear neutrophilic leukocytes.[374] In one interesting study utilizing lysed erythrocyte membranes recovered from blood of patients at the end of bypass surgery, C5b-9 components were identified on the red cell ghosts but not on intact erythrocytes. Moreover, the appearance of ghosts carrying C5b-9 neoantigens always coincided with hemolysis.[374] Thus, it now is thought that complement activation occurs as blood flows through the oxygenator, and the resultant deposition of C5b-9 on red cells leads to immediate intravascular hemolysis. The same reactions presumably lead to granulocyte activation and sequestration in the lungs.[373]

The hemolytic process is transient. Hematologic treatment is directed toward RBC support as needed until spontaneous resolution occurs.

CHAPTER 33

SICKLE CELL ANEMIA AND OTHER SICKLING SYNDROMES

Jane S. Hankins, Winfred C. Wang

This chapter discusses hemoglobin (Hb) variants that cause alterations in erythrocyte morphology and rheology. Hb S, or sickle Hb, is a variant Hb of tremendous clinical importance due to its high prevalence and worldwide distribution. Homozygous Hb SS (sickle cell anemia) alone is the most common heritable hematologic disease affecting humans.

Long before they were recognized in the Western hemisphere, sickling disorders were known in Africa by onomatopoeic names denoting the recurrent, unrelenting, and painful nature of the crises.[1,2] Although symptoms of sickle cell anemia (SCA) could be traced in one Ghanaian family to the year 1670,[3] disorders of Hb synthesis went unrecognized by the scientific community until 1910, when Herrick, a Chicago cardiologist, recorded observations made during investigation of anemia in a 20-year-old West Indian student.[4] Herrick's report led not only to the recognition of hundreds of abnormalities of Hb synthesis, but also to a series of remarkable scientific advances involving protein chemistry, molecular biology, physiology, and genetics. The term sickle cell anemia was first used in 1922, when it was recognized that a common African ancestry was present in all initial cases described.[5] In 1949, Linus Pauling and collaborators demonstrated for the first time that an abnormal protein could be causally linked to a disease.[6] A historical review has been published summarizing the major developments related to sickle cell disease in the first 100 years since the disease's description.[7]

The genetic basis for Hb synthesis is discussed in Chapter 22. Each major hemoglobinopathy occurs in both a heterozygous and a homozygous form. In the heterozygous state, red cells contain both normal adult Hb (Hb A) and the variant Hb. Because they rarely have phenotypic expressions of clinical significance, heterozygotes are said to have the trait for that abnormality, for example, sickle cell trait. In the homozygous state, Hb A is totally lacking, and clinical manifestations are of variable severity; individuals so affected have SCA. In addition, disease may result from the combination of two variant hemoglobins or from a variant Hb and an interacting thalassemia gene. These doubly heterozygous states are designated by both aberrant gene products, such as Hb SC disease or Hb S/β-thalassemia. The term *sickle cell disease* is used in a generic sense to refer to all of the sickling syndromes, although the compound heterozygous HbS/β^0-thalassemia is commonly classified as SCA, due to phenotypic similarity to HbSS.

EPIDEMIOLOGY

Hb S, so-called because of the sickle shape it imparts to deoxygenated red cells, is responsible for a wide spectrum of disorders that vary with respect to degree of anemia, frequency of crises, extent of organ injury, and duration of survival. Some of the sickling syndromes lack significant pathologic potential, but they are easily confused with clinically aggressive disorders on the basis of laboratory evaluation; consequently, precision in diagnosis is essential both to proper clinical management and to meaningful genetic counseling.

The highest prevalence of Hb S in the world is in sub-Saharan Africa, followed by the Arabian and Indian subcontinents. It occurs with lower frequency in the rest of the world as the result of voluntary or forced population migration from high prevalence areas. Results of studies of DNA polymorphisms linked to the β^S gene suggest that it arose from three independent mutations in tropical Africa.[8,9] The most common β^S chromosome is found in Benin and central West Africa. A second haplotype is prevalent in Senegal and the African West Coast, and a third haplotype is seen in the Central African Republic (Bantu-speaking Africa). The same three haplotypes are associated with the β^S gene in black Americans and Jamaicans.[10] The Hb S gene in the eastern province of Saudi Arabia and in Central India is associated with a different DNA structure that is not encountered in Africa and probably represents a fourth independent occurrence of the sickle cell mutation.[9] Only the Benin and Senegal haplotypes are prevalent among North Africans, Greeks, and Italians, suggesting that the β^S mutation spread to the Mediterranean basin from West Africa.[10,11] In some parts of Africa, as many as 25% of the population have sickle cell trait, whereas in the United States,[12,13] Latin America, and the Caribbean,[14] the prevalence of the sickle gene varies from approximately 2% to 8% (Table 33.1). In the United States, the expected incidence of SCA (Hb SS) at birth is 1 in 625. Taking into account recent trends of decreased mortality among children, approximately 100,000 cases of sickle cell disease would be expected among African Americans in the United States.[15]

Before this century, most individuals with SCA died before the age of reproduction. Without selective advantage to Hb S trait, the sickle gene would have been eliminated. The most widely accepted theory to account for the remarkable stability of the sickle gene in Africa is that of balanced polymorphism.[16,17] Recognition that sickle cell trait has its highest prevalence in areas that are hyperendemic for malaria suggested that Hb S afforded selective protection against lethal forms of malaria (Fig. 33.1).[18] Preferential sickling of parasitized cells has been observed in the blood of children with sickle cell trait and malaria.[17] Selective removal of sickled cells from the circulation probably reduces the degree of parasitemia and substantially limits the infectious process.

PATHOPHYSIOLOGY

The sickle mutation substitutes thymine for adenine in the sixth codon of the β gene (GAG $\rightarrow$ GTG), thereby encoding valine instead of glutamic acid in the sixth position of the β chain. This ostensibly minor change in structure is responsible for profound changes in molecular stability and solubility.

Molecular Basis of Sickling

An abundance of information indicates that the distortion of cells containing Hb S is the result of Hb polymerization.[19] Deoxy Hb S polymers in the cell exist in a spectrum of forms from scattered individual fibers to highly ordered fiber aggregates that essentially fill the cell and distort it into the classic sickle shape or other elongated forms. It is the presence of polymer that causes the

reversible, oxygen-linked changes in the rheologic properties of the sickle erythrocyte that characterizes the disease. Upon oxygenation, these polymers dissolve or "melt," and the sickle erythrocyte loses most of those pathologic properties caused by the presence of polymer. If the concentration of Hb S in such solutions or in the red cell approaches 30 g/dl, a semisolid gel forms.

Structure of Hemoglobin S Polymer

The structure of the deoxygenated Hb S polymer has been deduced from studies involving the use of electron microscopy (Fig. 33.2)[20] and x-ray diffraction.[21] The polymerized Hb fiber is a helical structure with 14 Hb tetramers in each layer; these form a central core of four strands and an outer sheath of 10 additional strands with a diameter of ~21 nm.[22] Only one of the two *b*6 Val residues appears to participate in the intermolecular contact; it fits into a hydrophobic pocket formed by a $b^{85\ Phe}$ and a $b^{88\ Leu}$ residue on a β chain of a nearby Hb S tetramer. Bonds between contact points include both hydrophobic and electrostatic forces.

Physiologic Determinants of Polymerization

The equilibrium of Hb S between its liquid and solid phases is determined by four variables: oxygen tension, Hb S concentration, temperature, and hemoglobins other than Hb S. Polymerization occurs only with deoxygenation, which results in a fall in oxygen affinity, thereby stabilizing the deoxy state. An increase in 2,3-diphosphoglycerate decreases the affinity of Hb S for oxygen and enhances gelation.[23] Likewise, a decrease in pH decreases oxygen affinity via the Bohr effect, thereby increasing the amount of deoxy Hb S at any given oxygen tension. There is a positive correlation between Hb S concentration and gelation.[24] Under standard laboratory conditions, gelation occurs as the concentration of deoxy Hb S is raised above 20.8 g/dl.[25] Because the mean Hb concentration of the red cell is normally >30 g/dl, intracellular gelation of Hb S is a predictable consequence of deoxygenation.

The influence of other hemoglobins on Hb S polymerization is variable. Both Hb A and Hb F have an inhibitory effect on gelation.[26] When these hemoglobins are deoxygenated, they enter the sickle polymer less readily than does deoxy Hb S, thereby retarding gelation by a dilutional effect. Because there are 20 surface amino acid differences between b^S and *g* chains and only a single residue difference between b^S and b^A chains, it is not surprising that Hb F is excluded from Hb S polymers to a greater extent than Hb A. Other hemoglobins interfere with polymer formation less well. By measuring the minimum gelling concentration of various mixtures of hemoglobins, the extent of interaction can be quantitated. Deoxy Hb S molecules copolymerize most effectively with other Hb S molecules and, in decreasing order, with Hb C, D, O Arab, A, J, and F.[27] These in vitro observations predict the clinical severity of disorders involving these variants. In contrast, the doubly heterozygous state for Hb S and hereditary persistence of fetal Hb (HPFH), in which red cells contain approximately 70% Hb S and 30% Hb F, is not associated with clinical disease.[28,29,30,31] It is possible to estimate how much inhibition of polymerization would result from therapeutic interventions such as altering Hb S solubility, which might be accomplished by modifying polymer structure, lowering mean corpuscular Hb concentration (MCHC), or elevating the fraction of Hb F.[32] Recently, the primary significance of polymerization has been called into question because modulators of polymerization, such as the Hb F level, neither correlate with the frequency nor predict the onset of pain crises, nor do they address the initiation of acute vascular occlusion.[33]

Kinetics of Sickling

Sickling is not an instantaneous phenomenon; the kinetics of sickling suggest that molecular polymerization occurs in stages. The delay period between deoxygenation and polymerization is attributed to nucleation processes, in which Hb S tetramers form small aggregates without modification of internal viscosity. When these aggregates reach a critical mass, a rapid addition of free Hb units occurs to form fibers that then undergo alignment to form a tactoid.[34] A red cell spends ~1 to 2 seconds in the arterial circulation and 1 second in the microcirculation; it then takes ~15 seconds returning to the lungs.[35] If the delay time is >15 seconds, the cell can return to the lungs and be reoxygenated before any significant polymerization has begun, but if the delay time is between 1 and 15 seconds, gelation occurs while the cell is in the venous circulation. Sickling in the large veins does not produce vaso-occlusion, but the cell membrane may be damaged, resulting in a loss of water and a shorter delay time in subsequent trips through the circulation. If the delay time is less than 1 second, gelation can occur while the cell is in one of the narrow vessels of the microcirculation. Because the cell is much less deformable, it may not be able to "squeeze" through and may become transiently or permanently stuck. Under physiologic conditions, the delay between complete deoxygenation and erythrocyte sickling is ~2 seconds. Small increments in deoxyhemoglobin concentration (e.g., those that occur with loss of cell water) profoundly shorten the delay time,[36] thereby potentiating sickling. The delay time, however, is strongly influenced by changes in Hb concentration, the presence of hemoglobins other than Hb S, temperature, pH, and 2,3-diphosphoglycerate.[37] Increased intracellular 2,3-diphosphoglycerate decreases the oxygen-binding affinity of

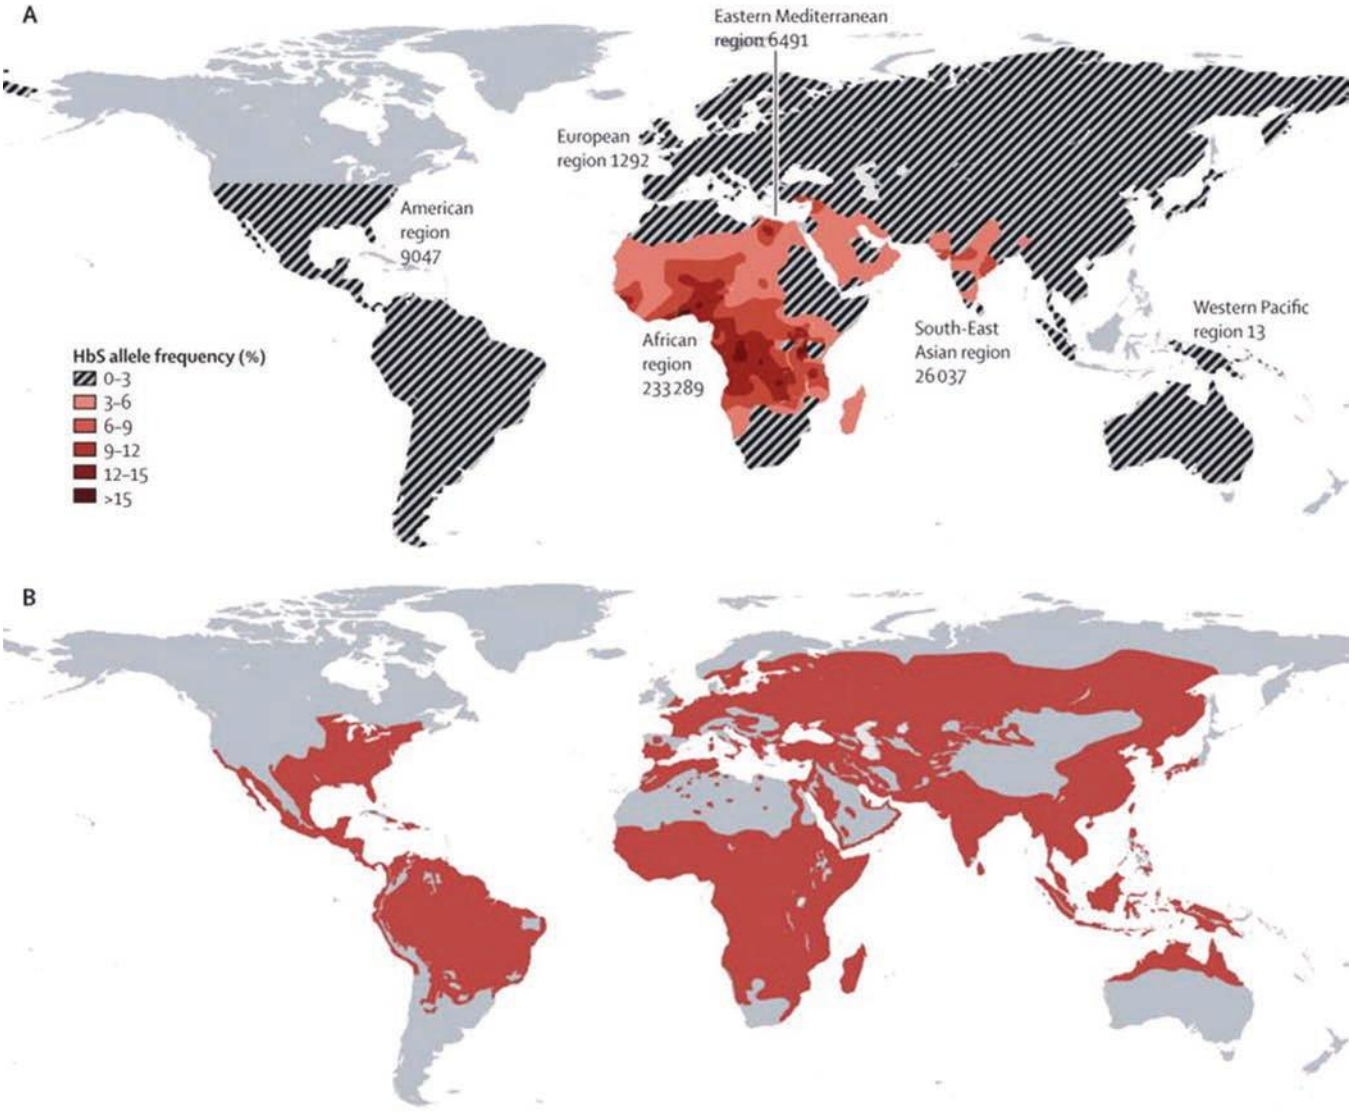

FIGURE 33.1. Global distributions of Hb S and malaria. This map shows the distribution of the Hb S allele. Hb, thereby inducing sickling. In a study of cultured human red cells and mice, the induction of adenosine A(2B) receptor led to increased levels of 2,3-diphosphoglycerate in the cells, consequently inducing more sickling.[38] Recent findings point to the role of free heme in the kinetics of sickling; increasing amounts of free heme added to dialyzed Hb S solutions enhances polymerization.[39]

Cellular Pathology

Red cells containing Hb S acquire the sickle-shape deformity upon deoxygenation because of the intracellular polymerization of Hb. This phenomenon may be monitored directly with light or scanning electron microscopy (Fig. 33.3) and indirectly by measuring changes in viscosity or filterability.[40] Electron micrographs demonstrate filaments in parallel array, some of which extend into the protuberances of sickled cells.[41] The membrane is secondarily involved by repeated or prolonged sickling. Irreparable damage to membrane structures obviates resumption of the normal disc shape despite solubilization of intracellular polymers and thus produces the irreversibly sickled cell (ISC).[42] Both Hb polymerization and membrane injury contribute to the pathophysiology of the sickling syndromes.

Red Cell Sickling

The sickling of erythrocytes containing Hb S is induced by the same physicochemical perturbations as those responsible for the gelation of Hb S solutions. Arterial blood, having a high oxygen saturation, contains fewer sickle cells than blood collected from various sites in the venous circulation.[43] The oxygen affinity is abnormally sensitive to pH fluctuations in the physiologic range; a decrease in pH from 7.4 to 7.2 results in twice the normal decrement in oxygen affinity.[44] Sickling is greatly potentiated by increasing the intracellular concentration of Hb S. Predictably, red cells containing relatively more Hb F sickle less readily and survive longer than cells containing little Hb F.

Membrane Alterations

Red cell sickling is associated with reversible membrane changes. With repeated cycles of sickling and unsickling, aberrations in membrane function and structure become increasingly pronounced, culminating in fixation of the membrane in the sickled configuration.[45]

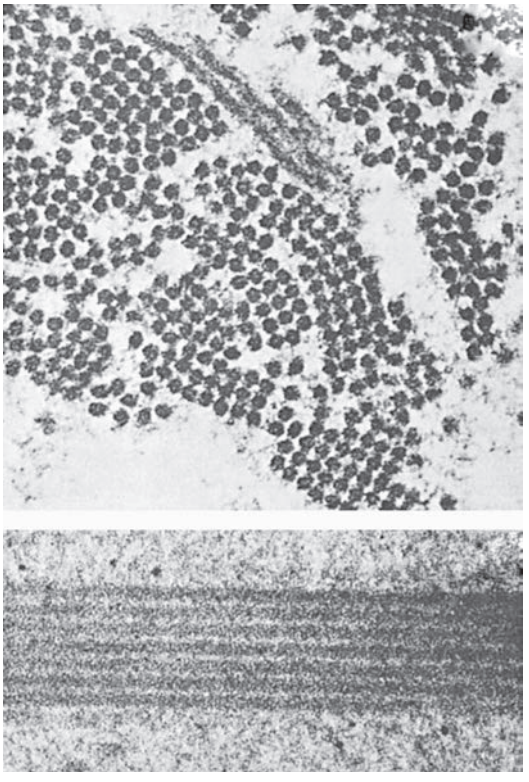

FIGURE 33.2. Electron photomicrographs of cell-free pellets of deoxyhemoglobin (Hb) S. **A:** Transverse section through fibers of polymerized Hb S (×97,000). **B:** Longitudinal section through same (×102,000). Reversibly and Irreversibly Sickled Cells

When red cells are sickled, they leak K^+ and gain Na^+, a phenomenon previously ascribed to partial failure of the Na^+, K^+-adenosine triphosphatase (ATPase) pump.[46] Because the net flux of Na^+ and K^+ is approximately equal in reversibly sickled cells, no change occurs in intracellular hydration or Hb concentration.[47] The intracellular concentration of Ca^{2+} is increased during sickling, owing in part to increased membrane permeability for Ca^{2+} and possibly to impairment of the ATPase-dependent Ca^{2+} pump.[48]

From 5% to 50% of cells from individuals with SCA are ISCs, permanently stabilized in their abnormal crescent or oval shape.[49] ISCs contain substantially less Hb F than reversibly sickled cells,[50] and their endowment of Hb F appears to be the primary determinant of irreversible sickling. In the ISC, the quantity of membrane lipids is decreased consistent with membrane loss, probably as a result of vesiculation.[51] The normal phospholipid organization of the red cell membrane (phosphatidyl choline and sphingomyelin in the outer monolayer and phosphatidyl ethanolamine and phosphatidyl serine [PS] in the inner monolayer) is altered by deoxygenation, resulting in negatively charged PS on the red cell surface. This phospholipid may initiate blood clotting by enhancing the conversion of prothrombin to thrombin, as suggested by the findings of increased plasma levels of fragment 1.2 in the circulation.[52]

Dehydration

Two pathways play a major role in formation of dense cells: the Ca^{2+}-activated K^+ channel (Gardos pathway) and the K–Cl cotransport channel (KCC). KCC regulates RBC volume, especially in reticulocytes, and its dominant isoform is KCC3.[53] The transient increase in free Ca^{2+} induced by red cell deoxygenation and sickling leads to activation of the Gardos pathway and subsequent activation of KCC with further K^+ loss. In ISCs, unlike reversibly sickled cells, K^+ loss exceeds Na^+ gain, and there is overall loss of cell water and increased concentration of intracellular Hb S. Although total cellular Ca^{2+} is increased, it is compartmentalized in cytoplasmic vesicles, resulting in normal levels of free cytoplasmic Ca^{2+} and prevention of dysfunction of the inner membrane.[54]

The rate of dehydration of sickle cells is uneven, and those destined to become ISCs dehydrate by a fast-track process. Reversible permeability pathways for Na^+, K^+, Mg^{2+}, and Ca^{2+}, sometimes referred to as the *sickling-induced pathway,* are the result of ionic shifts affecting cell hydration (58). The combined activity of the Gardos channel and K–Cl co-transport leads to rapid dehydration of a relatively young subpopulation of sickle cells, many with the characteristics of ISCs. The antimycotic agent clotrimazole is an inhibitor of the Gardos channel and prevents dehydration of sickle cells in vitro and in vivo.[55,56] An analog of clotrimazole (ICA 17043, Senicapoc) with greater potency and fewer side effects has been shown to prevent dehydration of red cells in a transgenic sickle mouse model[57] and was tested in clinical trials (see the section "Reduction of Red Cell Hemoglobin Concentration").

In vitro, KCC is activated by cell swelling, low pH, or urea.[58,59] When activated, K^+ and Cl^- leave the cell via facilitated diffusion down their concentration gradients. Water follows their efflux, leading to cell dehydration. The activity of the KCC is abnormally increased in SCA[58,60]; regulation of its activity involves phosphorylation and dephosphorylation reactions in membrane-bound serine/threonine kinases and phosphatases. Magnesium is abnormally reduced in sickle erythrocytes, and increasing cell magnesium produces a marked decrease in the activity of K–Cl cotransport.[56] Still another approach to prevention of red cell dehydration has been to inhibit chloride conductance with a reversible anion conductance inhibitor.[61] The sickling-induced permeability pathway may be affected by transport inhibitors, including dipyridamole at pharmacologic levels.[62]

Adhesion

Sickle red cells demonstrate abnormal adherence to vascular endothelium,[63,64,65] monocytes, macrophages, and model lipid membranes. Compared with normal red cells, sickle cells are 2 to 10 times more adherent to bovine and human endothelial cells.[63] This property of sickle blood is imparted by deformable sickle cells rather than by ISCs,[66,67] perhaps because rigid cells are unable to form multiple surface contacts with endothelial cells. Furthermore, red cell deformability has a strong positive correlation with the frequency and severity of pain crises.[66,68] Individuals who generate a relatively greater number of ISCs have decreased red cell deformability and milder disease compared with those whose red cells are more deformable. Presumably, rigid ISCs are unable to enter capillaries or to adhere tenaciously to capillary endothelium, whereas deformable sickle cells enter capillaries readily, adhere to the endothelium, and compromise blood flow.

When examined under dynamic conditions, red cell adherence is noted primarily at sites of turbulence rather than where flow is laminar.[69] Several mechanisms for increased adherence have been proposed.[70] The repellent force of the red cell is thought to reside in negatively charged sialic acid residues that are homogeneously distributed over the surface of the membrane. The distribution of negative charges on membranes of sickle red cells is patchy and interrupted,[63] creating surface areas that may have an electrostatic attraction for other cells. Alternatively, abnormal adherence may be a derivative of cellular dehydration, which induces an abnormality of negative charge distribution in normal red cells similar to that of sickle red cells.[71] Auto-oxidation of sickle red cells is yet another possible mechanism for increased adherence. Induction of excessive free radical generation in normal red cells is associated with increased adherence under conditions that allow the influx of calcium.[72]

Conditions and factors that promote the expression of adhesion receptors by endothelial cells include hypoxia, thrombin, tissue necrosis factor, platelet-activated factor, and interleukin-1.[73]

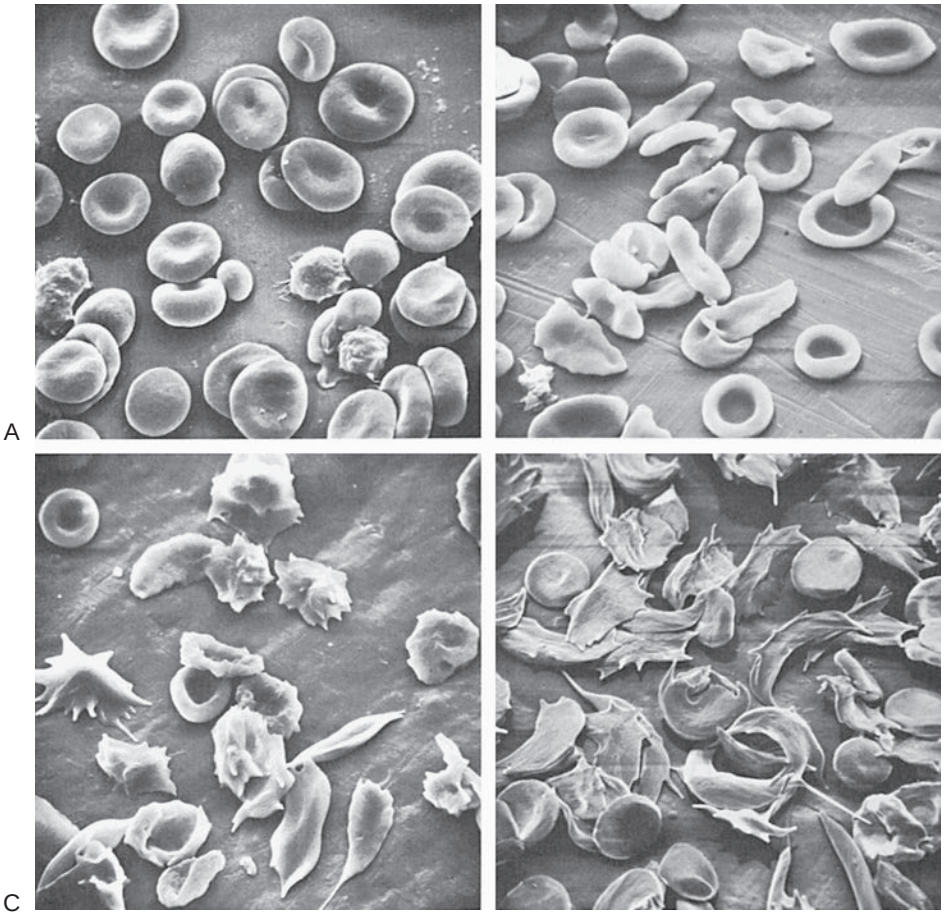

FIGURE 33.3. Erythrocytes from a patient with sickle cell anemia (SCA) examined with scanning electron microscopy. A: Oxygenated blood. Red cells appear normal except for one microspherocyte. Three leukocytes are evident in the field. **B:** Oxygenated irreversibly sickled cells are smooth in texture and outline but are ovoid or boatlike in shape. **C:** Partial deoxygenation causes the cells to assume bizarre shapes with spikes, spicules, and filaments that protrude from the cells. **D:** More complete deoxygenation causes the cells to assume sickled shapes with longitudinal surface striations.

These conditions/factors also cause increased adhesion of sickle cells to endothelium in vitro. Thrombospondin may be an important plasma adhesogen because of its ability to bridge CD36 expressed on sickle reticulocytes.[74] Thrombospondin-mediated adherence occurs under flow conditions with both microvascular and large-vessel endothelial cell assays. Thrombospondin levels are elevated in sickle cell patients during crisis,[75] perhaps as a result of platelet activation. Fibronectin may link endothelial receptors with the fibronectin receptor $\alpha_4 b_1$ (VLA-4) expressed on sickle reticulocytes.[76,77] Ultralarge forms of von Willebrand factor are postulated to promote adherence through nonreceptor mechanisms such as by binding with co-clustered hemichrome-band 3 aggregates on sickle membranes.[78] Erythrocyte membrane sulfatide, a sulfated glycosphingolipid, may also play an important role in adhesion and its blockage with specific antibodies significantly prevents endothelial adhesion.[79] Different mechanisms may predominate under various circumstances or in different parts of the circulation. Coagulopathy might cause thrombospondin release and precipitate vaso-occlusion in microvessels, and dehydration-induced vasopressin elevation might stimulate von Willebrand factor release and precipitate vaso-occlusion in large postcapillary venules. The increased sickle cell adherence to injured endothelium, the role of platelet and leukocyte receptors, and the possible stimulation of nitric oxide (NO) production by adherent red cells all require further evaluation.

Circulating activated endothelial cells have been assayed using immunohistochemical examination of buffy coat smears with antiendothelial cell antibodies.[80] In one study patients with SCA who had acute painful episodes had higher levels of circulating endothelial cells than patients with no recent events, who, in turn, had higher levels than controls. Circulating endothelial cells were predominantly microvascular ($CD36^+$) and expressed markers of endothelial cell activation (intercellular adhesion molecule [ICAM]-1, vascular cell adhesion molecule [VCAM]-1, E-selectin, and P-selectin). This suggested that vascular endothelium is activated in patients with SCA and that adhesion proteins on the cells may have a role in the vascular pathology. Using an animal model with the ex vivo rat mesocecum venules and human sickle cells, two monoclonal antibodies were demonstrated to inhibit interactions between sickle cells and endothelial cells by blocking ligand binding to integrin $\alpha_v b_3$, a molecule that binds to several adhesion proteins, including von Willebrand factor and thrombospondin.[73] P-selectin may also mediate SS red cell adhesion to endothelial cells in vitro.[81]

Rheology of Sickle Cells

The clinical features of SCA are directly or indirectly related to increased blood viscosity. The viscosity of plasma in sickle cell subjects is slightly higher than that of plasma from normal subjects because of higher total protein concentration.[82] However, at all shear rates, the viscosity of oxygenated sickle blood is lower than that of normal blood, mainly as a result of lower hematocrit values.[83] The viscosity of a sickle blood sample increases with decreased oxygen saturation, primarily because of reduced cellular deformability.[82,84] When the cell concentration of sickle blood is raised in vitro to 45%, viscosity becomes higher than that of normal blood. The extent to which membrane rigidity,[85] Hb polymerization,[86] and increased intracellular Hb concentration[83]

contribute to altered blood flow depends in part on the method used to study the properties of sickle red cells. Reduction in the cellular deformability of oxygenated sickle red cells has been demonstrated by increased viscosity of sickle blood (viscometry),[83] decreased filtration of dilute cell suspensions through narrow pores,[87] decreased ability of cells to undergo deformation in shear fields (ektacytometry),[88] and increased aspiration pressures needed to induce entry of cells into micropipets.[89] Cellular dehydration, as well as the resulting increase in cytoplasmic viscosity, is a major determinant of abnormal rheologic behavior of oxygenated sickled red cells. Sickled red cell membranes demonstrate extensional rigidity and persistent deformation, as documented by videomicrographs of micropipet aspiration.[89] The rheologic properties of oxygenated sickle cells are strongly influenced by the state of cell hydration and the increased propensity for oxidative damage to the membrane.[90,91] The already compromised deformability of oxygenated sickle cells is dramatically reduced further after deoxygenation. Under conditions of high shear stress, increased internal viscosity appears to determine the rheologic behavior of ISCs, whereas at low shear rates, membrane rigidity assumes greater significance.[92] Under physiologic conditions, increased viscosity results primarily from cellular dehydration. The poor deformability of ISCs, as measured by ektacytometry, can be rectified by osmotically hydrating them to a normal MCHC. The membrane rigidity of oxygenated sickle cells also can be returned to a normal level by replacing Hb S with Hb A, suggesting that the interaction of Hb S with the cell membrane is an important determinant of cellular rigidity.[93] Peripheral vascular resistance is increased in proportion to ISC numbers, the extent of ISC deoxygenation, and ISC density.[94] The functional significance of the impaired flow properties of sickle red cells has been demonstrated by measuring exercise tolerance before and after partial exchange transfusion. By increasing the relative number of cells containing Hb A without increasing the total Hb concentration, exercise capacity improved significantly.[95]

Pathogenetic Role of Hemolysis

Intravascular hemolysis results from the lysis of complement-sensitive red cells[96] and Hb lost during sickling- or shear-induced membrane fragmentation.[97] Extravascular hemolysis may occur by two mechanisms: monocyte and macrophage recognition and phagocytosis of red cells that have undergone sickling- or oxidation-induced membrane changes[98] and physical entrapment of rheologically compromised red cells.[99] Intravascular and extravascular patterns of hemolysis are believed to account for 1/3 and 2/3 of sickle hemolysis, respectively;[100] however, this information has not been re-evaluated using more modern diagnostic methods. The multiple mechanisms for intra- and extravascular hemolysis in SCA result in complex interactions involving red cell dehydration, sickling, increased sensitivity to complement-mediated lysis,[101] and clustering of membrane protein band 3 leading to accumulation of IgG and complement on the cell surface,[102] collectively leading to red cell trapping and fragmentation, osmotic lysis, and erythrophagocytosis.[103]

Hemolysis can be quantitated utilizing different biomarkers, but the accepted measures of hemolytic rate are the direct red cell survival (red cell lifespan) assessment or the amount of plasma Hb. Traditional red cell survival measurement involves exposure to radioactive chromium 51; however, more recent methods utilizing erythrocyte labeling with different biotin densities may be safer.[104] Several factors bear a strong relationship to the rate of hemolysis. Of greatest significance is the relative number of ISCs.[105] The extent of Hb polymer formation, calculated from the MCHC and the relative proportion of Hb fractions, also correlates closely with the severity of hemolysis.[106] Of particular interest is the relationship between hemolytic rate and adherence of sickle cells to macrophages.[107]

Cell-free Hb, a direct result of hemolysis, is a known cause of consumption of nitric oxide, although other mechanisms may also result in low NO levels, such as increased plasma arginase levels, and increased levels of an NO inhibitor, asymmetric dimethylarginine (ADMA).[108,109] SCA individuals are recognized to be NO-deficient, but the role of NO deficiency in the development of vasculopathy and endothelial dysfunction, is still incompletely understood. Because of the multitude of mechanisms involved in the pathophysiology of SCA (inflammation, adhesion, hemolysis, hypoxia-reperfusion injury, etc.), the contribution of NO consumption in the genesis of vascular dysfunction in SCA is not completely defined.

Two distinct clinical phenotypes have been proposed to classify patients based on the type of disease complications and the pathophysiologic role of hemolysis. The first includes clinical manifestations of sickle cell disease linked to hyperviscosity: vaso-occlusive pain crises and acute chest syndrome (ACS), which are associated with high white blood cell counts and relatively elevated steady-state hemoglobin levels.[110] The second encompasses clinical complications attributed to hemolysis-induced "dysregulation of NO metabolism" leading to endothelial dysfunction (vasculopathy), and includes pulmonary hypertension (PHT), leg ulceration, priapism, and possibly stroke. This classification has recently been called into question, as classic biomarkers of intravascular hemolysis, such as lactate dehydrogenase (LDH) and reticulocyte count, are not consistently elevated in all cases of "hyperhemolysis." Furthermore, in other conditions where intravascular hemolysis is marked, such as paroxysmal nocturnal hemoglobinuria, there is no significant increase in leg ulcers or stroke.[103,111,112] Additional mechanisms other than hemolysis-induced low NO levels may be involved in the promotion of endothelial dysfunction. For instance, the pathophysiology of renal dysfunction may be related to induction of heme oxygenase-1, release of heme, and HbS instability.[113]

Pathogenesis of Vaso-occlusion

Possible factors involved in the development of sickle cell vaso-occlusion include Hb S polymerization, sickle cell deformability, sickle blood viscosity, the fraction of dense cells, sickle cell–endothelial cell adherence, endothelial cell activation, hemostatic activation, vascular tone, white blood cell and platelet activation, enhanced local and regional inflammatory response, ischemia and reperfusion injury, and oxidative stress.[114,115,116] These processes and events are highly interconnected, leading to clinically significant outcomes, and often reinforcing or producing a "vicious cycle" of vaso-occlusion.[117] The mechanisms of vaso-occlusion may vary with anatomic site and with different circumstances. For example, there is functional heterogeneity of endothelial cells from large-vessel and microvessel sources, and there are organ-to-organ differences in microvascular architecture.[118] During inflammation, increased white blood cell interactions with endothelium could be a triggering event. Under other circumstances, platelet activation might result in an elevation in thrombospondin level or clinical dehydration might lead to an increased release of von Willebrand factor, thus promoting vaso-occlusion.

Because of their higher Hb S concentration, the densest cells are least deformable and are at greatest risk for intracellular polymerization. Obstruction by these cells develops at the arteriolar–capillary junctions in model systems.[118,119] The role of dense cells may be to create a "logjam" behind an obstruction rather than to initiate the vascular plug. The proportion of dense cells increases immediately before an acute pain crisis and falls during the first few days afterward.[120,121] Initiation of vaso-occlusion by adherent cells may explain the fractional reduction in the least dense, most adherent cells during the initial stages of a vaso-occlusive pain crisis. This is consistent with a correlation of the frequency of painful events and better red cell deformability, rather than poorer deformability as might be expected.

The abnormal interaction between sickle cells and vascular endothelium may be of greater relevance for vaso-occlusive events than alterations in red cell morphology or viscosity. Although endothelial adherence does not correlate with standard hematologic measurements, it correlates significantly with the severity of pain crises.[122] Likewise, patients with clinically less severe sickling disorders, such as Hb SC disease, tend to have less adherent red cells.[123] When red cells from patients with SCA are suspended in autologous plasma, however, dramatic increases in adherence are noted at the onset of vaso-occlusive events. Both plasma fibrinogen and fibronectin have been implicated as factors modulating adherence.[124] These findings from in vitro studies complement the classic clinical observation of a temporal relationship between infections and pain crises[125] and the demonstration of increased plasma fibrinogen levels during vaso-occlusive crises. Red cell adherence is also augmented by hyperosmolar conditions and by endothelial injury. Together, these observations suggest that alterations in the environment of the red cell predispose to vaso-occlusion by amplifying the abnormal attraction of sickle red cells to vascular endothelium.

Sickled red cells may adversely affect local regulation of vascular tone. Normal endothelial-cell–derived vasoactive factors include nitric oxide and prostacyclins (vasodilators) and endothelin-1 and platelet-derived growth factor-β (vasoconstrictors). These agents act on vascular smooth muscle cells and inhibit or stimulate platelet aggregation and adhesion. Vascular tone is also modulated by local oxygen tension and shear forces. An abnormal state of vasodilation and low vascular resistance in subjects with sickle cell disease occurs during steady-state periods, but during crisis states there is a decrease in the levels of vasodilator substances such as the prostacyclins and an increase in vasoconstrictor substances including endothelin and prostaglandins. This shift in the balance of vascular tone toward vasoconstriction results in slowing of vascular flow, further obstruction, and more profound deoxygenation of sickled red cells.[126] A family of enzymes termed nitric oxide synthase (NOS) catalyzes arginine and produces NO,[127] the major endothelium-derived relaxing factor in normal physiology. NO plays a central role in vascular homeostasis by maintaining vasomotor tone and limiting ischemia-reperfusion injury. [128] Plasma levels of the NO metabolites (nitrite and nitrate) and plasma arginine levels are depressed in sickle cell patients during vaso-occlusive crisis and the acute chest syndrome.[129,130] The rate of NO depletion correlates with the severity of hemolysis and is associated with the release of cell-free hemoglobin, which scavenges NO. The effect of scavenging is compounded by decreased bioavailability of the arginine substrate, which is rapidly consumed by erythrocyte arginase after its release from the hemolyzed red blood cell.[131,132] Downstream effects of intravascular hemolysis and NO consumption include increased endothelin-1 expression, heme- and free-iron–mediated oxygen radical generation, platelet activation, and increased endothelial adhesion–molecule expression.[133] Low arginine levels in sickle cell patients with vaso-occlusive crisis and ACS provide a rationale for arginine therapy in these conditions.[134]

Adhesion of red cells to endothelial cells alters vascular flow as described earlier. Specific ligands that may mediate adhesion of sickled red cells to endothelium include von Willebrand factor, thrombospondin, fibrinogen, fibronectin, laminin, and vitronectin.[135,136] Factors that act as vasoconstrictors, such as free radicals, prostaglandins (PGI_2 and PGD_2), and endothelin-1, may enhance adhesion of sickled red cells to the endothelium. Infection or tissue inflammation may exacerbate erythrocyte adhesion through inflammatory cytokines such as tumor necrosis factor.[137]

Alterations in the number and function of white blood cells may contribute to vaso-occlusive events.[138,139] Changes in chemotaxis and adhesion and increased stickiness of neutrophil membranes also have been observed in crisis states.[140,141] Leukocytes may interfere with microvascular flow by lodging in the capillary entrance or adhering to venous or capillary endothelium.[142] Increased white blood cell counts in patients with sickle cell disease have been associated with increased mortality[143] and SCI in the brain.[144] The beneficial effect of hydroxyurea in the Multi-Center Study of Hydroxyurea was associated with its effect in reducing leukocyte counts.[145] Data from the Cooperative Study of Sickle Cell Disease (CSSCD) showed that increased baseline white blood cell counts in infants are a predictive factor for severe manifestations of sickle cell disease in later childhood.[146] Furthermore, acute infection, possibly because of the attendant leukocytosis, is often a triggering mechanism for vaso-occlusive pain events. In addition, four separate reports have linked the administration of granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) to the initiation of severe or even fatal sickle cell crisis.[147–150] An experimental in vivo model using blood flow in the cremasteric muscle of sickle cell mice has indicated that leukocytes that are adherent to the vessel wall can contribute directly to vascular occlusion by means of their interaction with sickle red cells; inhibition of leukocyte adhesion by targeted disruption of P- and E-selectin expression can prevent vaso-occlusion.[151] Leukocytes may cause further tissue damage by release of inflammatory mediators and oxygen radicals. Endothelium adhesion molecules such as E-selectin, VCAM-1, and ICAM-1 mediate leukocyte recruitment and promote an inflammatory response, as may the release of heme from red cell lysis.[152]

It has been postulated that patients with sickle cell disease live in a state of "chronic inflammation." The heightened state of inflammation results from different factors, including constant red cell sickling, increased white and red blood cell adhesion and damage to endothelium, increased cytokine generation, or ischemia-reperfusion injury, all causing more vaso-occlusion and repeated endothelial damage (Fig. 33.4).[116] In sickle cell transgenic mice, induction of hypoxia followed by re-oxygenation enhances peroxide production and increases leukocyte recruitment.[153] In addition, ischemia-reperfusion injury causes inhibition of oxygen-sensing prolyl hydroxylase enzymes, leading to activation of hypoxia and inflammatory signaling cascades, altering the stability of transcriptional factors hypoxia-inducible factor (HIF) and nuclear factor-*k*B (NF- *k*B).[154,155] An inhibitor to the nuclear factor-*k*B was shown in a sickle cell mouse model to reduce the expression of ICAM-1 and VCAM-1 on circulating endothelial cells of patients with sickle cell disease.[156] Examples of biomarkers of inflammation that are elevated in sickle cell disease are C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), interleukins, and secretory phospholipase A_2, (linked to the development of ACS), among others.[117,157,158]

Consistent alterations in platelet number and function have suggested the involvement of platelets in vaso-occlusive events. Abnormalities include increased platelet counts, increased platelet volume,[159] decreased platelet survival,[160] and decreased platelet aggregation.[161] The latter has been attributed to a refractory state resulting from in vivo platelet activation. In support of this interpretation is the demonstration that plasma β-thromboglobulin, a measure of release activity from platelet α-granules, is elevated in the steady state and increases further during vaso-occlusive crises.[162] Elevated urinary levels of thromboxane metabolites and depressed platelet thrombospondin content provide evidence for platelet activation in steady-state sickle cell patients.[163,164] The levels of the contact factors (factor XII, prekallikrein, and high-molecular–weight kininogen) are low and decrease further during crises.[165] The coagulation inhibitors protein C and free protein S are reduced in steady-state sickle cell disease;[166,167] antithrombin III activity levels have been variable, but increased thrombin–antithrombin III complexes and plasma factor VII levels indicate increased tissue factor activity during the steady state.[168] Plasma prostacyclin activity, thought to be generated from vessel wall PG, is increased.[169] The level of fibrin d-dimer, a breakdown

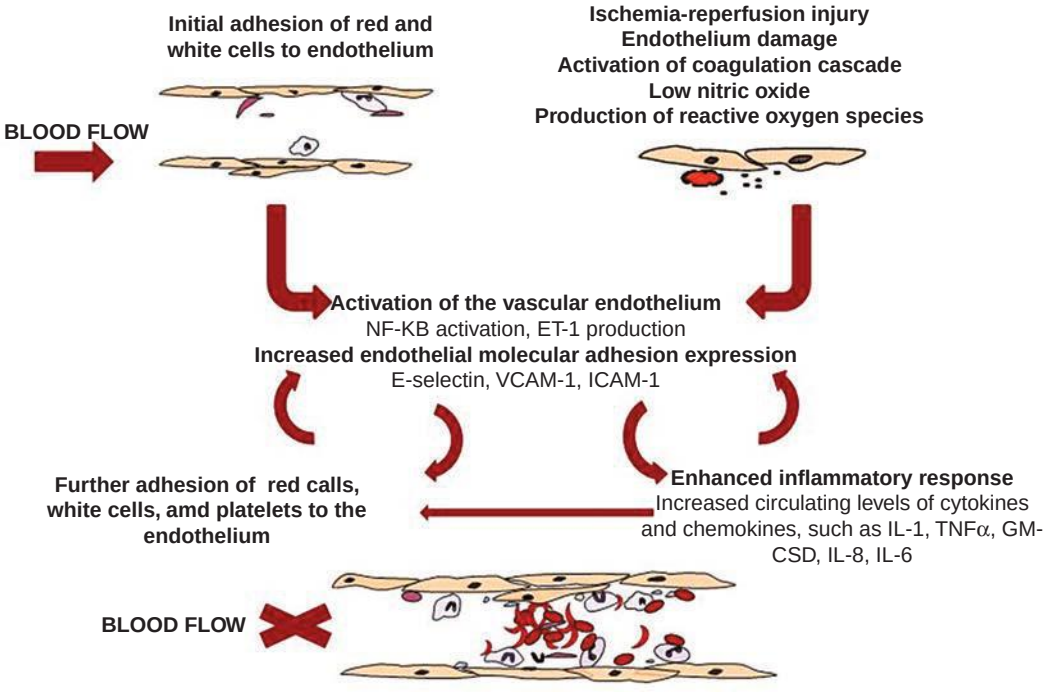

FIGURE 33.4. The chronic inflammatory state and vaso-occlusion. Hemoglobin S polymer formation leads red blood cell membrane surface exposure of glycolipids and protein epitopes. Red and white cell adhesion to the endothelium, coupled with endothelial damage due to cell-free hemoglobin and ischemia reperfusion injury, low nitric oxide bioavailability, and activation of the coagulation cascade by glycolipds, lead to activation of the vascular endothelium. Endothelial activation augments NFκB activity and endothelin-1 production, in association with increased surface adhesion molecule expression. Further adhesive interactions between the endothelium and red cells, leukocytes, and platelets are induced, coupled with a pancellular activation that results in an up-regulation of numerous inflammatory mediators. As such, a vicious circle of repeated cell activation, cellular adhesion, and inflammatory molecule production perpetuates the chronic inflammatory state that has a fundamental role in the vaso-occlusive process. Modified from Conran N, Franco-Penteado CF, Costa FF. Hemoglobin. 2009;33(1):1–16.

fragment of cross-linked fibrin, increases during vaso-occlusive crises and returns to normal after crisis resolution.[170] Platelet activation is profoundly inhibited by NO, and this inhibition is blocked by plasma hemoglobin-mediated NO scavenging.[171] Whether these alterations in hemostasis and fibrinolysis are of pathogenic significance or are simply epiphenomena remains to be determined.

SICKLE CELL ANEMIA (HEMOGLOBIN SS)

Clinical Features

The clinical features of SCA result more from the vaso-occlusive consequences of sickle cells than from the anemia itself. These features may be divided into those that characteristically are acute and episodic and those that are chronic and often progressive. Although signs and symptoms attributed to Hb S have been observed in early infancy,[172] affected individuals characteristically are asymptomatic until the second half of the first year of life. The lack of clinical expression of the Hb SS genotype during fetal and early postnatal life is explained by the production of a sufficient quantity of Hb F to limit clinically important sickling. Because erythrocytes contain increasing amounts of Hb S and proportionally decreasing amounts of Hb F over the first several months of life, the conditions for sickling under physiologic conditions gradually are met. Prospective studies of affected infants followed from birth indicate a close temporal relationship between the postnatal decline in Hb F and evolution of anemia.[173,174,175,176] Mild hemolytic anemia is apparent by 10 to 12 weeks of age (Fig. 33.5).[176,177]

Clinical features change with age. In the first year of life splenomegaly (usually noted after 6 months of age), dactylitis, and ACS are commonly seen.[173] Loss of function of the spleen has been documented as early as 5 months of age,[176,178] and death from overwhelming infection is an increased risk before 12 months of age.[175] The first vaso-occlusive episode is experienced before 4 years of age by the majority,[175] but not until late childhood or adulthood by a few. During adolescent and especially young adult years, organ dysfunction (e.g., renal, pulmonary, cardiac, and hepatic dysfunction) becomes more prevalent and, in older adults frequently causes mortality.[143,179]

The Cooperative Study of Sickle Cell Disease and the Jamaican Cohort Study, the two largest prospective sickle cell cohorts to date, have generated information regarding the "natural history" of sickle cell disease in thousands of pediatric and adult patients. More recently, the Dallas Cohort has offered important data about survival and risk factors in sickle cell disease.[180]

Compound heterozygote states, such as Hb SC and Hb Sβ^+-thalassemia, can exhibit any of the clinical features seen in Hb SS, but often do so with lesser frequency and severity. Hb Sβ^0-thalassemia has a very similar phenotype to Hb SS, and is often considered together with Hb SS in the literature, sometimes with both conditions being referred to as SCA. The term sickle cell disease is used to describe all clinically significant genotypes that involve Hb S.

Acute Events: Characteristics, Management, Prevention

Vaso-occlusive Events: Dactylitis and Pain

The term *sickle cell crisis* was introduced to describe a recurring attack of pain involving the skeleton, chest, abdomen, or all three. Using the term in a broader sense, vaso-occlusive "crises" comprise a variety of syndromes that are typically recurrent and potentially catastrophic. Clinical manifestations are sudden in onset and are directly attributable to obstruction of the

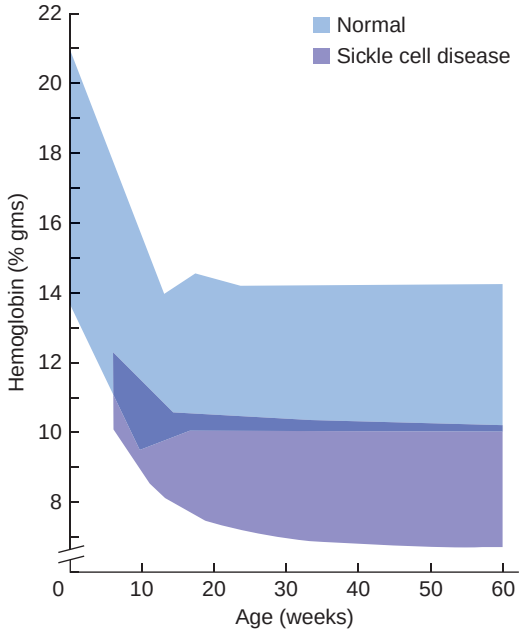

FIGURE 33.5. Hemoglobin concentration as a function of age in infants with sickle cell anemia (SCA). From O'Brien RT, McIntosh S, Aspnes GT, et al. Prospective study of sickle cell anemia in infancy. J Pediatr 1976;89:205, with permission.

microcirculation by intravascular sickling. Modest exacerbation of anemia and increased leukocytosis are common. Infections often precede vaso-occlusive episodes in children, suggesting that fever, dehydration, and acidosis may be contributing factors. In adults, a triggering event is not often identified, however.

The initial vaso-occlusive episode in infants, named hand-foot syndrome or dactylitis, often involves the small bones of the hands and feet. By 2 years of age, nearly 50% of Jamaican children and 25% of American children with SCA have experienced at least one episode of dactylitis.[173,181] Typically, the dorsa of the hands and/or feet are swollen, nonerythematous, and exquisitely painful. Fever and leukocytosis are common. Radiographic changes are limited initially to soft-tissue swelling; cortical thinning and destruction of metacarpals, metatarsals, and phalanges appear 2 to 3 weeks after the onset of symptoms. Dactylitis is sudden in onset and may last 1 or 2 weeks. It may recur on one or more occasions until the patient is ~3 years of age.[181]

Usually, after the first few years of life, interruption of blood flow occurs in the larger bones of the extremities, spine, rib cage, and periarticular structures, producing painful crises of the bones and joints.[182,183] The sinusoidal circulation of the bone marrow provides an ideal vascular bed for the sickling phenomenon.

In the CSSCD, epidemiologic features of pain crises were analyzed in a large group of patients with sickle cell disease.[184] The average rate of pain was 0.8 episode/patient-year in Hb SS, 1.0 episode/patient-year in Hb S β^0-thalassemia, and 0.4 episode/patient-year in Hb SC disease and Hb S β^+-thalassemia. However, the rate varied widely from patient to patient: 39% of patients with SCA had no episodes of pain, but 1% had more than six episodes per year. With Hb SS patients 5% accounted for almost one third of all the episodes. The pain rate increased moderately from childhood to the third decade of life. A higher rate of pain events has been associated with low nocturnal oxygen saturation detected by continuous monitoring during sleep.[185] When children with a history of asthma experience an episode of pain, antecedent or concurrent respiratory symptoms (cough, wheeze, tachypnea, retractions, or grunting) occur more frequently than in children without a history of asthma, suggesting that involvement of the respiratory system is a risk factor for these events.[186]

Pain resulting from ischemia of the bone marrow is gnawing and progressive in severity. Although pain can affect any bone in the body, the most frequent sites are the humerus, tibia, and femur. Involvement of facial bones is less common but is well documented. The swelling associated with infarction of the orbital bone may be sufficient to produce proptosis and ophthalmoplegia.[187] Swelling of the elbows or knees may mimic rheumatic fever or septic arthritis.[188] Infarcts involving deep bones are usually not associated with detectable swelling, erythema, or surface temperature change. Laboratory findings, too, are inconstant and nonspecific. The radiographic features of bone infarction and periostitis usually do not appear until after the resolution of symptoms. Increased signal with T2-weighted images is seen by magnetic resonance imaging (MRI) in approximately one third of pain crises.[189] Discrete areas of decreased localization of ^{99}Tc-sulfur colloid identify areas of decreased marrow blood flow, and ^{85}Sr or ^{99}Tc-phosphate localizes the increased osteoblastic activity that occurs with healing.[190] Although radionuclide bone and bone marrow scans theoretically enable differentiation of bone infarcts from osteomyelitis, in practice they are of limited value.[182] Unlike osteomyelitis, bone infarcts are associated with no more than a low-grade fever, little or no left shift in the leukocyte differential, and only occasional edema. As a cause of bone pain, infarction is >50 times as common as osteomyelitis.[182]

An abdominal pain crisis, a diagnosis of exclusion, is attributed to small infarcts of the mesentery and abdominal viscera. An abdominal pain crisis is characterized by severe abdominal pain and signs of peritoneal irritation; however, the differential diagnosis of other causes of abdominal pain (e.g., cholecystitis, pancreatitis, constipation) should always be considered. The persistence of bowel sounds differentiates pain crises from acute intra-abdominal disorders requiring surgical intervention. Diagnosis is facilitated by prior experience with the patient, because the pattern of pain tends to repeat itself from crisis to crisis. Atypical clinical or laboratory features should suggest one of several complications to which patients with SCA are especially susceptible, such as ACS, urinary tract infection, or cholecystitis.

On average, painful crises persist for 4 or 5 days, although protracted episodes may last for weeks, especially among adults. Data from the CSSCD indicate that an increased frequency of painful events is associated with a high hematocrit and a low Hb F level.[184] Adults with high rates of pain episodes tend to die earlier than those with low rates.[184] Of therapeutic significance, it was noted in the CSSCD that even when the Hb F level was low, a small increase was associated with an ameliorating effect on the pain rate and potentially improved survival.

No specific form of therapy has proven effective for acute vaso-occlusive crises. None of the many medications and manipulations that have been touted as beneficial have withstood critical scrutiny. Low-molecular–weight dextran, phenothiazines, fibrinogenolytic agents, bicarbonate and other alkalis, and urea solutions, when evaluated in controlled clinical studies, were found to be without apparent effect.[191–196] Other therapeutic strategies, although not subjected to randomized clinical trials, have enjoyed only fleeting popularity. These strategies have included carbonic anhydrase inhibitors,[197] vasodilators, anticoagulants, progesterone,[198] testosterone,[199] papaverine,[200] antithyroid drugs,[201] and hyperbaric oxygen.[202] Studies of pentoxifylline, an agent that increases red blood cell deformability and inhibits platelet aggregation,[203] and cetiedil, a smooth muscle relaxant that inhibits sickling and cell dehydration,[204] suggested a reduction in duration of painful crises, but results have not been substantiated by further trials. Poloxamer-188, a nonionic surfactant compound, reduced total analgesic use, but a Phase III trial demonstrated only a slight shortening of the duration of pain crises.[205] Phase II and III randomized, placebo-controlled, double-blind studies investigating the Gardos channel blocker Senicapoc (ICA-17043), showed improvement of anemia and reduction of dense erythrocytes and reticulocytes when compared to placebo; however, they

failed to demonstrate reduction of painful crises.[206,207] Despite encouraging results in Phase II trials, a prospective, multicenter, double-blind, randomized, placebo-controlled clinical trial for up to 72 hours of inhaled NO gas failed to demonstrate benefit in reducing duration of pain crisis or amount of narcotic use.[208] Vitamin D levels are reported low in the majority of individuals with sickle cell disease, and there are reports linking chronic pain with vitamin D insufficiency and deficiency.[209,210,211,212] Replacement of vitamin D has been reported in a few patients to improve symptoms of chronic pain.[213,214] The duration and severity of pain crises are notoriously variable, and the natural course is one of spontaneous improvement. Consequently, uncontrolled reports of effective therapies must be viewed with skepticism, especially if the proposed treatment entails an element of risk.

The cornerstones of present-day therapy are fluids and analgesics. The volume of fluids administered should be sufficient to abolish any deficit, correct hypertonicity, and fully compensate for ongoing losses imposed by fever, hyposthenuria, vomiting, or diarrhea. Typically 150% maintenance intravenous hypotonic fluids are used in the first 12 to 24 hours of the pain event, and subsequently reduced gradually. Precipitants of the crisis should be sought and eliminated. Infection, a common precipitating cause in children, may require antibiotic therapy. Acidosis is corrected readily with intravenous administration of sodium bicarbonate, but its etiology should be investigated and treated. Oxygen therapy in the absence of documented hypoxemia is without benefit and triggers an increase in the number of ISCs when discontinued.[215] Red blood cell transfusions are not indicated in the treatment of the acute pain crisis, unless there is associated accentuated anemia (e.g., parovirus B19 induced "aplastic crisis"). Furthermore, because fever and back pain are common features of pain crises, transfusion reactions may escape early recognition.[216]

Control of pain requires the liberal use of analgesics,[217] but narcotic addiction is unlikely as long as analgesics are closely monitored. Nonsteroidal inflammatory drugs (NSAIDs) used in association with opioids offer benefit, but should be used with caution in patients with renal dysfunction. Regardless of the use of opioids and/or NSAIDs, pain should be treated promptly (within 60 minutes from initial assessment) and re-evaluated within 30 minutes from first dose of analgesic, according to published quality of care indicators.[218] The use of patient-controlled analgesia enables patients to administer opioids to themselves as needed and provides an element of self-control in pain management.[219,220] Patient-to-patient variability in the response to pain treatment is common, and there has been great interest in developing individualized pain therapy to improve the efficacy of treatment, as well as patient experience and satisfaction.[221] Some of this individual variation may be explained by polymorphic enzyme cytochrome P450 (CYP) 2D6 variant alleles that are commonly observed among African Americans and may lead to impaired codeine conversion to morphine.[222] Nonpharmacologic management of pain, such as with self-hypnosis, has been used successfully for pain control in selected subjects.[223] Local use of warm packs may be beneficial in some. Prophylactic approaches to pain management are discussed later in this chapter.

Central Nervous System Events

Stroke is a catastrophic complication of SCA that affects 6% to 17% of children and young adults.[224,225] Data from the CSSCD, in which ~4,000 patients were followed for an average of 5 years, indicated that infarctive stroke was most frequent in children and older adults with Hb SS, whereas hemorrhagic stroke had the highest incidence in patients 20 to 29 years of age.[224] The mortality rate was 26% after hemorrhagic stroke, but 0% after infarctive stroke. Severe anemia, a history of recent or recurrent acute chest syndrome, previous transient ischemic attack (TIA), and hypertension were independent risk factors for ischemic stroke; anemia and leukocytosis were independent risk factors for hemorrhagic stroke.[224] The risk of stroke is increased in patients with Hb F levels <8%[226] and in patients with siblings who have had strokes. Data from the CSSCD also revealed that silent cerebral infarcts (SCI, areas of increased signal intensity, primarily in deep white matter or watershed areas of the cerebral cortex, not attributed to an overt neurologic event or finding) on MRI were a strong independent risk factor for stroke.[227,228] In addition, nocturnal hypoxemia is a risk factor for acute neurologic events (stroke, TIA, or seizures).[229] By far the best predictor of stroke risk at this time, however, is transcranial Doppler (TCD) velocity.[230]

The pathogenesis of cerebral vascular disease is incompletely understood (Fig. 33.6). Pathologically, vascular narrowing (stenosis) results from segmental proliferation and fragmentation of the intima. The internal elastic lamina may show degenerative changes, and the tunica media may be disrupted by fibrosis and hemorrhage. Occlusion is the result of progressive proliferation of vascular smooth muscle, superimposed thrombosis, or embolus.[231,232] Increased adherence of sickle red cells to the endothelium of vessel walls and decreased cerebral vessel CO_2 responsiveness (reflecting diminished reserve capacity for vasodilatation), may be additional mechanisms.[233,234] Aneurysms can be demonstrated in some patients who have sustained intracranial hemorrhage and may be observed as an incidental finding in children with cerebral vaso-occlusive disease.[233]

The distal internal carotid and proximal middle and anterior cerebral arteries are stenotic or occluded in sickle cell patients who have experienced a stroke.[235] In response to chronic anemia and hypoxemia, cerebral blood flow is markedly increased.[236] TCD velocities in the major cerebral arteries are influenced by both of these factors and are abnormally elevated in patients at high risk for stroke.[230,237] There are several factors that appear to modulate TCD velocities and stroke risk. Hb desaturation is linked to elevated TCD velocities and stroke,[238,239] whereas G6PD deficiency and elevated markers of hemolysis increase the risk of elevated TCD velocities.[240] The most common sites of ischemic stroke are the parenchymal areas supplied by the anterior and middle cerebral arteries and the border zones between their distal circulations.[241,242] When acute or chronic conditions arise leading to diminished oxygen availability (e.g., an episode of ACS, an aplastic crisis, nocturnal hypoxemia), the increased hypoxic stress coupled with the inability of the cerebrovasculature to undergo further dilatation leads to ischemia.[229]

Increasing evidence for genetic modifiers of stroke has accumulated. In a clinical epidemiology study, 42 sibships of patients with SCA in which one sibling had had a stroke revealed a greater than expected number of families having two or more children with a stroke.[243] In another study, children with SCA were far more likely to have an abnormally elevated flow velocity on TCD if they had a sibling with an abnormal TCD.[244] Specific β-S-globin gene haplotypes have been associated with increased stroke risk, but findings have been inconsistent.[245,246] Certain HLA alleles and the presence of alpha thalassemia are recognized protective factors for cerebrovascular disease.[240,247,248] Genes regulating immune function and inflammation, including Fcγ receptor and tumor necrosis factor-α (TNF-α), have not contributed to an increased risk of stroke, whereas single nucleotide polymorphisms (SNPs) within the vascular cell adhesion molecule (VCAM)-1 gene may influence this risk.[249,250] Other SNPs shown to be associated with increased stroke risk are ANXA2, TGFBR3, and TEK, whereas SNPs in the ADCY9 gene were linked to decreased stroke risk.[248]

A novel approach to "disentangling the web of interactions among genes, environment, and phenotype" has been the use of a Bayesian network, a multivariate dependency model that accounts for simultaneous associations and interactions among multiple genes and their interplay with clinical and physiologic factors.[251] Using data and stored samples from the CSSCD, 108 SNPs in 39 candidate genes from almost 1,400 individuals were analyzed. Candidate genes were involved in vasoregulation, inflammation,

cell adhesion, coagulation, hemostasis, cell proliferation, oxidative biology, and other functions. In 92 patients who had had an overt stroke, the network was used to determine 11 genes whose variants had a direct effect modulated by hemoglobin F levels and 9 genes whose variants were indirectly associated with stroke.

Clinically, strokes are characterized by the abrupt onset of hemiparesis, aphasia, seizures, sensory deficits, and altered consciousness, occurring singly or together. The patient may make a full recovery, but incomplete resolution of neurologic deficits may happen. Diffusion weighted imaging (DWI) MRI permits noninvasive and early visualization of focal ischemia. Emergent treatment of stroke includes vigorous hydration, simple transfusion, patient stabilization, followed by exchange transfusion once Hb concentration is at least 8 g/dl.

Strokes tend to be repetitive because of the progressive nature of cerebral vascular disease. Patients with moyamoya are more than twice as likely to incur subsequent stroke or transient ischemic attack despite transfusion treatment.[252] In general, unless patients begin a long-term transfusion program, they are at risk for recurrent cerebral infarctions with progressive neurologic deterioration. Chronic transfusion therapy designed to maintain the level of Hb S at <30% reduces the risk of recurrent strokes (within 36 months) from approximately 70% to 90% to 10% to 20%.[233] Interruption or termination of treatment, even after 8 years of chronic transfusion, is associated with a stroke recurrence rate similar to that of untransfused patients,[253,254] suggesting that transfusion therapy for secondary stroke prophylaxis should be continued indefinitely. However, reduction of the intensity of chronic transfusion to allow pretransfusion Hb S levels to reach 50% appears safe after the first few years of prophylaxis[255,256] and is routinely utilized by many sickle cell centers.[257] Many chronically transfused children have transfusions

discontinued when they reach adulthood. In one series of nine adult patients who stopped transfusion after a median of 6 years, none suffered recurrent stroke.[258] In an initial report, long-term treatment with hydroxyurea appeared to prevent stroke recurrence in children who were treated with relatively high doses (30 to 40 mg/kg/day).[259,260] In a larger prospective trial, 35 children with SCA and stroke had transfusions discontinued and hydroxyurea started.[261] Initially, transfusion was stopped before hydroxyurea therapy was started, but later, transfusion was overlapped until full-dose hydroxyurea therapy was tolerated. Overall, stroke reoccurred at a rate of 5.7 events per 100 patient-years, but children receiving overlapping therapy had only 3.6 events per 100 patient-years. In a cohort from Jamaica, where blood supply is limited, hydroxyurea therapy was the only reliable treatment option and was shown to prevent stroke recurrence in children with prior stroke events.[262] These findings led to the Stroke with Transfusions Changing to Hydroxyurea (SWiTCH) study, a phase III randomized, multicenter clinical trial, which compared standard treatment (transfusions with iron chelation) to alternative treatment (hydroxyurea with phlebotomy) for stroke prophylaxis in children who had experienced prior stroke.[263,264,265] SWiTCH was a noninferiority trial with a composite primary endpoint of stroke and hepatic iron overload. This study was interrupted early because more strokes were observed in the hydroxyurea/phlebotomy arm and only equivalence in liver iron content was seen in the two arms. Chronic transfusion therapy and iron chelation remains the standard treatment for secondary prevention of stroke in children with SCA. Unfortunately, chronic blood transfusion does not prevent progression of brain vasculopathy or silent cerebral infarcts in children receiving this therapy for secondary stroke prevention, which makes blood transfusion an imperfect choice for this indication.[263,264]

In a series of studies led by Robert Adams, an abnormal transcranial Doppler ultrasound examination (defined by a time-averaged mean maximum velocity ≥200 cm/s in the distal internal carotid or proximal middle cerebral artery) was predictive of a 40% stroke risk in HbSS patients.[230] In the Stroke Prevention in Sickle Cell Anemia (STOP) trial, 130 patients with abnormal TCD velocities were prospectively randomized to receive chronic transfusion or standard observation.[266] A 92% reduction in the risk of stroke occurred in the patients receiving chronic transfusion. The appropriate length of time for transfusion for primary stroke prevention in patients with abnormal TCD velocities was addressed by the STOP II Trial.[267] Patients enrolled in STOP II had had an initial abnormal TCD velocity and transfusion for at least 30 months, during which time the TCD velocity became normal (<170 cm/s). Patients were then randomly assigned to continue or stop transfusion, and the primary endpoint was stroke or a reversion to an abnormal TCD exam. Among the 41 children enrolled in the discontinuation-of-transfusion group, abnormal TCD results developed in 14 and stroke in 2 others within a mean of 4.5 months (range 2.1 to 10.1 months) of the last transfusion. None of these endpoint events occurred in the 38 children who continued to receive transfusions. A recent analysis of the participants of the STOP II trial demonstrated that among children who discontinued transfusions there was significant progression of SCI in comparison with those who continued transfusions.[268,268] In a separate cohort of children who were receiving chronic transfusion therapy for primary stroke prevention after having had abnormal TCD velocities, transfusions were successful in preventing progression of vasculopathy.[269] As discussed earlier, the same protection does not seem to be conferred by transfusions to children with prior overt strokes.

Overall, among 209 total patients who underwent randomization in STOP and STOP II, 20 strokes occurred. In all cases, the last TCD examination before the stroke showed an abnormal velocity.[270] The estimated stroke risk for untreated patients was 10% per year for an abnormal TCD and 2% to 5% per year for a conditional TCD. Extrapolation from these data has led to recommendations for the frequency of TCD screening in children with HbSS/Sβ^0 thalassemia between the ages of 2 and 16 years (Table 33.2).[271] Information regarding utility of TCD examination in adults is extremely limited, although velocities are probably intermediate between those found in children with sickle cell disease and normal adult controls.[272]

Since the results of the STOP trials, TCD programs have led to a dramatic reduction of stroke incidence in some centers.[271,273,274] However, despite the well-publicized results of the STOP Trials, performance of TCD screening has been variable. Preliminary data from the C-Data Registry of the Comprehensive Sickle Cell Centers indicate that a TCD exam was performed in the past year in only 42% of 2- to 12-year-old children with HbSS and Hb Sβ^0 thalassemia, the genotypes at greatest risk for stroke.[275] The greatest perceived barrier to TCD screening in children with sickle cell disease was poor patient adherence to TCD appointments, which in part was attributable to the second most common obstacle: distance to a "vascular laboratory."[276] There also has been concern about complications of chronic transfusion, particularly the risk of iron overload. The availability of oral iron chelators, may partially alleviate that concern.

The use of hydroxyurea for primary stroke prevention is currently under investigation. In a French study, 6 of 10 patients with abnormal TCD whose velocities normalized on transfusion were switched successfully to treatment with hydroxyurea.[277] In a Belgian study, patients with abnormal TCD were treated with hydroxyurea and observed for a total of 96 patient-years.[278] Only a single neurologic event, a seizure, was observed. In two different cohorts of children with SCA, hydroxyurea treatment resulted in significant decrease in TCD velocities.[279,280] In addition, hydroxyurea treatment of adult patients with sickle cell disease resulted in improved, but not normalized, cerebral oxygen levels.[281] The ongoing phase III multicenter randomized TCD with Transfusions Changing to Hydroxyurea (TWiTCH) trial aims at maintaining or lowering TCD velocities in children who have received blood transfusions for abnormal TCD velocities for at least 12 months. In the TWiTCH trial, children with abnormal TCD velocities are randomized to continue transfusions, or to discontinue transfusions and begin hydroxyurea after a period of overlap between the two treatment arms (clinicaltrials.gov # NCT01425307).

Although the relative risk of primary stroke is lower among patients with conditional TCD velocities (time-averaged mean maximum velocity 170 to 199 cm/sec) than those with abnormal velocities (risk 2 to 5 vs. 9% per year), more children have conditional TCD velocities (17% vs. 9% prevalence), so the absolute number at risk for stroke without therapy is comparable. The risk of conversion from a conditional to abnormal TCD velocity is

TABLE 33.2

RECOMMENDED TRANSCRANIAL DOPPLER (TCD) SCREENING SCHEDULE IN CHILDREN WITH SICKLE CELL DISEASE

Initial TCD Result[a]	Frequency of Testing		
	Age (years)		
	2–5	6–11	12–16
Normal	Yearly	Yearly × 3	Yearly × 2
Low conditional	Every 6 mo	Every 6 mo	Every 6 mo
High conditional	Every 3 mo	Every 3 mo	Every 3 mo
Abnormal	Within 1 mo	Within 1 mo	Within 1 mo

[a]TCD result: normal, <170 cm/s; low conditional, 170 to 184 cm/s; high conditional, 185 to 199 cm/s; abnormal, ≥200 cm/s.

highest in children under 10 years of age.[282,283] Currently, conditional TCD velocity is not an indication for treatment, but the ongoing phase III multicenter Sparing Conversion to Abnormal TCD elevation (SCATE) study is investigating whether hydroxyurea therapy in children under age 11 years with conditional TCD will be less likely to develop abnormal TCD velocities than those who are observed (clinicaltrials.gov # NCT01531387).

SCI occurs in 27% of children with SCA under 6 years of age,[284] and 37% by their 14th birthday.[285] Data from the CSSCD have shown that children with SCI had an increased incidence of new stroke and new or more extensive SCI [227] and that SCIs were the strongest independent predictor of stroke.[228] Data from the STOP trial indicated that those who had SCI as well as abnormal velocities were at higher risk for developing a new SCI or stroke than those whose MRI showed no abnormality.[286] However, a comparison of patients who were in both the CSSCD and STOP studies indicated that those who had abnormal TCDs did not have an unusually high frequency of MRI abnormality; conversely, those who had SCI did not have an unusually high frequency of abnormal TCD velocities, suggesting that those findings represent different aspects of the pathophysiology of the brain in children with sickle cell disease.[287] The ongoing Silent Cerebral Infarct Transfusion (SIT) trial is a phase III multicenter randomized study aiming at determining whether blood transfusion therapy will limit overt clinical strokes or new or progressive SCI in children with SCA and SCI identified by MRI screening in comparison with children randomized to observation (clinicaltrials.gov # NCT00072761).[288] Baseline results of the SIT trial showed that lower Hb concentration and higher systolic blood pressure were associated with SCI in children with SCA.[289]

Acute Chest Syndrome

Acute chest syndrome (ACS) is an acute illness characterized by fever and/or respiratory symptoms, accompanied by a new pulmonary infiltrate on a chest X-ray.[290] ACS remains one of the most common causes for hospitalization, critical care utilization, and mortality in children and adults with sickle cell disease.[291,292] The term *acute chest syndrome* was coined because it is not usually possible to determine the relative importance of vascular occlusion and infection in the acute pulmonary process in any given patient. Infection tends to predominate in children and infarction in adults, but the two processes are often interrelated and concurrent.[293] Impaired access of oxygen to infected segments of the lung likely enhances local sickling, with resulting focal microvascular thrombotic disease. Data from the CSSCD indicate that patients with Hb SS have an incidence of ACS of ~13/100 patient-years; the rate is highest in children 2 to 4 years of age (25/100 patient-years) and decreases gradually with increasing age to that seen in adults (9/100 patient-years).[294] A higher ACS rate is associated with a higher rate of mortality from all causes. The risk of ACS is associated with a lower fetal Hb level and a higher steady-state hematocrit and leukocyte count.[295]

Before the availability of pneumococcal vaccines and the widespread use of penicillin prophylaxis, pulmonary events in children typically were the result of bacterial infection.[276,296] *Streptococcus pneumoniae* was the most common causative organism. Infiltrates often affected multiple lobes, and resolution was slower than in the general population.[297] Identified infectious agents have included *Mycoplasma pneumonia,*[298] *Chlamydia pneumonia,*[299] parvovirus B19,[300] and respiratory viruses. The National Acute Chest Syndrome Study Group reported causes and outcomes based on analysis of 671 episodes of ACS.[301] Nearly half of the patients were initially admitted for another reason, primarily pain. The mean length of hospitalization was 10.5 days; 13% required mechanical ventilation, and 3% died. Patients who were 20 years of age or older had a more severe course. A specific cause of ACS was identified in 38% of all episodes and in 70% of episodes with complete data (Table 33.3).[301] The most common specific causes were pulmonary fat embolism, chlamydia, mycoplasma, miscellaneous viruses, and bacterial infections resulting from coagulase-positive *Staphylococcus aureus* and *Streptococcus pneumoniae*. Recently, influenza, especially H1N1, was shown to be associated with increased risk and severity of ACS, and therefore should be prevented whenever an outbreak or epidemic is detected.[302] In adults, an infectious basis for lobar consolidation is established less often than in children, and antibiotic therapy is without apparent effect on the duration or severity of symptoms.[303] In situ vaso-occlusion owing to erythrocyte stasis appears to be the more common primary event. Interestingly, an association between smoking and increased rate of ACS and pain events has been observed among adults with sickle cell disease.[304]

The relationship of asthma/reactive airway disease to ACS has been examined. In children with Hb SS, asthma is associated with an increased incidence of sickle-cell–related morbidity,

TABLE 33.3

CAUSES OF ACUTE CHEST SYNDROME

		Number of Episodes		Age at Episode of Acute Chest Syndrome	
Cause	(*N* = 670)	Percentage	0–9 years (*N* = 329)	10–19 years (*N* = 188)	≥20 years (*N* = 153)

Modified from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. New Engl J Med 2000;342:1855–1865.

including ACS and pain episodes, and mortality.[305,306] A similar relationship was observed between asthma and the incidence of ACS in pediatric patients with Hb SC.[307] Sickle cell patients with a history of asthma were four times more likely to develop ACS during a hospital admission for pain and had a substantially longer duration of hospitalization.[308] Similarly, children with pulmonary function test (PFT)-documented lower airway obstruction had a greater risk for pain and ACS hospitalization (risk ratio 2.0, CI: 1.3 to 3.3).[309] In Jamaican children with sickle cell disease, asthma and bronchiolar hyperreactivity were more common than in ethnic-matched controls and were associated with recurrent ACS.[310] Much less information is available for adult patients, but a high prevalence of airway hyperresponsiveness to methacholine challenge was noted in those with a history of reactive airway disease.[311] Hematologically, ACS is characterized by a sudden drop in Hb concentration and an increase in the number of platelets and leukocytes.[312] Rib infarcts are a primary trigger of ACS when bone pain is followed by soft-tissue reaction, pleuritis, splinting, hypoventilation, atelectasis, and the typical radiologic picture.[313] Incentive spirometry with the use of maximal inspirations every 2 hours has been shown to prevent ACS in patients with sickle cell disease who were hospitalized with chest or back pain.[314] Lung crises may result from embolization of fat from infarcted bone marrow (pulmonary fat emboli)[315] or deep-vein thrombi. Occlusion of major pulmonary vessels is a recognized cause of sudden death. Pulmonary fat emboli are found more commonly than previously appreciated when a diagnosis is sought by fat staining of pulmonary macrophages obtained by bronchoalveolar lavage.[315] Fat emboli are associated with bone pain, chest pain, neurologic symptoms, acute decreases in Hb level and platelet count, and prolonged hospitalization. Secretory phospholipase A_2 (sPLA2), an inflammatory mediator that liberates free fatty acids and lysophospholipids and may be responsible for acute lung injury, is markedly elevated in sickle cell patients 24 to 48 hours before the diagnosis of ACS in patients presenting with a pain event[316,317] and in most patients at the time of diagnosis of ACS.[318] A clinical trial involved patients hospitalized for pain who developed fever and elevated sPLA2 and were randomized to receive transfusion or observation.[158] Because of slow accrual, conclusions could not be reached regarding the effect of transfusion to pre-emptively avert an ACS event, but information regarding the sensitivity of this test was provided; a threshold level of sPLA2 $\geq$ 48 ng/ml offered 73% sensitivity and 71% specificity.

A comprehensive review of the management of ACS in children has been recently published and is a useful guideline for treatment of this complication.[319] Because the relative importance of infection and infarction is difficult to ascertain, broad-spectrum parenteral antibiotics, such as a third- or fourth-generation cephalosporin, should be provided for children with ACS. A macrolide antibiotic is indicated to cover *Mycoplasma* and *Chlamydia*. Of utmost importance is the correction of hypoxemia. If the arterial PO_2 value is <75 mm Hg or the O_2 saturation by pulse oximetry is significantly below baseline, the clinician should consider prompt simple or partial exchange transfusion.[320]

Intravenous dexamethasone was shown to result in a shorter hospital stay and reduced need for blood transfusion and oxygen when compared to placebo in children with ACS.[321] Because there appeared to be a high risk of recurrent symptoms and readmission to the hospital after dexamethasone was abruptly discontinued, a recent randomized study investigated the use of tapered oral dexamethasone for ACS treatment.[322] Despite a very small number of participants, this trial showed a reduction in hospitalization duration in the dexamethasone arm, but higher rates of rebound pain. sL-selectin was found elevated among patients with rebound pain and could be a useful biomarker during ACS. Nitric oxide inhalation has been utilized in the regulation of hypoxic pulmonary vasoconstriction,[323] but definitive trials have not yet substantiated its therapeutic role.

Priapism

Priapism is an unwanted, painful, and persistent erection of the penis. Useful reviews of this topic have been published.[324,325] The incidence of priapism in patients with sickle cell disease has been reported to be between 3% and 45%[326,327]; it has a bimodal distribution of age of onset, with peaks at 5 to 13 years of age and at 21 to 29 years of age.[328] Most priapism episodes begin during sleep[329] or early in the morning; they may be associated with physiologic dehydration and hypoventilation, which results in metabolic acidosis followed by increases in sickling and stagnation of blood within the penile sinusoids or the corpora cavernosa. In data from the CSSCD, subjects with priapism had significantly lower levels of hemoglobin and higher levels of bilirubin, reticulocytes, white blood cells, and platelets, suggesting an association of priapism with increased hemolysis, perhaps related to a diminished availability of circulating NO, which plays an important role in erectile function.[330] Although priapism is usually self-limited and of relatively short duration, it is often recurrent and may become chronic. "Stuttering" priapism refers to multiple episodes, each <4 hours in duration, which may occur several times a week and may herald a prolonged event. Usually, these do not require medical intervention. Typically, priapism results from engorgement of the paired cavernosal bodies with sparing of the glans and corpus spongiosum and is maintained by the partial obstruction of venous drainage. However, tricorporal priapism may occur, especially in postpubertal patients, and is associated with a poor prognosis.[331] Although it occurs with approximately equal frequency in prepubertal and postpubertal males, priapism is more difficult to manage in the latter group.[332,333] Numerous ISCs and clots are found in the distended sinuses when needle aspiration or incisional drainage is performed.[334] The repetitive trapping of cells in the corpora cavernosa, with or without surgical intervention, may lead to fibrosis of the septa and impotence.

Penile blood gas measurements and technetium-99 penile scintigraphy scans have been used to define intracorporeal hemodynamics and to guide therapy. However, these modalities are not readily available, and a more conventional approach to treatment is necessary. Of particular concern is an increased rate of impotence reported in sickle cell patients whose attacks lasted >24 hours[335,336] As with other complications resulting from the sludging of sickled erythrocytes, aggressive hydration and adequate analgesia are of primary importance and should be pursued within the first few hours of symptoms. If no response is seen within 12 to 24 hours, partial exchange transfusion to lower the Hb S level to <30% may be performed; this is occasionally sufficient.[337] However, an association of sickle cell disease, priapism, exchange transfusion, and neurologic events, including seizures and obtundation, referred to as ASPEN syndrome, is of concern.[338,339] If no resolution occurs within another 12 to 24 hours, corporal aspiration and irrigation with saline may be indicated through such means as a Winter procedure,[340] in which a fistula between the glans penis and the corpora cavernosa is created using a biopsy needle. The Dallas program reported rapid complete detumescence in 35 of 37 consecutive episodes of prolonged priapism in pediatric patients treated with aspiration and irrigation with a dilute epinephrine solution.[341] If penile aspiration is unsuccessful, creation of a cavernosa spongiosum shunt[342] or a venous bypass may be considered.

Prevention of recurrent priapism has been accomplished in some patients with chronic transfusion, particularly through exchange transfusion. α-Adrenergic agonists increase contraction of the smooth muscle of the trabecular arteries of the cavernosa and facilitate venous outflow from the corpora, promoting detumescence. α-Adrenergic agents including etilefrine, pseudoephedrine, and phenylephrine may be administered either orally or by intracavernous injection.[343,344] Other approaches have been the administration of diethylstilbestrol,[345]

the gonadotropin-releasing hormone analog leuprolide acetate,[346] low-dose antiandrogens,[347] finasteride,[348] and oral phosphodiesterase S inhibitor.[349] Sildenafil is reported to improve priapism, but can trigger pain as a side effect.[350] A polyethylene glycol-modified adenosine deaminase (PEG-ADA) has been used in transgenic sickle mice to reduce adenosine levels and promoted increased cavernosal relaxation, suggesting a possible new avenue of treatment for priapism.[351] Despite either conservative or aggressive treatment, >25% of patients have some degree of impotence[352] and may be candidates for a penile prosthesis after 6 to 12 months.[353]

Exacerbation of Anemia

Hematologic "crises," characterized by sudden exaggeration of anemia, are pathogenetically and temporally unrelated to vaso-occlusive crises. If they are unrecognized or untreated, the decrease in Hb concentration may be so precipitous and severe as to cause heart failure and death within hours.

Aplastic Crises. Aplastic crises are the most common of the hematologic complications. The pathogenesis and course of aplastic crises in SCA are similar to those of other chronic hemolytic states. Several characteristics are indicative of an infectious basis: the crises are characteristically preceded by or associated with febrile illnesses; several members of families with congenital hemolytic anemia may have concurrent aplasia;[354] recurrence of crisis within the same individual is not observed;[355] and most aplastic episodes occur during childhood.[356] Epidemiologic studies clearly implicate human parvovirus B19 as the cause for almost all aplastic crises.[355,356] Aplasia is the result of direct cytotoxicity of the parvovirus to erythroid precursors, especially colony-forming units, erythroid (CFU-E).[357] However, not all parvovirus infections result in problems; serologic evidence of previous infection was found in 71% of subjects with SCA who reached adulthood, but only 27% had a previous clinically recognized aplastic crisis.[358]

In the early phase of an aplastic crisis, peripheral blood reticulocytes and bone marrow normoblasts disappear or are greatly reduced in number. Because red cell survival in Hb SS is no more than 10 to 20 days, cessation of erythropoiesis is followed by a rapid decrease in Hb concentration. The process is self-limited, however; within 10 days, red cell production resumes spontaneously, and large numbers of reticulocytes and nucleated erythrocytes appear in the peripheral blood. Thereafter, the Hb concentration returns to its precrisis level. Often, the patient is first seen early in the recovery phase, when differentiation from a hemolytic crisis may be difficult. Although leukocytes and platelets are usually normal, all marrow elements may be affected.[359] Treatment consists of supportive care with red cell transfusion when necessary.

Susceptible hospital workers exposed to patients with aplastic crises are at high risk of contracting nosocomial erythema infectiosum.[360] Because infection during the midtrimester of pregnancy may result in hydrops fetalis and stillbirth, respiratory isolation precautions are a necessity if an aplastic crisis is suspected.[361]

In addition to causing aplastic crisis, an acute parvovirus event not infrequently will lead to a prolonged vaso-occlusive pain crisis or it may trigger acute splenic sequestration.[362–364] Less frequently, it is associated with long-term problems, such as glomerulonephritis, which may cause end-stage renal failure, cardiac dysfunction, and stroke.[365,366]

Splenic Sequestration. Splenic sequestration is characterized by sudden trapping of blood in the spleen. A splenic sequestration crisis is defined by a decrease in the steady-state Hb concentration of at least 2 g/dl, evidence of compensatory marrow erythropoiesis, and an acutely enlarging spleen.[367] This complication occurs in infants and young children whose spleens are chronically enlarged before autoinfarction and fibrosis. Although splenic sequestration has been documented in infants as young as 3 to 4 months of age,[368] it is observed most commonly during the second 6 months of life and is a less frequent finding after 2 years of age; however, it has been reported in adults.[367,369] In a large pediatric French cohort study, the risk of recurrence decreased with age: when the first episode occurred after 2 years, the risk was lower than when it occurred before 1 year of age (hazard ratio, 0.60).[370]

Children experiencing splenic sequestration may have an earlier onset of splenomegaly and a lower level of Hb F at 6 months of age.[371] Crises often are associated with respiratory tract infections or with parvovirus B19, usually in conjunction with an aplastic crisis.[372,373] The already enlarged spleen rapidly increases in size at the expense of blood volume; hypovolemic shock and death may occur within hours.[374] The sole pertinent postmortem finding is engorgement of splenic sinusoids with sickled cells. Individuals who survive have a tendency for recurrent episodes until 5 or 6 years of age, by which time sufficient fibrosis of the spleen has occurred to limit its expansion. There has been wide variability in the long-term management of patients with splenic sequestration, and currently, no consensus exists. Chronic transfusion and surgical splenectomy have both been used in an effort to avoid recurrence. Due to concerns with invasive encapsulated organisms, often monthly erythrocyte transfusions are used and total splenectomy is delayed until an age after which the risk of sepsis is lower. Partial splenectomy has also been used in an attempt to preserve immunologic function in children with SCA and severe splenic sequestration,[375] but the indications for this procedure and long-term outcomes are still under investigation. Although it is encountered much less frequently, sudden trapping of blood in the liver (hepatic sequestration crisis) also occurs.[376]

Hemolytic Crises (Hyperhemolytic Crises). Hemolytic (hyperhemolytic) crises result from a sudden acceleration of the hemolytic process. They have been described in association with co-inherited hereditary spherocytosis[377] and concurrent mycoplasma infection.[298] Other causes of hyperhemolytic crisis include acute or delayed hemolytic transfusion reactions (usually Coombs test positive),[378] and drug-induced hemolysis.[379] Although ~10% of black male patients with SCA have the unstable A variant of glucose 6-phosphate dehydrogenase (G6PD),[380] they have no more severe anemia and no greater frequency of acute hemolytic episodes than those with normal levels of G6PD, even when challenged with oxidant drugs and infections, because of the young mean age of sickle red blood cells.[381]

Megaloblastic Crises. Megaloblastic crises result from the sudden arrest of erythropoiesis by folate depletion.[382] Chronic erythroid hyperplasia imposes a drain on folate reserves, and biochemical evidence of mild folate deficiency has been demonstrated with high frequency in subjects with SCA.[383] Megaloblastic crises likely occur when food consumption is interrupted by illness or alcoholism or when the folate requirement is augmented by rapid growth or pregnancy. The inverse relationship between plasma homocysteine concentration and folate status has led to a series of reports describing homocysteine levels and the possible need for folate supplementation. However, both elevated homocysteine levels[384] and normal homocysteine levels have been reported.[385] Currently, folic acid deficiency, as a cause of exaggerated anemia in sickle cell disease, appears to be extremely rare in the United States. Nevertheless, it is common practice to prescribe prophylactic folic acid (1 mg/day) to patients with sickle cell disease in areas of the world where folate is not routinely added to grain-derived products.

Infections

Overwhelming infection may be the presenting manifestation of SCA in early childhood. Acute infection has been one of the most

common causes of hospitalization and previously was the most frequent cause of death, particularly during the first 3 years of life. *S. pneumoniae* is the usual infecting organism; the blood and spinal fluid are the major sites of infection.[386,387] Previously, the incidence of invasive infection with *S. pneumoniae* was ~7/100 patient-years in children with SCA who were <5 years of age; this rate was 30 to 100 times that which would be expected in a healthy population of this age.[387,388] More than 70% of meningitis in children with SCA also resulted from *S. pneumoniae.*[389] The mortality rate of pneumococcal sepsis was as high as 35%, but widespread improvement in parental education and aggressive management of the febrile child have greatly improved the likelihood of surviving a septic event.[390] Furthermore, penicillin prophylaxis and pneumococcal vaccines have dramatically lowered the risk of invasive pneumococcal infection. Despite the dramatic decline in the rate of pneumococcal sepsis in recent decades (secondary to widespread use of pneumococcal immunization and penicillin prophylaxis), invasive pneumococcal infection still exists and may be life threatening.[391,392] A major threat to continued success in prevention and management of *S. pneumoniae* invasive infection has been the emergence of antibiotic-resistant pneumococcal organisms over the past two decades.[391,392]

Beyond 5 years of age, Gram-negative bacteria replace *S. pneumoniae* as the major infectious agents.[295,387] In contrast to infections in young children, those in older children and adults generally have an identifiable source or focus (e.g., *Escherichia coli* associated with urinary tract infection).[387,393] Osteomyelitis, sometimes involving multiple sites, occurs with increased frequency at all ages. The increased risk of osteomyelitis may stem from tissue ischemia and infarction associated with pain crises; these provide a potential nidus for infection in the long bones. Although >80% of hematogenous osteomyelitis in the general population is caused by *Staphylococcus,* most cases of osteomyelitis occurring in individuals with SCA are caused by *Salmonella.*[394,395] Serum antibody levels against *Salmonella* antigens are normal, but microinfarcts of the intestinal mucosa may predispose to invasive infections.[396] A positive blood culture for *Salmonella* in a patient with SCA strongly suggests the diagnosis of osteomyelitis. Staphylococcal bone infection, clinically indistinguishable from *Salmonella* infection, also occurs with increased frequency in sickle cell disease.[397]

Bloodstream infections in hospitalized adults with sickle cell disease have been increasingly recognized. In one series,[398] 28% were caused by *Staphylococcus aureus,* the majority of which were methicillin-resistant. Gram-negative organisms, anaerobes, and yeast were also found and >80% of the infections were considered to be catheter-related. Bloodstream infections frequently are associated with bone and joint infection.[399]

The pathophysiologic basis for increased susceptibility to aggressive infection relates in large part to the loss of spleen function.[400] During the first few years of life, recurrent perivascular hemorrhage and infarction reduce the spleen to a small siderofibrotic vestige.[401] Despite the frequent occurrence of splenomegaly in the first few years, spleen function often is impaired by 6 to 12 months of age.[176] Howell-Jolly bodies and "pits" (depressions in the red blood cell membrane) are seen in peripheral blood erythrocytes,[402] and radiolabeled sulfur colloid is not cleared by the spleen.[403] Spleen function is temporarily restored by transfusion therapy in early life, suggesting that functional asplenia is a consequence of altered perfusion imposed by intrasplenic sickling.[404] In the absence of spleen function, bloodborne particulate antigens fail to elicit an expected antigenic response.[405] Spleen function is necessary for effective host response to *S. pneumoniae* in the absence of preformed antibodies; in the presence of antibody, organisms are trapped effectively at extrasplenic sites. Because the acquisition of pneumococcal antibodies occurs with advancing age, young children without spleen function fare less well than older children and adults. However, responses to conjugated *Haemophilus influenzae* vaccine in young infants with SCA were appropriate.[406] Other mechanisms may contribute to the vulnerability of children with sickle cell disease to infectious crises. Serum IgM levels are decreased.[407] The alternative pathway for complement activation may be defective.[408] Alterations of B- and T-lymphocyte number and function and of the function of neutrophils and monocytes are of uncertain significance.[409,410]

Prevention of Infection. The use of penicillin prophylaxis has been a major advance in the management of sickle cell disease. Two controlled trials, one in Jamaica and the other organized by the National Institutes of Health, led to the widespread acceptance of penicillin prophylaxis as standard therapy.[411,412] In the latter trial (PROPS), twice-daily oral penicillin V resulted in an 84% reduction in the incidence of pneumococcal bacteremia in infants <36 months of age. Current recommendations are to initiate penicillin prophylaxis by 3 months of age and to continue it at least until 5 years of age in children with Hb SS or Hb Sβ^0-thalassemia (or longer if there was a history of surgical splenectomy, incomplete pneumococcal immunization, or invasive pneumococcal infection). A multi-institutional controlled trial found no further advantage of penicillin in the prevention of invasive pneumococcal infection in children >5 years of age.[413] The use of prophylaxis in young children with Hb SC disease or Hb Sβ^+-thalassemia is controversial,[414] but many centers maintain all children with sickle cell disease on penicillin until 5 years of age. Of concern has been the question of whether prophylaxis might increase the risk of penicillin-resistant pneumococcal organisms. Its usage reduces nasopharyngeal colonization with *S. pneumoniae,* but the effect on the development of antibiotic resistance has been equivocal.[415–417]

Unfortunately, the pneumococcal serotypes that are most prevalent in the community and most highly virulent (types 6A, 14, 19, and 23F) are least immunogenic.[418,419] Although the immunologic response of children 2 years of age and older to polysaccharide-conjugated pneumococcal vaccine is comparable to that of the general population,[420] antibody titers fall more rapidly than in adults. Children with sickle cell disease should receive a primary immunization with the 23-valent polysaccharide vaccine at 2 years of age and a booster immunization 3 to 5 years later[421]; the vaccine is ineffective in children <2 years of age. Administration of booster doses of this vaccine to older children and adults with sickle cell disease is controversial, but a booster is administered to teenagers and adults once every 10 years in many centers.

In contrast, the seven-valent protein-conjugated pneumococcal vaccine (PCV-7) is immunogenic in the first few months of life and is routinely administered to infants in the United States. This vaccine (which includes serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F) is administered at 2, 4, 6, and 12 months of age (same immunization schedule as in the general pediatric population) and produces adequate antibody concentrations in the same range as those achieved among infants without sickle cell disease.[422,423] In addition, significant rises are seen in antibody concentration to all seven protein-conjugated pneumococcal vaccine serotypes after the administration of polysaccharide-conjugated pneumococcal vaccine at 24 months of age. Recently, the protein-conjugated vaccine has been reported to lower the incidence of invasive pneumococcal disease between 65% and to >90% in children with sickle cell disease,[424,425] but it has not completely eliminated invasive pneumococcal infection.[391] In 2010 the 13-valent pneumococcal conjugate (PCV13) vaccine replaced PCV-7 in the United States and the United Kingdom; PCV13 has the additional serotypes 1, 3, 5, 6A, 7F, and 19A.[426] It is unclear whether addition of the serotypes included in the PCV13 vaccine will significantly improve protection as replacement colonization has been with predominantly non-PCV13 serotypes, and a resurgence of invasive disease has been seen in some areas with predominantly non-PCV13 serotypes.[391]

The conjugated *H. influenzae* type B vaccine induces protective antibody levels in young infants with SCA[390,406] and has virtually eliminated invasive *H. influenzae* infection in this population. Yearly influenza virus vaccine (including H1N1 strains) and the complete series with 3 doses of hepatitis B vaccine offers further protection. Meningococcal polysaccharide diphtheria toxoid-conjugated vaccine offers protection against groups A, C, Y, and W-135 meningococcus and is recommended in children with sickle cell disease at age 2 with a booster at 5 years of age. It is unclear if adults should receive a booster of the meningococcus vaccination, but some centers offer boosters every 5 years. For updated information regarding the recommended schedule of immunization in children and adults in the United States, the Centers of Disease Control website (www.CDC.gov) should be consulted. The high frequency of parvovirus B19 infections in children with sickle cell disease, their life-threatening nature, and the associated risk of complications indicate the need for a vaccine that would confer lifelong immunity. A vaccine for parvovirus B19 (viral particles 1 and 2 proteins expressed in a baculovirus system with adjuvant MF-59) has been developed and undergone pilot testing, but side effects have stalled further studies.[427]

Management of Fever. Any fever ≥38.5°C in a child with SCA must be considered a medical emergency because of the potential risk of overwhelming pneumococcal sepsis, especially during the high-risk period between 6 months and 3 years of age. Previously, routine hospitalization of every febrile patient with SCA was standard management, to deliver intravenous antibiotic coverage until blood cultures were demonstrated to be negative. More recently, the majority of febrile patients have been managed in the emergency department and the outpatient setting if they do not have high-risk characteristics (e.g., toxic appearance, very high fever, serious localized infection, exceptionally high or low white blood cell count, a history of invasive infection, or inadequate capacity for close follow-up).[390,428–430] These children may be managed with prompt assessment, rapid administration of ceftriaxone, observation for at least 2 hours, and close outpatient follow-up.

Chronic Organ Damage

Growth and Development

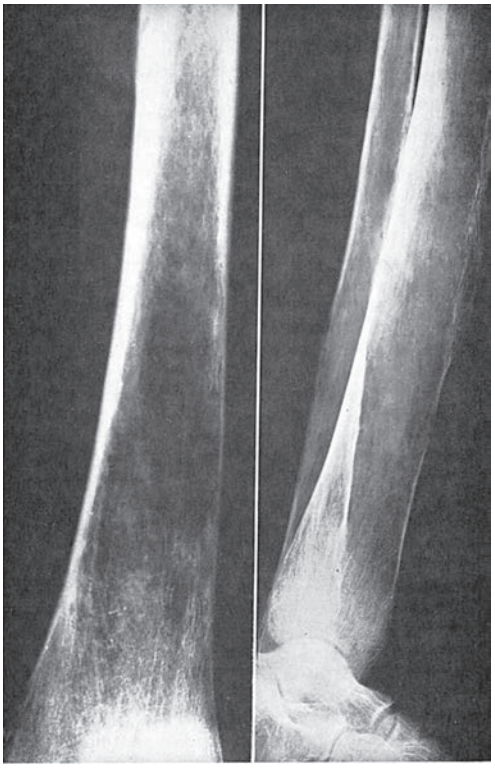
The sickling syndromes profoundly affect growth and development. Growth curves for the height, weight, and sexual development of children with SCA were constructed in the 1980s to permit the identification of individuals whose growth delay was greater than what could be accounted for by the hemoglobinopathy (Fig. 33.7).[431,432] Although normal at birth, the heights and weights of children with SCA were significantly delayed by 2 years of age.[431–433] The growth curves maintain a relatively normal configuration but deviate progressively from the normal curves. Increases in velocity of adolescent height and weight growth occur later, and the magnitude of the growth spurt is substantially less than in healthy children. Puberty also is delayed. Menarche occurs 2 to 3 years later than in the general population (median age, 14.0 to 15.5 years),[434] and Tanner stage V is not achieved until the median ages of 17.3 and 17.6 years for girls and boys, respectively.[432] As in normal subjects, progression through Tanner stages is orderly and appropriate for bone age, and the age of menarche correlates closely with age and weight. By adulthood, both men and women with sickle cell disease appear to acquire normal or near-normal heights, but their mean weights are still lower than those of controls.[432] Investigations in small numbers of subjects show that growth hormone, thyroid hormone, adrenocorticotropic hormone and cortisol levels, and pituitary responses to growth-hormone–releasing factor are normal.[435] Transient hypogonadism may occur in adolescence. The normal relationship of puberty and growth pattern seen in most patients suggests that the delay in skeletal maturation represents constitutional delay rather than gonadal or pituitary failure.[432]

Low weight appears to be the most critical variable influencing differences in physical maturation among the sickling syndromes.[432] The basis for delay in weight gain is not fully understood, although it has been hypothesized that chronic hemolysis leads to a state of high protein turnover and increased basal metabolic requirements.[436] Recent studies have shown that decreased growth velocity in children with SCA was independently associated with decreased Hb concentration and increased total resting energy expenditure (REE).[437] REE measured by indirect calorimetry is 15% to 20% greater in Hb SS patients.[436,438,439] Increased whole-body protein breakdown and protein synthesis may be related to increased bone turnover.[440] Prepubertal children with sickle cell disease do not compensate for their higher resting energy expenditure by increasing their energy intake, measured by weighing all food consumed during a 3-day period.[441] Furthermore, caloric intake is significantly decreased at the time of an admission for acute illness, contributing to an overall energy deficit.[442] When body composition of children and adolescents with sickle cell disease is measured by bioelectrical impedance analysis, male subjects have significantly lower fat-free mass and body fat compared with controls.[443] Response to nasogastric dietary supplementation has been reported.[444]

Other studies have suggested increased requirements for zinc, folate, riboflavin, vitamin B_6, ascorbate, and the fat-soluble vitamins A and E, but consistent correlations between deficiencies and growth retardation have not been established.[438,445–447] A relationship between zinc deficiency and hypogonadism in adults with SCA has been suggested.[448] Defective growth hormone secretion, decreased insulinlike growth factor-1, and partial resistance to growth hormone in short children with sickle cell disease were reported.[449,450]

Bones and Joints

In addition to the acute episodes of skeletal pain described previously, chronic and progressive destruction of the bones and joints may take place in the absence of clearly defined episodes of pain. The most prominent changes evolve slowly from the cumulative effect of recurrent small episodes of ischemia or infarction within the spongiosa of bone. Radiographs of the long bones of adults show a mottled strandlike increase in density randomly distributed within the medullary region (Fig. 33.8). These irregular areas of increased density are produced by new bone laid down on devitalized trabeculae.[451] Because the bone is weakened during the early stages of repair, weight bearing may collapse the femoral head, producing the clinical and radiologic features of osteonecrosis, which affects patients with all the genotypes of sickle cell disease but occurs most often in those with Hb SS and α-thalassemia (4.5 cases/100 patient-years).[452] The overall prevalence of osteonecrosis of the hip in persons with sickle cell disease is approximately 10%, but it occurs in 50% in those >35 years of age.[452] The prevalence of osteonecrosis of the humoral head is approximately one half as much.[453] Typically, the pain from osteonecrosis of the hip begins insidiously, is brought on by walking or quick movements, and is localized to the groin or buttock. After several months, radiographs may show areas of increased density mixed with areas of increased lucency, followed by the appearance of a "crescent sign," segmental collapse, molding of the femoral head, loss of joint space, involvement of the acetabulum, and complete degeneration of the joint. When osteonecrosis occurs in the femoral capital epiphysis before closure, healing with minimal destruction may occur. However, long-term follow-up shows that in the majority of cases, the hip is painful and permanently damaged.[454] Because weight bearing is not required of the shoulder joint, the prognosis of osteonecrosis of the humeral head is substantially better. Only ~20% of patients have pain or limited range of movement at the time of diagnosis,[453] but functional abnormalities of the shoulder may be a long-term consequence in adults.[455]



A B

FIGURE 33.8. Sickle cell anemia. A: Femur. The cortex is thinned, and the normal bony architecture is disturbed. Adjoining small areas of translucency are areas of sclerosis. **B:** Tibia and fibula. Marked thinning of the cortex of the bones as well as periosteal reaction and disarrangement of the trabeculae. The latter changes and the extensive coarseness of the cortical layers suggest the bone is involved from within.

Avoidance of weight bearing in the early phases of bone necrosis may permit sufficient repair to preserve reasonable joint function. More often, however, the deformity is progressively crippling. Total hip replacement is usually recommended for the painful hip in stage III or IV or for restoration of joint movement, if this is desired. However, the prognosis for hip replacement has been suboptimal, with a 30% chance that arthroplasty will require revision within 4 to 5 years.[456,457] For stage I and II osteonecrosis, core decompression, in which a core of cancellous bone ~8 mm in diameter is removed from the neck and head of the femur through an incision in the lateral cortex, has been of benefit.[458,459] In a prospective randomized trial, physical therapy alone appeared to be as effective as hip core decompression followed by physical therapy, improving hip function and postponing the need for additional surgical intervention at a mean of 3 years after treatment.[460] Grafting with autologous bone marrow obtained from the iliac crest is a possible new option for osteonecrosis of the hip.[461] This technique, which is currently investigational, appears most effective in the early stages of osteonecrosis, before subchondral collapse has occurred, and provides progenitor cells to the proximal femur which stimulate bone remodeling.

Another characteristic bone change develops in the vertebral column of some individuals during the second decade of life. Recurrent infarcts of the main vertebral arteries lead to ischemic damage of the central portion of the vertebral body growth plates. Because the outer portion of the plates is supplied by numerous apophyseal arteries, vertebral growth is irregular, producing a "fish-mouth" deformity in which symmetric cuplike depressions are confined to the central three fifths of the vertebral plates.[462] Other skeletal changes result from expansion of medullary cavities owing to long-standing erythroid hyperplasia. Radiographs of the skull show a thickening of the diplöe and thinning of the outer table of the calvaria in the frontal and parietal regions. Gnathopathy (prominent maxillary overbite) may result from overgrowth of maxillary bone and frequently leads to significant malocclusion.[463]

Low bone mass density (osteopenia and osteoporosis) has been recognized in adults and more recently in children.[209,464] and has been associated with the severity of hemolysis.[465] Vitamin D replacement in those cases of vitamin D deficiency has been reported to offer salutary effects on bone mass density.[466]

Joints may be affected by avascular necrosis of adjacent bone.[467] The joint effusion, pain, fever, and leukocytosis accompanying such infarcts make differentiation from septic arthritis difficult. Numerous neutrophils and sickled erythrocytes are found in the joint fluid.[468] Less commonly, joint disease is related to infection,[469] gout,[470] or synovial hemosiderosis. Adults may have deformities of the hands and feet with shortening of the digits, the remote sequelae of dactylitis during early childhood.[471]

Cognitive Function

Multiple studies have reported deficits in global and specific neuropsychologic functioning in school-aged children with sickle cell disease when compared with their siblings or healthy children.[472–474] Children with SCA who have experienced an overt stroke have significant cognitive impairment, reduced language function, and problems in adjustment.[475] Diminished performance has been noted in the areas of visual–motor integration, attention and concentration, arithmetic, memory, and reading. Similarly to children, adults with SCA have poorer cognitive performance when compared with healthy controls, even without a history of prior stroke.[476] Significant areas of deficit in adults with SCA were in working memory, processing speed, and measures of executive function.

MRI data from several studies investigating the central nervous system of children with Hb SS without a history of overt stroke show a prevalence of SCI varying from 11% to 37%.[284,285,477,478] Data from the CSSCD gathered over a 10-year period of follow-up of school-aged children with Hb SS indicated that those with SCI had significantly lower scores for math and reading achievement, full-scale intelligence quotient (IQ), verbal IQ, and performance IQ, when compared with individuals with normal MRI of the brain.[472] However, even in children with normal MRI findings, the scores for verbal IQ and math achievement declined with increasing age.[479] A meta-analysis of 17 reports of cognitive functioning in children concluded that sickle cell disease is associated with detrimental effects even in the absence of cerebral infarction on MRI.[480] Direct effects of sickle cell disease on brain function or indirect effects of chronic illness may be important. A multi-institutional study from France in which children with sickle cell disease were compared to sibling controls reported impaired cognitive function in patients both with a history of stroke and with SCI.[481] In addition, a hematocrit <20% and a platelet count >500 × 10^9/L were independent risk factors for cognitive deficiency. Patients with infarction in the frontal lobe differed from their peers in measures of attention, executive function, and memory.[482,483] In another study, children with SCI had twice the rate of school difficulties as those without infarcts, including poor educational attainment, defined as repeating a grade in school because of lack of educational progress, a requirement for special educational services, or both.[484]

Lower Hb concentration is a reported risk factor for both the development of SCI and neurocognitive impairments.[289,485,486] Other recognized risk factors for decreased cognitive function are hypoxemia and age. Nocturnal hemoglobin oxygen desaturation has been examined in a small group of children with SCA and found to be associated with lower neuropsychological measures of executive function.[487] In addition, elevated blood flow velocity by TCD in children with SCA was associated with decreased language function (syntactical skills), even when controlling for the degree of anemia.[488]

New MRI modalities that examine cerebral blood flow, such as arterial spin-labeled (ASL) perfusion, and the effect of oxygenation on the magnetic properties of blood Hb, such as blood oxygenation level-dependent (BOLD) signal changes, deserve further investigation, but may prove useful in diagnosing and monitoring brain microvasculature damage in sickle cell disease.[489–491]

Interventions for improving neurocognitive performance in patients with sickle cell disease are lacking. An association of oral hydroxyurea (HU) therapy with improved cognitive functioning on tests of verbal comprehension, fluid reasoning, and general cognitive ability has been seen in a small group of children with sickle cell disease and may be an effect of improved blood and oxygen supply to the brain or reduced fatigue and illness related to HU treatment.[492] Because several reports support the hypothesis that the severity of anemia is related to cognitive functioning,[481,493,494] a multicenter study has been performed to determine whether short-term transfusion results in improved neurocognitive performance in adults with sickle cell disease; however, results are not yet available. In addition, neuropsychologic performance in patients who have undergone successful bone marrow transplants has been measured, and it appears that full-scale IQ levels have at least stabilized.[495,496]

Cardiovascular System

Cardiac enlargement, particularly an increase in left ventricular (LV) dimensions and mass, results from an increase in cardiac output imposed by chronic anemia and has its onset in early childhood.[497] The typical physical examination reveals cardiomegaly, a hyperdynamic precordium, and a grade II–III (out of VI) systolic ejection murmur with wide radiation. An ejection click from pulmonary artery dilatation and an S3 or apical diastolic rumble also may be heard. Autopsies have revealed that right and left ventricular dilation is common in both children and adults.[498] Right ventricular (RV) preload and systolic function do not worsen during childhood; however, RV mass index and the prevalence of PHT increase, consistent with rising pulmonary vascular resistance.[499] Significant LV dilatation and LV hypertrophy due to abnormal loading conditions was also found in children.[500] Echocardiography, performed on adult sickle cell patients from the CSSCD in their baseline state, showed striking left atrial and biventricular enlargement, normal shortening fraction, prolonged ejection time, and increased stroke volume.[501] Adult sickle cell patients may have RV enlargement and dysfunction (decreased RV ejection fraction) even in the absence of overt PHT.[502] Brain natriuretic peptide (BNP) mediates natriuresis and vasodilation and its elevation is associated with diminished exercise tolerance and poor prognosis in patients with LV cardiac failure. Increased BNP in patients with sickle cell disease reflects the increased cardiac chamber volume and pressure overload. Elevation of N-terminal (NT)-proBNP is observed in the setting of PHT and is associated with functional impairment and increased mortality.[503,504]

Systolic dysfunction is rare in young patients with sickle cell disease, but diastolic dysfunction is common and easily diagnosed and monitored using new tissue Doppler and speckle tracking echocardiography techniques.[505,506] LV diastolic dysfunction is associated with hemoglobin concentration, but not with iron deposition in the myocardium.[507] Diastolic dysfunction, as reflected by a low E/A ratio, was associated with mortality with a risk ratio of 3.5, even after adjustment for tricuspid regurgitation jet velocity (TRV). The presence of both diastolic dysfunction and PHT conferred a risk ratio for death of 12.0.[508]

In general, there is an absence of atherosclerotic heart disease, although one study reported myocardial infarction and fibrosis in 17% of patients.[509] Adults with sickle cell disease may present with clinical signs of acute myocardial infarction in the absence of atherosclerosis or coronary occlusion, but this is uncommon.[510] In children, rare cases of myocardial infarction and transient ventricular dysfunction have been reported,[511,512] although myocardial perfusion abnormality measured by thallium-201 single-photon emission computed tomography may be relatively frequent.[513–515] Congestive heart failure generally does not occur in the absence of extracardiac complications of sickle cell disease.[501] However, physical performance is severely compromised; adults are usually unable to exceed 50% of expected work capacity,[516,517] and children and adolescents have 60% to 70% work capacities.[518–520] This is the result of a high cardiac output at rest and an inability to increase output as an adaptive response under stress and increased physical demand.

Electrophysiology changes have also been noted in patients with sickle cell disease. In a screening study of sickle cell subjects between the ages of 10 and 24 years, prolongation of the QTc interval was observed in 29/76 (38%) subjects, and was not associated with the presence of LV hypertrophy.[521]

Other factors may compound the cardiac embarrassment resulting from anemia. The shunting of blood through infarcted, nonaerated segments of the lung compromises arterial oxygen saturation, and sludging of sickled erythrocytes in small pulmonary arteries may result in PHT. Myocardial injury or infarction may be associated with fat embolism.[522] Myocardial hemosiderosis, the consequence of long-standing transfusion therapy, may be responsible for intractable heart failure, but is an uncommon finding in patients with sickle cell disease compared to patients with thalassemia major, who frequently develop this complication.

Pulmonary System

Chronic pulmonary disease, an event more commonly observed in adults with sickle cell disease, is presumably related to recurring episodes of ACS, and is characterized by lung fibrosis on high-resolution chest computerized tomography, decreased radiolucency of the lungs, and impairment of pulmonary function,

primarily in a restrictive pattern.[523,524] Typically, the vital capacity and total lung capacity are reduced, and gas mixing and exchange are compromised. Less often, obstructive lung disease is noted. Blood is shunted through poorly aerated or collapsed segments of the lung, creating a disparity between ventilation and perfusion. The resulting reduction in the functional pulmonary vascular tree is responsible for a decrease in arterial oxygen tension (70 to 90 mm Hg) and desaturation of arterial blood. Hb oxygen saturation is lower in children with Hb SS/Sβ^0 thalassemia compared with those with Hb SC/Sβ^+ thalassemia.[525–527] Although pulse oximetry may underestimate true arterial saturation, pulse oximetry values correlate positively with Hb and fetal Hb levels in patients with Hb SS.[528–530]

There is a high prevalence of asthma and airway responsiveness among pediatric patients with sickle cell disease.[310,531,532] The morbidity of asthma among adults is less defined; however, wheezing (without necessarily a formal diagnosis of asthma) has been associated with increased pain and ACS events.[533] Because of the high prevalence of asthma and airway hyperresponsiveness in sickle cell disease, the overlap of symptoms of asthma exacerbation and ACS, and the inheritance pattern of asthma within families of patients with sickle cell disease, it is hypothesized that the asthma (or airway hyperresponsiveness) symptoms are in fact part of the pathophysiology of sickle cell disease, rather than there being two separate co-morbid conditions.[534] Further investigation is needed to confirm this hypothesis.

Sleep disordered breathing (obstructive sleep apnea, snoring) may be increased among patients with sickle cell disease, although most studies did not utilize polysomnography to confirm findings, but relied on validated sleep disorder questionnaires.[263] Further investigation in this area might establish supportive therapeutic options to reduce nightly oxygen desaturation. Pulmonary hypertension (PHT) is a major cause of morbidity and mortality among adults with sickle cell disease.[535–538] It is not known why PHT was rarely recognized as a complication of sickle cell disease in earlier studies, but it is possible that the high frequency seen in older patients reflects current success in preventing mortality in severely affected children and young adults.[536,539] PHT is defined by a mean pulmonary artery pressure ≥25 mmHg, and includes pulmonary arterial hypertension (PAH), pulmonary venous hypertension (PVH) (which results from LV dysfunction), or a combination of both (mixed disease). It is important to note that high cardiac output can also elevate pulmonary artery pressure, adding to the complex and multifactorial pathophysiology of PHT in sickle cell disease. Tricuspid regurgitant jet velocity (TRV) has been a noninvasive surrogate measure of PHT. Specifically, TRV values ≥2.5 m/s measured by Doppler echocardiography are suggestive of PHT, and values ≥3.0 m/s are highly indicative of PHT.[132] In a landmark study, 32% of adults with Hb SS had TRV ≥2.5 m/s; this was associated with a tenfold increase in risk of death and a mortality rate of ~16% at 18 months and 40% at 40 months of follow-up. Subsequently, other studies utilizing TRV as a noninvasive screening test also found significant associations between elevated TRV and increased mortality.[540,541] Markers of hemolytic anemia, including low hemoglobin level, high reticulocyte count, and high LDH, were associated with elevated TRV, as were a history of renal or cardiovascular complications, increased systemic systolic blood pressure, and priapism. In subsequent studies, TRV was validated against direct right heart catheterization in adults, and 25% to 65.5% were shown to have true PHT, for a prevalence of PHT in the total screened population varying from 6% to 10%.[539,542,543] TRV as measured by echocardiogram should not be used alone to establish a diagnosis of PHT. Definitive diagnosis requires right heart catheterization and a mean pulmonary artery pressure ≥25 mmHg. A potential screening for PHT in adults with sickle cell disease has been proposed utilizing a combination of TRV, NT-proBNP, and 6-minute walk tests results.[524] TRV elevation has been reported in children; however, it does not seem associated with increased mortality and it is unclear if it truly reflects PHT in children.[544] It is possible that TRV elevation reflects increased cardiac output in children,[545] therefore there is no recommendation at present for using TRV as a screening test in children with sickle cell disease.

PHT may represent one element of generalized vasculopathy seen in some patients with sickle cell disease (associated with systemic hypertension, renal dysfunction, priapism, and cerebrovascular events), but it is not associated with markers of inflammation, fetal hemoglobin level, or platelet count.[133] There is growing evidence that altered arginine metabolism is involved, in particular, the intravascular release of arginase activity from ongoing hemolysis.[108,536]

Therapeutic intervention for PHT has been limited. Arginine supplementation lowered pulmonary artery pressures by >15% after 5 days of therapy in a pilot study;[546] however, a larger study failed to show benefit (unpublished). Sildenafil, a phosphodiesterase 5-inhibitor, resulted in decreased pulmonary artery systolic pressure and increased exercise tolerance in a small group of adults.[547] Sildenafil was tested in a large multicenter placebo-controlled double-blinded trial of adults with sickle cell disease with elevated TRV and low exercise capacity by the 6-minute walk distance test (walk-PHaSST study); however, the trial was stopped early due to a higher percentage of subjects experiencing serious adverse events (pain) in the sildenafil arm.[548] There was no evidence of a treatment effect on the 6-minute walk distance test, TRV, or N-terminal pro-BNP. It is unclear why sildenafil increased the incidence of painful events, but lowering of the pain threshold has been postulated as a possible explanation. Other management considerations include endothelin receptor agonists (ambrisentan and bosentan), hydroxyurea treatment, chronic transfusion therapy (especially for severe PHT), and various forms of prostaglandin therapy.[133] Endothelin receptor agonists were tested in 2 clinical trials (ASSET studies), but due to low accrual rate, the studies were interrupted early, and were therefore underpowered to show any benefit.[549] Treatment of risk factors such as hypoxemia, severe anemia, or LV systolic and diastolic dysfunction is indicated.

Hepatobiliary and Gastrointestinal Systems

Liver enlargement is present by 1 year of age and persists to a moderate degree throughout life. Analysis of histologic sections reveals distention of sinusoids with sickled cells, Kupffer cell erythrophagocytosis, and varying degrees of periportal fibrosis and hemosiderin pigment.[550] Sickle cell disease may be associated with disturbance in hepatic function.[551] Acute enlargement of the liver, such as may occur with sequestration of sickle cells, subcapsular infarction, or hepatic vein thrombosis,[552–554] is associated with tenderness or right upper quadrant pain. Intrahepatic infarcts may be complicated by abscess formation. In addition, hepatic function as assessed by lidocaine metabolism is impaired in patients with sickle cell disease, suggesting caution when using hepatically metabolized medication in these patients.[555]

It is not unusual for hyperbilirubinemia (with increases in both direct and indirect bilirubin) to punctuate the course of SCA. These episodes may result from hemolysis, intercurrent infectious hepatitis, intrahepatic sickling (hepatic crisis, "sickle hepatopathy"), or choledocholithiasis. It has been suggested that coexistent glucose 6-phosphate dehydrogenase deficiency may be a contributing factor.[556]

The clinical picture of acute viral hepatitis is similar to that seen in non-sickle–cell patients except for the remarkable elevation of serum bilirubin concentration (which may reach 100 mg/dl).[557] Hepatitis A virus may be a frequent cause of acute icteric hepatitis in endemic areas and may result in fulminant hepatic failure and death.[558] Sickle cell patients respond normally to hepatitis B vaccine,[559] although surface antibody titers after immunization

should be measured to identify those who do not convert and require booster injections.[560] Evidence of prior hepatitis C virus infection has been found in 10% to 21% of SCA patients,[561,562] but since the advent of screening of transfused blood for hepatitis C, new cases of this infection have become extremely rare. Liver biopsies may show progression to chronic active hepatitis and cirrhosis. Orthotopic liver transplantation has been used in a few patients with sickle cell disease with success; however, the frequency of neurologic complications during the transplant may be disproportionally high.[563]

The histologic consequences of intrahepatic sickling include impaction of hepatic sinusoids with sickled erythrocytes, patchy areas of hepatocellular necrosis, engorgement of Kupffer cells, and bile stasis.[550,564] In a recent report, sickle hepatopathy was defined by a total serum bilirubin concentration >13 mg/dl, not explained by severe acute hemolysis, viral hepatitis, extrahepatic obstruction, or hepatic sequestration.[565] In children, manifestations of sickle hepatopathy are relatively mild and transient. These include right upper quadrant pain, hepatomegaly, fever and leukocytosis, mild elevation of serum transaminase levels, and moderate to marked elevation of serum bilirubin and alkaline phosphatase levels.[566] Although the course in children is benign and symptoms usually resolve in 1 to 3 weeks, progression to fulminant hepatic failure, generalized bleeding, and death are much more frequent in adults[565] and are occasionally seen in adolescents.[567] Prompt exchange transfusion and, occasionally, chronic transfusion have been the only effective therapies in these patients.[567–569]

Because of a sustained increase in heme catabolism, the frequency of pigmentary gallstones in sickle cell disease is high. These stones, which may be either radiolucent or radio-opaque, have been documented in children <5 years of age.[570–572] The incidence of gallstones increases with age, from 12% in the 2- to 4-year-old age group to 42% in the 15- to 18-year-old age group and 60% in adults.[572] In Jamaica, the prevalence of gallstones was 53% at 23 years of age in Hb SS and 20% in Hb SC.[573] When ultrasonography is used routinely, the finding of gallbladder sludge with or without concurrent stones is common;[574] even if it is not present initially, patients with sludge eventually develop stones. Genetic variations in the uridine diphosphate–glucuronosyltransferase 1α promoter significantly influence serum bilirubin levels and the development of symptomatic cholelithiasis in children with SCA.[575] Chronic transfusion, even if used for prolonged periods, does not seem to prevent the development of gallstones.[576] Although patients are not always able to distinguish the pain of choledocholithiasis from that of abdominal vaso-occlusive crises, elective cholecystectomy may be followed by a dramatic decrease in the frequency of abdominal crises.[577] Laparoscopic cholecystectomy has replaced open cholecystectomy in most centers because it results in shorter hospitalization and decreased postoperative pain and other complications.[578–580]

Although duodenal ulcer disease has been reported in patients with SCA,[581] there is no clear evidence that it is more common than in the general population. Gastric acid output is not increased in patients with duodenal ulcers.[582] Severe ischemic colitis has been reported in several patients,[583–585] and pancreatitis has been a rare problem in sickle cell disease.[586]

The chronic use of blood transfusions will eventually lead to accumulation of iron in the liver (hemosiderosis). Although iron initially accumulates in reticuloendothelial cells of the liver (sinusoids), with continued transfusions, it is incorporated in parenchymal cells (hepatocytes), increasing the risk of liver injury with hepatocyte damage, synthetic dysfunction, fibrosis, and eventually cirrhosis.[587]

Kidneys

A variety of defects in renal function has been described,[588] and a number of histologic alterations noted,[589] Even in the absence of clinically apparent renal disease, small cortical infarcts of varying ages are evident,[590] hemosiderin is deposited in the epithelium of proximal convoluted tubules, glomerular arterioles are dilated and congested, glomerular surface area relative to kidney size is increased,[589] and varying degrees of juxtamedullary glomerular hypertrophy and sclerosis are seen. Symmetric enlargement of the kidneys is a regular feature, and distortion of the collecting system has been a common finding on intravenous pyelograms.[590] Frank papillary necrosis may occur.

Hyposthenuria[591,592] and a limited capacity for hydrogen ion excretion[593–595] are a result of tubular damage, and are present after 6 to 12 months of age. Hyposthenuria may be corrected temporarily by red cell transfusions until up to 15 years, but not thereafter.[591] Disruption of the countercurrent multiplication system owing to sludging of sickle cells in the more hypertonic portions of the renal medulla has been proposed as the mechanism responsible for the concentrating defect.[591] The demonstrated obliteration of a portion of the vasa rectae is in keeping with this hypothesis.[590] Presumably because of the large fluid consumption necessitated by the renal-concentrating defect, most patients experience enuresis.[596] Enuretic sickle cell patients have nocturnal urine osmolality equivalent to that of nonenuretic patients but may respond to desmopressin.[597,598] In addition, enuretic patients have a higher rate of psychosocial problems than sibling controls.[599]

Urinary acidification is abnormal in sickle cell patients, probably resulting from an incomplete form of distal tubular acidosis attributable to diminished ability of the collecting duct to maintain hydrogen ion gradient.[593,595] Impaired potassium excretion by the kidney and subsequent hyperkalemia, increased phosphate reabsorption, and increased uric acid clearance have also been described.[600–602]

Hematuria is common and may be both brisk and prolonged. Bleeding may originate in one kidney or both, or it may take place in an alternating fashion. The most common lesion is an ulcer in the renal pelvis at the site of a papillary infarct.[603,604] The possibility that painless hematuria may be the result of poststreptococcal glomerulonephritis,[605] renal medullary carcinoma,[606] or other disorders unrelated to the hemoglobinopathy should not be overlooked. Idiopathic hematuria rarely requires more than symptomatic treatment. The risk of clotting within the collecting system is best minimized with a high fluid intake. Although there is no controlled study of its use, ε-aminocaproic acid is said to shorten the duration of hematuria in both SCA and sickle trait patients.[607,608] Its use, however, is attended by a risk of ureteral obstruction resulting from blood clots.

The nephrotic syndrome is an infrequent but well-documented complication of SCA that occurs in adolescents and adults. The syndrome may be associated with hypertension, hematuria, parovovirus B19 infection,[366] and progressive renal insufficiency culminating in renal failure. Pathologic lesions include glomerular enlargement and focal segmental glomerulosclerosis.[564,609] In more advanced disease, a lesion that resembles membranoproliferative glomerulopathy has been described;[610] immune complex nephropathy has also been reported.[611] Glomerular enlargement is secondary to the increased glomerular filtration rate and effective renal plasma flow that are found in children but that decline to subnormal levels with increasing age or from adverse effects of nonsteroidal anti-inflammatory agents.[612,613] In addition, the increased cardiac output and vasodilation from increased production of prostacyclins contributes to the glomerlular hyperfiltration. Glomerular damage in adults is very common and associated with albuminuria and progressive renal failure.[614] Glomerular hyperfiltration also occurs in children, with a prevalence of 76% in one pediatric cohort, progressive decrease with age, and inverse association with cystatin-C levels and systolic blood pressure.[615] Microalbuminuria occurs commonly in adults (37%),[616] but in children its prevalence is lower and is reported from 16% to 18%.[615,617] The use of angiotensin-converting enzyme inhibitors (ACEi) might be beneficial in preventing progression of microalbuminuria and proteinuria in sickle cell disease, but prospective studies have

not been conducted. In addition, hydroxyurea, used in conjuction with ACEi or alone, might offer additional benefit in reducing proteinuria and improving renal urine concentrating ability.[618,619] However, chronic red cell transfusion begun at an early age may be protective against microalbuminemia.[620] Approximately one fourth of adult sickle cell patients have at least 1+ proteinuria, and 7% have serum creatinine concentrations above the normal range.[621] The overall incidence of hypertension in patients with Hb SS is low (2% to 6%), compared with a published incidence of 28% for the black population in the United States.[622] Data from the CSSCD confirmed that individuals with sickle cell disease have a significantly lower blood pressure than the general population, but hypertension is still a risk factor for stroke and increased mortality.[623] Intermittent hypertension occurring during sickle cell crises and associated with transient elevation of plasma renin activity has been attributed to the reversible sludging of red cells in the small vessels of the kidney.

Renal failure, which occurs in ~4% of patients with SCA at a median age of onset of 23 years,[624,179] is a significant cause of mortality in adults.[143] The preazotemic manifestations of hypertension, proteinuria, and increasingly severe anemia predict end-stage renal failure with an average survival (despite dialysis) of 4 years after diagnosis.[624] Potentially valuable newer measures of declining renal function include serum cystatin-C and markers of tubular damage (increased serum β2 microglobulin, increased urinary N-acetylglucosaminidase or endothelium-1).[625,626] In addition, 2 genes (MYH9 and APOL1) have been identified as having SNPs associated with proteinuria and end-stage renal disease.[627,628] Management of renal failure is the same as that for renal insufficiency resulting from other causes. Both hemodialysis[629] and peritoneal dialysis, when used in conjunction with a transfusion program, are efficacious in transiently correcting uremic complications. The role of renal transplantation has not been well established because of limited numbers of patients and posttransplant problems of increased pain crises, graft thrombosis, and recurrence of sickle nephropathy.[630] A report from the North American Pediatric Transplant Cooperative Society described nine patients with end-stage sickle cell nephropathy for whom graft survival was 71% at 2 years after transplant.[631] In another report, 82 patients with end-stage sickle cell nephropathy received renal allografts.[632] The short-term result was similar to that seen with other causes of end-stage renal disease, and this approach seems to improve survival in comparison with those patients managed with chronic dyalisis.[633] Pharmacologic doses of exogenous erythropoietin have been effective in correcting anemia,[634] but higher hematocrits have been associated with increased pain crises.[635]

Eyes

A variety of ocular lesions results from occlusion of the small vessels of the eye by sickled erythrocytes (Fig. 33.9). The prominence of end arterioles within the retina renders this tissue especially vulnerable to irreversible injury after vascular occlusion.

Sludging of blood in conjunctival vessels is responsible for the so-called conjunctival sign,[636] which consists of dark red, comma-shaped, or corkscrew-shaped vascular fragments that appear to be isolated from other vessels. The anomalous segments are seen most often in that part of the temporal bulbar conjunctiva covered by the lower lid. A direct relationship between the prominence of these saccular segments and the number of ISCs on blood smears has been noted.[637,638]

There is partial resorption and exposure of a darkened area that was the probable site of intraretinal hemorrhage. **D:** Old pigmented chorioretinal scar. Photographs by Professor Mansour Armaly, The George Washington University Medical Center.

Vaso-occlusive disease of the retina is responsible for both nonproliferative and proliferative (neovascular) changes.[639,640] The former consist of "salmon patches," produced by small intraretinal hemorrhages; iridescent spots, representing collections of iron-loaded retinal macrophages; and schisis cavities, left after resorption of blood. Hemorrhages that break into the potential space between the sensory retina and pigment epithelium stimulate pigment production and migration, giving rise to black, disc-shaped scars known as "black sunbursts." Proliferative changes begin with the formation of arteriovenous anastomoses, followed by the development of vascular fronds resembling sea fans.[641] Immunohistochemical techniques have been used to demonstrate the association of vascular endothelial growth factor and fibroblast growth factor with sea fan formation.[642] Vessels grow anteriorly toward the pre-equatorial, ischemic portion of the retina. Inspection of sea fans with ultraviolet light after the intravenous injection of fluorescein usually reveals small leaks into the vitreous. Major hemorrhages from sea fans that extend into the visual axis can generate visual symptoms. More often, however, they are confined to the peripheral portions of the retina and go undetected except by ophthalmoscopy. With time, repeated vitreous hemorrhages cause vitreous degeneration and vitreoretinal traction, which in turn produces retinal holes, tears, and detachment. Although these changes may culminate in loss of vision, they do so less often in association with Hb SS than in association with Hb SC disease.[641,643,644]

The prevalence of sickle retinopathy (both proliferative and nonproliferative) increases with age and is more common among patients with HbSC than those with HbSS. In a large study of sickle cell patients, the prevalence of sickle retinopathy was 54.6% and 18.1% in patients with HbSC and HbSS, respectively, and was more common among men than women.[645] No correlation has been found between retinopathy and various hematologic parameters except Hb F level, which is higher in less-affected patients.[646] Screening for sickle retinopathy is recommended beginning at 10 years of age, and should be done annually for HbSC or bi-annually for other genotypes.

Diagnosis and monitoring of sickle retinopathy generally has been performed with noncontact wide-field fundus photography (Fig. 33.9). However, current technology utilizing wide-field angiography offers a 200° field of view in a single frame, allowing better visualization of peripheral proliferative changes, and a scanning laser ophthalmoscope; this requires a bolus dose of 5 ml of 10% sodium fluorescein. In a small study of 6 patients with this technique, peripheral vascular changes were detected that would have been missed using standard techniques.[647]

Proliferative retinal disease may be arrested by laser photocoagulation or cryocoagulation,[637] to seal off the feeder vessels of neovascular patches and coagulate vascular leaks. However, because the long-term complication rate is relatively high, most retinal specialists have abandoned feeder vessel treatment in favor of scatter photocoagulation, except in recalcitrant cases with repetitive bleeding.[648] Vitreous hemorrhages can be removed by pars plana vitrectomy followed by photocoagulation. Retinal detachment is treated by scleral buckling surgery, although potential complications include persistent intraocular hemorrhage, hyphema with secondary glaucoma, infarctions of the macula and optic nerve from elevated intraocular pressure, and the potential for intraoperative sickling crises.[648]

An additional ocular complication of sickle cell disease is hyphema. Bleeding into the anterior chamber leads to trapping of sickled red cells, mechanical obstruction of the outflow apparatus, compromised circulation of the aqueous humor, and increased intraocular pressure, which may result in sudden blindness.[649] This complication, which also can occur with sickle cell trait red cells, may be managed effectively by lowering intraocular pressure through anterior-chamber paracentesis.

Mild edema of the eyelids is frequently seen in association with vaso-occlusive pain crises, but more significant sickle "orbitopathy" has been described in approximately 20 patients.[650,651] A vaso-occlusive process in the marrow space around the orbit may result in frontal headache, fever, eyelid edema, and orbital compression. Subperiosteal hematomas are common and appear to result from bone marrow infarction. Although supportive care is usually adequate, the presence of optic nerve dysfunction or unusually large hematomas may require surgical evacuation to prevent loss of vision.[650]

Leg Ulcers

Breakdown of the skin over the malleoli and distal portions of the legs is a recurring problem during adult life (Fig. 33.10).[652] Stasis of blood in the small vessels supplying these areas may interfere with the healing of minor traumatic abrasions. Venous incompetence detected by Doppler ultrasonography was more frequent in Jamaican patients with Hb SS than in controls and was highly associated with leg ulcers.[653] These were observed in 2.5% of sickle cell patients >10 years of age in North America,[654] but they affect as many as 75% of adults with SCA who live in tropical areas.[655] A number of other risk factors have been identified. Ulcers are common in patients with Hb SS but quite rare in those with Hb SC disease or Hb Sβ^+-thalassemia.[654] They are more common in men than in women and in those >20 years of age. There is a positive correlation with a low steady-state Hb concentration and with a low level of Hb F.[654] Recently, associations with severity of hemolysis and with single-nucleotide polymorphisms in the Klotho gene and TGF-β pathway genes have been reported.[112]

The ulcers typically form a shallow depression with a smooth and slightly elevated margin; often, they have a surrounding area of edema. There may be exudation, crusting, and granulation at the base. Secondary infection of the ulcer with undermining of the edges and progressive extension are common. Single or multiple bacterial organisms may be cultured from the lesions and may contribute to their refractoriness. Healing leaves a thinned depigmented epithelium that is often surrounded by areas of hyperpigmentation and hyperkeratosis. This fragile epithelium is likely to break down with minimal trauma or edema, leading to recurrence rates >70%.[656]

Healing of leg and ankle ulcerations is facilitated by bed rest, elevation of the affected extremities, wet-to-dry dressings, and eradication of documented wound infections with systemically administered antibiotics. When acute inflammation has subsided, occlusive zinc-oxide–impregnated gel boots (Unna boots) are applied, and partial ambulation is permitted. In refractory

FIGURE 33.10. Chronic leg ulcers in an adult patient with sickle cell anemia (SCA).

or progressive cases, the healing process may be enhanced if the level of Hb S is maintained at <40% with transfusions. Split-thickness skin grafting may be necessary.[657] A number of alternative approaches have also been described in recent years. Zinc deficiency has been invoked to explain slow tissue healing,[658] and oral zinc therapy may hasten healing in some patients.[659] Erythropoietin and hydroxyurea may improve healing by increasing fetal or total Hb levels (or both).[660,661] Hydroxyurea has been linked to the development of leg ulcers anecdotally, but larger studies have not found this association. The use of collagen-matrix dressings (RGD peptide matrix) resulted in greater ulcer closure in a controlled collaborative trial.[662] Recently a phase II clinical trial in 23 adults with refractory leg ulcers compared standard care with arginine butyrate (500 mg/kg, 5 d/week) plus standard care.[663] Healing of the ulcers was significantly better in the arginine butyrate arm.

Pregnancy

Pregnancy poses potentially serious problems for the woman with SCA, as well as for the fetus and neonate.[664–666] In the absence of medical supervision, the mortality for mother and infant has been as high as 20% and 50%, respectively.[667] With optimal care, mortality and morbidity are reduced substantially, even in difficult settings in Africa.[668] The jeopardy imposed by pregnancy is explained in part by marginal health status before conception and in part by the sinusoidal circulation of the placenta, whereby a high degree of oxygen extraction provides an excellent milieu for sickling, stasis, and infarction. Although life-threatening complications generally are not encountered until the third trimester, an increased incidence of pyelonephritis, hematuria, and thrombophlebitis is noted throughout pregnancy.[669] Anemia is more severe and may be compounded by folate deficiency. During late pregnancy and the postpartum period, major infarctions may involve the lungs, kidneys, or brain. Toxemia, heart failure, and postpartum puerperal endometritis occur with greater frequency in women with SCA than in the general population.[669–671]

The risk to the fetus is serious; fetal wastage results from a combination of abortion and stillbirth.[669] The incidence of congenital malformations or susceptibility to complications is comparable to that shared by all preterm infants.[672] Opiates are not associated with teratogenicity, congenital malformations, or toxic effects other than transient suppression of movement and variability in fetal heart tones.[673] Hydroxyurea, even when used throughout pregnancy, has not been associated with teratogenic changes, both in a small number of pregnancies, and among adults who participated in the MSH trial and were followed for up to 17 years.[674,675] Nevertheless, it is a teratogen in animals and should be stopped once pregnancy is recognized.[664]

Infants born to women with SCA are at greater risk of preterm birth, low birth weight, being small for gestational age, and neonatal jaundice,[670] but since 1980, the neonatal mortality rate has ranged from 0% to 10%.[664] According to a CSSCD report 21% of infants were small for their gestational age.[671] Possible etiologic factors are severe maternal anemia; frequent episodes of vaso-occlusion leading to hypoperfusion and hypoxia of the placenta; increased risks of abruptio placentae, placenta previa, and toxemia of pregnancy; diminished maternal nutrition; and increased narcotic use in the mother. Pre-eclampsia and acute anemic events were risk factors identified by the CSSCD.[671] The increased risk of preterm labor and prematurity may be caused by similar factors, including anemia, abruptio placentae, placenta previa, toxemia, and narcotic use, as well as increased urinary tract infection and chorioamnionitis. A high maternal Hb F level may have an ameliorating effect on perinatal mortality.[676] Treatment of sickle cell disease during pregnancy may include repeated blood transfusions, but this is not indicated in all cases (see "Treatment" section).

The efficacy and safety of various methods of contraception have not been investigated systematically in women with sickle cell disease. Despite a theoretical possibility of enhancing thrombotic risk, low-estrogen–dose birth control pills are sometimes recommended. Studies in Nigeria and Brazil found no adverse effects from the progestational contraceptive implant and a possible improvement in fetal Hb level.[677,678] An association of pain crises and menstrual periods seen in 37% of women suggests the use of a continuous combined contraceptive pill regimen or medroxyprogesterone (Depo-Provera) to induce amenorrhea in severe cases.[679] A review of progesterone-only contraceptive use suggested that they are safe and result in less frequent and severe painful crises.[680]

Prognosis

The prognosis for persons with SCA has undergone dramatic change as a result of early diagnosis, improved patient education, and effective therapeutic interventions. In a retrospective review of autopsy cases from the United States in 1972, 20% to 30% were <5 years of age at the time of death.[334] The median age at death was 14 years, and survival beyond 40 years of age was unusual. In a 1976 report of a screening program that used cord blood samples, 31% of children diagnosed at birth died before 15 years of age at a mean age of 2 years.[681] The disproportionate number of reported deaths occurring in early childhood was the result of overwhelming bacterial infections and splenic sequestration crises.[175,682]

Newborn screening for sickle cell disease and greater awareness of the unique needs of affected infants and children have resulted in an improved prognosis.[683,684] The simple adoption of a standardized protocol for the management of febrile illnesses reduced the mortality in children with SCA 0 to 5 years of age from 3.2/100 patient-years to 1.4/100 patient-years.[390] In 1989, the CSSCD documented an 85% survival rate at 20 years of age.[685] In that study, peak incidence of death (mostly resulting from infections) occurred between 1 and 3 years of age. Cerebrovascular accidents and traumatic events exceeded infections as a cause of death in the second decade of life. Mortality data for young children with Hb SS born in the early 1990s in three large states with newborn hemoglobinopathy screening indicated that 1% died as a result of sickle cell disease related causes during the first 3 years of life.[686] In the Dallas newborn cohort study, infants identified by newborn screening were followed for up to 18 years.[687] The cumulative overall, sickle cell related, and stroke-free survival rates were approximately 86%, 94%, and 88.5% by age 18 years. It was concluded that childhood mortality from sickle cell disease is decreasing and that a smaller proportion of deaths are from infection.

In a report from the CSSCD,[143] causes of death for 209 adult patients who died during the study were analyzed. Among adults with Hb SS, the median age at death was 42 years for males and 48 years for females. However, among those with Hb SC disease, the median age at death was 60 years for males and 68 years for females. Only 18% of deaths occurred in patients with chronic organ failure; of these, 58% had chronic renal failure, 29% had chronic congestive failure, and 23% had chronic debilitating stroke. One third of the deaths occurred in the context of hospitalization for an acute painful episode, ACS, or stroke, which was predominantly hemorrhagic. Six percent died from infection, 6% had perioperative deaths, and 6% died from trauma. Miscellaneous causes included cancer, gastrointestinal bleeding, and fulminant hepatic failure. In ~23%, the exact cause of death was unknown. Statistical modeling revealed that in patients with SCA, ACS, renal failure, seizures, baseline white cell count >15,000/mm^3, and a low level of fetal Hb were associated with an increased risk of early death. It was concluded that a high level of fetal Hb is a relatively reliable childhood forecaster of improved adult life expectancy.

In a four-decade prospective cohort study from Los Angeles involving more than 1,000 patients, it was noted that children born after 1975 had an 89% survival to age 20 years.[179,688] A higher rate of hospitalization for sickle cell pain crises in adults was associated with increased rates of avascular necrosis, leg ulcers, chronic lung disease, renal failure, and early death. Of the patients who died, 73% had one or more forms of irreversible organ damage. By the fifth decade, nearly one half of the surviving patients had documented irreversible organ damage, including end-stage renal disease, chronic pulmonary disease with PHT, retinopathy, and cerebral infarctions, underscoring the need for preventive therapy to ameliorate the progression of sickle vasculopathy.

Overall, although mortality in children with sickle cell disease has progressively decreased in developed nations, the burden of mortality in sickle cell disease is increasingly shifting to adults, particularly among young adults (18 to 30 years) who have recently transitioned out of pediatric sickle cell programs.[15,180,689] Mortality during childhood years, especially before 5 years of age, remains elevated in developing nations, however.[690,691]

Determinants of Severity

Extensive data from the CSSCD highlighting frequency/incidence and risk factors for various complications of sickle cell disease have been published.[692] Because of the large number of patients involved and the efforts to avoid patient selection bias, these data represent an ambitious attempt to describe the natural history of sickle cell disease. A large, carefully followed cohort of sickle cell patients from Jamaica described in numerous publications and a textbook provides another major source of data for prognostic analysis.[14]

SCA is remarkably variable in its clinical expression, even among affected members of the same family. Whereas many individuals have recurrent severe complications, others enjoy a relatively benign, virtually symptom-free course.[693] Occasionally, patients with apparently mild SCA are found on further study to be doubly heterozygous for Hb S and another Hb variant having the same electrophoretic mobility as Hb S or to be heterozygous for both Hb S and HPFH. That clinical heterogeneity is related to genetic variables is suggested by the tendency for differences in disease severity to follow selected geographic and ethnic lines. In the eastern oases of Saudi Arabia, for example, SCA is clinically benign,[694,695] whereas in western Saudi Arabia, it is comparable in severity to that seen in African Americans.[696] Several important modulators of hematologic and clinical severity have been identified; however, Hb F level, the presence of α-thalassemia, and the β-globin gene cluster haplotype are the most important ones.[240,245,697–699]

Because Hb F is excluded from the Hb S polymer, individuals with relatively greater amounts of Hb F should have less severe disease than those with less Hb F. The level of Hb F in patients with SCA is determined by the number of red cells containing Hb F (F cells), the Hb F concentration within F cells, and the survival of F cells.[700] The proportion of reticulocytes containing Hb F is relatively constant over time, but it varies greatly among affected individuals (2% to 50%). Other confounding factors in studies to determine the prognostic significance of Hb F include the variability in techniques used to measure fetal Hb and the fact that Hb F levels in sickle cell patients gradually decline over a long period of childhood and do not reach equilibrium until 12 years of age. The expression of high levels of Hb F and F reticulocytes may be inherited as an autosomal dominant characteristic.[701,702]

In the eastern province of Saudi Arabia[694,703] and in Kuwait,[704] Iran,[705] India,[706] and the West Indies,[707] mild disease is associated with Hb F levels of 15% to 30%. Levels of Hb F influence the age at which symptoms develop[277] and partially determine the risk of acute splenic sequestration,[174,371] stroke,[233,235] ACS,[294] leg ulcers,[654] pain crises,[181] loss of spleen function,[277] and mortality.[708] Among patients of West African ancestry, higher levels of Hb F are associated with an improvement in hematologic features,[181,709] but an improvement in measures of clinical severity related to increased Hb F has been difficult to establish. One study concluded that Hb F levels substantially <20% conferred minimal benefit on disease severity, indicating a threshold effect.[709] However, evidence from the CSSCD indicates that even when the fetal Hb level is low, small increments in the level may have an ameliorating effect on the pain rate and may ultimately improve survival.[184] The limited capacity of Hb F levels to predict disease severity, however, does not negate the importance of Hb F production. Hb F levels are determined not only by synthetic rates but also by the extent to which F cells are enriched by differential cell survival. Thus, high levels of Hb F may reflect increased synthesis, resulting in mild disease, or greater amplification through accelerated destruction of cells containing no Hb F, a manifestation of more severe disease.[700]

Co-inheritance of SCA and α-thalassemia is not an unusual event. Nearly 30% of black Americans have a single α-gene deletion, and in ~2%, deletion of two of the four α-globin genes has been found. Hematologic studies provide support for the clinical relevance of α-thalassemia. Subjects with SCA and α-thalassemia have a higher Hb concentration, lower MCV and MCHC, fewer ISCs, a lower reticulocyte count, lower serum bilirubin concentration, and relatively more Hb A^2 than subjects without concurrent α-thalassemia.[698,710–713] The α-gene deletion also is associated with improved cell deformability,[714] a decreased fraction of dense cells,[714,715] protection against cation leak,[716] and improved red cell survival.[717] There is relatively little effect of α-thalassemia on Hb F levels,[711,712] although in patients with the Senegal haplotype, Hb F levels are higher.[718] The mechanism responsible for these differences in hematologic status is probably mediated by a decrease in the MCHC, because the extent and the rate of Hb S polymerization are highly dependent on the cellular concentration of Hb S.

Data from the CSSCD demonstrated that coexistent α-thalassemia is associated with a diminished mortality risk in patients >20 years of age.[143] In addition, stroke risk is decreased in the presence of alpha thalassemia.[240,247,248] The rheologic benefits of more deformable α-thalassemic sickle cells are offset by rheologic impairment associated with the greater viscosity of a higher hematocrit induced by α-thalassemia.[719] Thus, α-thalassemia is associated with more frequent vaso-occlusive pain crises by virtue of its effect on hematocrit.[184] Osteonecrosis and perhaps sickle retinopathy occur more often in sickle cell subjects with coexistent α-thalassemia.[720–722] Sickle cell trait is also influenced by α-thalassemia.[723] Subjects with lower fractional content of Hb S associated with α-thalassemia have less severely impaired urinary-concentrating ability.[724]

Genetic factors that modulate the phenotype of sickle cell disease are associated with restriction fragment length polymorphic sites within the β-globin-like gene cluster.[725] These β-globin gene haplotypes are characteristic of different populations; most patients with SCA in the United States have the Benin haplotype, with fewer having the Bantu (Central African Republic) and Senegal types. The origin of these genes in malarial regions of Africa is shown in Figure 33.1.[18] In Mediterranean populations, the b^s gene is usually associated with a Benin haplotype, whereas the haplotype found in eastern Saudi Arabia and parts of India resembles but is distinct from that of Senegal. The Senegal haplotype is associated with higher levels of Hb F [718,726–728] and with fewer hospitalizations and painful episodes.[245,729] By contrast, the Bantu haplotype has been associated with the highest incidence of organ damage, particularly renal failure.[245]

Fetal Hb levels in both sickle cell patients and normal individuals have been found to be partially controlled by an X-linked gene located at Xp22.2, the F-cell production locus.[697] Female

gender increases the expression of Hb F in patients with SCA and in normal individuals.[697] Multiple regression analysis in one study showed that the F-cell production locus was the strongest predictor of Hb F level, although not accounting for approximately one half of the variation.[730] When β-globin haplotype and gender were considered together, the Hb F level in female patients of all haplotype groupings was higher than that in male patients, with the highest level occurring in female patients with one Senegal haplotype chromosome (Hb F, 12.8%).[731] Thus, gender and β-globin gene cluster haplotype interact in the modulation of Hb F and Hb level in SCA. Recent discoveries demonstrate physical interactions between the β locus control region and the downstream structural γ- and β-globin genes, and with transcription factors and chromatin remodeling complexes. These interactions all play roles in globin gene expression and globin switching at the human β-globin locus.[732] In Jamaica, high levels of Hb F (and a normal α-globin gene complement) have been associated with benign disease, which occurred in 15% of patients.[700]

A cohort of 392 infants with Hb SS or Hb Sβ^0-thalassemia from the CSSCD were followed for an average of 10 years beginning at <6 months of age. Eighteen percent had an adverse outcome, defined as death, stroke, frequent pain, or recurrent ACS.[146] Three statistically significant predictors of an adverse outcome could be identified at 2 years of age: Hb level <7 g/dl, leukocytosis in the absence of infection, and an episode of dactylitis before 1 year of age. However, in a report from the Dallas newborn cohort, hospitalizations in the first 3 years of life for pain (other than dactylitis), ACS, and dactylitis did not predict death or stroke.[733] Nevertheless, early pain and ACS both predicted a modest increase in later pain episodes, and early ACS strongly increased the odds of more frequent ACS throughout childhood.

Sickle cell disease should no longer be considered a single-gene disorder,[734] because a number of epistatic and pleiotropic genes have been defined.[735,736] Genomewide association studies (GWAS), which have been used to identify common genetic factors that influence health and disease, are hard to perform in sickle cell disease due to the large datasets required. The few GWAS studies that have been conducted in patients with SCA have examined SNPs associated with elevated bilirubin levels, cholelithiasis, fetal hemoglobin levels, and disease severity.[737,738,739,740] Some SNPs appear to be significant from these studies, such as SNPs in KCNK6 (a potassium channel gene) and telomere length regulator gene TNKS, which were both associated with increased disease severity.[739] The most striking and potentially important information from recent GWAS studies has been the discovery of 3 loci with large effects on HbF production: the gene encoding B-cell lymphoma/leukemia (BCL) 11A (chromosome 2), genes encoding HB1SL (chromosome 6), and Myb, a transcription factor.[741–744] Together these 3 loci explain 40% of the variation in the amount of HbF produced.[741] Understanding the role of BCL-11A and other loci, and their relationship with the globin switch that occurs early in life may potentiate the development of treatment compounds and gene therapy strategies that reactivate HbF production.[745,746]

Laboratory Features

Red Blood Cells

In SCA, a moderately severe normocytic, normochromic anemia manifests by 3 months of age[670] and persists throughout life.[176] The average Hb concentration is 8 g/dl, with a range from ~6 to 10 g/dl. Mean Hb levels vary with gender and with age; they are higher in adult men compared with women and higher in males between the ages of 20 and 39 years.[747] In adults with Hb SS, the mean MCV is ~90 fl, and the mean MCHC is ~34.0 g/dl.[747] The MCV and MCHC are substantially lower (means 72 fl and 32.5 g/dl, respectively) in patients with concurrent α-thalassemia minor (–α/–α genotype) and in children with incidental iron deficiency.[748] The MCV in males with SCA is less than that for females in almost all age groups;[749] this may reflect the higher Hb F concentration seen in female patients. Automated blood cell counters (based on aperture and impedance or light-scatter techniques) may result in overestimation of the MCV and underestimation of the MCHC[750] because of the inability of dehydrated, dense sickled red cells to deform like normal cells as they pass through the narrow counter aperture. However, the use of two-angle light-scattering technology permits accurate measurement of MCV and MCHC and generation of histograms of these properties.[751] This allows quantitation of the percentage of dense, dehydrated red cells.

Blood smears contain variable numbers of sickled forms, target cells, and ovalocytes (Fig. 37.11). The great variety of sickle cells is best appreciated by scanning electron microscopy (Fig. 37.2). The morphologic features of accelerated erythropoiesis, which include polychromatophilia, basophilic stippling, and normoblastosis, are prominent. The mean reticulocyte count is ~10%, with a range of 4% to 24%.[747] Howell-Jolly bodies reflect functional asplenia. Numerous pits in red cell membranes, also a feature of the asplenic state, require phase-interference contrast microscopy for visualization.[402] With transmission electron microscopy, dense aggregates of Hb can be seen adjacent to red cell membranes.[752]

Erythrokinetic studies performed in the steady state indicate a four- to fivefold increase in red cell production and erythron iron turnover and a comparable shortening of red cell survival. The curves of cell survival obtained with ^{3}H- or ^{32}P-labeled diisopropylfluorophosphate indicate a random rather than a senescent mode of cell destruction.[753] This pattern of cell loss is explained by the lack of dependence of ISC formation on cell age.[105] Chronic

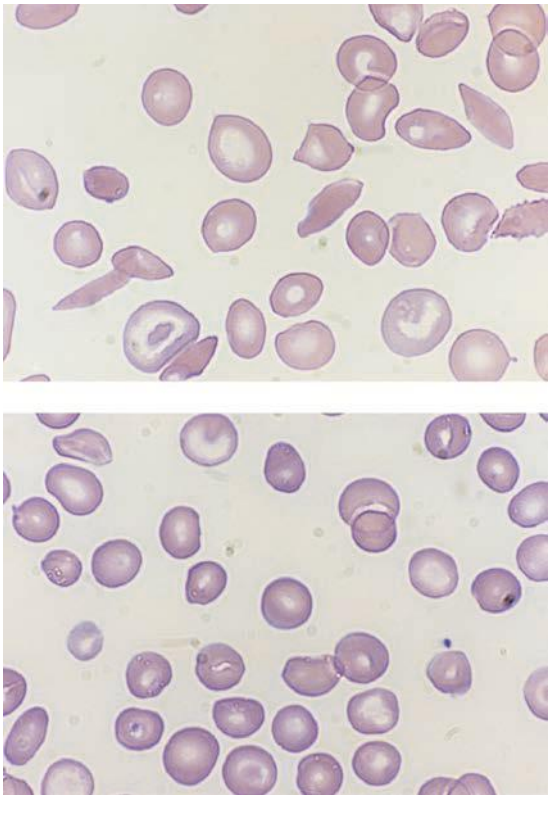


FIGURE 33.11. Blood smears of patients with hemoglobin (Hb) SS and Hb SC disease. A: Red blood cell morphology in sickle cell anemia (SCA) is characterized by sickled forms (dense elongated cells with pointed ends), target cells, ovalocytes, and polychromatophilia. **B:** Hb SC disease is characterized by target cells, relatively few sickled forms, and a small proportion of cells that contain dark blunt protuberances (hemoglobin "crystals").

hemolysis, some of which is intravascular, is responsible for an increase in endogenous carbon monoxide generation and for elevated serum levels of unconjugated bilirubin and heme proteins.[754] Serum immunoreactive erythropoietin levels are lower than those noted in association with other anemias of comparable severity.[755]

White Blood Cells

The white blood cell count is consistently elevated owing to an increase in the number of mature granulocytes. The mean leukocyte count under steady-state conditions is 12 to 15 $\times$ 10^9/L, with a range of 6 to 20 $\times$ 10^9/L.[749] This increase is explained to a large extent by a shift of granulocytes from the marginated to the circulating compartments.[138] Both total and segmented leukocyte numbers increase during vaso-occlusive crises and infections, but only with bacterial infections does a consistent increase occur in bands (nonsegmented neutrophils), often to levels >1 $\times$ 10^9/L.[139]

Platelets and Coagulation

The platelet count is increased (mean, approximately 440 $\times$ 10^9/L), reflecting reduced or absent splenic trapping.[159,749,756] Totals of both platelets and megathrombocytes decrease during vaso-occlusive crises.[159,160] Platelet aggregation is decreased, the likely result of in vivo platelet activation.[161,757] The plasma β-thromboglobulin level is elevated.[162] The contact factors are decreased,[165] whereas factor VIII activity, fibrinogen concentration, and fibrinolytic activity are increased.[758–760] Some of these alterations likely reflect vascular endothelial damage inflicted by the sickling process and not primary perturbations responsible for crises.

Other Laboratory Tests

Inflammatory markers are increased in sickle cell disease and reflect the "heightened inflammatory state" of the disease. Inflammatory markers, such as CRP, $sPLA_2$, fibrinogen, Von Willebrand factor, interleukines, serum ferritin, and TNFα, are all elevated,[117,761] in addition to elevation of WBC. The sedimentation rate is difficult to interpret due to the presence of anemia, hyperfibrinogenemia, and the failure of sickle cells to undergo rouleaux formation.

Diagnosis

The diagnosis of SCA (HbSS) rests on the electrophoretic or chromatographic separation of hemoglobins in hemolysates prepared from peripheral blood. The predominant hemoglobin is S; Hb F is present in varying concentrations; and Hb A^2 is normal. There is no Hb A. Electrophoresis using cellulose acetate and an alkaline buffer is rapid, inexpensive, and effective in the separation of normal hemoglobins from common variants. Whole blood, blood specimens dried on filter paper, or Hb solutions may be used.[762] However, several relatively rare Hb variants have an electrophoretic mobility identical to that of Hb S on cellulose acetate. Because most of these variants do not co-polymerize with Hb S on deoxygenation, the doubly heterozygous states are seldom associated with the clinical and hematologic features of sickling. The interaction of Hb S with β^0-thalassemia also gives an electrophoretic pattern that is indistinguishable from that of homozygous SCA, except for an increase in Hb A_2. In general, the appropriate diagnosis can be made by taking into consideration associated hematologic data (Table 33.4). However, detailed family studies, Hb separation by isoelectric focusing or high-performance liquid chromatography (HPLC), globin-chain electrophoresis, or structural analysis of Hb [by protein chemistry, mass spectrometry, or sequencing of polymerase chain reaction (PCR)-amplified DNA] may be required to characterize accurately the genotypic basis for a sickling disorder.

A variety of simple tests permits detection of Hb S. The sickling phenomenon can be induced by sealing a drop of blood under a coverslip to exclude oxygen or by adding agents that induce chemical deoxygenation, such as 2% sodium metabisulfite or sodium dithionite.[763] The decreased solubility of deoxy Hb S forms the basis for tests in which blood is added to a buffered solution of a reducing agent such as sodium dithionite. Hb S is insoluble and precipitates in solution, rendering it turbid, whereas solutions containing hemoglobins other than Hb S remain clear. Hyperglobulinemia and other sickling hemoglobins may cause false positive results;[764] false negatives may result from the addition of an inadequate number of red cells. Neither the sickle cell preparation nor solubility tests differentiate SCA from sickle cell trait or detect Hb variants that interact with Hb S. Thus, they should never be used as a primary screening test. Their principal value has been as an adjunct to electrophoretic identification of Hb S.

Quantitation of Hb A_2 is performed by HPLC. Quantitation of Hb F can be carried out by alkali denaturation, HPLC, or radioimmunodiffusion.[752,765] The distribution of Hb F in red cells may be analyzed by its resistance to acid elution or, more precisely, by Hb F-specific antibodies that measure the number of "F cells."[766]

Although the diagnosis of Hb SC disease is straightforward, that of Hb Sβ-thalassemia may sometimes be problematic. In Hb Sβ^+-thalassemia, there is a preponderance of Hb S, with Hb A comprising 5% to 30% of the total, and elevation of HbA_2. This must be distinguished from sickle cell trait, in which Hb A exceeds Hb S, and from the presence of Hb A resulting from red blood cell transfusions within the previous 3 to 4 months. Hb Sβ^0-thalassemia produces an electrophoretic pattern that is

TABLE 33.4

DIFFERENTIAL DIAGNOSIS OF ELECTROPHORETIC PATTERN OF HEMOGLOBIN (HB) SS AT PH 8.6

Diagnosis	Symptoms	Anemia	Red Blood Cell Morphology	Distinguishing Features
Sickle cell anemia (Hb SS)	Present	Moderate or severe	ISCs, target cells	—
Hb S/β^0-thalassemia disease	Present	Moderate or severe	ISCs, target cells, hypochromia, microcytosis	Hb A_2 increased; mean cell volume and mean corpuscular Hb concentration decreased
Hb S/hereditary persistence of fetal Hb	Absent	Absent	Target cells	Hb F evenly distributed in erythrocytes
Hb S/D-Punjab disease	Present	Moderate	ISCs, target cells	Hb S and D separable on citrate agar at acid pH

ISC, irreversibly sickled cell.

visually indistinguishable from that of SCA, but a diagnosis can be made by the presence of an elevated Hb A_2 level and a decreased MCV. In addition, upon exam of the peripheral blood, both HbSβ^+-thalassemia and HbSβ^0-thalassemia display large numbers of target cells. However, because SCA with coincident α-thalassemia also has a phenotype with reduced MCV and mildly elevated Hb A_2, family- or DNA-based studies may be necessary to make this distinction.

Neonatal Diagnosis

The first statewide newborn hemoglobinopathy screening program was initiated in New York in 1975,[767] but the impetus for universal screening came from the demonstration that early diagnosis and comprehensive care could reduce morbidity and mortality in infants with SCA through the prevention of pneumococcal sepsis with penicillin prophylaxis.[411] A National Institutes of Health Consensus Conference concluded that every child should be screened early for sickle cell disease,[768] leading to statewide newborn screening programs in all 50 states.[769] Universal rather than targeted screening is necessary to ensure that all with disease are identified and none are discriminated against or stigmatized.[768]

It is estimated that between 2,000 and 3,000 children are born yearly with sickle cell disease in the United States,[15] and approximately 280,000 worldwide.[770] Most newborn screening programs use dried blood spots on filter paper, because Hb testing can easily be integrated into existing metabolic programs with established methods of sample collection, specimen processing, data management, and quality control.[771] A comparison of liquid cord blood and heel-puncture blood on filter paper showed that both systems were subject to a small error rate, primarily involving carrier phenotypes, but cord blood testing was more prone to lead to inconclusive results and noncompliance in sample collection.[772] Isoelectric focusing and HPLC have replaced cellulose acetate electrophoresis in most screening programs.[773]

The primary goal of newborn screening for sickle syndromes is reduction of morbidity and mortality by identifying affected infants at birth, referring them to treating centers, initiating prophylactic penicillin early, and providing ongoing care by knowledgeable health professionals.[771] The number of early deaths avoided has been estimated at 0.6 to 1.2/100 births.[774] All cases of suspected disease still must be confirmed with a separate sample from the infant, because clerical errors may be encountered.[772] A common problem is the need to establish a mechanism for educating and counseling parents of carriers detected by testing at birth.[768] Using public health and state genetic program resources, it is possible to provide parents with individual counseling, education, and extended family testing.[775] Prenatal education for expectant mothers, which includes information about newborn sickle cell screening, significantly increases the follow-up rate for infants with sickle cell trait and contributes to a greater retention of information.[776]

Each of these techniques allows the detection of minor Hb components in the presence of large amounts of Hb F. The pattern in infants destined to develop SCA comprises Hb F, a relatively small amount of Hb S, and no Hb A. Neonates who are doubly heterozygous for Hb S and β^0-thalassemia and for Hb S and HPFH have a Hb "FS" separation pattern indistinguishable from that for Hb SS. They may be differentiated by hemoglobinopathy testing of the parents or by repeat testing of the infant at a later age, when the production of HbA_2 will be high enough to allow detection of its elevation above the normal range. Another potential pitfall is misdiagnosis of Hb Sβ^+-thalassemia by incorrect identification of an FS or FAS (sickle cell trait) pattern rather than the correct FSA pattern.[777] Molecular genetic analysis using PCR-based techniques may provide reliable confirmatory testing (e.g., for distinguishing Hb Sβ^0-thalassemia from Hb SS).[778,779] The combination of isoelectric focusing and HPLC also is an effective strategy for dramatically reducing the risk of errors.[780]

Prenatal Diagnosis

The clinical application of recombinant DNA techniques to the prenatal diagnosis of SCA permits a high level of diagnostic accuracy with relatively little risk to the fetus.[781] Guidelines for the ethical application of prenatal diagnosis have been developed,[782] and the use of routinely incorporating screening and counseling into the early prenatal care of populations at risk has been demonstrated.[783]

Initially, prenatal diagnosis required fetal blood sampling. Subsequently developed assays permit the use of DNA prepared from amniotic fluid cells obtained at 15 to 20 weeks' gestation or from a biopsy of chorionic villi obtained at 10 to 12 weeks' gestation. The latter technique is an outpatient procedure that involves passing a catheter through the cervix with ultrasonographic guidance.[784,785] It provides earlier diagnostic information, thereby permitting termination of pregnancy in the first trimester, when it is simpler, safe, and less psychologically stressful. The least invasive method of prenatal diagnosis uses fetal cells from the maternal circulation isolated by a variety of techniques such as flow cytometry.[786] Preimplantation genetic diagnosis (PGD) allows couples who are sickle cell carriers to select unaffected embryos prior to in vitro fertilization. In some cases, PGD has been performed in combination with HLA typing, allowing the delivery of an unaffected child who is also HLA identical to an affected sibling, therefore providing an ideal stem cell donor for the affected child.[787] However, PGD is expensive and has a pregnancy success rate of only 13% to 30%.[787–790] Although prenatal diagnosis of fetuses conceived by couples at risk of having children with sickle cell disease is widely accepted in some countries,[791] use of this technology has been infrequently requested by couples at risk in the United States. Reduction in the rate of affected births has not been observed in the United States, despite genetic counseling efforts by sickle cell programs. Recently Greece has observed a decline in the number of new births with sickle cell disease and thalassemia, which has been attributed to aggressive education and early pregnancy termination.[792]

Several strategies have been used successfully for the analysis of fetal DNA. Methods that involve the use of restriction fragment length polymorphisms are indirect and suitable only for those cases in which the parents at risk can be shown to carry the appropriate linked polymorphism.[793] The most widely used approach is based on the fact that the DNA mutation in the β^S gene is itself a cleavage site for the restriction enzyme Mst II,[794,795] which cleaves DNA at the normal sixth codon and, therefore, generates abnormally long DNA fragments with base mutations involving this codon. Synthetic oligonucleotides that are specific for the b^S nucleotide substitution also permit direct, rapid, and sensitive detection of the β^S gene.[796] The use of the PCR to amplify β-globin sequences enzymatically before restriction enzyme or oligonucleotide analysis greatly increases the sensitivity and speed of the procedure, making it possible to provide genetic diagnoses within a few hours.[796,797] The dot-blot method of allele-specific hybridization uses fixation of PCR-amplified target β-globin DNA to filters and hybridization of the filters with labeled probes complementary to β^A and β^S sequences.[798] Prenatal screening of single-gene disorders from maternal blood is possible using cell-free fetal DNA obtained from maternal plasma.[799]

Treatment

In addition to prophylactic measures aimed at preventing specific complications of sickle cell disease, three treatment options have been used increasingly for overall management: chronic blood transfusion, hydroxyurea, and stem cell transplantation. Gene therapy remains a future goal.

Preventive Measures

Until a safe and widely applicable mechanism for the prevention of intravascular sickling is found, a high priority must be placed on the prevention of complications. Because vaso-occlusive crises are precipitated by infection, fever, dehydration, acidosis, hypoxemia, and cold exposure, measures to prevent or remedy these conditions assume importance. Optimal hydration is essential, especially during febrile illnesses. In estimating fluid requirements, the hyposthenuria of SCA, as well as increased insensible losses, must be considered. Because the liberal use of salicylates imposes an acid load, acetaminophen is the preferred antipyretic. Sudden transition to high altitude and exposure to situations likely to cause chilling should be avoided.

The high risk of overwhelming pneumococcal disease in children mandates the use of penicillin prophylaxis and pneumococcal vaccination. Preventive measures and early medical intervention for febrile illnesses substantially reduce mortality.[386] Effective primary prevention of stroke through the use of TCD screening has been discussed above.

Blood Transfusion

One of the most effective therapeutic measures presently available is the transfusion of normal red cells.[800,801] However, because of the complications of transfusion therapy, it is reserved for selected indications, such as severe anemia, stroke prevention, pregnancy, progressive or recurrent organ damage, preparation for surgery, and certain severe acute vaso-occlusive events. Transfusion therapy facilitates improved blood and tissue oxygenation, reduces the propensity for vaso-occlusion by diluting host cells, and temporarily suppresses the production of red cells containing Hb S. With chronic transfusion support, splenic involution and fibrosis are reversed in some patients.[802] The viscosity of deoxygenated sickle cell blood is disproportionately reduced by the addition of normal red cells. A mixture of one-fourth Hb A cells and three-fourths Hb S cells reduces the viscosity of deoxygenated blood by 50%.[86] Accordingly, the relative number of Hb S-containing cells needs to be reduced only to ~40% to prevent most clinically significant vaso-occlusive events.[803] Replacement of patient cells with donor cells is readily accomplished by a limited exchange transfusion, in which patient blood is removed before or during packed cell transfusion.[804,805] Repeated partial exchange transfusion, which can be performed through erythrocytapheresis, greatly reduces the net gain of iron.[806,807] However, the long-term central venous access, which is often required, may be associated with an unusually high rate of catheter infection, thrombosis, and premature removal of the central line.[808,809] Repeated simple transfusions are probably equally effective in terminating the consequences of in vivo sickling. Packed red cell transfusions at 3- to 4-week intervals generally are sufficient to maintain the relative number of donor cells in the circulation at >70%, but Hb S is more easily suppressed in some patients than others.[810] Furthermore, chronic transfusion may result in recurrent splenomegaly and the additional problem of hypersplenism.[811]

Although it is effective in circumventing the numerous complications of SCA,[812] chronic transfusion therapy is limited by logistic and toxicologic considerations. The requisite commitment of personnel and blood resources is considerable, and the risks of alloimmunization and hemosiderosis are cumulative and potentially life-limiting. Among individuals with SCA, 18% to 36% become alloimmunized, considerably more than with other forms of anemia.[813,814] The greater risk of alloimmunization in SCA is primarily a result of racial differences between the blood donor and recipient populations. The development of multiple antibodies is a relatively common problem;[814] antibodies against C, E, and Kell (K) antigens account for most of the alloantibodies. The use of racially matched and selected minor blood-group antigen-matched blood for chronically transfused patients with sickle cell disease has been recommended to prevent alloimmunization.[812,814] Hemolytic transfusion reactions are associated with as many as 3% of transfusions. Most occur several days after the transfusion and are accompanied by a falling hematocrit, hemoglobinuria, increased jaundice, and, frequently, a pain episode.[216,815] In some cases, a delayed hemolytic transfusion reaction may lead to a fall in Hb level to a level lower than before transfusion, with a life-threatening or fatal outcome resulting from attempts to provide further transfusions.

Iron overload has been an inevitable result if chronic transfusion is not performed by partial exchange methodology, such as erythrocytapheresis. The severity of iron overload has traditionally been monitored with serum ferritin concentration, and there is a strong intrapatient correlation between ferritin levels and volumes transfused.[816] However, there is wide interpatient variability, indicating a need to assess iron stores more directly, such as by liver biopsy, to determine the necessity for iron chelation.[816,817] As little as 10 units of packed red blood cells (PRBCs) per year will increase the liver iron concentration (LIC) obtained by biopsy above 3 mg Fe/g of dry weight liver, the normal upper limit of LIC.[818] Calibration studies have shown excellent correlation between LIC and quantitative MRI (both R2* and R2) at low and moderate LIC values.[819–820,821] These noninvasive MR methods to measure iron levels have improved the clinical management of iron overload in target organs such as the liver and, more recently, the heart.[820,821,822] The superconducting quantum interference device (SQUID) also has been utilized successfully for monitoring liver iron but has limited availability.[823]

With repeated transfusions, iron will accumulate progressively in several organs in addition to the liver, including the heart, pancreas, kidneys, pituitary, and gonads. Iron endocrinopathy and myocardial hemosiderosis have not been as problematic in SCA as in thalassemia major.[507,824] Similarly, liver fibrosis is less common in sickle cell disease than thalassemia major, but does occur.[587,825] Reasons for these differences are not completely understood, but might be related to the age when transfusions are initiated, total cumulative volume of transfusion, differences in iron metabolism (e.g., lower nontransferrin bound iron levels in sickle cell disease), and the chronic inflammatory state of sickle cell disease, which might confer hepcidin-mediated protection against the toxic effects of iron on the tissues.[826,827]

Although chelation with desferrioxamine (Desferal) has reduced organ damage and significantly prolonged life expectancy in transfused thalassemia patients, its use has several serious limitations. The administration of desferrioxamine as a life-long, daily, subcutaneous, or intravenous infusion is cumbersome and has caused logistical hardships that promote inconsistent adherence to treatment.[828] In addition, vision and hearing need to be monitored yearly due to the potential of the drug for ototoxicity and retinal damage.

Deferiprone (L1; Ferriprox), an oral chelator licensed in the United States in 2011, is a small molecule with a short half-life that is believed to have better access to intracellular iron. It is administered three times a day and its side effects are well recognized: agranulocytosis occurring in 0.6/100 patients per year, and, more commonly, transient neutropenia, arthropathy, zinc deficiency, increased transaminase levels, and gastrointestinal symptoms.[829] Encouraging preliminary reports suggestive of effective penetration into cardiac cells prompted a large retrospective study, which showed a significantly lower rate of cardiac death and cardiac events in patients treated by deferiprone (75 mg/kg/day) compared to those treated by standard subcutaneous desferrioxamine.[830] Randomized prospective trials have shown an advantage of deferiprone over desferrioxamine in decreasing myocardial iron as measured by T2* MRI and in improving LV function in thalassemia patients.[831,832]

The tridentate chelator deferasirox (ICL670; Exjade) is given as a single daily oral dose because of its long half-life. The dissolvable powder has a recommended daily dose ranging from 20 to 40 mg/kg/day. Deferasirox was studied extensively in murine models and in adults and children >2 years old,[833,834] and was approved in the United States in 2005 for transfusion-induced iron overload. Several clinical trials have shown its efficacy in reducing LIC, and recent evidence points toward use of higher doses of deferasirox (30 to 40 mg/kg/day) to produce adequate liver iron clearance.[835–837] In addition, there is some evidence to support the efficacy of deferasirox in reducing myocardial iron and improving function.[838–840] However, a comparison in a prospective randomized trial of deferasirox and deferiprone for removing cardiac iron has not been performed. Common side effects of deferasirox included rash (11%) and transient gastrointestinal symptoms (10% to 15%), in addition, many patients complain of unpleasant drug taste (personal communication). The drug combination of an oral chelator and desferrioxamine has been used in patients with thalassemia major and provided improved negative iron balance,[841] but no large trials have been conducted in patients with sickle cell disease. A phase II trial of a new tridentate oral iron chelator, FBS0701, has been completed in adult patients with thalassemia. The drug has also shown efficacy in reducing LIC without serious drug-related side effects.[842] FBS0701 is available in capsule form, potentially reducing the inconvenience of unpalatable taste.

Although oral chelators have the potential to improve therapy for iron overload by improving compliance and therefore clinical response, suboptimal adherence has been reported.[843,844] Current recommendations for the management of iron overload in sickle cell disease are to monitor serum ferritin and LIC (by liver biopsy or MRI) longitudinally, and to initiate iron chelation when LIC becomes ≥7 mg Fe/g of dry weight liver. During ongoing transfusion therapy LIC at least should be maintained between 5 and 7 mg Fe/g of dry weight liver.[845,846]

Indications for Transfusions

Anemia. Anemia with Hb levels as low as 5 g/dl generally is well tolerated and requires no therapy. During hematologic crises, however, the Hb concentration may fall precipitously, requiring rapid correction. An aplastic crisis caused by parvovirus infection often requires a single packed red cell transfusion before erythropoiesis eventually returns. A severe splenic sequestration crisis may require an immediate transfusion to restore blood volume and oxygen-carrying capacity. If the patient does not have an elective splenectomy, chronic transfusion therapy to maintain splenic function has been used as an alternative. However, recurrences of sequestration have occurred despite transfusion.[847] The experimental use of polymerized bovine Hb in adult patients and polymerized human Hb along with erythropoietin in a sickle cell patient with multiple red cell antibodies has been described,[848] but overall evidence of efficacy is lacking and there is concern about effects on NO metabolism.

Progressive Organ Damage. The risks and expense of a long-term transfusion program are justified if progressive or recurrent vaso-occlusive events threaten major organ function.[849] Chronic transfusion therapy minimizes the risk of recurrent or progressive neurologic deterioration in children who have had a stroke.[233,850,851] In addition transfusions have a role in primary stroke prevention.[266] Progressive retinopathy, sickle cell renal disease, and cardiac decompensation may also be arrested with repeated transfusions. Short-term transfusion therapy may be of benefit for a variety of complications, including ACS, pain events, priapism, protracted hematuria, and chronic skin ulcerations.[852]

Surgery. Anesthesia, surgery, and postsurgical convalescence expose patients to the formidable consequences of hypoventilation, hypotension, cooling, dehydration, acidosis, and immobilization. Although recommendations regarding the preparation of patients for surgery have varied, simple transfusions before elective procedures and partial exchange transfusions before emergency surgery have been used.[853] The CSSCD noted a perioperative mortality rate over a 10-year period of 1.1%.[854] A large multicenter prospective trial compared the rates of perioperative complications among patients randomly assigned to receive either an aggressive transfusion regimen (to decrease the Hb S level to <30%) or a conservative regimen (to increase the Hb level to 10 g/dl).[855] Perioperative complications, including ACS, were similar in the two groups except for transfusion-associated complications, which were more common in the aggressively treated group. It was concluded that with good perioperative management, it is unnecessary to reduce markedly the Hb S level before surgery.[855] In a recent national survey of practice in the United Kingdom, it was found that most patients undergoing cholecystectomy and adenoidectomy do so without preoperative blood transfusion, whereas almost all patients undergoing hip arthroplasty are prepared by exchange transfusion.[856] There was no difference in the rate of postoperative complications in patients who received a transfusion and those who did not.[857]

Pregnancy. As do women who are hematologically normal, women with SCA experience a decrease in Hb concentration during pregnancy as a consequence of hemodilution. In general, however, the minor aggravation of anemia is without symptomatic consequence, and no therapy is indicated. However, the final weeks of pregnancy are often complicated by vaso-occlusive events that may have devastating consequences for both mother and fetus. In an attempt to prevent progressive placental infarction and premature delivery, some authors advocate the use of transfusion therapy during the third trimester.[671,858] In the only randomized study of its effectiveness, however, prophylactic transfusion therapy did not have a favorable impact on maternal morbidity (other than a reduction in the number of pain crises) or fetal wastage.[859]

Pharmacotherapy

Hemoglobin F Inducers

Reversal of ontogeny with re-institution of Hb F synthesis[860] is a long-standing objective that appears increasingly attainable. This therapeutic strategy is based on the observation that clinical expression of the sickle gene is prevented by Hb F synthesis in the perinatal period, as well as throughout life in individuals with HPFH.

Initial attempts to augment γ-globin synthesis were based on the observation that DNA in the vicinity of a wide variety of expressed genes is undermethylated relative to the DNA flanking inactive genes.[861,862] 5-Azacytidine, a cytidine analog that blocks DNA methylation, reactivated dormant genes in cultured cells and increased Hb F synthesis in anemic baboons.[863] When given to patients with severe SCA, 5-azacytidine caused a four- to sixfold increase in net γ-globin synthesis, a marked increase in the proportion of reticulocytes containing Hb F (F reticulocytes), and a precipitous decrease in the number of ISCs and dense red cells.[864,865]

Because of the known carcinogenic potential of 5-azacytidine, alternative stimulants of fetal Hb were sought. Hydroxyurea, a cytotoxic drug that has no known effect on DNA methylation, also increases Hb F production in anemic primates[866] and in patients with severe SCA.[867,868] Hydroxyurea preferentially arrests the development of the more mature erythroid precursors, perhaps resulting in the recruitment of earlier erythroid progenitors with a greater capacity for Hb F synthesis.[869] Alternatively, hydroxyurea may have a direct effect on "reprogramming" globin synthesis by early erythroid progenitors, a suggestion that is supported by the fact that the increase in F-reticulocyte numbers

that follows hydroxyurea administration occurs sooner (within 2 to 3 days) than would be expected if the effect represented recovery from bone marrow suppression.[867,868,870] Alterations in the physical properties of red cells produced under the influence of 5-azacytidine and hydroxyurea appear to be out of proportion to modest changes in the level of Hb F. This disparity is attributed in part to reduced β^S-globin synthesis and in part to increased formation of $\alpha 2 g b^S$ tetramers, which do not participate in polymer formation.

Patients taking hydroxyurea consistently develop macrocytosis, which may occur before any change in Hb F takes place (Fig. 33.12). They also show a rapid correction toward normal red cell density distribution and improved whole-blood viscosity. The density profile is characterized by the disappearance of two red cell populations: the densest, most dehydrated, ISC-enriched fraction and the least dense, most hydrated cells.[661] The least dense cells tend to adhere most tenaciously to the endothelium, and the most dense cells are the least deformable. It is possible that these changes in red cell density distribution may be unrelated to the increased Hb F induced by hydroxyurea therapy.[871] Hydroxyurea therapy is associated with the intravascular and intraerythrocytic generation of NO, which may have a role in the clinical response that precedes the improvement in fetal Hb level.[872,873,874]

In 1995, a double-blind multi-institutional trial of hydroxyurea versus placebo (Multicenter Study of Hydroxyurea, MSH trial) in ~300 adults with moderate to severe SCA was concluded with convincing evidence of clinical benefit from the drug.[875] Patients treated with hydroxyurea had ~50% lower rates of pain crises, ACS, hospitalization, and transfusion. There was wide variability in drug tolerance and clinical response, but the primary toxicity and dose-limiting factor was mild neutropenia. In addition to reducing acute events, hydroxyurea therapy has been reported to reduce mortality among adult patients with SCA. Patients with absolute HbF levels above 0.5 g/dl, in response to hydroxyurea therapy, had a 40% reduction in mortality.[876] Data from an extended (17 years of follow-up) nonrandomized prospective study of adults with sickle cell disease in Greece showed that mortality could be reduced by 73% through hydroxyurea therapy.[877] Because of the favorable outcome in the majority of treated patients, hydroxyurea has become widely used in the treatment of adult patients who experience frequent vaso-occlusive crises[878] and was approved by the Federal Drug Administration in the United States for this indication.

A multicenter phase I–II trial indicated that school-aged children treated with hydroxyurea had increases in fetal Hb, Hb concentration, and MCV similar to those of adults and suggested that clinical benefit and toxicity may also be similar.[879–883] Long-term hydroxyurea therapy at a maximum tolerated dose (MTD) (average dose 25 mg/kg/d) was well tolerated by pediatric patients and had sustained hematologic efficacy with apparent long-term safety.[884] Preliminary studies have pointed to a possible beneficial effects on organ function. A return of splenic function was noted in several patients treated with hydroxyurea,[878,885,886] and lack of progression of silent cerebral infarcts was also noted in children.[887] Hydroxyurea can be utilized as an oral solution (100 mg/ml), which is especially convenient for young children.[888] Pilot trials suggested that hydroxyurea with or without concurrent phlebotomy may be substituted for chronic transfusion in the prevention of recurrent stroke;[260,261] however, a randomized phase III trial (SWiTCH study) comparing hydroxyurea versus transfusions did not support this initial observation (see above).[265]

Studies in young children, 6 to 24 months of age at onset of treatment and 2 to 5 years of age, have not indicated unusual toxicity from hydroxyurea.[889,890] Further follow-up of the younger group indicated that after 4 years, hydroxyurea was associated with increased Hb concentration, percentage of Hb F, and MCV, and decreased reticulocytes, WBC, and platelets. In general, infants with SCA tolerated prolonged hydroxyurea therapy with sustained hematologic benefits, fewer ACS events, and improved growth.[891] The phase III randomized placebo-controlled trial for infants (ages 9 to 18 months) with SCA (BABY HUG study) assessed the effect of hydroxyurea therapy on organ dysfunction and clinical complications, and examined laboratory findings and toxic effects.[892] Ninety-six patients received hydroxyurea and 97 placebo. Hydroxyurea significantly decreased pain, dactylitis, ACS, hospitalization rates, and transfusion requirement. Spleen and renal functions were not improved when assessed by ^{99}Tc-spleen scan and^{99} Tc- DTPA clearance, respectively. Analysis of secondary endpoints of the BABY HUG study, however, did show reduction of pitted cell and Howell-Jolly body counts, suggesting improvement of splenic function in the hydroxyurea-treated arm. In addition, urine specific gravity improved and total kidney volume decreased at study exit, suggesting preservation of renal function. Toxicity was limited to mild-to-moderate neutropenia. The positive results of the BABY HUG study warrant consideration of hydroxyurea for all children with SCA.

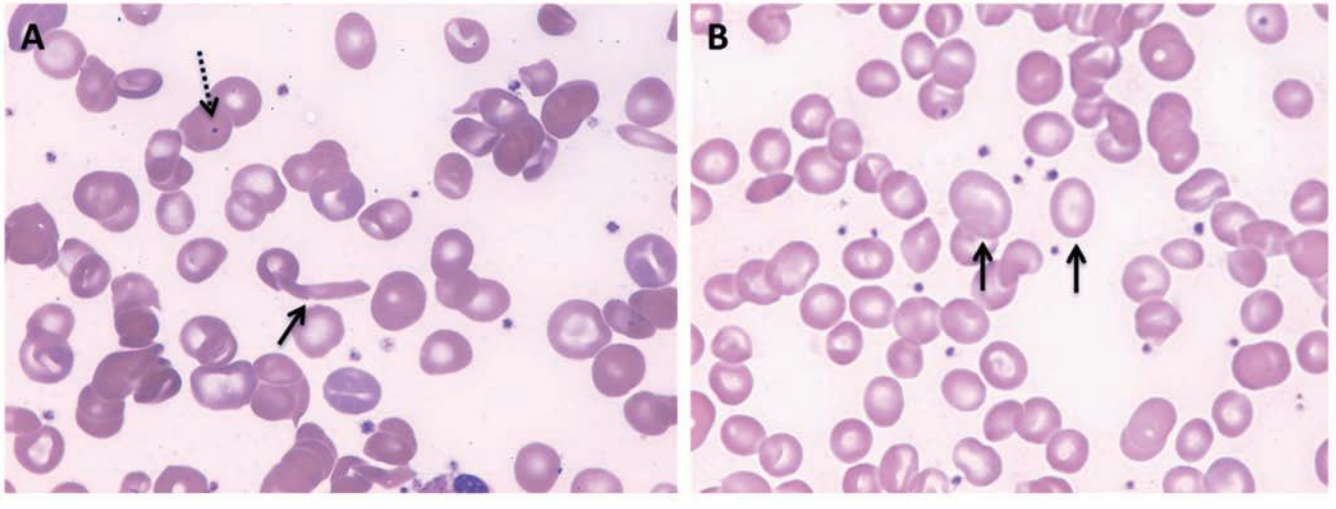

FIGURE 33.12. Effect of hydroxyurea on red blood cells. A. Peripheral blood smear of patient with Hb SS prior to treatment with hydroxyurea showing sickle forms (*solid arrow*), polychromasia, Howell-Jolly body (*dashed arrow*), and anisocytosis. **B.** Peripheral blood smear of same patient after 12 months of hydroxyurea therapy shows significant decrease in number of sickle forms, macrocytosis (*solid arrows*), and decreased polychromasia.

Hydroxyurea has led to weight gain and improved exercise performance in adults[893] and growth in children.[894] A modified dose based on hydroxyurea pharmacokinetics in patients with renal dysfunction has been recommended.[895]

Cross-sectional and prospective studies of hydroxyurea treatment have examined potential acquisition of genotoxicity with chromosomal karyotype, illegitimate VDJ recombination events, white cell cytostasis and cytotoxicity development, and micronucleated reticulocyte formation. These have not shown significant increases in genotoxicity compared with the measurements prior to initiation of therapy or those performed on placebo-controlled sickle cell disease subjects.[896,897,898,899] Although caution about the long-term carcinogenic and teratogenic potential of hydroxyurea needs to be exercised, to date there is no evidence that the drug leads to an increased cancer risk or to congenital anomalies in offspring of women who inadvertently became pregnant while taking hydroxyurea.[900,901] Prediction of fetal Hb response in patients with sickle cell disease receiving hydroxyurea has been difficult,[902] but the multicenter phase I–II trial found that baseline Hb F and Hb concentrations, maximum tolerated dose, compliance, and therapy-related changes in blood counts had predictive value.[903]

Increased levels of Hb F during stress erythropoiesis result from premature maturation of early erythroid progenitor cells under the influence of high concentrations of erythropoietin.[904] In patients with SCA, doses of erythropoietin >1,000 units/kg were shown to increase Hb F levels modestly.[905] In one study, erythropoietin given in combination with hydroxyurea failed to show any additional effect on Hb F production,[906] but another trial in which hydroxyurea was alternated with erythropoietin and supplemental iron did result in a significant further increase in Hb F level.[907] A recent report suggests that erythropoietin therapy may allow more aggressive HU dosing in high-risk sickle cell patients and in the setting of mild renal insufficiency, common to the older sickle cell population.[908] Furthermore, erythropoietin appears to be safe when used in conjunction with hydroxyurea.

Butyrate is a short-chain fatty acid known to induce gene expression by inhibiting histone deacetylase and changing chromatin structure.[909] Butyrate was found to be the likely cause of the delayed γ- to β-globin switch in infants of mothers with poorly controlled diabetes.[910] Subsequently, parenteral infusions of butyrate were shown to augment Hb F production in primates.[911] Short courses of intravenous arginine butyrate administered to children with SCA were associated with increases in F reticulocytes and relative rates of γ-globin synthesis,[912] but administration of the drug over a 10-week period did not demonstrate a hematologic response.[913] Subsequently, intermittent or pulse dosing of butyrate for 4 days at a time resulted in a sustained increase in Hb F in most patients.[914] Oral sodium phenylbutyrate has also been shown to increase fetal Hb levels,[915] as has the antiepileptic drug valproic acid.[916] In a phase II clinical trial of arginine butyrate there was improvement of refractory leg ulcers.[663]

Decitabine, an azacytidine analog (5-aza-2′-deoxycytidine), causes induction of Hb F through DNA hypomethylation.[917] In recent small-scale clinical trials in patients with sickle cell disease, treatment with decitabine resulted in significant increases in mean γ-globin synthesis, Hb F levels, and the number of F cells (RBC that contain Hb F).[917–919] Interestingly, increased Hb F levels were observed in 100% of patients with sickle cell disease who received decitabine, including patients who had previously failed to respond to hydroxyurea.[920] A current clinical trial is testing decitabine in adults with sickle cell disease who do not tolerate hydroxyurea due to hematologic or other toxicities (clinicaltrials.gov # NCT01375608).

Recent findings from GWAS studies have identified BCL11A as a critical modulator of the fetal-to-adult hemoglobin switch in humans and a silencing factor for the γ-globin genes.[745,921,922] Down-regulation of BCL11A results in robust induction of fetal hemoglobin,[921] and suggests developing strategies to down-regulate or inhibit BCL11A function.

Antisickling Agents Acting on Membrane

Poloxamer-188, also known as RheothRx, is a nonionic copolymer emulsifying agent that may counteract the tendency of sickle cells to adhere to endothelium by decreasing the interaction between red cells and fibrinogen.[923] In phase II trials the duration of painful episodes was reduced, particularly in younger patients and in those receiving hydroxyurea.[205,924]

Reduction of Red Cell Density

Therapy designed to reduce the MCHC is based on the fact that small decrements in the MCHC significantly delay the rate of deoxy Hb S polymerization and inhibit red cell sickling. The delay time of gelation of deoxy Hb S is inversely proportional to the 30th power of Hb S concentration.[925] Anecdotal accounts of patients with a low MCHC on the basis of iron deficiency led to the suggestion that symptomatic crises were fewer[926] and red cell survival was longer.[927] One approach to reduction of the MCHC used the long-acting antidiuretic hormone desmopressin, salt restriction, and water loading. When combined, these measures induced sufficient hyponatremia and osmotic swelling of red cells to reduce the MCHC by 2 to 3 g/dl,[928] but clinical testing uncovered problems related to poor compliance, fluctuating levels of serum sodium, neurologic complications, and lack of efficacy.[929]

The Ca^{2+}-activated K^+ channel (Gardos channel) contributes to the deleterious dehydration of sickle cells. One of the membrane-active agents, cetiedil, appears to inhibit sickling by inducing red cell swelling and decreasing the MCHC as a result of inhibiting the Gardos pathway and increasing passive Na^+ influx more than K^+ efflux. In a placebo-controlled study, cetiedil appeared to shorten the duration of pain crises but had no effect on the total analgesic requirement.[204] Clotrimazole and other imidazole antimycotics also prevent sickle cell dehydration by inhibiting the Gardos pathway. In a small group of sickle cell patients, clotrimazole resulted in reduced red cell dehydration, increased cell potassium content, and increased Hb levels.[817] A more potent analog, ICA-17043 (Senicapoc) was developed and shown to decrease the RBC membrane cation permeability by decreasing the Gardos channel activity and calcium-induced K^+ efflux. ICA-17043 was shown to reduce RBC density in mice in comparison with untreated controls, even in the setting of hypoxia-induced RBC dehydration.[930] These preliminary results, coupled with the long half-life of ICA-17043 (allowing once-daily dosing) and minimal side effects, fostered further investigation in a clinical trial of adults with sickle cell disease.[931] A phase II clinical trial randomized 90 adult patients with sickle cell disease to receive a loading dose of 150 mg of ICA-17043 followed by 10 mg daily, a lower loading dose of 100 mg followed by 6 mg daily, or placebo.[206] Study participants were treated for 12 weeks, and hematologic efficacy was demonstrated in the higher dose treatment arm by a significant increase in Hb concentration, and decrease in LDH, bilirubin, reticulocyte count, and dense RBCs. In this phase II study, the activity of the Gardos channel decreased significantly and hemolysis was reduced. However, in a phase III multicenter clinical trial, ICA-17043, failed to reduce the frequency of painful events, leading to an early closure of the study. Because the K–Cl co-transporter is a major determinant of sickle cell dehydration and is inhibited by increasing red cell magnesium, phase I and II trials of oral magnesium pidolate in adult sickle cell patients have been conducted.[932,933] In 10 adult patients with Hb SS, a 4-week course of oral magnesium supplementation (using magnesium pidolate) resulted in increased red cell Mg^{2+} and K^+ concentrations, a reduction in K–Cl co-transport activity, and a decrease in the number of dense Hb SS erythrocytes.[932] A subsequent study on 20 patients with Hb SS involved the administration of magnesium pidolate for 6 months.[933] In this

unblinded study, a reduction in the number of pain crises was noted during the period of magnesium supplementation. In both studies, a significant decrease in red cell density was noted and clinical toxicity was absent except for mild reversible diarrhea. The combination approach of oral hydroxyurea and magnesium treatment was used in children with SCA in a phase I study.[934] The maximum tolerated dose of magnesium pidolate when used in combination with hydroxyurea was 125 mg/kg/day. K–Cl co-transporter activity significantly declined after 3 months of magnesium pidolate.

Anti-inflammatory Agents

Sickle cell disease patients live in a state of "baseline heightened inflammation," which contributes to and sustains the pathophysiologic cycle of vaso-occlusion and tissue damage. Attenuation of the inflammatory response in sickle cell disease could potentially ameliorate symptoms of the disease.

Adenosine is a purine nucleoside that modulates many intracellular processes, such as signal transduction and energy transfer. The concentration of adenosine rises rapidly in response to cellular damage, such as tissue ischemia. Adenosine functions through signaling of four receptor subtypes: A_1, A_{2A}, A_{2B}, and A_3.[935] There is evidence of excessive adenosine signaling in sickle cell disease, as both adenosine and 2,3-diphosphoglycerate (DPG) concentrations were elevated in individuals with sickle cell disease and induce sickling in vitro.[38] Adenosine A_{2A} receptor activation in invariant natural killer T (iNKT) and natural killer (NK) cells reduced inflammation and lung injury in sickle cell mice.[936] A current phase I trial is evaluating the safety and maximum tolerated dose of an adenosine A_{2A} receptor agonist (Lexiscan) in adolescents and adults with SCA (clinicaltrials.gov # NCT01085201).

Adenosine A_{2B} receptor-mediated induction of 2,3-DPG decreases the oxygen binding affinity of Hb and induces erythrocyte sickling (caused by excess adenosine) in cultured human RBCs and in sickle cell disease transgenic mice,[38] suggesting a possible role of excessive adenosine signaling through the A_{2B} receptor in the pathogenesis of sickle cell disease. A_{2A} receptor activation or A_{2B} receptor blocking could be two new avenues of therapy for sickle cell disease that have the potential of reducing its exaggerated inflammatory response.

Bone Marrow (Hematopoietic Stem Cell) Transplantation

Bone marrow transplantation has the potential to normalize Hb synthesis in patients with SCA and is currently the only curative treatment for sickle cell disease. The first transplant was performed in a child with both SCA and acute myeloblastic leukemia in 1984; bone marrow from an HLA-identical sibling abolished both diseases.[937] Since then, hundreds of patients with severe SCA have been transplanted using human leukocyte antigen (HLA)–identical sibling donors. The four largest HLA-matched sibling donor transplant series collectively have shown excellent results, with overall survival ranging from 92% to 94%, event-free survival 82% to 86%, and rejection rate 7% to 13%.[495,938,939,940] The incidence of graft-versus-host disease (GVHD) has varied from 10% to 20%. Treatment-related mortality has ranged from 2% to 7%, and the most common causes of death have been complications of GVHD, sepsis, and stroke (primarily hemorrhagic). These four reports have described myeloablative regiments utilizing pretransplant conditioning regimens of busulfan, methotrexate, cyclophosphamide, and antithymocyte globulin (ATG) in most cases.

Current indications for stem cell transplant in sickle cell disease are broad, but have in common increased disease severity (e.g., stroke, recurrent ACS, intractable pain, red cell alloimmunization, AVN of the hip). Abnormal TCD velocities are another potential indication for transplant, although there is not a consensus among hematologists regarding this.[941]

Previous reports have indicated the effectiveness of conventional stem cell transplants in preventing recurrence of CNS events following transplant.[495] Brain parenchymal damage has been reported in a study of nine children with severe sickle cell disease in whom CNS evaluations were performed serially before and after transplant.[496] Neurologic examinations and neuropsychometric tests were stable, but serial MRI/magnetic resonance angiogram (MRA) studies showed that new brain parenchymal lesions occurred in all seven patients who had pretransplant lacunae or infarcts.

The possibility of infertility is a concern among patients undergoing myeloablative conditioning regimens for stem cell transplant. Recently ovarian stimulation followed by oocyte retrieval and cryopreservation provided fertility preservation in an adolescent with severe sickle cell disease scheduled to undergo a hematopoietic stem cell transplant.[942] This approach, along with sperm banking, can be alternatives for young sickle cell patients who will undergo stem cell transplant and aspire to have families in the future.

The availability and the relative success of bone marrow transplantation worldwide have raised a number of social and ethical questions about its use. For example, how severe must sickle cell disease be to justify a transplant-associated mortality rate of 5% to 10%? In the United States, only 6% of patients with SCA met the criteria for transplantation specified in the study protocol; furthermore, a survey of children with SCA in the San Francisco area estimated that only 18% would have sibling donors.[943] Although these criteria would result in approximately 1% of American children with SCA being eligible for transplantation, criteria used in Belgium were based on the poor prognosis of children with sickle cell disease who were returning to a setting of limited medical care in central Africa.[747] Another point of view has been that transplantation is warranted in virtually all patients for whom a suitable donor is available,[944] particularly before organ dysfunction and transfusion exposure occur. It has been noted that the transplant enrollment criteria parallel those of studies using hydroxyurea treatment.[945] When these two modalities are compared, transplantation offers a definitive cure for SCA but a significant risk of mortality, whereas hydroxyurea offers amelioration of the clinical symptoms with short-term complications that appear to be reversible and small. When transplantation, periodic prophylactic blood transfusion, and hydroxyurea were compared in a decision analysis study for children with severe sickle cell disease, bone marrow transplant was the strategy treatment of choice.[946]

Other approaches to transplantation have been developed outside of sickle cell disease. Cord blood stem cells harvested from HLA-identical newborn sibs, as well as unrelated donors, have been successfully transplanted.[947,948] Directed donor banking of cord blood from a sibling of a child with a disorder treatable by stem cell transplantation provided a cord blood allograft that was successful in 16 of 17 cases.[949] Unrelated donor cord blood stem cell transplants, on the other hand, have not had favorable outcomes, likely due to the HLA mismatches that result from ethnic and racial differences between donors and recipients.[950,951]

When stable mixed chimerism is established after stem cell transplant, even a minority of donor cells with a selective advantage may overcome a genetic defect. In an analysis of 50 patients with successful allografts, five had chimerism with a relatively low proportion of donor cells (range, 11% to 74%). These five patients had normal Hb levels and much lower Hb S fractions than the proportion of donor chimerism, suggesting that donor erythroid progenitors or erythrocytes had a survival advantage over their recipient sickle cell counterparts.[952] Because these patients were also clinically asymptomatic, it appears that full-donor chimerism is not necessary to cure nonmalignant disorders, and reduced intensity regimens that allow mixed chimerism may be effective.[952,953] In fact, reduced intensity stem cell transplantation

from matched donors has been described in 10 adults with sickle cell disease, and sustainable marrow engraftment with stable mixed chimerism was achieved in 9 out of the 10 subjects. This regimen utilized low-dose total body irradiation, alemtuzumab, and sirolimus, and appears to be a viable option for patients who would otherwise not be able to tolerate an aggressive conditioning regimen.[954]

Worldwide, hematopoietic stem cell transplant is underutilized in patients with sickle cell disease, a multifactorial phenomenon resulting from high costs, lack of expertise, lack of available HLA-matched donors, insufficient referral to transplant centers, and increased use of disease-modifying therapies (hydroxyurea, erythrocyte transfusions) among other reasons. Therapy preference and decision making among patients with severe SCA and their families was analyzed after they received standardized nondirective presentations and educational materials. Ten percent expressed preference for stem cell transplant, 17% for chronic transfusion, and 70% for hydroxyurea.[955] However, many patients and families still perceive this treatment to be dangerous in comparison with other therapies, such as hydroxyurea and chronic transfusions, and choose not to pursue transplant even when a matched HLA sibling donor is available.[955,956]

Gene Therapy

Gene therapy offers great promise as a potential cure for sickle cell disease, but there are currently concerns about random genomic insertion that must be resolved.[957] In the past, low efficiency of gene transfer to stem cells and suboptimal globin gene expression, as well as safety concerns, have limited progress. The insertion of a therapeutic globin gene does not necessarily confer selective advantage to transduced stem cells, therefore complex DNA regulatory sequences have to be preset within the transfer vector for proper gene expression. Recent use of lentiviral vectors derived from the HIV genome have allowed more efficient transduction of human cells. Two transgenic mouse strains with human SS disease have been transduced using lentiviral vectors using globin genes linked to regulatory elements of the LCR, resulting in reduced sickling, improved renal-concentrating capacity, and human β-globin synthesis at 10% to 50% of the level of endogenous β-globin production.[958] Proof of concept of gene therapy as a viable strategy for hemolgobinopathies has been shown in an adult with thalassemia (HbEβ^0-thalassemia) who has remained transfusion-independent 33 months after lentiviral β-globin gene transfer.[959]

SICKLE CELL TRAIT

Sickle cell trait, the heterozygous state for the Hb S gene, is present in ~8% of black Americans and in as many as 20% of some African populations (Table 33.1). The red cells of such individuals contain both Hb A and Hb S, but there is always more Hb A than Hb S.

Clinical Features

Sickle cell trait is known to confer a better prognosis from malarial infection.[960] It rarely is associated with clinical or hematologic manifestations of significance. Individuals have no anemia, and red cell morphology is normal. Growth and development proceed normally,[961] and no increased frequency of bone and joint disease is observed.[962] A prospective study of pregnant women with sickle cell trait documented an overall incidence of complications and a distribution of birth weights similar to those of a control group.[963] Life expectancy and overall mortality rate for persons with sickle cell trait are the same as for the general population. The prevalence of the trait among professional football players is the same as that in the black population, suggesting that it imposes no limitation in physical capabilities.[964] Nevertheless, most of the complications associated with SCA have been described in individuals with sickle cell trait. In such reports, the presence of Hb S was likely an incidental finding, unrelated to the observed deficit. For example, studies of sudden death in soldiers and athletes undergoing strenuous physical conditioning lack pertinent information concerning the relative amounts of Hb A and Hb S and the presence of potential but undetected underlying illness.[965,966] Nevertheless, a comprehensive analysis of sudden unexplained deaths among more than 2 million recruits undergoing basic training in the United States Armed Forces demonstrated a small increase of such deaths, especially those related to exertional heat illness (EHI), in association with sickle cell trait.[967] Following this finding, an interventional trial examined the hypothesis that preventing EHI would reduce mortality for all recruits, including those with sickle cell trait.[968,969] The intervention consisted of monitoring of core temperature, minimizing efforts in hot weather, increasing water consumption, and use of light clothing, among other measures. No deaths among individuals with or without sickle cell trait were observed when precautionary measures were undertaken, which was a significant decline from the predicted 13 deaths among recruits with sickle cell trait. Currently, sickle cell trait is not a disqualifying condition for entry into the United States Armed Forces, and universal precautions against EHI have been fully implemented.

A study of almost 2 million National Collegiate Athletic Association (NCAA) athletes found 273 deaths between 2004 and 2008, with five (2%) of these deaths occurring in athletes with the sickle cell trait, all in association with heat exertion (exertional deaths).[970] The study concluded that the risk of exertional death was 37 times greater in athletes with sickle cell trait than that among those without it. This study, however, did not have information of the sickle cell trait status of the entire cohort, and estimated trait prevalence based on prior epidemiologic studies (1:12 African Americans are sickle cell trait carriers). The results of this study prompted the NCAA to adopt a policy requiring Division I institutions to perform testing for sickle cell trait in all incoming athletes in the United States. Because the risk under even the most adverse circumstances is low (1 in 3,200 in the Armed Forces study), it is important that the millions of black individuals, including aspiring athletes, with sickle cell trait not be stigmatized or labeled as sick. Due to this concern, the American Society of Hematology (ASH) released a statement in 2012 opposing testing or disclosure of sickle cell trait status as a prerequisite for participation in athletic activities. This position was subsequently adopted by the Sickle Cell Disease Association of America (SCDAA) among other professional societies.

Other complications of the trait are well documented but relatively rare: hematuria, urinary tract infection, and splenic infarction. The former generally is transient and probably is related to poor perfusion of the renal papillae.[588,607,971] Frank renal papillary necrosis has been described.[604] Renal medullary carcinoma is a rare malignancy of the renal medulla; most of the reported cases have occurred in individuals with sickle cell trait.[606,972] Urine-concentrating ability also is impaired, although renal acidification is normal.[973] A Jamaican study of older adult women showed an increased frequency of bacteriuria in those with sickle cell trait.[974] During pregnancy, women with sickle cell trait have increases in bacteriuria and pyelonephritis.[975] There are numerous reports of splenic infarction in individuals with sickle cell trait who were exposed to altitudes of 10,000 feet or more in unpressurized aircraft, but this has not been reported in commercial flights, in which cabin pressure is equivalent to ~8,000 feet.[976] Individuals with sickle cell trait, especially whites, have suffered splenic infarction at mountain altitudes.[977] Most individuals with sickle cell trait, however, tolerate simulated high

altitude with impunity.[978] A case control study identified sickle cell trait as a risk factor for venous thromboembolism;[979] however, further investigation linking thrombosis risk and sickle cell trait is necessary to establish this association.

Diagnosis

Sickle cell trait is characterized by an electrophoretic pattern containing both Hb A and Hb S, with more Hb A than Hb S. The interaction of α-thalassemia with sickle cell trait is responsible for a trimodal distribution of Hb S with means of ~41%, 35%, and 28%, corresponding to the $\alpha\alpha/\alpha\alpha$, $-\alpha/\alpha\alpha$, and $-\alpha/-\alpha$ genotypes, respectively.[980,981] The positive correlation between the proportion of Hb S and the output of α genes indicates the greater affinity of β^A chains than of β^S chains for α chains in the formation of Hb tetramers. Excess β^S chains presumably are destroyed by proteolysis.[982] The relative amount of Hb S is also decreased by iron[983] and folate[984] deficiencies.

Screening Programs

There are two possible reasons to screen groups for the presence of sickle cell trait: (a) to inform affected persons of health risks and (b) to provide information that might affect an individual's reproductive decisions. Most hemoglobinopathy screening is now done to identify sickle cell disease in neonates. Therefore, identification of sickle cell trait occurs at a time when counseling of the affected individual is impossible. Counseling of family members of newborns with sickle cell trait may be of value but is only performed sporadically in most states.

The technique chosen for screening should be genetically diagnostic and should clearly differentiate between sickle cell trait and those disorders of Hb that have implications for health. Conventional Hb electrophoresis [985] and thin-layer isoelectric focusing on acrylamide gel[986] and high-performance liquid chromatography have been adapted satisfactorily to mass screening. Because solubility tests do not detect β-thalassemia trait, Hb C, and other Hb variants that interact with Hb S to cause disease, they should not be used for screening.

OTHER SICKLING SYNDROMES

Several of the doubly heterozygous states for Hb S and a second disorder of Hb synthesis are characterized by clinical and hematologic aberrations that to some extent mimic the features of SCA. The clinically significant disorders resulting from double heterozygosity for Hb S and a second Hb variant are considered to be forms of sickle cell disease.

Hemoglobin SC Disease

The sickling disorder known as *hemoglobin SC disease* results from the inheritance of an Hb S gene from one parent and an Hb C gene from the other parent. Red cells contain approximately equal amounts of the two hemoglobins. Hb A is absent, and Hb F is normal or slightly increased. The disorder occurs with an approximate frequency of 1 in 1,100 births among black Americans[767] and 1 in 1,400 births in Jamaica.[987] In Ghana, the presumed site of origin of the Hb C mutation,[988] Hb SC disease is as prevalent as SCA, and in some regions it affects as many as 25% of the population.[1]

The clinical and laboratory features of Hb SC disease cannot be explained by co-polymerization of Hb C with Hb S.[989] The solubility of mixtures of deoxy Hb S and Hb C is no different from that of mixtures of Hb S and Hb A.[990] Differences in the sickling properties of sickle trait cells and Hb SC cells are related to two factors: a higher proportion of Hb S and a higher concentration of hemoglobin in Hb SC cells compared with Hb AS cells.[989,991] The 10%-to-15% greater proportion of Hb S in Hb SC cells is the result of differences in rates of subunit assembly, which, in turn, are determined by the net surface charges of β^A, β^S, and β^C.[989] The higher MCHC of Hb SC cells is the result of Hb C inducing, by mechanisms not fully understood, an increase in the activity of K–Cl co-transport, which causes loss of K^+ and consequently of intracellular water.[992]

Clinical Features

The clinical manifestations of Hb SC disease are similar to, but on average less frequent than, those of SCA.[14,992] Growth and sexual development are delayed compared to normal children, but less so than in children with SCA.[435] Symptoms in the first year are rare, and one fourth of affected individuals remain asymptomatic throughout the first decade of life.[992,993] The most common symptom is episodic abdominal or skeletal pain, qualitatively similar to that caused by vaso-occlusive events in SCA. The average number of painful episodes per year for Hb SC patients is approximately one half that for persons with SCA (0.4 vs. 0.8 episodes per year).[184] Moderate enlargement of the spleen is present in approximately two thirds of children and often persists into adult life. Spleen perfusion is intact, however, and as a result, symptomatic splenic infarction[994] and acute splenic sequestration[995–997] may occur in adults as well as in children. Loss of spleen function is more gradual and occurs at a later age than occurs in SCA.[178] The frequency of infections of patients with Hb SC disease is increased, but fatal pneumococcal septicemia, although well documented,[998] is less of a risk than is noted in SCA.[999] In contrast to the infectious complications of SCA, those of Hb SC disease are characteristically associated with a primary focus, tend not to recur, and respond promptly to therapy.[1000,1001] *S. pneumoniae* is the most common bacterial isolate, and the respiratory tract is the most common focus.[1000–1002] The incidence of bacteremia drops abruptly after 2 years of age, a contrasting pattern to SCA, in which the incidence declines gradually between 2 and 6 years of age.[387] Because bacteremia rarely progresses to septicemia and a fatal outcome in young children with Hb SC disease, some investigators believe that prophylactic penicillin is not necessary.[414] However, fatal pneumococcal septicemia was reported in a series of seven children with Hb SC, six of whom were >3 years of age.[1003] Central nervous system deficits, asymptomatic hematuria, ankle ulceration, priapism, and other complications of sickling occur with Hb SC disease but are infrequent events. In the United States, the median lifespan for male and female Hb SC patients is 60 and 68 years of age, respectively.[143]

Because of the frequency with which they occur, certain complications of Hb SC disease deserve special comment. Proliferative retinopathy is more common and more severe than in SCA.[641,643,644] Progressive loss of vision may have its onset early in the second decade, and patients should be encouraged to have an annual ophthalmologic examination starting at 10 years of age. Aseptic necrosis of the femoral head has been reported to have a greater frequency in Hb SC disease than in Hb SS, but the age-adjusted prevalence is lower.[452] ACS, attributed to fat emboli after bone marrow infarction, occurs most commonly during the final months of pregnancy[1004,1005] in women with Hb SC. The exaggerated vulnerability of individuals with Hb SC disease to certain complications is thought to be a function of the higher viscosity of the blood relative to that in SCA. Two analyses of adults with Hb SC disease[688,1006] have re-emphasized the common clinical features of pain crises, avascular necrosis of the hip, proliferative sickle retinopathy, and splenic infarction/sequestration. In one series, it was noted that co-morbidity of obesity, hypertension, and type 2 diabetes mellitus were common.[1006] In the other, decreased morbidity was noted in patients who had concurrent α-thalassemia 2.[688]

Moderately severe complications of in vivo sickling occur in Hb SC-Harlem disease[1007] and in the Hb SC/α-thalassemia syndrome.[1008] Combined Hb SC disease and hereditary spherocytosis was documented as the cause of recurrent splenic sequestration crises.[1009]

Laboratory Features

Anemia is mild or nonexistent; 75% of children 2 to 15 years of age have a hematocrit between 28 and 38, and 75% of adults have a hematocrit between 28 and 42 (with males having higher levels than females).[749] Compared with Hb SS, the MCV may be decreased (10 to 15 fl lower), and the MCHC may be increased owing to cellular dehydration.[749,1010] Reticulocytes are modestly increased in number. Blood films contain as many as 50% target cells. Although sickled cells are relatively rare, cells containing Hb "crystals" are noted regularly.[1011] These hyperchromic shrunken cells are distorted into pyramidal or elongated contours by condensed aggregates of Hb (Fig. 33.11). The white blood cell count and leukocyte differential are normal.[139]

Treatment

Unlike the extensive investigations of the use of hydroxyurea in adults and children with Hb SS, data in patients with Hb SC disease are lacking. One study involving six adult Hb SC disease patients noted that hydroxyurea resulted in an increase in hematocrit and MCV, improved cell hydration, and no significant difference in Hb F level.[1012] In a study of six severely affected children with Hb SC disease, MCV and Hb F increased, and patients improved clinically, but Hb concentration did not change after hydroxyurea treatment.[1013] One symptomatic patient with a high hematocrit responded to recurrent phlebotomy.[1014] The first randomized clinical trial specifically targeting individuals with Hb SC was a phase II multicenter double-blinded trial comparing the effects of hydroxyurea and magnesium (pidolate).[1015] Subjects were randomized to hydroxyurea + placebo, magnesium + placebo, hydroxyurea + magnesium, or placebo + placebo. The primary endpoint was the proportion of hyperdense red blood cells after 8 weeks of treatment. Thirty-six subjects were evaluable, but the study was terminated early because of slow enrollment. In the combined hydroxyurea groups, MCV and HbF were increased, but differences were not seen in hyperdense red cells or vaso-occlusive events.

Hemoglobin S–β-Thalassemia

The doubly heterozygous condition of Hb S and β-thalassemia is designated as Sβ^0-thalassemia if there is no β-globin synthesis from the affected allele and Sβ^+-thalassemia if β-globin synthesis is present but reduced. The clinical manifestations are quite variable, and patients may be nearly asymptomatic or have problems similar to those occurring in the worst cases of SCA.[1016] In general, Hb Sβ^0-thalassemia resembles Hb SS in severity (and therefore is sometimes included under the designation "sickle cell anemia"), and Hb S β^+-thalassemia is somewhat milder than Hb SC disease. Patients with Hb Sβ^0-thalassemia have a slightly higher Hb level, a greater Hb A_2 level (4% to 6%), and a smaller MCV (65 to 75 fl) than those with Hb SS. Hb Sβ^+-thalassemia patients have a higher Hb level and lower reticulocyte count than those with Hb Sβ^0-thalassemia.[1016,1017] In children with Hb Sβ^0-thalassemia, splenic dysfunction measured by pit cell counts occurs within the first year of life, but only 20% of those with Hb Sβ^+-thalassemia have elevated pit counts by 20 years of age.[1018] Patients with Hb Sβ^+-thalassemia, unlike those with SCA, often have splenomegaly beyond the first few years of childhood.

Hemoglobin S/Hereditary Persistence of Fetal Hemoglobin

In HPFH, Hb F levels are elevated relative to the patient's age. Deletional mutations typically involve large segments of DNA and result in a pancellular distribution of Hb F. Approximately 1 in 1,000 African Americans carry the deletion HPFH gene. Nondeletion mutations result in more variable levels of Hb F (4% to 30%) and heterocellular or pancellular distribution. The doubly heterozygous condition for Hb S and HPFH results in a heterogeneous disorder that is generally extremely mild and associated with a pancellular distribution of Hb F, normal blood counts, microcytosis, target cells, and 20% to 30% Hb F.[14,30,31] Overall, there is ~1 case of Hb S/HPFH for every 100 cases of Hb SS, but it is important to identify this condition because of its extremely good prognosis.

Hemoglobin SE Disease

Hb E is characterized by the substitution of lysine for glutamic acid at position 26 of the β chain and results in a mild β-thalassemia phenotype. Because of the increase in the Asian population in the United States, the doubly heterozygous condition of Hb SE is now occasionally seen. Patients with Hb SE may have mild anemia and microcytosis along with ~30% Hb E, but blood smears look relatively normal (except for target cells), and patients are usually asymptomatic.[31,1019]

Hemoglobin SD Disease

Of the 16 variants fulfilling the electrophoretic and solubility criteria for Hb D or Hb G, at least nine have been recognized in association with Hb S.[1020] With one exception, the doubly heterozygous states for Hb S and Hb D or Hb G are clinically silent. Hb D-Punjab (Hb D-Los Angeles) interacts with Hb S to produce mild hemolytic anemia and symptoms that mimic those of mild sickle cell disease. The Hb SD-Punjab syndrome was first detected in a Caucasian man[1021] whose case had been previously reported as an instance of SCA in the white race. Subsequently, Hb SD-Punjab disease was recognized in a number of subjects, most of African origin.[1022,1023] In each of these subjects, the clinical and hematologic features were those of mild sickle cell disease. Elevation of Hb F, however, is not protective among individuals with Hb SD as it is for those with Hb SS. For example, in Middle Eastern Kuwaiti sickle cell patients, elevated Hb F level was not protective against pain events in patients with Hb SD.[1024]

Hemoglobin SO-Arab Disease

Hb O-Arab interacts strongly with Hb S in vitro. As would be predicted, the doubly heterozygous state is clinically and hematologically indistinguishable from SCA.[27,1025,1026] Functional asplenia occurs at an early age and is followed by progressive splenic infarction. The disorder is differentiated readily from Hb SC disease, with which it is confused on electrophoretic grounds, by the greater prominence of symptoms, the severity of the anemia, and the presence of numerous ISCs on blood smears.[1027]

Hemoglobin C Disorders

In Hb C, lysine replaces glutamic acid in the sixth position of the β-chain. The positive charge resulting from this substitution gives the variant a slow electrophoretic mobility at both an acid and an alkaline pH. This variant appears to have originated on the west coast of Africa,[1027] where the carrier rate is as high as 25%. Although less convincing than for Hb S, the distribution of Hb C in Africa suggests that it also may have conferred a survival advantage in areas endemic for malaria. Among the Dogon of West Africa, where the gene frequency of Hb C is high and

that of Hb S is low, cerebral malaria and other forms of severe malaria are uncommon in those having Hb C.[1028] Although not providing full protection against malaria, Hb C appears to minimize the risk of severe infection. These clinical observations are supported by in vitro studies that demonstrate the inability of Hb CC red cells to release merozoites by cell lysis at the appropriate stage of parasite development.[1029] The heterozygous state is noted in 2% to 3% of blacks, and homozygous Hb C disease affects ~1 in 5,000.[13] As with Hb S, Hb C has been identified in individuals with no known African ancestry.[1030] The β^C gene can be identified in fetal DNA by using restriction fragment length polymorphisms[725] and by sequence-specific oligonucleotide probes.[1031]

Hemoglobin C Trait

The heterozygous state for Hb C (Hb AC) is clinically silent. Although the hemoglobin concentration is within the broad range of normal, the mean for groups of subjects is low. The red cell mass and red cell survival also may be decreased.[1032] Reticulocyte numbers, however, are not increased. The physiologic basis for the apparent failure of appropriate erythropoietic response to shortened cell survival is probably similar to that operative in Hb CC disease. The peripheral blood smear contains moderate numbers (5% to 30%) of target cells. By electrophoretic analysis, 30% to 40% of the hemoglobin is Hb C, and 50% to 60% is Hb A; Hb A_2 (separated chromatographically) is increased slightly. The relative amount of Hb C with coexistent α-thalassemia is less, reflecting the higher affinity of β^A-compared with β^C-globin for limited amounts of α-globin during hemoglobin assembly.[1033]

Hemoglobin C Disease

Hemoglobin C disease (Hb CC) is a mild disorder that characteristically is detected through newborn hemoglobinopathy screening programs or during the investigation of an unrelated medical problem.[1034] Growth and development are appropriate, and pregnancy and surgery are well tolerated. Mild intermittent abdominal discomfort, arthralgia, and headaches are noted in some reports, but their relationship to the hemoglobinopathy, if any, is unclear. The spleen is enlarged in many affected individuals, and spontaneous rupture of the organ has been reported.[1035] Spleen function is unaffected, however, and unusual infectious problems are not observed. As with other hemolytic disorders, cholelithiasis occurs with increased frequency.

Anemia is mild to moderate in severity.[1036] The mean packed cell volume is 33%; individual values often fall within the normal range. Reticulocyte counts are elevated only slightly (2% to 6%). Erythrocyte morphology is strikingly abnormal, with microcytosis, target cells (≥90%), occasional spherocytes, and cells distorted by what appear to be crystals of hemoglobin.[1011,1037] Target cells appear more plump and smaller in diameter than those seen in individuals with liver disease, although their resistance to osmotic lysis is similar to that of other target cells.[1037] Red blood cell survival is shortened with evidence of splenic sequestration. Considering the relative indolence of the hemolytic process, it is surprising that anemia is not fully compensated by a greater erythropoietic effort. This apparent inconsistency is explained by a decrease in the oxygen affinity of hemoglobin of Hb CC erythrocytes, which have an intracellular pH lower than that of normal cells.[1038] The right-shifted oxygen dissociation curve of whole blood permits normal tissue oxygenation in spite of a smaller than normal red blood cell mass. Shortened red cell survival probably is related to the decreased solubility of deoxy-Hb C, a consequence of electrostatic interactions between positively charged β-6 amino groups and negatively charged groups on adjacent molecules.[1037] When suspended in hypertonic medium, Hb CC cells form intracellular crystals, a process that begins along the membrane[1039] and is enhanced by deoxygenation.[1037] Intracellular aggregates of hemoglobin limit cell deformability by increasing internal viscosity,[1040] thereby predisposing to fragmentation, spherocyte formation, and splenic sequestration. Diagnosis rests on the electrophoretic or chromatographic analysis of hemoglobin. The major fraction is Hb C, Hb A is absent, and Hb F is slightly increased. Relatively more Hb F (to 22%) is present in individuals who have coexistent Hb CC disease and α-thalassemia.[1041] Therapy is neither available nor needed; however, genetic counseling and clinical monitoring are advised.

KEY POINTS

1. Sickle cell disease is a common worldwide genetic disorder with an autosomal recessive pattern.
2. Sickle cell disease is a chronic condition with intermittent and unpredictable acute vaso-occlusive episodes (e.g., pain, ACS, splenic sequestration, priapism, etc.).
3. The most common and also the most severe genotype is Hb SS (sickle cell anemia). HbSβ^0-thalassemia is frequently classified with Hb SS due to its similar phenotype.
4. Pathophysiology involves a complex intertwined array of processes including vaso-occlusion in the microcirculation, hypoxia-reperfusion injury, chronic hemolysis, increased endothelial adhesion, hypercoagulability, and enhanced inflammatory response.
5. All tissues can be affected, causing progressive organ dysfunction and eventually organ failure.
6. The overall survival in sickle cell disease has improved in the last few decades due to early diagnosis, prophylaxis against infection, and use of disease-modifying therapies.
7. Effective therapies include hydroxyurea, chronic blood transfusion, and stem cell transplantation.

WEBSITES OF INTEREST

The following websites offer useful information about sickle cell disease, both for patients and medical providers:

- **www.NHLBI.gov**
- **www.CDC.gov**
- **www.SCDAA.org**

The website www.clinicaltrials.gov offers information about prospective clinical trials. Using the search option, trials investigating sickle cell disease can be retrieved. In addition to these websites, two textbooks offer particularly extensive information about sickle cell disease.[14,1042]

CHAPTER 34

THALASSEMIAS AND RELATED DISORDERS: QUANTITATIVE DISORDERS OF HEMOGLOBIN SYNTHESIS

Caterina Borgna-Pignatti, Renzo Galanello*

The thalassemias are a group of congenital anemias that have in common deficient synthesis of one or more of the globin subunits of the normal human hemoglobins (Hbs). The primary defect is usually quantitative, consisting of the reduced or absent synthesis of normal globin chains, but there are mutations resulting in structural variants produced at reduced rate (e.g., HbE, Hb Lepore) and mutations producing hyperunstable hemoglobin variants with a thalassemia phenotype (thalassemic hemoglobinopathies). Therefore, a rigid differentiation from the qualitative changes of hemoglobin structure that characterize the hemoglobinopathies is no longer appropriate. According to the chain whose synthesis is impaired, the most common thalassemias are called α-, β-, γ-, or $\delta\beta$-thalassemias. These subgroups have in common an imbalanced globin synthesis, with the consequence that the globin produced in excess is responsible for ineffective erythropoiesis (intramedullary destruction of erythroid precursors) and hemolysis (peripheral destruction of red cells). In the last few years, the advances of DNA analysis have permitted understanding the basic aspects of gene structure and function and the characterization of the molecular basis for deficient globin synthesis. The thalassemias result from the effect of a large number of different molecular defects, which may interact, leading to a variety of clinical and hematologic phenotypes.

PREVALENCE, GEOGRAPHIC DISTRIBUTION, AND THE ROLE OF MALARIA

Thalassemia is considered one of the most common genetic disorders worldwide. It occurs in a particularly high frequency in a broad belt extending from the Mediterranean basin through the Middle East, Indian subcontinent, Burma, Southeast Asia, Melanesia, and the islands of the Pacific. According to data collected through the Hereditary Disease Program of the World Health Organization and based on local surveys and reports by visiting experts, the carriers of hemoglobin disorders in the world are estimated to be 269 million.[1] Recent global epidemiologic data on the demographics and prevalence of hemoglobinopathies have established that these disorders represent a significant health problem in 71% of 229 countries and that around 1.1% of couples worldwide are at risk for having children with a hemoglobin disorder.[2] From data available it has been estimated that the annual number of births is 22,989 for β-thalassemia major; 5,183 for Hb Bart hydrops fetalis syndrome; 9,568 for hemoglobin H disease (the intermediate form of α-thalassemia); and 19,128 for HbE/β-thalassemia.[2,3]

Diseases caused by α-thalassemia are encountered commonly in Southeast Asia and China with up to 40% of the regional population being carriers, and less commonly in India, Kuwait, the Middle East, Greece, Italy, and Northern Europe.[4] Southeast Asia is the area of the world where the frequency of α-thalassemia is so high as to cause a major public health problem, because of the increased number of patients with severe HbH disease and fetuses with Hb Bart hydrops fetalis. In the eastern oasis of Saudi Arabia, more than 50% of the population appears to have a clinically silent form of α-thalassemia, and HbH disease is recognized with increasing frequency.[5] In a random population sample, the gene frequency of deletion-type α-thalassemia-2 (-α) was 0.18 in Sardinians and 0.07 in Greek Cypriots; the occurrence of nondeletion α-thalassemia is estimated to be one-third that of the deletion-type.[6] In African-Americans, α-thalassemia is relatively common, but rarely is it of clinical significance. Of 211 healthy African-Americans in whom the α-globin genotype was characterized, 27.5% lacked a single α-globin gene, and 1.9% lacked two of the four α-globin genes.[7] With the rise in Asian immigration to North America over the past few decades the prevalence of α-thalassemia and other hemoglobinopathies has increased steadily.[8] The epidemiologic changes in the prevalence of hemoglobin disorders have important implications for public health programs, including new laboratory strategies, newborn screening, counseling, and patient management.[9,10] About 3% of the world's population (150 million people) carry β-thalassemia genes. In Europe they are particularly prevalent in inhabitants of Italy and Greece. In Italy, the highest prevalence of the carrier state, in descending order, has been found in Sardinia (10.3%), the Delta region of the Po River near Ferrara (8%), and Sicily (5.9% with an almost equal distribution over the entire island).[11,12,13] In Greece, the prevalence varies considerably, ranging from <5% to nearly 15% in the southern and central areas.[32,33] In Cyprus, one individual in seven is a carrier of β-thalassemia and one individual in 1,000 is currently homozygous.[1] In Sardinia the incidence of homozygous β-thalassemia is 1 in 250 live births. There are an estimated 3,500 individuals with thalassemia major in Greece and 4,300 in Italy[14] (Cianciulli personal communication). β-Thalassemia is encountered less often in the northern and western parts of Africa. In the Maghreb (African countries opening on the Mediterranean) frequencies vary from 3% in Algeria to 7% in Morocco and Lybia.[15] In Egypt, thalassemia represents a serious health problem, with a predicted 1,000 new patients born each year.[16] In Turkey, the frequency varies from 0.8% to 10.8%.[17] It has been described in high frequencies (10% to 20%) in Indian and Kurdish Jews.[18] In Arabs it averages 2%.[19] Few data are available for Pakistan.[20] Among Indians, frequencies between 3.5% and 14.9% have been reported.[21] In North America, thalassemia used to affect mainly individuals of Mediterranean origin and African-Americans, but is, at present, most frequently observed in Asians. In fact, increases in Asian immigration and births in the United States, particularly in California, have led to a prevalence rate of HbE/β-thalassemia among Southeast Asians of ~1 in 2,200.[22] In one survey of healthy black men, heterozygous β-thalassemia was documented in 1.4%.[23] β-Thalassemia in Jamaica may have its origin in both the African and Asian immigrant populations.[24] In sporadic cases, β-thalassemia has been noted in Northern Europeans with no apparent Mediterranean or Asian ancestry.[15] Although well documented in natives of Southeast Asia and southern China, β-thalassemia is far less prevalent in these regions than is α-thalassemia.[25] HbE, the hallmark of Southeast Asia, is most frequently found at the border of Thailand, Laos, and Cambodia, where the frequencies may reach 50% to 60%. In Great Britain, which today is a multiethnic society due to substantial

Dedication: We wish to dedicate this chapter to Rino Vullo and Antonio Cao who passed away on June 22, 2010, and June 21, 2012, respectively.
Rino Vullo in Ferrara and Antonio Cao in Cagliari pioneered a new way of approaching thalassemia, believing in the power of science to change the fate of what was considered for many decades a hopeless disease. Their scientific and human contributions will remain in the history of hematology.
*Dr. Renzo Galanello died on May 13, 2013. He was a pediatrician, a hematologist and a geneticist of enormous competence. We will miss his enthusiastic approach to science, to medicine, to life itself.

migration from Cyprus, the Indian subcontinent, Southeast Asia, and the Middle East, it is estimated that 0.37 per 1,000 fetuses have a major hemoglobin disorder, 20% being thalassemias and 80% being sickle cell disease. A formal patient register was also recently established in Great Britain in 1997. At the end of 1999, 807 patients with thalassemia major were alive and residing in the United Kingdom, most of whom were of Pakistani or of Cypriot origin.[26] Detailed information on the frequency of thalassemia in different world regions is available from Modell and Darlison,[2] and Galanello et al.[27]

The Role of Malaria

Even in the first description from Italy of children affected by thalassemia, Maccanti observed that all the patients came from malarial areas and, 20 years later, Vezzoso noted that the distribution of Cooley's anemia in Italy coincided with that of malaria.[28,29] The hypothesis that malaria had an influence in maintaining the high prevalence of hemoglobinopathies in the world was first suggested in 1949 by Haldane, who also proposed that the small red cells of the carriers of thalassemia could be more resistant to the malaria parasites.[30] A few years earlier, Neel and Valentine had calculated that, in the absence of some kind of selective pressure, the mutation rate for thalassemia had to be in the order of 1 in 2,500.[31] Carcassi et al. and Siniscalco et al. in Sardinia obtained suggestive epidemiologic data on the distribution of thalassemia and malaria, but their results were not confirmed in other populations.[32] Molecular biology studies helped to clarify at least some aspects of the problem. In fact, they revealed the very high number of β-thalassemia mutations that are, for the most part, regionally specific, as well as the association of particular mutations with specific β-globin gene haplotypes. The regional specificity of mutations suggests local processes for their elevation to high frequencies, while the close association with specific haplotypes suggests a recent cause. These observations point to the conclusion that the selective pressure of malaria has amplified the β-thalassemia genes to high frequency so recently that neither migration, recombination, nor genetic drift could have had sufficient time to bring them into spatial or genetic equilibrium with their background.[33]

The mechanism by which the thalassemia heterozygote could be protected from malaria is still not clear. Several studies have demonstrated reduced red cell invasion by malaria parasites in the severe forms of thalassemia, but the results in the heterozygous states for α- and β-thalassemia have been contradictory.[34–36] A provocative study performed in newborns with α-thalassemia revealed an increased susceptibility to infection by *Plasmodium vivax*, a less severe form of malaria, and suggested that this could confer permanent cross-species protection against *Plasmodium falciparum*.[37] Both parasites invade preferentially young circulating red cells, and early infection in a period of life when maternal antibodies are still present could protect them from later severe disease. Also, some form of immunologic mechanism could be involved in protecting carriers of thalassemia from malaria and possibly from other diseases as well.[38] However, recent in vitro studies using red blood cells (RBCs) with common hemoglobinopathies (e.g., α- and β-thalassemias, HbS, HbC, HbE) and enzyme (glucose-6-phosphate dehydrogenase [G6PD]) defects have shown a reduced parasite invasion/growth and an increased susceptibility to phagocytosis of the infected RBC as a malaria-protective effect.[39,40] A recent systematic review and meta-analysis of studies that estimated the risk of malaria in patients with and without hemoglobinopathies, showed a decreased risk of severe *P. falciparum* malaria in sickle cell carriers, homozygous and heterozygous hemoglobin C, and homozygous and heterozygous α-thalassemia.[41] These hemoglobinopathies differ substantially in the degree of protection provided and confer mild or no protection against uncomplicated malaria and asymptomatic parasitemia.

Moreover, evidence has been obtained for complex epistatic interactions among different inherited hemoglobin disorders with respect to malaria protection, at least partly explaining some profound differences in their distribution among different populations.[3]

GENETIC MECHANISMS AND MOLECULAR PATHOLOGY

Synthesis of hemoglobin, the molecule used for oxygen transport, is directed by two gene clusters: The α locus, which contains the embryonic ζ gene, plus the two adult α genes; and the β cluster, which contains the embryonic ε, the fetal Gγ and Aγ, and the adult δ and β genes (Fig. 34.1). Different hemoglobins are produced during development and two globin gene switches take place: the embryonic to fetal switch (ε to γ and ζ to α), which starts very early in pregnancy and is completed at 10 weeks of gestation; and the fetal to adult switch (γ to β), which occurs during the perinatal period.[42] The globin gene switches, besides the changes in hemoglobin composition, come with changes in other morphologic and biochemical characteristics of the erythropoietic cell line, including the shift from the nucleated megaloblast to macrocyte and to the definitive normocyte; the shift in the site of erythropoiesis from the yolk sac to liver, spleen, and bone marrow; and changes in the membrane antigenic profile and in the red cell glycolytic activity.[43] Recent discoveries about transcriptional regulation of fetal hemoglobin represent a major advance in understanding the switching mechanisms and for developing targeted approaches to ameliorate the severity of β-hemoglobinopathies. Genetic linkage and genome-wide association studies have led to the identification of a variety of nuclear factors acting as multiprotein complexes, involved in globin gene regulation and switching.[44,45,46,47,48,49] The most relevant are *BCL11A* and *KLF1*. BCL11A is a zinc-finger transcription factor necessary for normal B and T lymphopoiesis, that in cooperation with other transcriptional factors, acts also as a direct developmental stage-specific repressor of fetal hemoglobin expression.[50] KLF1 is a zinc-finger erythroid-specific transcriptional regulator, known as an activator of the β-globin gene through direct binding to the critical CACCC box promoter element, that activates *BCL11A* expression by associating with the *BCL11A* promoter.[48,51] Therefore, KLF1 has a dual role in globin gene regulation, functioning as a direct activator of the β-globin gene and an indirect repressor of the γ-globin gene.[52–54] Protein–protein and protein–DNA interactions, involving the β-globin gene cluster and the locus controlling region (LCR), result in complex developmental-related chromatin modifications that activate or repress the different globin genes (Fig. 34.2). The globin genes are relatively small and composed of three exons, coding for functional domains of the hemoglobin, and two intervening sequences (introns).[43] The different globin gene expression during development is controlled through the action of transcription factors and regulatory elements (promoters, enhancers, and silencers) that flank each globin gene, and of more remote sequences important for the regulation of all of the cluster (see below). The promoter of each globin gene contains sequences that act as binding sites for erythroid-restricted or ubiquitously expressed transcription factors responsible for tissue-specific and developmental-specific regulation of the globin genes. Particularly relevant promoter sequences are the TATA box, situated 30 bp upstream of the initiation site, and the CAAT and CACCC boxes at approximately –70 and –110 bp from the initiation site, respectively. Among the transcription factors, some have been studied in detail for their role in the regulation of globin gene expression. GATA-1 is the first of a family of DNA-binding proteins, whose binding sites are present in one or more copies in almost all the regulatory elements of the globin genes.[55] Nuclear factor-erythroid 2 (NFE2), EKLF, FOG-1, and SP1 are other transcription factors involved in the expression

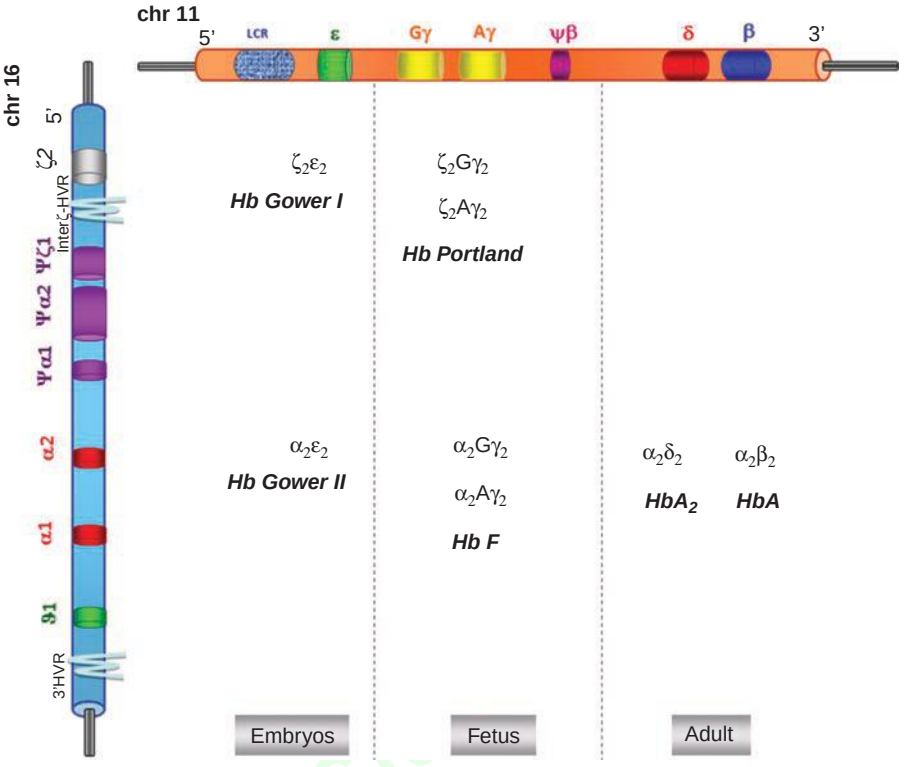

FIGURE 34.1. α- and β-globin gene cluster and hemoglobins (Hbs) produced during development. LCR, locus control region.

of the β-globin gene.[56–59] Like other genes, globin genes possess a series of motifs critical for their expression: the CAP site, which indicates the start of transcription; the AGT initiation codon, which is the signal for starting translation in messenger RNA (mRNA); the donor and acceptor splice sites, which are involved in the processing (splicing) of mRNA; the termination codon, which interrupts translation; and the polyadenylation signal, which is crucial for the addition of a poly (A) tail to the mRNA. The importance of these critical sequences is underscored by the fact that nucleotide substitutions that either alter them or create new similar consensus sequences in a globin gene cause abnormal mRNA processing and constitute the molecular basis for most types of thalassemia. Detailed information on positions, genotypes, and phenotypes for the known globin gene variants are available at the websites listed at the end of this chapter. Essentially the process of globin gene expression consists of the following steps: Transcription of DNA into a primary mRNA transcript; processing of the primary mRNA, involving modifications at both its 5′ (capping) and 3′ (polyadenylation) ends together with removal of the introns and joining of the exons (splicing) to produce mature mRNA, the final template for protein synthesis; and translation of mRNA in the globin protein. Transcription and RNA processing occur in the nucleus, while translation occurs in the cytoplasm [for review, see (15,60)]. Thalassemia syndromes result from a large series of molecular defects, which alter the expression of one or more globin genes.

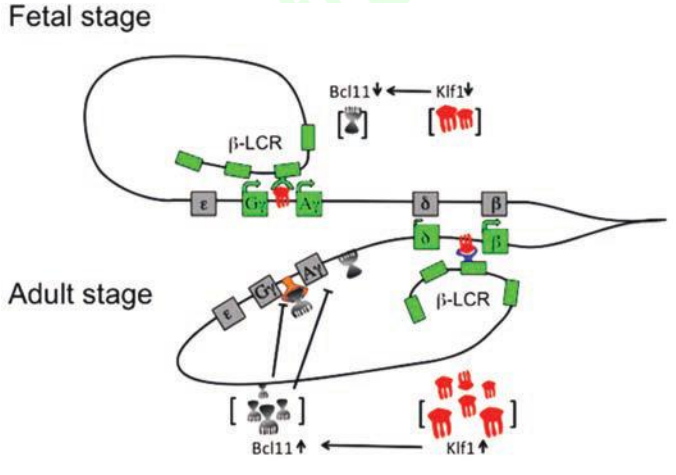

FIGURE 34.2. Current hemoglobin switching model. Bcl11A, B cell lymphoma 11; KLF, Krueppel-like factor; LCR, locus control region. (Reprinted with permission of Cao A, Moi P, Galanello R. Recent advances in β-thalassemias. Pediatr Rep 2011;3:e17.)

α-Thalassemia

The α-globin genes are duplicated and located in the telomeric region of chromosome 16 (16p13.3) in a cluster containing an embryonic α-like gene (ζ_2) and three pseudogenes (pseudo ζ_1, pseudo α_1, pseudo α_2) (Fig. 34.1).[61] A gene (θ) with unknown function, but whose mRNA can be found through all stages of development, is part of the α cluster. Several regions of the cluster contain tandem arrays of short GC-rich sequences (minisatellites), identified as hypervariable regions, and many Alu family repeats.[62,63] The α cluster is surrounded by widely expressed genes (MPG, C16 orf 35 and Luc 7L). Upstream of the α cluster there are four highly conserved noncoding sequences or multispecies conserved sequences (MCS), called MCS-R1-R4, that are involved in the regulation of the α-like globin genes.[64] When the multipotent hemopoietic progenitors committed to the erythroid lineage start their differentiation to mature erythrocytes, several specific erythroid transcription factors, including GATA-1, GATA-2, SCL NF-E2, and cofactors, such as FOG, pCAF, and p300, bind to the MCS-R elements and the α-like globin gene promoters, causing extended modifications associated with chromatin activation. Then, RNA polymerase II is engaged both at the upstream regulatory regions and at the globin gene promoters beginning transcription in erythroid progenitors.[64] The importance of the MCS as regulatory elements is suggested by the presence of rare deletions of this region that produce α-thalassemia, although both

α genes on each chromosome are intact (see below). The human α-globin gene cluster of apparently normal individuals contains a series of DNA sequence variations (e.g., single nucleotide polymorphism [SNP], variations in the number of tandem repeats [VNTRs]; and copy number variants [CNVs], which have been of considerable value in the analysis of evolutionary aspects of the gene cluster, in defining the origin of many of the α-thalassemia mutations, and in identifying functionally important areas of the cluster.)[65,66] The α complex is arranged in the order in which it is expressed during development: 5′ζ_2 … α_2-α_1. There is a very high homology between α_2 and α_1 genes; they differ only in the IVS-2 (two base substitutions and a 7-bp insertion/deletion) and in the 3′ noncoding region (18 base substitutions and a single-base deletion in the 3′ untranslated region).[67,68] This remarkable homology has been maintained during evolution through repeated rounds of gene conversion.[67,68,69] The embryonic ζ gene shows only 58% homology with the α genes in the coding region. The level of transcription of the two α genes differs: the α_2 gene expresses two to three times more α-globin than α_1.[70,71] This would imply that the globin structural variants of the α_2 gene should represent about 35% of the total hemoglobin, while the α_1 globin mutants should represent about 15%. However, contrasting results have been reported on this point. Shakin and Liebhaber have reported identical translation profiles of α_2- and α_1-mRNA, and higher percentages of α_2-globin variants (24% to 40% as compared to 11% to 23% for the α_1-globin variants).[72] Molchanova et al. confirmed the average ratio of 2.6:1, observed for α_2- and α_1-mRNA, but reported an average percentage of the abnormal hemoglobin in heterozygotes with α_2 mutations (23.5%) to be only slightly higher than that in heterozygotes with α_1 mutations (19.7%), suggesting a less efficient translation of α_2-mRNA.[73] It should be pointed out that, besides the rate of transcription and efficiency of translation, other factors, such as the stability of the variant, the affinity of the variant for β-chains, and the number of active α genes, may influence the final level of the abnormal hemoglobin. The issue of different expression of the two α genes is important not only for the α-globin structural variants, but also for the pathophysiology of the deletional and nondeletional forms of α-thalassemia. Normal individuals have usually four α-globin genes, but as a result of unequal genetic exchange, some may have five or six α genes while still being phenotypically normal.[74–76] Multiple arrangements with three to six ζ-like embryonic genes have also been reported.[77,78]

The α-thalassemias are classified generally into the α° thalassemias, in which there is absence of α-chain production from the affected chromosome, and the α^+ thalassemias, in which the production of the α-chains from the mutated chromosome is reduced.

Deletion α-Thalassemia

α-Thalassemia is caused most frequently by deletions of DNA that involve one or both α-globin genes. The α-globin genes are embedded within two highly homologous regions extending for about four kb, whose sequence homology has been maintained by gene conversion and unequal crossover events.[61,79] Three homologous subsegments (X, Y, and Z) separated by nonhomologous elements have been defined. Reciprocal recombination between Z boxes, which are 3.7 kb apart, and between X boxes, which are 4.2 kb apart, gives rise to chromosomes with only one α-gene. These α-thalassemia determinants, which are the most common, are referred to as –α 3.7 kb rightward deletion and –α 4.2 kb leftward deletion, respectively (Fig. 34.3).[80] Based on the exact location within the Z box where the crossover took place, the –α 3.7 kb deletion is further subdivided into –α 3.7 I, –α 3.7 II, and –α 3.7 III.[69] Besides the deletion α-thalassemia determinants, the nonreciprocal crossover produces chromosomes with three α-globin genes: ααα anti-3.7 and ααα anti-4.2.[81,82] More complex recombination events result in chromosomes with four or five α genes.[73] In addition to the common –α 3.7 kb and –α 4.2 kb deletions, an increasing number of deletions that produce α^+-thalassemia have been reported.[83,84] Most of the deletions are rare or highly region-specific. The result of a single α-globin gene deletion is a reduced production of α-chains from the affected chromosome (α^+-thalassemia). Measurements of α-globin mRNA in patients with –α 4.2 determinants suggest that there is a compensatory increase in expression of the remaining α_1 gene, while in the chromosome with –α 3.7 deletion, the remaining α gene is expressed roughly halfway between a normal α_2 and α_1 gene.[85,86] These differences in expression most likely are a consequence of changes in the rate of transcription, due to the new combinations of flanking sequences, to the modification in chromatin structure resulting from the deletion, or to variation in the interaction with the HS-40 (MCS-R2) regulatory element.[87] Deletions that remove all or part of the α-globin gene cluster, including both α genes (entirely or in part) and sometimes the embryonic ζ_2 gene, result in α^0-thalassemia. The extent of the deletions, completely removing both α-globin genes, is from 100 kb to over 250 kb and sometimes other flanking genes, such as a DNA repair enzyme, a protein disulphide isomerase, and several anonymous housekeeping genes, are removed (Fig. 34.3).[66,84] However, interestingly, in subjects with these large deletions, the only phenotypical manifestation is α-thalassemia. Several molecular mechanisms (illegitimate recombination, reciprocal translocation, truncation of chromosome 16) have been described as responsible for these large deletions.[63] The associated phenotype is the α^0-thalassemia phenotype. At present approximately 50 deletions completely or partially deleting both α-globin genes, therefore resulting in α^0 thalassemia, have been reported.[64,66] A series of naturally occurring human deletions that remove MCS regulatory elements have been identified.[88–90] Despite the presence of intact α-globin genes of carriers, these deletions have the α° thalassemia phenotype. A shown by human deletions and by studies of transgenic mice, among the four regulatory elements (MCS-R1 to R4), the most relevant for α-globin gene expression is MCS-R2, located 40 kb upstream from the ζ globin gene.[91] An interesting patient with a severe hemoglobin H disease phenotype and all four α intact genes, but lacking MCS-R2 in both chromosomes and also MCS-R1 and R3 in one chromosome, has been recently described.[92] This report proves that the complete loss of the major MCS-R2 regulatory element severely downregulates α-globin gene expression but is not associated with the complete absence of α-chain production. A novel deletion involving the α_1 and θ gene that inactivates the intact α_2 gene has been reported.[93] Subsequent studies have shown that the deletion juxtaposes to the structural normal α_2 globin gene a downstream widely expressed gene (*Luc 7L*).[94] Transcription of antisense in RNA from *Luc 7L* through the α_2 gene mediates methylation of the associated CpG island with silencing of α_2 globin gene expression. These findings identify a new mechanism underlying human genetic disease.

Nondeletion α-Thalassemia

Single nucleotide mutations or oligonucleotide deletions/insertions in regions critical for α-globin gene expression produce α-thalassemia. Nondeletional α^+-thalassemia are relatively common, except the Constant Spring mutation, which is quite frequent in Southeast Asia. Several molecular mechanisms (mutations affecting RNA splicing, the poly [A] addition signal, the initiation of mRNA translation, chain termination mutations, in-frame deletions, frameshift mutations) and at least 72 well-defined types of nondeletion α-thalassemia have been described.[84] The majority (50) of nondeletional mutants occur in the α_2 gene and, as expected, have a more severe effect on α-globin gene expression, while 17 have been reported in the α_1 gene, and 5 on a –α chromosome. Hb Constant Spring (α 142 TAA→CAA, StopSGln) is the most common of the nine potential chain termination mutants, which

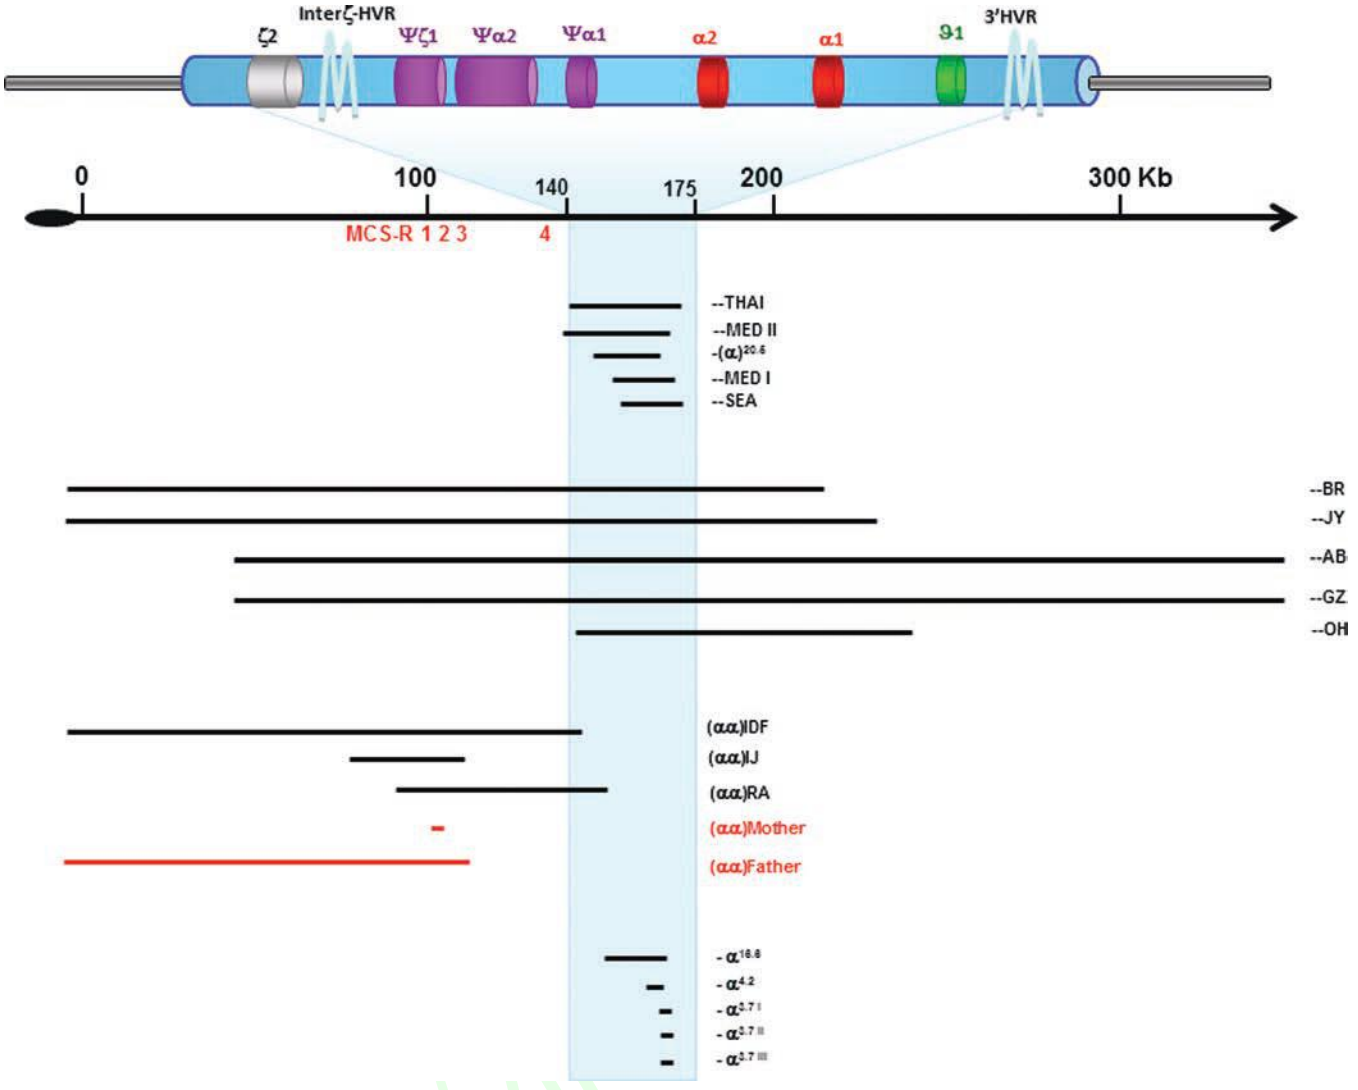

FIGURE 34.3. Most common deletional α-thalassemia defects.

change the stop codon to one amino acid, allowing mRNA translation to continue to the next in phase stop codon located within the polyadenylation signal. The result of this class of mutation is the production of a very low amount (~1%) of an α-chain variant elongated by 31 amino acids. It has been suggested that the reason for the reduced production of the elongated variants is the instability of the mRNA due to disruption of the 3′ untranslated region.[95] Other extended α-chain variants are Hb Icaria (α 142 Lys), Koya Dora (α 142 Ser), Seal Rock (α 142 Glu), and Paksé (α 142 Tyr). Heterozygotes for α-globin elongated chains, besides the presence of a very small amount of the hemoglobin variant, have the phenotype of α-thalassemia. Mutations of α-globin genes, which result in the production of highly unstable globin variants such as Hb Quong Sze (α 125 Leu→Pro), Hb Heraklion (α 37 Pro→0) and Hb Agrinio (α 29 Leu→Pro), unable to assemble in stable tetramers and thus rapidly degraded, produce the phenotype of α-thalassemia.[96] A regularly updated overview of these variants can be found at the Hb Var website. A novel mechanism for nondeletion α-thalassemia has been suggested to explain the α-thalassemia phenotype with intact α genes in some Melanesian patients.[64] Among 283 single nucleotide polymorphisms (SNP) identified by resequencing of approximately 213 Kb of DNA containing the α cluster and the surrounding regions, one SNP creating a GATA-1 binding site, always linked with α-thalassemia phenotype, has been identified.[97] This new GATA-1 site, which binds transcription factors in vivo and is activated in erythroid cells because it is located closer to MCS elements, competes most efficiently with the α-globin promoters, thereby causing α-thalassemia.

β-Thalassemia

The β-globin gene is located in the short arm of chromosome 11 in a region containing also the δ gene, the embryonic ε gene, the fetal Gγ and Aγ genes, and the pseudogene β1 (Fig. 34.1).[98] The five functional globin genes are arranged in the order of their developmental expression. The complete sequencing of the β-globin gene complex has shown interspersed repetitive sequences (microsatellite repeats of [CA]n, an [ATTTT]n repeat, AluI and KpnI families of repeat DNA sequences), which may play a role in the generation of the deletions of the β cluster. The region also contains many polymorphic base substitutions, which produce restriction fragment length polymorphisms (RFLPs), combined in a restricted number of haplotypes in linkage disequilibrium with β-thalassemia mutations.[99] Haplotype analysis provides information relevant for population genetics of the hemoglobinopathies. A1 with the α-like globin genes, variations in the number of β cluster genes, mostly involving the γ genes (which may be present in one to five copies), have been reported.[100,101] Like the α genes, β-globin genes are

subject to a very complex regulatory mechanism, acting at the level of single genes as well as of the entire β cluster.

The appropriate expression of the different β-like globin genes in erythroid tissues during development depends on a major regulatory region highly conserved in mammals named the locus control region (LCR), located 5 to 25 kb upstream from the ε-globin gene.[102] Five DNAase hypersensitive sites (HSs) have been described in this region and each HS contains one or more binding motifs for erythroid-specific transcriptional activator1 (GATA-1 and NF-E2) and for ubiquitous DNA-binding proteins.[103] The importance of the LCR for the control of β-like globin gene expression has also been suggested by a series of naturally occurring deletions that totally or partially remove the HS sites and result in the inactivation of the intact downstream β-globin gene.[104,105] β-Thalassemia mutations result in either a complete absence of β-globin chains (β^0-thalassemia) or in a largely variable reduction of β-globin output (β^+-thalassemia). More than 200 different mutations producing β-thalassemia have been so far described; the large majority are point mutations in functionally important sequences of the β-globin gene; while, in contrast to α-thalassemia, gene deletion is a rare cause of β-thalassemia (Table 34.1). A complete updated list of β-thalassemia mutations has been published and is also available through the globin gene server websites (see the end of the chapter).

Nondeletion β-Thalassemia

Point mutations resulting in β-thalassemia are single nucleotide substitutions or oligonucleotide insertions/deletions that affect the β gene expression by a variety of mechanisms (Table 34.1).

Three main categories can be identified: (a) mutations altering β gene transcription (promoter and 5′ untranslated region mutants); (b) mutations affecting mRNA processing (splice junction and consensus sequence mutants, exon and intron cryptic site mutants, the polyadenylation site and other 3′ untranslated region mutants); and (c) mutations resulting in abnormal mRNA translation (nonsense, frameshift, and initiation codon mutants).

Transcription Mutations

Promoter Mutations

Several mutations have been described in or around the conserved motifs in the 5′ flanking sequence of β-globin genes (TATA box, proximal and distal CACCC box). They reduce binding of RNA polymerase, thereby reducing the rate of mRNA transcription to 20%–30% of normal. They result in a moderate decrease of β-globin chain output (β^+-thalassemia) and hence in a mild phenotype. One mutation C→T at position –101 to the β-globin gene (distal CACCC box) is unusually mild and associated with a silent phenotype in carriers and in a very mild thalassemia intermedia clinical picture in genetic compounds with severe β-thalassemia mutations.[106,107] The promoter mutations –28 A→G and –29 A→G are relatively common in Chinese and black populations, while –87 C→G and the silent –101 C→T have been described in the Mediterranean population. The first mutation in the conserved CCAAT box at positions –76 to –72 of the β-globin gene (–73 A→T) has been described in a Chinese patient.[108]

5′ Untranslated Region Mutations

Several mutations (single-base substitution and minor deletions) have been reported in this 50-nucleotide region; all have mild effects on gene transcription. Heterozygotes have normal or borderline red cell indices and HbA2; and compound heterozygotes, with severe β-thalassemia alleles, usually have a mild phenotype. The only homozygous state for a mutation at the β-globin gene mRNA capsite (Cap +1 ASC) shows hematologic values of a thalassemia trait.[109]

Mutations Affecting mRNA Processing

RNA processing essentially consists in the removal of the intervening sequences and in the splicing of the coding regions to produce functional mRNA. The precision of this process relies on critical sequences present at intron/exon boundaries: the invariant dinucleotides—GT—at the 5′ (donor) and—AG—at the 3′ (acceptor) splice junctions and the flanking sequences (consensus sequences) that are rather well conserved.[110]

Splice Junction and Consensus Sequence Mutants

Mutations of the invariants 5′—GT— and 3′—AG—dinucleotides completely abolish normal splicing and result in β^0-thalassemia. Twenty-seven base substitutions or short deletions involving the invariant dinucleotides have been identified. Other cryptic

splice sites present elsewhere in precursor mRNA are used for alternative splicing, but the misspliced mRNA cannot be translated into functional β-globin.[111,112] The efficiency of normal splicing may be decreased by mutations within the consensus sequences immediately adjacent to the splice junctions. The reduction of β-globin production is quite variable and the resulting phenotypes range from mild to severe. For example, the mutations at position five of IVS-1 (G→C, G→T, G→A) produce a consistent reduction of β-globin synthesis and hence a severe β^+-thalassemia phenotype; while the IVS-1–6 T→C mutation (Portuguese mutation), quite common in Mediterraneans, only mildly affects normal splicing and results in a mild thalassemia intermedia clinical picture.[113] Even in the consensus sequence mutations, abnormal alternative splicing using neighboring cryptic sites may occur.[112]

Cryptic Site Mutants in Introns and Exons

Along introns and exons there are sequences similar to those found at the intron/exon boundaries, which normally are not used for splicing ("cryptic" splice sites). A number of nucleotide substitutions involving these sequences transform a cryptic site into a legitimate one. This new splice signal competes with the normal consensus sequence for splicing and, in some cases, is used preferentially (up to 90% in the IVS-1–110 G→A substitution and almost 100% in the IVS-1–116 T→G substitution), resulting in a severe β^+- or β^0-thalassemia phenotype.[114,115] Two cryptic splice site mutations in IVS-1 and three in IVS-2 have been described. In the exons, three cryptic splice sites can be activated by nucleotide substitution: one at codon (cd) 10 (C→A), a second at codon 19 (A→G), and a third by mutations at codons 24 (T→A), 26 (G→A), 26 (A→C), or 27 (G→T). The nucleotide substitutions partially activate the cryptic splice sites, resulting in both normally and abnormally spliced β-mRNA. Mutations at codon 19, 26, and 27 result in the production of abnormal hemoglobins (cd 19, Hb Malay [Asn→Ser], cd 26 HbE [Glu→Lys], cd26 Hb Tripoli [Glu→Ala] cd 27 Hb Knossos [Ala→Ser]) and are associated with a mild or silent phenotype because of the preferential use of the normal splice sites.[112,116–118]

Poly (A) and Other 3′UTR Mutants

Downstream of the mRNA terminal codon there is a highly conserved AAUAAA sequence, which represents a signal for cleavage and polyadenylation reaction, as a part of the RNA transcript processing. Since polyadenylation is important in determining the stability of mRNA, mutations at the AAUAAA sequence affect the efficiency of translation, resulting in β^+-thalassemia of variable, but usually mild, severity. Seven nucleotide substitutions at different positions, two oligonucleotide deletions (of two and five bases), and one deletion of the total AATAAA sequence have been described. Other mutations in the 3′ untranslated region (+1480 C→G) also produce β^+-silent thalassemia.

Mutations Affecting mRNA Translation

A very large group of mutations alter the different steps of mRNA translation. Three categories of mRNA translation mutations can be identified: initiation codon mutations, nonsense mutations, and frameshift mutations.

Initiation Codon Mutations

The initiator codon ATG, which encodes for methionine, is a critical signal for starting translation. Nine different point mutations of the initiation codon have been reported as a cause of β^0-thalassemia.

Nonsense Mutations

Single nucleotide substitutions may change a codon for a given amino acid to one of the three possible chain termination codons: TAA, TAG, or TGA. The result is a premature interruption of mRNA translation, with absence of β-globin production (β^0-thalassemia). A very low level of β-mRNA has been detected in erythroid cells affected by mutations in exons 1 and 2 as a consequence of rapid degradation of the mutant β-mRNA.[119,120] This process is referred to as nonsense-mediated decay and may be a mechanism to eliminate mRNAs encoding truncated polypeptides, with potential harmful effects for the erythroid cell.[121,122] Nonsense mutations in exon 3 are associated with β-mRNA levels comparable with normal levels. The protective process does not occur, and mutant β-mRNA is probably translated to produce the abnormal globin (see Hyperunstable Globins, below).[123]

The most common nonsense mutation in the Mediterranean population, particularly in Sardinians, where it accounts for more than 95% of the cases of β-thalassemia, is the C→T base substitution at codon 39, while the nonsense mutation at codon 17 A→T shows a high frequency in the Chinese and Thai populations.[124,125]

Frameshift Mutations

Insertion or deletion of one or a few nucleotides (other than three or multiples of three) alters the reading frame of the encoded mRNA starting at the site of the mutation. The new reading frame usually results in a novel abnormal amino acid sequence and in a premature termination further downstream. The mutant globin chain is rapidly degraded and the final result is a β^0-thalassemia. The frameshift resulting from a single-base deletion at codon 6 (-A) is relatively common in the Mediterranean population, while the –4 nucleotides deletion at codons 41 and 42 are particularly common in Chinese and Asian Indian populations.[126] The position of the premature termination (in exon 1, 2, or 3) caused by the frameshift mutation affects the mutant mRNA level and processing as previously reported for nonsense mutations.

β-Globin Gene Deletions

Several deletions affecting only the β-globin gene and ranging in size from 290 bp to about 67 kb have been reported. Only one, the 619-bp deletion, removing the 3′ end of the β-globin gene, is relatively common in the Sind and Punjab populations of India and Pakistan.[127] All the others are extremely rare and have in common the deletion of the promoter region and at least part of the β-globin gene. The phenotype is that of β^0-thalassemia with unusually high levels of HbA2 and F in heterozygotes. This is probably the result of the removal of competition for the upstream LCR, thus allowing an increased interaction between the LCR and the γ and δ gene in cis, with a consequently more efficient expression of these genes.[128] Other deletions causing β-thalassemia remove either the whole β-globin cluster or the LCR. Total deletions of the β cluster result in lack of any globin production and, hence, in $(\varepsilon\ G\gamma\ A\gamma\ \delta\beta)^0$-thalassemia. Deletions of the β-LCR leaving the β gene intact inactivate the β gene. To date a total of ten deletions removing the whole β-globin cluster and eight removing the upstream LCR have been reported [original references in (129)]. These deletions confirm, in vivo, the critical importance of the LCR for the control of expression of the β-globin genes.

β-Thalassemic Hemoglobinopathies

This group includes some structurally abnormal hemoglobins associated with a thalassemia phenotype. They can be classified according to the molecular mechanism in:

1. δβ hybrid genes,
2. activation of cryptic splice sites,
3. hyperunstable β-globins, and
4. unknown mechanism.

δβ Hybrid Genes

Unequal crossing over between the homologous δ- and β-globin genes results in the formation of hybrid δβ and βδ genes, referred to as Lepore and anti-Lepore genes, respectively. The Lepore hemoglobins contain the N-terminal amino acid sequence of the normal δ-chain and the C-terminal sequence of the normal β-chain, and depending on the point of transition from δ to β sequence, three different variants of Hb Lepore have been described: Boston or Washington (δ87/βIVS-2–8), Baltimore (δ68/β84), and Hollandia (δ22/β IVS-1–16).[130–133] The rate of production of the Lepore hemoglobins (about 10% in the carriers) likely depends on the structure of the hybrid gene, which has the promoter of the δ gene (this would explain the lower Hb Lepore amount as compared to normal HbA); and the IVS-2 of the β gene, which probably contains an enhancer (this would explain the higher level of Hb Lepore as compared with HbA2). Moreover, a relative instability of the Lepore mRNA may be responsible for the low level of synthesis. Nonhomologous crossing over between the β and δ genes also results in the production of a hybrid βδ gene in a chromosome also containing the normal β and δ genes. These anti-Lepore genes produce about 15% to 20% of the abnormal hemoglobin. Based on the position of the fusion point, several anti-Lepore hemoglobins have been identified (Hb Miyada, P Congo, P Nilotic, and Hb Lincoln Park, which has in addition a valine residue deleted at position 137), and carriers have normal hemoglobin levels and normal red cell indices.

A similar nonhomologous crossing over involving the Aγ- and β-globin gene produces an abnormal hybrid chain, which contains γ and β sequences (Hb Kenya). Restriction enzyme analysis in these patients shows a deletion of about 22.5 kb and the loss of sequences extending from exon 2 of the Aγ gene to exon 2 of the β gene.[134]

Activation of Cryptic Splice Sites

This group, including the HbE, Hb Malay, and Hb Knossos, has been previously described.

Hyperunstable Globins

A singular group of β-globin gene mutants are characterized by amino acid substitutions, additions, or deletions in the β-globin chain associated with a clinically detectable thalassemic phenotype in the heterozygous state. For this reason, these forms are also referred to as dominantly inherited β-thalassemia. The molecular lesions include 12 missense mutations, 9 small deletions or insertions of intact codons resulting in severe β-globin destabilization, 2 premature terminations, and 23 frameshift or aberrant splicing producing elongated or truncated β-globin chains. Most of these mutations are located in the exon 3.[135]

In contrast with the typical recessively inherited forms of β-thalassemia, which lead to a reduced synthesis of normal β-globin chains, this group of mutations results in the production of β-globin variants, which are extremely unstable. These hyperunstable globins fail to form functional tetramers and precipitate in the erythroid precursors, leading to ineffective erythropoiesis, which is exacerbated by the concomitant relative excess of α-chains. Most of the patients present the phenotype of thalassemia intermedia; a few patients have a thalassemia trait; and some may even have a severe anemia requiring red blood cell transfusions. Laboratory findings consist of varying degrees of hypochromic microcytic anemia, increased HbA2 and an imbalanced α- to β-globin synthesis ratio. In most of the cases the hemoglobin variant cannot be detected in the peripheral blood.

Unknown Mechanism

Adams et al. reported a patient with 8% of an abnormal hemoglobin (Hb Vicksburg β75 Leu→0) and the phenotype of thalassemia intermedia.[136] The reason for the thalassemia intermedia phenotype associated with Hb Vicksburg has not yet been defined.

The original patient has been re-examined and, despite the use of the new technologies of DNA analysis, the predicted Hb Vicksburg deletion was not present.[137] Moreover, even the Hb variant was not detected on two occasions, while HbA, absent at the beginning, has now been found. DNA analysis showed that the patient was a compound heterozygote for the –88 C→T β^+ allele and IVS- 2–849 A→G mutation that causes β^0-thalassemia.[137,138] It has been proposed that Hb Vicksburg arose as a stem cell mutation on the β^+-thalassemia chromosome. The variable hemoglobin composition at different ages suggests that over time there were at least two clones of erythroid progenitors contributing to erythropoiesis.[137,138] A phenotype of mild heterozygous β-thalassemia with microcytosis and increased levels of HbA2 has been reported in patients with two hemoglobin variants: Hb North Shore (β134 Val→Glu) and Hb Woolwich (β132 Lys→Glu).[138,139] In both cases, a mild deficit of β-globin chain synthesis has been reported. DNA analysis of these patients has not been performed and the mechanism responsible for the thalassemic phenotype remains unknown.

δ-Thalassemia

Several mutations of the δ-globin gene, which result in reduced (δ^+-thalassemia) or absent (δ^0-thalassemia) production of δ-globin chains, have been described. These conditions do not have clinical relevance, but the coinheritance with β-thalassemia mutations may create problems in β-carrier identification, since the HbA2 may be normal or borderline. The classes of mutations are similar to those responsible for β-thalassemia. Some δ-thalassemia mutations have been described in cis to β-thalassemia. The δ^+27 C→T, fairly common in the Mediterranean population, has been reported in cis to β^+IVS-2–745 C→G, $\beta^0$39 C→T, and β^+27 G→T (Hb Knossos).[140–142] Also the Corfu deletion (–7.2 kb) has been reported isolated or associated with the β^+IVS-1–5 G→A mutation.[143,144]

δβ-Thalassemia

δβ-Thalassemia includes a group of disorders characterized by reduced or absent production of both δ- and β-globin chains and by a variable increase in γ-chain synthesis, which is only partially able to balance the δ- and β-chain deficiency. The most common molecular mechanism consists of deletions of variable extent of the β-like globin cluster, which involve the δ- and β-globin genes. Based on the presence of one (Gγ) or both (Gγ and Aγ) globin genes, and hence on the residual synthesis of only Gγ- or both Gγ- and Aγ-globin chains, two groups of $\delta\beta^0$-thalassemia have been identified: Gγ $(A\gamma\ \delta\beta)^0$- and Gγ Aγ$(\delta\beta^0)$-thalassemia. In Table 34.2 the different varieties with the size of the deletion are summarized. Some have been described in a single family or a few families, while others, such as the Sicilian, the Spanish Gγ.

Aγ$(\delta\beta^0)$, and the black Gγ $(A\gamma\ \delta\beta)^0$, are more common. Homozygotes have been reported as well. For some deletions, the 3′ breakpoint has not been defined. The majority of the deletions that result in δβ-thalassemia are due to illegitimate recombination. Similar but more complex mechanisms have been invoked to explain other $\delta\beta^0$-thalassemias such as Macedonian/Turkish Gγ $A\gamma(\delta\beta)^0$ thalassemia, which is characterized by a double deletion/inversion rearrangement.[145,146] The reasons for the increased expression of the γ genes in $\delta\beta^0$-thalassemia and for the differences between $\delta\beta^0$-thalassemia

and hereditary persistence of fetal hemoglobin (HPFH, see below) have not been defined. Juxtaposition to the globin genes of new sequences as a result of the deletion; removal of intergene sequences critical for control of γ-globin gene expression; and altered spatial relationships between the LCR and the genes of the β cluster (with changes in LCR/globin gene promoter interaction and competition) have been postulated to explain the upregulation of the γ-globin genes and the phenotypic differences between δβ-thalassemia and deletion HPFH. It is possible that a combination of the above mechanisms plays a role, and that a balance between regulatory sequences, with positive or negative effects on the γ gene expression, may finally determine the amount of HbF in the red cells. A recent study of three families with elevated HbF identified using comparative genomic hybridization, breakpoint DNA sequencing, and chromatin immunoprecipitation identified a 3.5 kb intergenic region near the 5′ end of the β-globin gene, which is necessary for γ-globin gene silencing.[147] This region binds the fetal hemoglobin silencing factor BCL11A and its partners in the chromatin of adult erythroid cells. The Corfu δβ-thalassemia is characterized by a deletion of 7.2 kb, which removes the δ gene associated with the β-IVS-1–5 G→A mutation.[148] Carriers for this mutation have the unusual hematologic phenotype of heterozygous β-thalassemia with normal levels of HbA2, while homozygotes have relatively high levels of HbF and a mild clinical phenotype.[144] The 7.2-kb deletion has been reported isolated as a deletion form of δ-thalassemia not associated with increased HbF.[144,145] Two varieties of nondeletion δβ-thalassemia have also been described. One, relatively common in Sardinia, is of the $\delta\beta^0$ type and presents two mutations in cis: the common $\beta^0$39 C→T nonsense mutation, and a point mutation at position –196 in the Aγ gene promoter, which is responsible for the Italian/Chinese nondeletion Aγ HPFH (see below).[149] The other, reported in two Chinese families and characterized by decreased expression of the β-globin gene and increased expression of both Gγ and Aγ globin genes ($\delta\beta^+$-thalassemia), showed no deletion in the β-globin cluster.[150] In one of these families, the –29 A→G mutation in the promoter of the β gene (a mild β^+ allele) and a non-polymorphic C→T substitution in the 3Aγ enhancer have been identified.[151,152]

Hereditary Persistence of Fetal Hemoglobin

HPFH is characterized by the presence of increased levels of HbF in adult life in the absence of relevant hematologic abnormalities. The amount of HbF is quite variable, ranging in the carriers from 2.0% to 30%, and this variability reflects a marked molecular heterogeneity. Both deletion and nondeletion defects have been identified. The deletions resulting in HPFH, listed in Table 34.3, extend from 13 kb (HPFH-5 or Sicilian HPFH) to about 106 kb (HPFH-1 or black HPFH).[153,154] They remove δ- and β-globin genes, but spare both Gγ and Aγ genes. As in $\delta\beta^0$-thalassemia, the most common mechanism producing deletions is an illegitimate recombination followed by unequal crossing over. Nondeletion HPFH usually is the result of mutations in the promoter regions of Gγ and Aγ genes (Table 34.3). Most of these mutations are single nucleotide substitutions in or very close to the conserved sequences that bind various regulatory transcription factors. As a consequence, there are changes in the binding of repressor or activator proteins that may modify the balance of the competition between the promoter and the LCR, ultimately resulting in increased HbF synthesis in adult life.[129] In some families, mostly with interacting β-thalassemia or sickle cell anemia, it has been shown that HPFH may segregate unlinked to the β-globin cluster.[155–157] Several patterns of inheritance have been identified: autosomal or X-linked dominant and autosomal recessive. The locus for the X-linked form seems to reside at Xp22.2-22.3.[158] Craig et al., by using polymorphic markers covering the whole genome to study a single very large family, localized a putative locus for HPFH at 6q22.3-q24.[157] Candidate-gene association studies and genome-wide association studies allowed the identification of common single nucleotide polymorphism (SNPs) in the HBS1L-MYB intergenic region on chromosome 6p23, and in the IVS2 of BCL11A gene in chromosome 2p16.1, associated with increased HbF levels in healthy subjects, in β-thalassemia, and in sickle cell anemia.[45,159,160,161]

These SNPs explain a significant proportion of the interindividual variation of HbF levels and of the thalassemia severity, and represent potential therapeutic targets for HbF induction.[162,163,164]

Unusual Causes of β-Thalassemia

Insertion of a transposable element into IVS2 of the β-globin gene, resulting in the expression of approximately 15% of normal β-globin mRNA, has been reported with the phenotype of β-thalassemia.[165] Mutations in the general transcription factor TFIIH, involved in basal transcription and DNA repair, cause trichothiodystrophy and are frequently associated with the

phenotype of the β-thalassemia trait.[166] Some mutations in the erythroid transcription factor GATA have been reported as a cause of β-thalassemia associated with thrombocytopenia.[167,168] Large somatic deletions at chromosome 11 p15.5, including the β-globin cluster and leading to thalassemia intermedia, have been reported in heterozygous β-thalassemia patients.[169,170] The deletion in a subpopulation of erythroid cells resulted in a somatic mosaic with 10% to 20% of erythroid cells heterozygous with one normal copy of the β-globin gene, and the rest homozygous without any normal β-globin gene.

PATHOPHYSIOLOGY

Pathophysiology of the thalassemia syndromes is extremely complex and encompasses intracellular processes as well as their consequences for the organism as a whole. The complete comprehension of the pathophysiology of the thalassemias is essential for the understanding of the differences in clinical expression between α- and β-thalassemia, the high variability of the clinical phenotypes, and potential therapeutic treatment.

β-Thalassemia

The basic defect in β-thalassemia is a reduced or absent production of β-globin chains with relative excess of α-chains. The direct consequences are a net decrease of hemoglobin production and an imbalance of the globin chain synthesis. The former is more evident in carriers, leading to a reduction of mean cell hemoglobin (MCH) and mean cell volume (MCV), and has a minor clinical significance. The latter has dramatic effects on the red cell precursors, ultimately resulting in their extensive premature destruction in the bone marrow and in the extramedullary sites. This process is referred to as ineffective erythropoiesis and is the hallmark of β-thalassemia. Using ferrokinetic analysis, it has been shown that in β-thalassemia patients only 15% of 59Fe was incorporated in circulating erythrocytes, indicating that ineffective erythropoiesis could account for as much as 60% to 75% of total erythropoiesis.[171,172] Hemolysis of the erythrocytes containing inclusions that reach peripheral blood is a minor cause of anemia, particularly in thalassemia major (Fig. 34.4).

The excess α-chains may, in minor amounts, combine with residual β- (in β+-thalassemia) and γ-chains (whose synthesis persists usually in small quantity after birth), undergo proteolysis, or in large part become associated with the erythroid precursors and red cell membrane, with deleterious effects on erythroid maturation and survival. Therefore, the main determinant of the clinical severity is the extent of the relative excess of α-chains in red cell precursors and hence the degree of α/non-α imbalance. In 1966, Fessas et al. described the presence of inclusion bodies in erythroblasts of thalassemic patients, suggesting that they were precipitated by α-chains.[174] The composition of inclusion bodies in β-thalassemia, completely consisting of precipitated α-chains, has been confirmed by immunoelectron microscopy.[175] Oxidation of excess α-chains results in the formation of hemichromes, whose basic structure consists of the covalent binding of distal histidine E7 to the sixth coordination site of the heme iron. Irreversible hemichromes and denatured α-chains precipitate as inclusion bodies early during differentiation and throughout erythroid maturation.[176] α-Chain precipitation in the red cell membrane causes structural and functional alterations with changes in deformability, stability, and red cell hydration.[174,177] Isolated red cell membranes from β-thalassemia intermedia, particularly from splenectomized patients, are rigid and unstable. Protein 4.1, a major component of the cytoskeleton, undergoes partial oxidation in β-thalassemia, resulting in its defective capability to mediate the formation of the spectrin–protein 4.1–actin complex, which is critical to maintain cytoskeleton stability.[178] In vitro experiments, using purified α-chains released within normal red blood cells, support the role of aggregated α-chains in causing red cell membrane rigidity.[179] A further consequence of the membrane-bound hemichromes is their association with the cytoplasmic domain

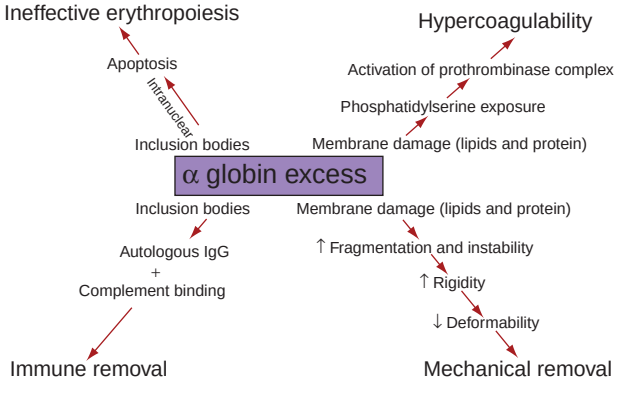

FIGURE 34.4. Pathophysiology of β-thalassemia. Ig, immunoglobulin.

of protein band 3, creating a neoantigen, which is subjected to opsonization with autologous immunoglobulin G (IgG) and complement and immune removal of the cell by macrophages.[180,181] Red blood cells in β-thalassemia lose K^+, store Ca_2^+, and are dehydrated, resulting in altered deformability.[174] Besides oxidation, free α-chains are subjected to degradation, resulting in the formation of denatured α-globin protein, heme, and free iron. These degradation products play a role in damaging erythroid precursors and red cell membranes.

Free iron, via the Fenton reaction, generates reactive oxygen species, which cause lipid and protein peroxidation with consequent damage to red cell membranes and intracellular organelles.[182] High levels of iron, closely associated with denatured hemoglobin, have been found in the membrane of β-thalassemic red cells.[183] In vitro and in vivo experiments (in humans and animals) have shown that the oral iron chelator deferiprone, which may enter the cells, is able to remove free iron from thalassemic red cells, resulting in an improvement of red cell survival.[184,185] These results confirm the role of free iron in damaging the red cell membrane structure. Also, heme, and its oxidized form hemin, produce oxidative damage to the different components of the red cell membrane with consequent structural and functional alterations.[177,186] Recently a new protein relevant for α-globin stabilization has been discovered and its function deeply analyzed.[187] This protein, named α-hemoglobin–stabilizing protein (AHSP), is an abundant erythroid protein that specifically binds free α-globin chains, stabilizes their structure, and limits their ability to participate in chemical reactions that generate reactive oxygen species.[188]

All the above-reported alterations of erythroid precursors cause their extensive premature death by apoptosis in the bone marrow, significantly contributing to ineffective erythropoiesis.[189] Of the two major pathways of apoptosis, the mitochondrial pathway and the cell surface death domain pathway, the death domain pathway seems to be mainly involved.[190] Both FAS and FAS ligand appear to be upregulated at all stages of β-thalassemic erythroid progenitors. Procaspase 8, one of the initiator caspases, whose activation is a hallmark of the death receptor domain pathway, is also activated.[190] In turn, caspases inactivate GATA-1, a transcription factor necessary for erythroid growth maturation, thereby suppressing and limiting the thalassemic erythropoiesis.[191] Other recent studies in mouse models of β-thalassemia have shown that increased or excessive activation of the Jak2/STAT5 pathways promotes unnecessary disproportionate proliferation of erythroid progenitors, exacerbating ineffective erythropoiesis.[192]

The ineffective erythropoiesis and anemia have several consequences in the organism as a whole, producing the clinical picture of the disease. The first response to anemia is an increased production of erythropoietin, causing a marked erythroid hyperplasia, which may range between 10 and 30 times normal.[172] Anemia may produce cardiac enlargement and sometimes severe cardiac failure. Erythroid expansion produces skeletal deformities, osteoporosis, and occasionally extramedullary masses, and contributes to splenomegaly. Untreated or undertreated thalassemia major patients have retarded growth as a result of anemia and the excessive metabolic burden imposed by erythroid expansion. Environmental factors, such as poor nutrition and infections, may contribute to growth failure. The high vascularization of expanded marrow results in an increase in plasma volume, which, associated with splenomegaly, aggravates the anemia.

Ineffective erythropoiesis is associated with increased iron absorption, whose mechanism has been recently clarified.[193]. Expression of growth differentiation factor-15 (GDF-15), a TGF-β superfamily member, usually associated with cellular stress or apoptosis, has been found at particularly high levels in the serum of patients with thalassemia and other conditions associated with ineffective erythropoiesis. Elevated levels of GDF-15 contribute to the suppression of hepcidin, a small peptide produced in the liver, considered the major regulator of iron.[194] Low levels of hepcidin result in increased intestinal iron absorption and most of that excess iron is stored in the liver.[195] A second novel erythroid regulator of hepcidin expression, i.e., twisted gastrulation factor 1 (TWSG1), has been recently identified in thalassemic and human cells.[196] In transfusion-dependent patients, iron overload is largely increased by repeated blood transfusions (see Complications of Transfusions). Iron overload damages several organs (myocardium, liver, endocrine glands), leading to severe complications. Removal of the abnormal red blood cells by the reticuloendothelial elements of the spleen results in splenomegaly and hypersplenism, which, when severe, may exacerbate anemia and cause thrombocytopenia and leukopenia.

A further consequence of the red blood cell membrane damage is the loss of the normal asymmetric distribution and increased surface exposure of the procoagulant, negatively charged phospholipids phosphatidylserine and phosphatidylethanolamine. Perturbation of the cell membrane causes thalassemic RBCs to become rigid and deformed, increasing their cohesiveness and tendency to aggregate.[197] The anionic phospholipids increase thrombin generation, which leads to activation of platelets and endothelial cells.[198,199,200] Further evidence of the chronic platelet activation has been well documented in patients with thalassemia, as evidenced by increased platelet aggregation and expression of CD62P (P-selectin) and CD 63, shorter platelet survival, and elevated levels of urinary metabolites of prostacyclin (PGI2) and thromboxane A2 (TXA2), two markers of hemostasis.[197,201,202] Moreover, thrombocytosis and increased platelet aggregation associated with splenectomy contribute to the higher risk of thromboembolic events. Decreased levels of naturally occurring anticoagulants, such as protein C and protein S, and elevated plasma levels of the thrombin–antithrombin III complex, have been reported.[203,204] It has also been shown that adherence of thalassemic red cells to endothelial cells is markedly enhanced as compared to that of normal red cells, and elevated levels of endothelial adhesion proteins (intracellular adhesion molecule-1, E-selectin, vascular cell adhesion molecule-1, von Willebrand factor) in the serum and plasma of thalassemic patients have been described.[205,206] Activated monocytes and granulocytes, found in patients with thalassemia, could contribute to the endothelial damage and the hypercoagulable state.[207,208]

α-Thalassemia

As in the case of β-thalassemia, the primary defect of α-thalassemia is the imbalance of globin biosynthesis, with an excess of β- and/or γ-globin chains. Unlike α-chains, which are highly unstable and unable to form soluble tetramers, excess γ-chains in fetal life and β-chains in extrauterine life associate to form relatively soluble γ4 tetramers (Hb Bart) and β4 tetramers (HbH), respectively. These excess non–α-chains damage mostly mature red cells and to a lesser extent erythroid precursors, leading mainly to hemolysis and minimally to ineffective erythropoiesis. The different characteristics of the excess chains in α-thalassemia are of great importance in determining its pathophysiology; but in addition, the functional properties of HbH and Hb Bart and the number of α genes contribute to the difference in severity of α-thalassemia as compared to β-thalassemia syndromes. Red blood cells in α-thalassemia are rigid, as in β-thalassemia, but unlike β-thalassemia, they are hyperhydrated and have red cell membranes that are hyperstable. The reason for hyperhydration has not been clearly defined, but is likely a consequence of the effect of β-chain excess on the KCl cotransporter system. Membrane skeletal-bound β-globins become partially oxidized, with consequent membrane damage. In vitro studies have shown that entrapment of β-chains in normal red cells does not result in any significant change in membrane protein function or thiol concentrations, but rather produces changes in red cell deformability,

as reported in vivo in patients with HbH disease.[209,210] Interaction of excess β-globin with the cytoplasmic domain of protein band 3 is abnormal in erythrocytes of patients with HbH disease, since β4 tetramers tend to adhere tightly to protein band 3.[211] β-Globin tetramers precipitate as the red cell becomes old, forming inclusions. These inclusions can be induced in vitro by vital stains, such as brilliant cresyl blue or new methylene blue, and are more common in splenectomized patients.[212] Studies using monoclonal antibodies have shown that red cell inclusions in HbH disease are composed of β-globin. Membrane-bound inclusion bodies perturb the flow velocity during transit through the spleen capillaries, ultimately resulting in mechanical trapping and macrophagic phagocytosis.[213] Red cell hemolysis is a significant pathophysiologic mechanism of HbH disease, but ineffective erythropoiesis is a component, even if moderate. This has been suggested by morphologic and ferrokinetic studies and by the analysis of plasma levels of the transferrin receptor.[214,215] Excess β-chains accumulate and precipitate not only in old red cells, but also in marrow erythroid precursors, where they may cause some intramedullary cell death. β_4 inclusion bodies alter the normal membrane phospholipid bilayer, exposing phosphatidylserine, which represents a signal for the development of apoptosis and red cell removal by the macrophages in the spleen and other reticuloendothelial organs.[216,217] Programmed cell death has been found moderately increased in patients with HbH disease. Red cell membrane deformability and stability is even more affected in patients with HbH/Hbcs.[218] As compared with patients with HbH disease, HbH/Hbcs patients have a higher amount of HbH and a higher percentage of erythrocytes with inclusion bodies and with translocated phosphatidylserine.[213,217,219] All these characteristics may account for the increased hematologic severity of HbH/Hbcs disease. γ-Globin tetramers (Hb Bart) are much less prone than β-globin tetramers to precipitate and form inclusions.[220] Besides the characteristics of excess β- and γ-globin chains discussed above, other functionally abnormal properties are important in determining the pathophysiology of α-thalassemia. HbH and, even more, Hb Bart, have a very high oxygen affinity and show no heme/heme interaction or Bohr effect, hence severely reducing their oxygen-carrying capacity.[221,222] Some α-globin chain variants barely symptomatic in the heterozygous state, are either unstable because of folding defects and/or defective in binding to α-hemoglobin–stabilizing protein (AHSP) and are associated with the α-thalassemia phenotype.[96] When the patients are homozygous for such variants or compound heterozygotes with another α thalassemic defect, they present the phenotype of HbH disease or chronic hemolytic anemia or even hydrops fetalis syndrome.

GENOTYPE–PHENOTYPE CORRELATION IN THALASSEMIA

Progress in molecular biology and the wide availability of methods for DNA analysis have allowed for the definition of globin gene defects in thalassemia syndromes and for the understanding of the mechanisms of globin gene regulation and expression, and have partially elucidated the relationship between genotype and phenotype. This knowledge is helpful in clinical practice for planning the management of the patients, and in genetic counseling for the prediction of phenotype from genotype in couples at risk. In patients, the differentiation at presentation between thalassemia major and intermedia is essential to design the appropriate treatment. In fact, the prediction of a mild phenotype may avoid unnecessary transfusions and their complications, while the diagnosis of thalassemia major will allow an early start of the transfusion program, thus preventing hypersplenism and the red cell sensitization often associated with a delayed start of red cell administration.[223] As reported above, in β-thalassemia the globin chain imbalance is the main determinant of clinical severity. Therefore, the presence of factors able to reduce the globin chain imbalance results in a milder form of thalassemia. These factors are the coinheritance of α-thalassemia or of genetic determinants that increase γ-chain production and the presence of silent or mild β-thalassemia alleles, associated with a high residual output of β-globin. Examples of these alleles are the silent –101 C→T and the mild IVS-1–6 T→C mutation in the Mediterranean population and the –29 A→G in Africans. Deletion and nondeletion HPFH mutations, associated with a high HbF level in carriers, when in genetic compounds with severe β-thalassemia alleles, result in mild thalassemia intermedia. A mild phenotype may also be determined by coinheritance of genetic determinants associated with γ-chain production, mapping outside the β-globin cluster. Several single nucleotide polymorphisms (SNPs) at the *BCL11A* gene on 2 p16.1 and *HBS1L-MYB* intergenic region on 6q23.3 have been associated with variable HbF levels in patients with thalassemia and sickle cell disease.[45,160,224] The effect of α-thalassemia determinants in ameliorating the disease severity is less consistent, but the coinheritance of the deletion of two α-globin genes with homozygous β^+-thalassemia, and sometimes even with β^0-thalassemia, produces the clinical picture of thalassemia intermedia.[15,225] Variants at the three main quantitative trait loci (QTLs) regulating HbF levels (i.e., *BCL11A*, *HBS1L-MYB* intergenic region, Xmn1 CG −γ gene) and α-thalassemia have been associated with the mild thalassemia intermedia phenotype and with a delayed need for transfusions in patients with homozygous β zero thalassemia.[163,226]

The precise definition of the phenotype from the genotype is helpful also in genetic counseling, since it may avoid prenatal diagnosis in cases of expected very mild thalassemia intermedia in the fetus. Prenatal diagnosis in at-risk couples where the –101 C→T mutation is present should not be considered and the same applies to the coinheritance of the triple α-gene arrangement or of the HPFH mutations associated with high levels of HbF. The ameliorating effect that results from the presence of mild β-thalassemia alleles is less constant. The mild β-thalassemia allele IVS-1–6 T→C, common in the Mediterranean population, shows remarkable phenotypic diversity in some populations, such as the Jewish population.[227] Despite the progress in better defining genetic determinants able to influence the clinical severity of β-thalassemia, phenotype prediction from genotype is not always accurate. However, the information obtained from extended genetic analysis may be used for planning appropriate management and for providing adequate genetic counseling, and may also reveal potential new targets for therapeutic intervention. As reported above, the wide range of phenotypic manifestations of thalassemia results from the heterogeneity of the primary mutation and from the coinheritance of other globin gene-associated determinants, which may ameliorate or worsen the disease severity.[228] However, other known or unknown genetic determinants may modify the clinical expression of the thalassemia syndromes. Several secondary genetic modifiers have been identified in the recent years. The presence of (TA)7 polymorphism in the promoter region of the uridine diphosphoglucuronosyltransferase gene, which in the homozygous state is associated with Gilbert syndrome, is a risk factor for the development of cholelithiasis in thalassemia major and intermedia patients and in patients with HbE/β-thalassemia.[229,230] Other candidate genes for modification of the thalassemia phenotype are the apolipoprotein E ε4 allele, which seems to be a genetic risk factor for left ventricular failure in homozygous β-thalassemia.[231] Less consistent data have been reported for genes involved in iron metabolism (C282Y and H63D HFE gene mutations), probably because their effect on iron overload is hidden as a result of treatment (e.g., secondary iron overload from red cell transfusion and iron chelation).[232,233]

In α-thalassemia, the symptomatic form of HbH disease shows a wide phenotypic diversity. The phenotype varies depending on the number of α genes affected and on the type of mutation

present.[234,235] Studies that have correlated hematologic and clinical findings with α-globin genotypes indicate that HbH patients with nondeletion α-thalassemia defects have a more severe clinical expression (see below).[236,237,238,239]

Unlike with β-thalassemia, limited progress has been made in the search for genetic modifiers of HbH disease.[238] One type of genetic modification is coinheritance of β-thalassemia mutations, also referred to as the HbH/β-thalassemia trait. Subjects with this genotype have severe hypochromia, microcytosis, and anemia, and do not present HbH at the electrophoresis.[240]

CLINICAL AND LABORATORY FEATURES

α-Thalassemia: Clinical Forms

Despite the large number of different α-thalassemia alleles (overall more than 100) only four hematologic and clinical conditions of increasing severity are recognized: silent carrier, α-thalassemia trait, HbH disease, and Hb Bart hydrops fetalis.[241,242]

Silent Carrier

This condition results from the presence of a single α-globin gene defect associated with the 3.7 or 4.2 kb deletion (-α/αα) and from nondeletion defects. This genotype is characterized in the newborn period by a very mild increased percentage (1% to 2%) of Hb Bart, a tetramer of four γ-globin chains (γ4), which is produced when there is an excess of γ-chains in relation to α-chains. However, failure to demonstrate Hb Bart in cord blood does not exclude the silent carrier state.[243,244] Among black Americans, the incidence of the silent carrier state determined by gene mapping is about 27%, yet Hb Bart is detected in only 12% of cord samples. Similar trends have been found in Mediterranean and Saudi Arabian populations.[245,246]

Adult individuals with three functional α genes may have a completely silent phenotype (normal red blood cell indices) or present a moderate thalassemia-like hematologic picture (reduced MCV and MCH and very mild anemia) with normal HbA2 and F.[241,242] Analysis of globin chain synthesis in vitro in peripheral blood reticulocytes displays a reduced α:β ratio in the range of 0.8 to 0.9. It has been shown that, at birth, children with the –α4.2 deletion, which removes the α_2 gene, have a more severe phenotype than children with the –α3.7 deletion, which deletes most of the less productive α_1 gene, resulting in a hybrid gene consisting of the 5′ part of the α_2 gene linked to the 3′ part of the α_1 gene.[86,246] However, with increasing age, the two genotypic forms become phenotypically indistinguishable, presumably because of upregulation of α-globin production by the α_1-gene in subjects with the –α4.2 deletion.[87,247]

α-Thalassemia Trait

This condition is characterized in the newborn by more markedly increased levels of Hb Bart (5% to 6%) and in the adult by thalassemia-like red cell indices, normal HbA2 and F, and a reduced α:β-globin chain synthesis ratio in the range of 0.7 to 0.8.[241,242] Subjects with two residual functional α genes, either in cis on the same chromosome (–/αα or α^0-thalassemia carriers) or in trans in opposite chromosomes (-α/-α, homozygous α^+-thalassemia), clearly show the α-thalassemia carrier state. Carriers of nondeletion defects have quite variable hematologic phenotypes ranging from the α-thalassemia trait to the silent carrier state (see above). Double heterozygotes for –α/and nondeletion α-thalassemia (-α/[αα]T) and homozygotes for nondeletion defects ([αα]T/[αα]T) have the typical phenotype of the α-thalassemia carrier state. However, homozygotes for some nondeletional forms of α-thalassemia may have a mild HbH disease.[248] It should be pointed out that homozygotes for the Hb Constant Spring mutation, the most common nondeletion defect in the Asian population, have a clinical syndrome that is similar to HbH disease (see below).[249] The α-thalassemia carrier state should be differentiated from iron deficiency and from δ- and β-thalassemia interaction (see carrier detection). This differentiation has important practical consequences.

Hemoglobin H Disease

HbH disease is common in Southeast Asia and relatively frequent in Mediterranean countries and parts of the Middle East, while occurring rarely in populations of African descent. This clinical condition results from the presence of only one functional α gene, usually as a consequence of the compound heterozygous state for α^0-thalassemia/α^+-thalassemia (–/-α or –/αTα). As a consequence of the relative excess of β-chains, individuals with HbH disease produce a variable amount of this abnormal hemoglobin, a tetramer of β-globin chains (β4). The HbH is unstable and precipitates inside the red cells and to some extent in erythroid precursors, causing membrane damage and premature erythrocyte destruction. As reported above, both hemolysis and ineffective erythropoiesis contribute to anemia in HbH disease, but the predominant mechanism is hemolysis. HbH has a much higher oxygen affinity than HbA and this may worsen the severity of anemia in patients with HbH disease. In the neonatal period, subjects with the HbH disease genotype have a consistently elevated Hb Bart (~25%), which may still be detected in small amounts in some adults with HbH disease. The syndrome of HbH disease shows a considerable variability in clinical and hematologic severity. The majority of patients have minor disability, a few are severely affected requiring regular blood transfusions, and rare cases of HbH disease have been described with the hydrops fetalis clinical picture (see below).[15,65] The most relevant features are microcytic and hypochromic hemolytic anemia, hepatosplenomegaly, jaundice, and moderate thalassemia-like skeletal modifications.[65,237,238,239] The hemoglobin concentration is usually in the range of 7 to 10 g/dl and the MCV varies with age (being around 58 fl in childhood and around 64 fl in adulthood), while the MCH is around 18 pg irrespective of age. Reticulocytes range between 5% and 10%, and the α:β-globin chain synthesis ratio is markedly reduced, in the order of 0.20 to 0.60. Hemoglobin electrophoresis at alkaline pH shows a fast-moving band (HbH) in amounts ranging from 1% to 40%. Sometimes, because of the low quantity and the possible loss due to instability in the preparation of the hemolysate, HbH may escape detection. The most sensitive method to detect HbH consists of the incubation of peripheral blood cells for 1 to 2 hours at 37°C in the presence of supravital dyes (brilliant cresyl blue or methyl violet), which induce precipitation of the abnormal hemoglobin as inclusion bodies, easily recognizable at the microscope (Fig. 34.5). Determination of the α-globin genotype may be useful for prognosis of HbH disease, because the nondeletion forms are more severe than the deletion forms. Anemia is accentuated during pregnancy and may worsen quite dramatically with infections, fever, ingestion of oxidant drugs, aplastic anemia associated with Parvovirus B19, and hypersplenism.[237] A variable spleen enlargement is almost always present, while liver enlargement is less common. A mild phenotype of HbH disease may result from the homozygous state for nondeletional α-thalassemia. Although the phenotype in some cases is closer to that of the homozygous state for α^+-thalassemia, the degree of anemia and hypochromia may be more severe.[250] In particular, homozygotes for the elongated α-chain variant Hb Constant Spring are asymptomatic, but show mild pallor and jaundice with liver and spleen enlargement in about 50% of the cases.[15,251] The hemoglobin level ranges from 9 to 11 g/dl and the MCV tends to be normal (88 ± 6 fl), while the MCH is slightly reduced (26 ± 3 pg). The peripheral blood contains HbA2, A, Hb Constant Spring, and traces of Hb Bart

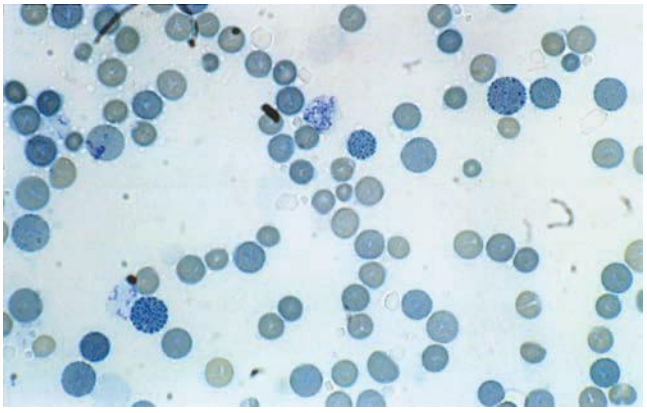

FIGURE 34.5. Hemoglobin H inclusion bodies.

rather than HbH.[15] The severity of HbH disease shows a good correlation with the degree of α-chain deficiency. Thus, the more severe and variable phenotypes are associated with interactions involving nondeletion α-thalassemia defects that affect the dominant α_2 gene, including (–/αConstant Springα), (–/αNcoIα) and (–/αHphIα).[237,238,239] Patients with the nondeletional genotypes present earlier, with more severe hemolytic anemia, significant growth delay, dysmorphic facial features, and more marked hepatosplenomegaly; they require more transfusions. Few patients with HbH disease resulting from the interaction of α^+-thalassemia (-α) with the deletion of the MCS regulatory region have been reported.[66] A severe case of HbH disease due to deletions of variable extent of both upstream MCS-Rs while all four downstream α-globin genes are intact has been recently described.[92]

A very few cases of unusually severe HbH disease associated with hydrops fetalis due to coinheritance of α^0- and α^+-thalassemia have been described.[65,252–254] In four cases, the α^+-thalassemia alleles were mutations of the α_2 gene associated with hyperunstable α-globin variants. The interaction between two relatively common forms of α-thalassemia ($-^{Med}/\alpha^{TSaudi}\alpha$) can present with HbH hydrops fetalis.[255] In these families, prenatal diagnosis can be indicated.

Patients with HbH disease may develop complications including hypersplenism, leg ulcers, gallstones, and abnormal left ventricular dysfunction. Hypersplenism has been reported in 10% of Thai patients with HbH disease, but seems to be rare elsewhere.[256] Iron overload as assessed by serum ferritin is increased in a large proportion (50% to 75%) of patients and is significantly correlated with age.[237,239,257] Some patients develop increased liver iron concentration.

In general, patients with HbH disease do not need any treatment. Some clinicians recommend folic acid supplementation as for other hemolytic anemias. Patients should be advised to avoid oxidant drugs because of the risk of hemolytic crisis. Occasional blood transfusions may be required when the hemoglobin level suddenly drops as a consequence of hemolytic or aplastic crisis. Pregnant women with HbH disease need careful monitoring of the hemoglobin levels. Splenectomy may be indicated in the presence of hypersplenism, but the potential complication of venous thrombosis, reported in some patients with HbH disease following splenectomy, should be considered.[258,259] Chelation therapy should be initiated in patients with elevated serum ferritin and/or liver iron concentration.

Hemoglobin Bart Hydrops Fetalis Syndrome

Hb Bart hydrops fetalis syndrome is the most severe α-thalassemia clinical condition, often associated with the absent function of all four α-globin genes (homozygous α^0-thalassemia or –/–). A few cases of hydrops fetalis have been reported in infants with very low levels of α-chain synthesis, resulting from interaction of common α^0-thalassemia determinants with uncharacterized nondeletion defects.[253,254,256] Hb Bart hydrops fetalis syndrome is relatively common in Southeast Asia, while in Mediterranean populations it is relatively rare due to the low frequency of α^0-thalassemia.[15,260,261] Because of the extreme rarity of the –/$\alpha\alpha$ genotype, this disorder rarely, if ever, affects infants of African descent. A fetus homozygous for α^0-thalassemia produces mainly Hb Bart (γ4), which is functionally useless for oxygen transport, and his or her survival to late pregnancy is due to the presence of small amounts of embryonic hemoglobins Portland 1 ($\zeta_2\gamma_2$) and Portland 2 ($\zeta_2\beta_2$). There is a marked variability in the intrauterine clinical course of fetuses with Hb Bart hydrops fetalis. Many pregnancies terminate unnoticed or early in gestation. In some cases pregnancy proceeds to term, but the fetus is stillborn or severely ill; in others the fetus does not become hydropic and is born normally.[262,263] The clinical features of this syndrome are those of a very severe anemia (Hb level range, 3 to 8 g/dl), with marked hepatosplenomegaly, generalized edema, signs of cardiac failure, and extensive extramedullary erythropoiesis in many organs.[15,264] Other congenital abnormalities, particularly of the skeletal, cardiovascular, and urogenital system, have been reported. Complications during pregnancy are common and include severe and mild pre-eclampsia (hypertension, fluid retention with or without proteinuria), polyhydramnios or oligohydramnios (increased or reduced accumulation of amniotic fluid, respectively), and antepartum hemorrhage. Postpartum complications include placenta retention, eclampsia (fits and coma), hemorrhage, anemia, and sepsis. At present there is no effective treatment for the Hb Bart hydrops fetalis syndrome. Early treatment with intrauterine transfusions after noninvasive monitoring by Doppler ultrasonography or in utero hematopoietic stem cell transplantation have been attempted, but may not be justified because of the unknown future risks for infants of severe developmental abnormalities.[265,266,267,268,269] Given the severity of this syndrome and of the maternal obstetric complications, early termination of at-risk pregnancies is recommended and several regions have initiated universal prenatal screening programs to address homozygous α-thalassemia.[270,271]

Unusual Forms of α-Thalassemia

There are two unusual forms of α-thalassemia: one is the acquired HbH disease associated with myelodysplasia, and other is the α-thalassemia associated with mental retardation syndrome.

α-Thalassemia/Myelodysplasia Syndrome (OMIM catalog #300448)

Patients with myelodysplasia may rarely develop an unusual form of HbH disease characterized by the presence of classic HbH inclusion bodies in red blood cells, often detectable levels of HbH (1% to 57%), and a severe microcytic and hypochromic anemia with anisopoikilocytosis.[272] The α- to β-globin mRNA ratio, studied in a few patients, showed a marked reduction (0.06 to 0.50), and the α- to β-globin chain synthesis ratio was similarly reduced (α:β ratio = 0.28).[273] Structural analysis of the α-globin genes and of their flanking regions has revealed no abnormalities in such patients.[274] Recent studies have shown that some patients with α-thalassemia/myelodysplasia syndrome have point mutations and/or splicing abnormalities in the ATRX gene (see below).[275] In one patient a large deletion of the telomeric region of the short arm of one allele of chromosome 16, including both α-globin genes, was reported.[276]

α-Thalassemia and Mental Retardation Syndromes

There are two different syndromes in which α-thalassemia is associated with mental retardation.[235,277] The first is characterized by a relatively mild mental retardation and a variety of facial and

skeletal abnormalities. These subjects have extended (1 to 2 megabases) deletions resulting from rearrangements of the short arm of chromosome 16. The deletions remove both α-globin genes and up to 52 other genes.[278] Two common patterns of α-thalassemia have been described: One is characterized by parents with a normal α-globin genotype (αα/αα) whose affected offspring have the phenotype of severe α-thalassemia trait (genotype –/αα). In the other, one parent has the phenotype of the mild thalassemia trait and the child has HbH disease. This condition is called ATR-16 syndrome (OMIM catalog #141750).

The second group of patients has a complex phenotype characterized by severe mental retardation, quite uniform clinical features (hypertelorism, flat nasal bridge, triangular upturned nose, wide mouth, urogenital abnormalities), other developmental abnormalities, and defective α-globin synthesis, resulting in a relatively mild form of HbH disease. No structural changes of the α cluster or 16p chromosome have been found in these patients and the transmission is X-linked. Recently it has been shown that this syndrome is associated with mutations in an X-encoded gene, the ATRX gene, a member of the DNA helicase family.[279–281] To date 128 acquired and/or inherited mutations predominantly lying in 2 highly conserved domains of the ATRX protein have been identified.[282] ATRX, a large protein with 2492 residues, is a member of the snf2 family of ATP-dependent remodeling proteins and a key regulatory component of nucleosomal dynamics and higher order chromatin conformation. ATRX protein plays a prominent role in the control of gene transcription and in the maintenance of chromosome stability.[283,284] Mutations in this gene downregulate the expression of the α-globin genes and of other unidentified genes, producing the complex phenotype. This condition is referred to as Atrx syndrome (OMIM catalog #301040).

More detailed information about the forms of α-thalassemia associated with mental retardation or myelodysplasia and about the role of ATRX are reported in published reviews.[272,282]

α-Thalassemia in Association with Structural Variants

A number of syndromes result from the interaction of α-thalassemia genes with those producing structurally abnormal hemoglobins. In some disorders, thalassemia genes that otherwise would have gone unnoticed are given clinical expression by the variant hemoglobin; in others, the relative amount of the variant hemoglobin is altered by the thalassemia gene. Features common to all these syndromes are red cell hypochromia and microcytosis, in addition to the presence of a hemoglobin variant. Some of the mutations causing α-chain structural variants appear to have occurred in chromosomes with only a single α-globin gene. Thus, Q/α^0-thalassemia has a clinical phenotype similar to that of HbH disease.[285] Affected subjects synthesize no HbA. This disorder has been described in individuals from Thailand, China, Iran, and India.[286,287] The mutation responsible for HbG-Philadelphia sometimes occurs on a chromosome with a single α-globin gene and other times on a chromosome containing both α genes. This variant is encountered primarily in black individuals.[288] In persons with a normal α-globin gene on the same chromosome containing the HbG mutation, HbG-Philadelphia/α^0-thalassemia (αGα/–) is characterized clinically by α-thalassemia minor; whereas in individuals with no normal α-gene cis to the α^G-gene (-α^G/–), the doubly heterozygous state resembles clinically HbH disease. The variant hemoglobin constitutes approximately 40% of the total concentration of hemoglobin in the former situation, and more than 90% in the latter.[37] HbI/α-thalassemia has been reported in a black patient.[289] That the gene for HbI is not linked in cis with an α-thalassemia gene is indicated by the presence of 30% HbA. The combination of α-thalassemia with β-chain variants is associated with a decrease in the relative amount of the variant hemoglobin and a clinical picture similar to that of the heterozygous state for the structural variant.[15] The lower than usual percentage of the variant hemoglobin is attributed to the preferential binding of α-chains with βA-chains. The β-chain variants noted in association with α-thalassemia include HbS, HbC, HbE, and HbJ Bangkok.[15] The interaction of α-thalassemia and the HbS trait produces a trimodal distribution in the relative amount of HbS. Individuals with a full complement of α-globin genes have more than 35% HbS, compared with 28% to 35% in those with the (–α/αα) genotype, 25% to 30% in those with the (-α/-α) genotype, and no more than 20% in those with the rare (–/-α) genotype.[290,291] Reductions in MCV and MCH are also observed. α-Thalassemia modifies some of the hematologic consequences of homozygous sickle cell anemia. Subjects with the (-α/-α) genotype have a higher hemoglobin concentration, lower red cell indices, fewer irreversibly sickled cells, a lower reticulocyte count, and lower serum bilirubin levels than subjects without concurrent α-thalassemia.[292–294] The ameliorating effect of α-thalassemia is probably mediated by a decreased red cell concentration of HbS. α-Thalassemia fails, however, to temper significantly the clinical expression of sickle cell anemia. More information on the effects of α-thalassemia on sickle cell anemia can be found in Steinberg MH[66] and in the chapter on sickle cell anemia in this book. For the interaction of α-thalassemia and HbE, see Hemoglobin E Syndromes in this chapter.

β-THALASSEMIA MAJOR

From a clinical point of view, the β-thalassemia syndromes represent the most relevant forms of thalassemia. The designations commonly used to describe the β-thalassemia syndromes are based on clinical severity. The most severe form is defined as *β-thalassemia major* and is characterized by transfusion-dependent anemia. *Thalassemia intermedia* is the term used to designate a form of anemia that, independently from the genotype, does not require transfusion, or only sporadic or intermittent transfusions. *Thalassemia minor* indicates the heterozygous state, which is usually completely asymptomatic. *Thalassemia minima* was used in the Italian literature to indicate a carrier in whom no hematologic or clinical symptoms were recognizable, but the term should probably be abandoned. Some authors use the term *thalassemia minima* to indicate the condition of silent carrier.

History

Originally, there was a disease called *anemia splenica infantum* that included several conditions, often not well distinguished from one another. Syphilis was considered a possible cause, as were tuberculosis and leishmaniosis. These children were usually born normally and grew normally until the second half of the first year, when they were noticed to become paler and paler, and to develop an enormous abdomen, containing a spleen that could extend from a few centimeters below the left costal margin to the iliac crest and below, sometimes visible from the outside. At this time in the disease course, the patients liked to be left alone and to lie down "in a monotonous morbid state."[28] Bone deformities, especially of the skull, soon appeared, giving the children a distinctive "Mongolian" appearance.[295,296] The disease was often present in more than one sibling; or, more frequently, other siblings had previously died of the same disease. The first systematic descriptions of what was going to be identified as thalassemia major came from Cooley and Lee[295] from Michigan, who observed the disease in Italian and Greek children, and from Maccanti, a pediatrician from Ferrara, Italy, who also noted that the children were often coming from malarial areas near the Po river.[28,295] Anemia, leukocytosis, and normoblastemia were always present. Both groups tried unsuccessfully the entire armamentarium of therapies then available (arsenium, fresh veal bone marrow, sunshine, the

quartz lamp, cod liver oil, and, of course, iron) and even blood transfusions, which were helpful but short-lasting in one patient but caused increased hemolysis in another.[28] This is not surprising, considering the very limited blood matching available at the time and the already enormous size of the spleen at presentation. Splenectomy and Roentgen irradiation of the spleen were also performed without benefit. All the children died shortly after presentation. Detailed autoptic data, showing peculiar abnormalities in the bones and spleen fibrosis, are available. Almost at the same time, Rietti, also from Ferrara, had reported three adult patients, two of whom were father and son, who presented with "primitive hemolytic jaundice" associated with decreased osmotic fragility.[297] Anemia, microcytosis, anisocytosis, and basophilic stippling were noted. The syndrome was probably a form of thalassemia intermedia, and for a long time the eponymic title of *Rietti-Greppi-Micheli* was used in Italy, from the names of those who in those years described similar clinical pictures. In 1932, in consideration of the Mediterranean origin of the patients affected by Cooley anemia, Whipple and Bradford proposed the name of *thalassemia*, from the Greek word *thalassa*, meaning sea.[298] Subsequently, the severe and the mild form of thalassemia were denominated *thalassemia major* and *minor,* respectively.[299]

Unfortunately, the lack of communication between the two sides of the Atlantic made the research in this field, as in others, proceed slowly in parallel.[300,301] In 1940, Wintrobe reported the presence of a familial hemopoietic disorder in adolescents and adults of Italian origin, while in Italy, between 1943 and 1947, Silvestroni and Bianco defined the hematologic, clinical, and epidemiologic characteristics of thalassemia minor and its relationship with thalassemia major.[302] A detailed report of that research can be found in a comprehensive book on thalassemia by Ida Bianco Silvestroni.[303] The picture was further clarified by the identification of HbA2 and its increase in the parents of patients affected by thalassemia major.[304,305] The patients, on the other hand, were found to be completely devoid of HbA and to have, in addition to HbA2, only an alkali-resistant variant usually found in the newborn, HbF.[306] The newly born erythrokinetic technique defined the enormous and ineffective erythropoiesis present in this disease.[307] Between 1956 and 1961 the chemical structure of hemoglobin was described, and soon the complete sequences of globin chains were clarified.[308]

The idea of thalassemia resulting from a defect in the production of adult hemoglobin is due to the contribution of several authors. Globin chain synthesis was able to confirm this hypothesis.[309] The developments in molecular biology are recent history and continue to clarify more aspects of the disease.

Clinical Features

The clinical picture of β-thalassemia major includes features that are due to the disease itself and others that represent the consequences of therapy and are, in a sense, iatrogenic.

Anemia

The early symptoms of the disease appear usually in the first year of life, at the time when the synthesis of γ-chains is not replaced by the synthesis of β-chains. In an ethnically composite population of transfusion-dependent children diagnosed in the United Kingdom, the mean age at presentation was reported to be 6 months, while in a study from Greece the age was 13.1 months, ranging from 2 to 36 months.[310,311] In a study from Sardinia the disease was recognized at around 8 months in patients with transfusion-dependent thalassemia but at age 2 years in non–transfusion-dependent children.[312] The age at diagnosis is influenced by the molecular defect and by the degree of suspicion of the treating physician. Pallor is usually the first sign, accompanied by splenomegaly of various severity, fever, and failure to thrive.

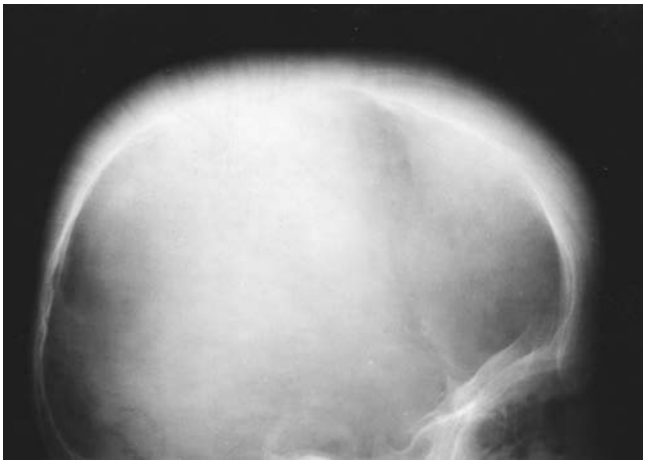

FIGURE 34.6. Radiograph of the skull. In the frontal area, the bone has a lamellated structure, parallel to the inner table of the diploe. In the parietal area, erythroid hyperplasia has perforated the outer table, producing a characteristic "hair on end" appearance. (Courtesy of Dr. C. Orzincolo.)

Bone Deformities

Untransfused or poorly transfused patients with thalassemia develop typical bone abnormalities that were described even in the first reports of the disease and that are due to the extremely increased erythropoiesis, with consequent expansion of the bone marrow to 15 to 30 times normal. The skull is large and deformed by frontal and posterior bossing with the diploe increased in thickness to several times normal. The outer and inner tables are thin and the trabeculae are arranged in vertical striations, resulting in a "hair on end" appearance. A peculiar, stratified appearance of the skull has been reported (Fig. 34.6).[313] The zygomatic bones are prominent, the base of the nose is depressed and pneumatization of the sinuses is delayed. Overgrowth of the maxilla produces severe malocclusion, with a rodent-like appearance. Metatarsal and metacarpal bones are the first to expand as a consequence of increased erythropoiesis (Fig. 34.7). The ribs are broad, often with a "rib-within-rib" appearance, and the vertebral bodies are square. The trabeculation of the medullary space gives the bones a mosaic pattern. Shortening of long bones is frequent, as a result of premature fusion of the humeral and femoral epiphyseal lines.[314,315] Extramedullary erythropoiesis gives rise to masses that protrude from bones where red marrow persists.[316]

Overgrowth from the vertebral bodies can cause cord compression and paraparesis.[317] Ear impairment due to extramedullary marrow growing in the middle ear, and progressive visual loss caused by compressive optic neuropathy have been reported.[318,319] This kind of picture is more often present in patients with thalassemia intermedia, in whom transfusions are avoided at the price of intense autologous marrow hyperactivity. Improvement in the radiologic bone appearance in the cohorts of patients who have undergone regular transfusions from an early age has been striking. The lack of severe skull deformities is reflected in the mildness of thalassemic features that are now observed in most patients. However, bone lesions of a different nature are often observed as a consequence of excessive deferoxamine (DFO) therapy.

Osteoporosis

Reduced bone mineral density and consequent susceptibility to fractures have been observed in thalassemia patients and, in recent years, have been the subject of intense research. Mineral density is usually investigated with dual-energy x-ray absorptiometry (DEXA) at the spinal (L1 to L4) and femoral neck level. Osteoporosis is defined as a decrease in bone mineral density

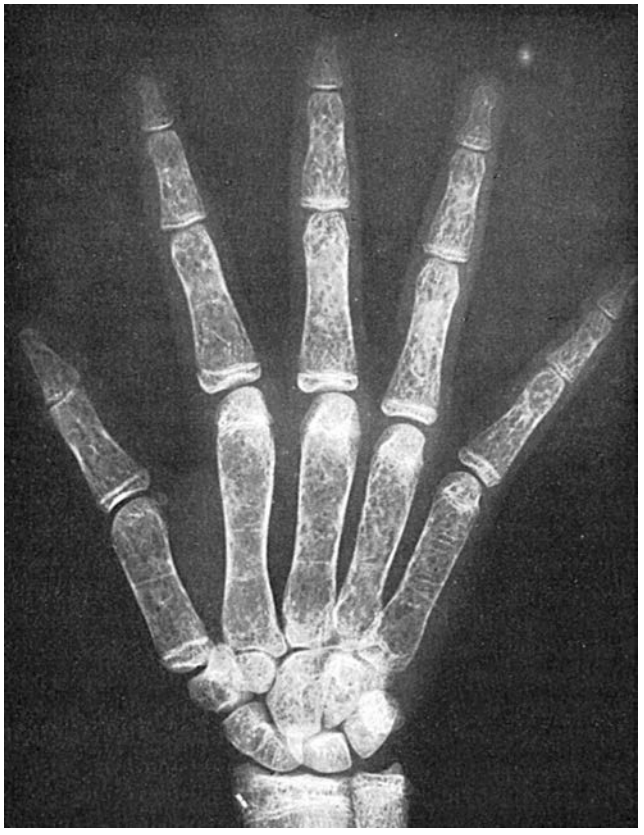

FIGURE 34.7. Mosaic pattern produced by trabeculation in the bones of the hand of a patient with thalassemia major. Note the rectangular contour of the metacarpals.

≥2.5 SD below the young adult mean value, while a decrease between –1 and –2.5 SD is defined as osteopenia.[320] Osteoporosis in thalassemia has been found to affect 48% of the patients, with an additional 44% affected by osteopenia.[321] Although more frequent and severe in males than in females, this complication represents an important cause of morbidity in adult patients of both sexes.[321] The pathogenesis of osteoporosis in thalassemia major is multifactorial and results from a variety of genetic and acquired factors. The polymorphism at the Sp1 site of the collagen type I gene (COLIA 1) has been associated with severe osteoporosis and pathologic fractures of the spine and the hip.[321–323] Moreover, the vitamin D receptor (VDR) Bsm1 and Fok1 polymorphisms were found to be risk factors for bone mineral damage, low bone mineral density, and short stature in prepubertal and pubertal patients.[324] However, different studies of genetic polymorphisms have given contradictory results.[322,325] Acquired factors include the primary disease itself, causing ineffective hematopoiesis with progressive bone marrow expansion; and several secondary factors such as endocrine dysfunction, iron overload and chelation therapy, vitamin deficiencies, and decreased physical activity.[326,327] In particular, vitamin D deficiency is frequent among adolescents.[328] Male sex, lack of spontaneous puberty, and diabetes represent significant risk factors for osteoporosis, while transfusional history, chelation, and erythropoietic activity do not.[329]

Defective osteoblastic activity is thought to be the major pathogenetic mechanism for osteoporosis. There are data demonstrating in thalassemia patients increased serum levels of Dickkopf-1, a soluble inhibitor of osteoblast differentiation that correlates with reduced bone mineral density. Also sclerostin, an inhibitor of osteoblast function, is increased and correlates with bone mineral density of the spine, radius, and femoral neck.[330] In addition, there is evidence of increased osteoclast activation. Elevated markers of bone resorption, such as urinary N-terminal peptides of collagen type I and serum tartrate-resistant acid phosphatase isoform 5b, have been demonstrated.[331,332] The increased osteoclast activity seems to be due to an overproduction of cytokines that are involved in osteoclast differentiation and function.[333] There is evidence that the receptor activator of nuclear factor kappa B ligand (RANKL)/osteoprotegerin (OPG) pathway mediates osteoclast proliferation in thalassemia and contributes to the pathogenesis of osteoporosis.[334] The hypothesis that the RANKL/OPG system is involved in mediating the action of sex steroids on bone[334] has not been confirmed.[335] Fractures, often secondary to mild or moderate trauma, are more frequent in thalassemia patients than in the general population. In a retrospective study, 12% of patients with thalassemia major were found to have suffered from fractures, with an equal distribution between males and females. Prevalence increased with age. The presence of other endocrinopathies, anthropometric parameters, heart disease, or hepatitis C were not significant independent predictors of fractures.[336,337] Bone pain of varying severity is a common complaint among adult patients and has been attributed to expanded bone marrow with consequent pressure on the cortical bone.[338] Magnetic resonance imaging (MRI) in these cases may show the reappearance of hypercellular areas in bones previously replaced by fatty marrow. Reduced and irregular mineralization of the bone has been found using microradiography and X-rays in thalassemic patients with and without clinically evident bone abnormalities.[339] Back pain is sometimes associated with compression fractures and intervertebral disc degeneration.[327,340]

In a recent study, pain was found to be associated with low vitamin D, lower bone density, and bisphosphonate use.[341] Osteoporosis is a progressive disease, thus early detection, prevention, and treatment are essential for effective control of this potentially debilitating condition.[326] Annual follow-up should be started during adolescence.[342] Therapy includes sex hormone replacement therapy, regular exercise, and a diet rich in calcium and vitamin D. In consideration of the pathogenetic data suggesting that in thalassemia patients the reduced osteoblastic activity is accompanied by a comparable or even greater increase in bone resorption, antiresorptive drugs such as bisphosphonates are being increasingly used. To date, alendronate, pamidronate, and zoledronate have been reported to be effective in increasing bone mineral density and normalizing bone turnover.[343–345] Neridronate has improved bone mineral density and reduced back pain in a cohort of thalassemia patients with osteoporosis.[346] One study evaluating the effect of calcitonin on bone mass showed that it prevented bone pain, improved radiologic findings, and decreased the number of fractures.[347] Other agents, like teriparatide and strontium ranelate, are being studied, but their effects remain to be proven.[342]

Cholelithiasis

Gallstones have been reported in patients with thalassemia[348,349] (Fig. 34.8). The percentages found were variable, depending on the transfusion regimens and consequent residual inefficient erythropoiesis and hemolysis, on the time of splenectomy, and, more importantly, on the associated presence of the (TA)7 promoter mutation of the gene of uridindiphosphoglucoronyl-transferase.[350] A recent cooperative study including 858 patients with transfusion-dependent thalassemia found a prevalence of cholelithiasis of 30%. The Gilbert genotype [homozygosity for (TA)^7 motif] influenced both the prevalence of cholelithiasis and the age at which it developed.[351] Ultrasonography of the gallbladder should be checked regularly. If gallstones are present at the time of splenectomy, cholecystectomy should be performed at the same time.

Thromboembolic Complications

Numerous reports of thromboembolic complications in thalassemia have been published. In a multicenter study the

FIGURE 34.8. Spine of a 35-year-old patient with thalassemia major. Reduced mineral bone density is evident, in addition to a gallstone-filled gallbladder.

frequency of thromboembolic events was found to be 4% in patients with thalassemia major and 10% in patients with thalassemia intermedia.[352] Other groups have reported similar prevalences.[353] In a large study of 8860 patients from different countries, female sex, previous splenectomy, and profound anemia were found to represent risk factors.[354] A chronic hypercoagulable state has been observed even in childhood.[205] The mechanisms underlying hypercoagulability in thalassemia are still unclear. Several authors[197,200] have suggested that the presence of a chronic hypercoagulable state could be due to the procoagulant effect of the anionic phospholipids exposed on the surface of the damaged circulating red blood cells and to endothelial derangement occurring as a consequence of an inflammatory state associated with the disease. Also, blood cells and platelets have an important role in increasing the thrombotic risk in thalassemia.[355]

In addition, vascular endothelial cell injury and the peroxidative status due to iron overload are possible pathogenetic mechanisms.[198,206,356]

Concomitant prothrombotic conditions are frequently present in thalassemia patients after the first decade of life: insulin-dependent diabetes, estrogen therapy, atrial fibrillation, and postsplenectomy thrombocytosis, among others. Prophylactic measures are necessary when additional risk factors (e.g., surgery, parturition, immobilization) are present.[354] (See also thalassemia intermedia.)

Pseudoxanthoma Elasticum

Pseudoxanthoma Elasticum (PXE) is an autosomal recessive multisystem disorder affecting elastic tissues. In the majority of families affected by PXE the gene carrying mutations is the ABCC6 gene, encoding a transmembrane transporter protein probably involved in calcium and phosphate homeostasis and primarily expressed in the liver, the kidneys, and the intestine. More than 300 mutations have been identified and lead to the absence of a functional ABCC6 protein. This absence results in a deficiency of circulating factors which should prevent aberrant mineralization, and induces the accumulation of calcium phosphate in skin, eye, and vascular lesions.[357,358] Clinically it is characterized by typical lesions of the skin (small yellowish papules or larger coalescent plaques), eyes (breaks of the elastic lamina of Bruch's membrane called angioid streaks), and arteries (degeneration of the elastic lamina of the arterial wall often accompanied by arterial calcification).[359,360] An acquired PXE-like syndrome has been described in several hemolytic disorders.[361,362] The first reports of typical skin lesions, angioid streaks in the retina, calcified arterial walls, and aortic valve disease in two patients affected by thalassemia was published by Aessopos et al. in 1989.[363] Several subsequent reports have confirmed the existence of a clinical syndrome resembling PXE in thalassemia patients.[364–366,367] It appears to be age-dependent and it is more common in thalassemia intermedia than in thalassemia major. In a study published in 1998 and including patients affected by thalassemia intermedia older than 30 years, arterial calcifications were found in 55%, skin lesions in 20%, and ocular alterations in 52%. Eighty-five percent had at least one of the three typical lesions.[368]

In PXE-like syndromes, lesions are structurally indistinguishable from those of the inherited form. The typical histopathologic features are the abnormal, mineralized, and fragmented elastic fibers (elastorrhexia) in skin, eyes, and arterial blood vessels. Nevertheless, β-thalassemia patients do not harbour mutations in the ABCC6 gene,[366,369] and the pathophysiology remains unclear. At first, it was suggested that, like so many other complications of the disease, this syndrome could be the result of an iron-induced oxidative tissue damage, caused by hemolysis and iron overload.[368,370] Recently, it has been demonstrated that a significant, progressive, liver-specific downregulation of Abcc6 expression can be found in the mouse model of β-thalassemia. Despite the fact that these mice do not develop connective mineralization, they could represent a model for clarifying the increased susceptibility to dystrophic mineralization in dermal, ocular, and vascular tissue of β-thalassemia patients.[371] The abnormalities in elastic fibers of arterial walls may lead to several serious and life-threatening vascular complications in both the inherited and acquired forms. In the thalassemic population several cases of cardiac involvement have been reported, including rupture of chordae tendineae and aneurysmatic dilatation of the ascending aorta.[368,372–375] In an Italian study, five out of 14 thalassemia patients with a PXE-like syndrome died because of cardiovascular complications. Thrombotic events and gastrointestinal and intracranial bleeding, which preclude the use of platelet antiaggregants, can also complicate the clinical course.[376] Close surveillance of these patients is therefore mandatory.

No effective therapy is available for PXE and PXE-like syndromes. Several promising avenues for the treatment are currently being explored. The phosphate binders, a group of drugs given in the attempt to limit the intestinal absorption of phosphate, and consequently normalizing the serum calcium phosphate product, could offer a means of reducing the calcium/phosphate load in patients with PXE. Histopathologic regression of skin calcifications was demonstrated in 3 out of six patients treated with aluminum hydroxide for 1 year, and in all six no progression of the ocular angioid streaks was observed.[377] In a knocked-out ABCC6 gene (Abcc6 –/–) mouse model of PXE, a magnesium carbonate–enriched diet completely prevented mineralization of the vibrissae,

an early biomarker of the mineralization process.[378] The mechanisms by which magnesium may prevent calcium phosphate deposition in tissues are not clear, but a marked increase in the urinary output of calcium, with concomitant reduction in phosphate, has been obtained in these mice.[378,379]

These results suggest that changes in diet, and specifically changes in dietary magnesium and phosphate binders, may offer a potential treatment modality for this so far intractable disease.[380] Recent reports on the use of intraocular injection of antiangiogenic agents targeting vascular endothelial growth factor in age-associated macular degeneration have suggested that significant improvements in visual acuity could also be achieved in patients with PXE.[381,382]

Molecular strategies based on specific mutations identified in the ABCC6 gene, gene therapy approaches targeting a transgene to restore its function in the liver, and anti-mineralization factors with a potential role as modifiers (fetuin-A, for example) are still being tested.

Secondary Gout

Hyperuricemia is not unusual in thalassemia patients, but gouty arthritis has rarely been reported.[383]

Laboratory Findings and Diagnosis

Laboratory data at presentation are characterized by HbF levels ranging from 10% to 100%; HbA2 may be normal or increased up to 5% to 7%; and the remaining percentage is constituted by HbA. HbF is heterogeneously distributed among red cells. The reticulocyte count is low, usually below 1%. MCV is typically 60 to 70 fl and MCH is 12 to 18 pg/cell. In the peripheral blood smear a great variation in size and shape of the erythrocytes is always evident. Microcytes, tear drop cells, and nucleated red cells are present, together with large and pale target cells (Fig. 34.9). The Hb composition varies mainly accordingly to the patient's genotype. Homozygotes for β^0-thalassemia mutations have only HbF (93% to 97%) and HbA2 (3% to 7%) and no HbA, while homozygotes for β^+-thalassemia mutations and β^0/β^+ genetic compounds have HbA, HbA2, and a variable, but always significantly elevated, amount of HbF (10% to 90%). HbA2 in homozygous β-thalassemia may be normal or increased and so of no diagnostic value. Hb separation to determine the hemoglobin pattern can be performed with different methods (electrophoresis at alkaline or acidic pH, isoelectric focusing, high performance liquid chromatography [for details, see (384,385)]). In the case of transfused patients, diagnosis can be made by globin chain synthesis analysis from peripheral blood reticulocytes, which shows a severe α/non-α imbalance (usually higher than 2), or by β-globin gene analysis to identify the various DNA mutations (details on DNA methods can be found in specific surveys and laboratory manuals).[386]

Therapy

Blood Transfusion

The decision on whether and when to start transfusion therapy in a child with thalassemia is not an easy one and should be based on a precise molecular diagnosis indicating the severity of the thalassemic defect, on the level of hemoglobin, and on general conditions and satisfactory growth. Evidence of increasing splenomegaly, of bony expansion, and of consequent modification of facial features should also be considered. The age at which starting transfusion becomes necessary in thalassemia varies according to the prevalent genotypes in a particular ethnicity. Delaying the age of transfusion increases the risk of developing allo- and autoantibodies.[223]

For many years after the description of thalassemia major as a clinical entity, therapy was limited to blood transfusion when symptoms of anemia were so severe as to incapacitate the patient. The corresponding levels of hemoglobin (Hb) were different in different patients, but varied between 6 and 7 g/dl. As a consequence of continuous anemia, erythropoiesis, although inefficient, was intense, the bone marrow underwent an enormous expansion, and the plasma volume increased greatly. In addition, the liver and spleen increased in size as a consequence

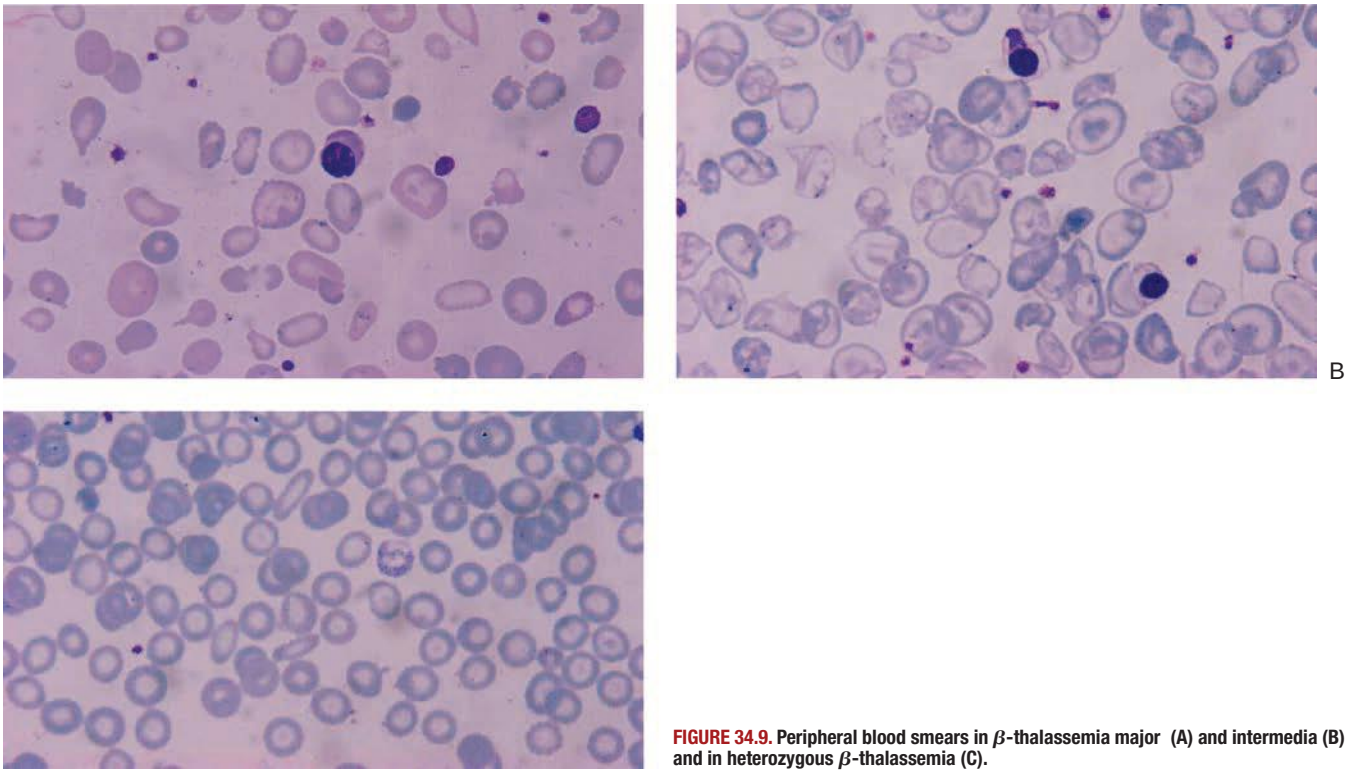

FIGURE 34.9. Peripheral blood smears in β-thalassemia major (A) and intermedia (B) and in heterozygous β-thalassemia (C).

of both extramedullary erythropoiesis and hemolytic activity in the reticuloendothelial tissue. The bone deformities caused by the expanded marrow are typical of thalassemia and gave to all the poorly transfused patients similar features (see above). In the 1960s, however, the superiority of regular and methodically repeated transfusions was recognized, first by Orsini in France, and later by Wolman in Philadelphia and Piomelli in New York, who started a program of chronic transfusion directed at maintaining a baseline Hb level adequate to eliminate hypoxia and thus suppress its consequences.[387–389] It was calculated then that the amount of iron administered to maintain a minimum Hb of 9.5 g/dl was only 50% greater than that resulting from a baseline Hb of 6 g/dl, and that the additional iron intake could be counterbalanced in part by the reduction of intestinal iron absorption. This kind of regimen, that never allowed Hb level to fall below 9.5 to 10 g/dl, was termed "hypertransfusion." Complete bone marrow suppression, however, is seldom obtained at these Hb levels, and therefore some bone remodeling and expansion of the blood volume persist. To completely correct the effects of anemia, Propper et al. in 1980 launched what was called a "supertransfusion" regimen, where the pretransfusion hematocrit was kept at ≥ 35%.[390] The hypothesis was that, as a consequence of the reduction of the blood volume, the amount of blood needed to maintain a higher baseline would not have been greater than the blood volume used for the lower baseline. A few papers from Europe confirmed the data; but, since the blood that is destroyed between transfusions and that needs replacing is a percentage of the patient's red cell mass, patients kept at a higher baseline Hb level require a larger amount of blood and therefore accumulate more iron.[391–393] In a study of patients kept at a pretransfusion hemoglobin level between 9 and 10 g/dl, the erythroid marrow activity, evaluated through the measurement of serum transferrin receptor, did not exceed two to three times normal levels. On the basis of these studies, the majority of centers choose to transfuse at a Hb level of 9 to 10.5 g/dl.[394] The recommended post transfusion Hb is 14 to 15 g/dl. Leuko-reduced packed red cells are recommended for eliminating the adverse reactions attributed to contaminating white cells and for preventing platelet alloimmunization. The number of residual leukocytes should not be higher than 1×10^6. At present the preferred method for leukoreduction is prestorage filtration of whole blood with an inline filter within 8 hours after blood collection. Alternatively, laboratory filtration can be used pretransfusion. With this method, packed red blood cells are prepared from donor whole blood, then filtered prior to release from the blood bank. Finally, the packed red cell unit can be filtered at the bedside.

The current recommended practice is to use red cell units that have not been stored more than 2 weeks. Extended red cell antigen typing, including at least the Rh antigens, Duffy, Kidd, and Kell, is recommended before the patient is started on a transfusion regimen. Transfusion of young red cells (neocytes) obtained by centrifugation has been proposed in the attempt to reduce the total blood requirement, but the results obtained were not sufficient to justify the increased cost and the exposure to a larger number of donors.[395,396]

In general, the transfusion rate is 5 to 6/ml/kg/hour. In the case of patients with cardiac failure, blood should be infused at a slower rate (no more than 3 to 4 ml/Kg/h), and the administration of diuretics before transfusion is advised. The recommended interval between transfusions should take into account the patient's practical needs, as long as a pretransfusional Hb ranging between 9 and 10.5 g/dl is maintained. It is important to keep an accurate record of the amount transfused, in order to calculate the iron intake of the patient. The annual intake is expressed in ml/kg/yr of pure red cells, assuming that 1 ml of pure red cells contains 1.08 mg of iron.[397] It has been observed that the level of Hb maintained during the warm months is lower than that during the cold months. Possible mechanisms include expansion of plasma volume with resultant hemodilution in the patient, and lower hemoglobin content in donor blood.[398]

For the comfort and safety of the patient, there should be a designated area at the hospital where transfusions will be administered and supervised by regular staff, well known to the patients and their families. It is often necessary for the center to be able to provide after hours transfusions, especially for children going to school and for working patients.

Complications of Transfusions

Although blood transfusions are life-saving for thalassemia patients, who no longer die of anemia, they can be complicated by transfusion reactions, alloimmunization, infections, and hemosiderosis.

Febrile Nonhemolytic Transfusion Reactions. A cooperative effort conducted 20 years ago, the Cooleycare initiative, reviewing more than one hundred thousand red cell transfusions in Italy and Greece, found that transfusion reactions complicated 1% of all transfusional events in 16% of the patients.[399] About 90% of the red cell units infused were leukocyte-poor. Chills, fever, urticaria, headache, and chest pain accounted for more than 80% of symptoms reported, and in two-thirds of cases, reactions were reported during transfusion.[400] Alloimmunization to HLA-antigens on leukocytes is the most common cause of febrile reaction in multiply transfused thalassemic patients. If blood is not filtered prestorage, cytokines may develop during storage and be responsible for the reaction. Treatment includes acetaminophen or hydrocortisone. Allergic reactions, due to plasma proteins and manifesting as hives, pruritus, and more rarely edema, are best treated with an antihistaminic drug.

Alloimmunization. Alloimmunization and autoimmunization can complicate transfusion therapy. The frequency of alloimmunization against red cells is variable, the lower percentages being found in patients who received blood matched for the ABO, Rhesus, and Kell systems from their first transfusion. In a multicenter study, allo- and autoantibodies were reported in 16.5% and 4.9% of patients, respectively. Splenectomized patients were 2.5 times more likely to have developed alloantibodies.[401]

Another study from a single large center found that 19.5% of the thalassemia patients developed alloantibodies, 94% of them being against the Rhesus or Kell antigens. Older age, higher transfusion frequency, and splenectomy were risk factors for alloimmunization.[402]

The risk of developing alloantibodies is not uniform and is probably genetically determined. Transfusion in infancy seems to induce immune tolerance.[223] Asians appear to be at a higher risk of developing allo- and autoantibodies.[403] In addition, the risk of alloimmunization is higher in individuals from ethnic minorities that, in general, donate less. In the US, the donation rates of African-American are 25% to 50% of that of white individuals.[404]

This phenomenon is present also in Europe, where the immigrant population, potentially at risk for hemoglobinopathies, is increasing in recent years. Donation by minorities should be encouraged to prevent the formation of red blood cell alloantibodies, which can result in hemolytic transfusion reactions and difficulty in finding appropriate red blood cells for future transfusions.

Infections. The risk of transfusion-transmitted viral infection is well known. Among the most frequent and clinically relevant are the widely diffused hepatotropic viruses hepatitis B and C (HBV, HCV). The prevalence of infection of these viruses in multitransfused patients is different in different parts of the world and is directly related to the frequency in that population. Worldwide, from 0.3% to 5.7% of thalassemia patients are hepatitis B surface antigen (HBsAg)–positive[405,406,407] and from 4.4% to 85% are positive for anti–hepatitis C antibodies.[408,409] The prevalence of HBV chronic infection is higher in countries in Asia and Southeast

Asia, whereas HCV chronic infection is widespread throughout the world. The DNA-recombinant vaccine against hepatitis B virus, safe and effective, is available and should be administered to all patients who have not yet been infected. Hepatitis G virus and GB virus C (GBV-C) are RNA viruses that were independently identified in 1995, and were subsequently found to be two isolates of the same virus. Together with transfusion-transmitted (TT) virus, they are common among thalassemia patients but have not been found to contribute to chronic hepatocellular damage.[410] West Nile Virus infection has become of concern in recent years. Epidemics have been reported, and the virus can be transmitted through blood transfusion.[411,412] In the United States, testing for West Nile virus antibodies has been implemented in 2003,[413] and nucleic acid testing is widely used in Europe in endemic areas.

CMV is widespread in most populations. A European collaborative study revealed a positive CMV IgG test in two-thirds of the thalassemia patients examined.[414]

HIV infection was acquired almost exclusively before the systematic screening of blood donation. In 1987 the prevalence of HIV in thalassemia patients from 13 European or Mediterranean countries was found to be 1.56%. Two years later no HIV seroconversion was observed in the same areas when a total of 2,972 patients affected by thalassemia who had received 96,518 blood units were examined.[415] Since 2004, several cases of transfusion-associated variant Creutzfeld-Jacobs Disease (vCJD) have been reported and linked to blood collected from preclinically affected donors. Animal data suggest that all blood components are vectors for prion disease transmission.[416] Malaria can be transmitted by transfusion in endemic areas.[417] A screening program for *Trypanosoma cruzi*, a parasitic infection endemic in Central and South America, which is spreading into nonendemic countries with the migration of infected individuals, was developed in 1998 in the United Kingdom[418] and in 2007 in the United States.[413] Although significant improvements have been made to further decrease the incidence of transfusion-transmitted infections, risks remain for infectious disease agents specific to red blood cell concentrates including emerging viruses, bacteria, protozoa, and residual contaminating leukocytes.[419–421] Pathogen and leukocyte inactivation of red blood cells is therefore of potential relevance in order to transfuse patients with completely pathogen-inactivated blood units. A pathogen inactivation system for red blood cells, based on a nucleic acid (DNA and RNA) targeting and crosslinking compound, is being actively developed and is reaching clinical application.[422]

In a recent review, the major results from more than 150 articles published by the Retrovirus Epidemiology Donor Study (REDS), conducted from 1989 to 2001, and the REDS-II, conducted from 2004 to 2012, were reported. These were National Heart, Lung, and Blood Institute–funded, multicenter programs focused on improving blood safety and availability in the United States. REDS-II also included Brazil and China, while the just launched REDS-III will also include South Africa. The three major research domains of REDS/REDS-II have been evaluation of infectious risk, blood donation availability, and blood donor characterization. Blood safety studies have included protocols evaluating epidemiologic and/or laboratory aspects of human immunodeficiency virus, human T-lymphotropic virus 1/2, hepatitis C virus, hepatitis B virus, West Nile virus, cytomegalovirus, human herpesvirus 8, parvovirus B19, malaria, Creutzfeldt-Jakob disease, influenza, and *Trypanosoma cruzi* infections.[423]

Predisposing factors for bacterial infections include prior splenectomy, iron overload, and use of the iron chelator deferoxamine. Despite the availability of prophylactic measures against encapsulated organisms, the risk of severe, sometimes fatal, infections is still high in splenectomized patients.[424] Iron overload and deferoxamine favor the growth of organisms such as *Yersinia enterocolitica* and *Klebsiella pneumoniae*, *Yersinia* being more prevalent in temperate regions and *Klebsiella* in tropical and subtropical areas. *Yersinia* infection should be suspected in the presence of fever, diarrhea, right-lower-quadrant abdominal pain, and a palpable abdominal mass. Abdominal suppurative complications have been reported.[425] Deferoxamine, but not deferiprone or deferasirox, increases growth of *Yersinia* both in vivo and in vitro. In fact, being a siderophore, deferoxamine can be used by this organism as a source of iron. Growth of *Klebsiella*, on the contrary is only moderately enhanced by DFO in vitro and not at all by deferiprone or deferasirox. Several reports have described infection with *Aeromonas hydrophila* in Asia. The growth of *Aeromonas hydrophila*, however, does not seem to be affected by any of the three chelators.[426]

Hemosiderosis

In patients who undergo transfusional therapy for several years, the accumulation of iron, if untreated, causes considerable morbidity and ultimately leads to death. Since each unit of blood contains approximately 200 milligrams of iron, a patient who receives 25 to 30 units of blood a year, by the third decade of life, in the absence of chelation, will accumulate over 70 g of iron.[427] In addition to the iron administered through blood transfusions, a hyperactive bone marrow will favor increased intestinal iron absorption that will contribute, although marginally, to the total body load. This mechanism has recently been clarified. Duodenal iron absorption is regulated by the hepcidin-ferroportin axis, and hepcidin, in turn, is regulated by plasma iron concentration and iron stores. Hepcidin is a 25–amino acid peptide, synthesized in the hepatocytes, that controls the concentration of ferroportin on the intestinal epithelium. Ferroportin is the primary means of cellular iron efflux and a key component of iron metabolism. Hepcidin regulates ferroportin activity by inducing its internalization and degradation. Low levels of hepcidin correlate with higher levels of ferroportin, resulting in increased intestinal iron absorption.

In addition, hepcidin is homeostatically regulated by the iron requirements of erythroid precursors for hemoglobin synthesis. In iron-loading anemias associated with ineffective erythropoiesis, hepcidin production is suppressed by a signal mediated by growth differentiation factor 15 (GDF15), which is expressed at high levels in conditions of intense erythropoietic drive.[430] As a consequence, in β-thalassemia, whenever the bone marrow is not completely suppressed by blood transfusions, iron absorption is increased, even in the presence of iron overload.[195,428–431]

Excessive iron may damage the cell by several mechanisms. In patients who have fully saturated transferrin, a significant fraction of the total iron in plasma circulates in the form of low molecular weight complexes not bound to transferrin.[432] Although the exact mechanism of tissue damage remains unclear, the most important pathogenetic factor appears to be iron-induced peroxidative injury to the phospholipids of lysosomes and mitochondria. The redox active component of non-transferrin–bound iron is referred to as the labile plasma iron and it can be identified with oxidant-sensitive fluorescent methods.[433–435]

Control of circulating labile plasma iron is crucial to prevent oxidative damage and to decrease the risk of organ dysfunction. At present, an easy method for serial labile plasma iron measurements is not available.[436,437]

Excessive iron stores lead to depletion of substances that defend against free radical attack, e.g., among others, ascorbic acid, which is oxidized to oxalate, and vitamin E.[438] This in turn causes sequestration of the iron in the reticuloendothelial system, somehow protecting tissues from siderosis.[439] At suboptimal concentration, ascorbic acid is a pro-oxidant and enhances the catalytic effect of iron in free radical formation. The presence of the genetic hemochromatosis mutations does not seem to influence the degree of iron overload and its consequences in regularly transfused and chelated patients with thalassemia major.[232]

Assessment of Iron Stores. The iron status of multitransfused patients can be assessed by several methods. The use of two or more parameters will usually provide a good estimate of the total amount of iron accumulated. Serum iron is always elevated. Transferrin saturation correlates reasonably well with serum ferritin.[440,441] After only a few years of transfusion, however, transferrin is completely saturated in the majority of patients. In thalassemia major, serum ferritin has, in general, been found to correlate well with iron stores, as measured by phlebotomy, and with liver iron, either measured directly by liver biopsy or by MRI.[195,429] (Fig. 34.10) Significantly higher ferritin levels are present in patients with endocrinopathies,[442,443] cardiac failure, and arrhythmias than in patients without such complications. Levels above 2,500 ng/dl have been reported to be associated with a four-fold higher risk of death.[444]

Several variables can interfere with the reliability of ferritin as a marker of iron overload. Ferritin, being an acute phase reactant, is increased in chronic disease, malignancy, or inflammatory disorders. A ferritin concentration of 4,000 mcg/L is considered the maximum level of physiologic synthesis, while higher values would represent the release of intracellular ferritin from damaged cells.[445] Ascorbic acid deficiency can lead to decreased synthesis and release of ferritin. This can therefore lead to ferritin levels that are only mildly elevated, even in the presence of massive iron stores.[446] A low level of hepcidin also results in iron depletion of macrophages, decreasing their secretion of ferritin and, therefore, serum ferritin levels. This phenomenon is particularly evident in thalassemia intermedia.[195] Conversely, patients with active liver disease may have high levels of serum ferritin that do not mirror the body iron load.[447]. Despite all this, serial measurements of serum ferritin remain a reliable means, and the easiest one, to evaluate iron overload and efficacy of chelation therapy. The measurement of iron excretion over 24 hours, after an intramuscular injection of 500 mg of desferrioxamine was, in the past, used largely to establish the time to start chelation therapy or to evaluate the iron burden. Unfortunately, the correlation between urinary excretion and body iron is not very good, as many factors, including dose of chelator administered per unit of weight of the patient and vitamin C status, contribute to influence iron excretion.

The total iron burden can be estimated by direct measurement of iron concentration in the liver. Needle biopsy specimens of 1 mg dry weight are adequate. The measurement is done by atomic absorption spectrometry on ashed or lyophilized samples and correlates well with the total amount of blood transfused and with the extent of hepatic fibrosis.[448] Removal of body iron by phlebotomy after bone marrow transplantation has demonstrated that total body iron stores (in milligrams per kilogram of body weight) are equivalent to 10.6 times the hepatic iron concentration (in milligrams per gram of liver, dry weight). The correlation's standard error is <7.9. In the absence of cirrhosis, the correlation is linear up to a body iron burden of 250 mg/kg.[448]

The variation in iron concentration throughout the liver, however, increases with the iron loading and in the presence of cirrhosis. The coefficient of variation for multiple needle biopsy measurements ranges from an average of 19% for disease-free liver to more than 40% for end-stage cirrhosis.[450,451] Magnetic susceptometry, a noninvasive method, is based on the magnetic response of ferritin and hemosiderin iron contained in the liver.[452,453] The equipment necessary for this measurement (SQUID: superconducting quantum interference device) is available in two sites in the US, one in Germany, and one in Italy.

At present, MRI R2* assessed clinically via its reciprocal, T2-star (T2*), is widely used for the evaluation of iron in myocardium and liver. The T2* technique for the measurement of tissue iron, was developed in 2001 by Anderson and colleagues, and validated by chemical estimation of iron in patients undergoing liver biopsy.[454]

T2* is a magnetic relaxation property of any tissue and is inversely related to intracellular iron stores. Iron deposits shorten T1, T2, and T2*. T2* has become the most widely used because it is the most sensitive to iron deposition. Measurement is simple, quick, and robust, and has high reproducibility. An additional advantage of the technique that makes it particularly helpful for measuring heart iron is its ability to measure ventricular function. As myocardial iron increases, there is a progressive decline in ejection fraction. In the original study all patients with ventricular dysfunction had a myocardial T2* of <20 ms.

Iron calibration in humans for cardiovascular magnetic resonance R2* against myocardial iron concentration has been reported.[455] An MRI multislice multi-echo T2* technique for global and segmental measurement of iron overload in the heart, whose reproducibility has been validated, is in use in most Italian centers.[454,456,457]

A validated, noninvasive method of measuring and imaging liver iron concentration in vivo using a magnetic resonance imaging unit (MRI) was reported by St. Pierre et al.[450] High degrees of sensitivity and specificity of mean liver proton transverse relaxation rates (R2) were found at clinically significant liver iron concentrations. Although most 1.5 Tesla magnets are able to perform iron estimation measurements, specialized software and local expertise are required for accurate assessment. As a result, some centers have chosen to purchase commercial software or outsource their image analysis to a central facility where the data are sent by telemedicine.

More recently MRI T2* was used for assessing iron in the pancreas,[458–460] hypophysis,[461] and kidneys.[462,463]

Clinical Manifestations of Iron Overload

Heart

Cardiac complications are frequent and heart failure and arrhythmias are responsible for 70% of the deaths of patients treated with deferoxamine[442]. A recent Italian cooperative study, performed as a part of the MIOT (Myocardial Iron Overload in Thalassemia) initiative, demonstrated that out of 776 thalassemia major patients, 22% had a diagnosis of one or more cardiac problems, including heart dysfunction (66%), arrhythmias (14%), and both heart dysfunction and arrhythmias (19%).

The prevalence of heart dysfunction and/or arrhythmias is significantly higher in males than in females.[464]

Heart disease, a consequence of iron overload, is mediated through the labile iron-induced peroxidative injury to the phospholipids of lysosomes and mitochondria, demonstrated both in vitro and in the experimental animal.[434,465] In the absence of chelation, subclinical dysfunction appears in the second decade of life, or when approximately 20 grams of iron have been accumulated. Subsequently, cardiomegaly and left ventricular deterioration progress to congestive heart failure. Arrhythmias can cause sudden death.[466] In asymptomatic thalassemia patients with normal myocardial mass, diastolic dysfunction appears to be an early event, even when the systolic function is only mildly impaired. The classic picture of end-stage iron-induced cardiomyopathy is a combination of left ventricular diastolic dysfunction, pulmonary hypertension, and right ventricular dilatation.[467]

Although chelation has a crucial role in preventing or correcting the cardiac damage, iron accumulation has been documented in patients with good compliance and low ferritin and liver iron concentration.[468,469]

The measurement of cardiac iron, until recently, was difficult to obtain. The results of endomyocardial biopsies are not accurate,[470] and traditional diagnostic tools (ECG, 24-hour tracings, echocardiography, nuclear studies), although routinely utilized, are not predictive of subsequent cardiac dysfunction. When positive, the myocardiopathy is often advanced. As mentioned above, the cardiovascular magnetic resonance relaxation parameter R2* (assessed clinically via its reciprocal, T2*) measured in the ventricular septum has greatly increased the amount of information obtainable on heart iron content and function. A fast spin-echo sequence is available to permit acquisition of multiple images in one breathhold.[471] The technique has recently been validated against 12 human hearts from transfusion-dependent patients.[445]

The predictive value of cardiac T2* for heart failure and arrhythmia in thalassemia has been assessed on 652 thalassemia major patients from 21 UK centers. The relative risk of developing heart failure within 1 year was 160 with cardiac T2* values <10 ms (compared with >10 ms) and 270 with a T2* <6 ms. Cardiac T2* was <10 ms in 98% of patients who developed heart failure and had a greater predictive value than serum ferritin and liver iron concentration.[472] (Fig. 34.11).

Right ventricular dysfunction, which mirrors the decrease in left ventricular function, has been demonstrated with worsening of cardiac iron loading.[473,474]

A poor correlation between myocardial and liver iron has been clearly documented[468] (Fig. 34.12).

The prognosis for thalassemic patients with heart failure has always been considered dismal.[475] More recently, however, the availability of more intensive chelation regimens, particularly effective on the cardiac iron load, has modified the course of the disease, and cardiac failure and arrhythmias can be considered reversible complications in a large number of patients. Improvements of as little as 2% to 3% in ejection fraction, measured by MRI, have been found to reduce significantly the risk of cardiac failure within a year.[476]

Deferoxamine has been crucial in improving survival and decreasing iron-induced heart disease. However, with the introduction of MRI T2*, myocardial siderosis was found in two-thirds of thalassemia major patients on deferoxamine treatment and was associated with a high prevalence of left ventricular dysfunction.[469]

It has been suggested that deferiprone is more effective than deferoxamine in chelating iron from the heart. In a 9-year study, we observed 52 cardiac events, including ten cardiac deaths, in patients treated with deferoxamine only, while no cardiac event developed in patients who were switched to deferiprone.[444] No data are yet available on the efficacy of deferasirox on life expectancy, but continuous treatment with deferasirox for 2 years at a high dose has been shown to remove iron from the heart in patients with mild, moderate, and severe cardiac siderosis.[477]

In another MRI study, monotherapy with deferasirox was effective in patients with mild to moderate iron stores, but failed to remove cardiac iron in patients with severe hepatic iron burdens, and the left ventricular ejection fraction was unchanged. At present, for patients with severe myocardial siderosis and impaired left ventricular function, combined chelation therapy with subcutaneous deferoxamine and oral deferiprone is indicated. There are data, in fact, that combined therapy reduces myocardial iron and improves cardiac function.[478]

In a long-term study from Cyprus, combined therapy with deferoxamine and deferiprone was shown to prevent deaths related to iron overload.[479] Results of multivariable analysis demonstrated a 7.4-fold improved survival for each year on combination therapy.[480]

Similarly, a Greek study reported a risk of cardiac death of 9.5 per 1,000 patient-years for deferoxamine, 2.5 for deferiprone, and 1.4 for combination therapy. In the deferasirox group no cardiac deaths were recorded. The risk for a de novo cardiac event for patients on DFO was 9.1 times greater than for patients

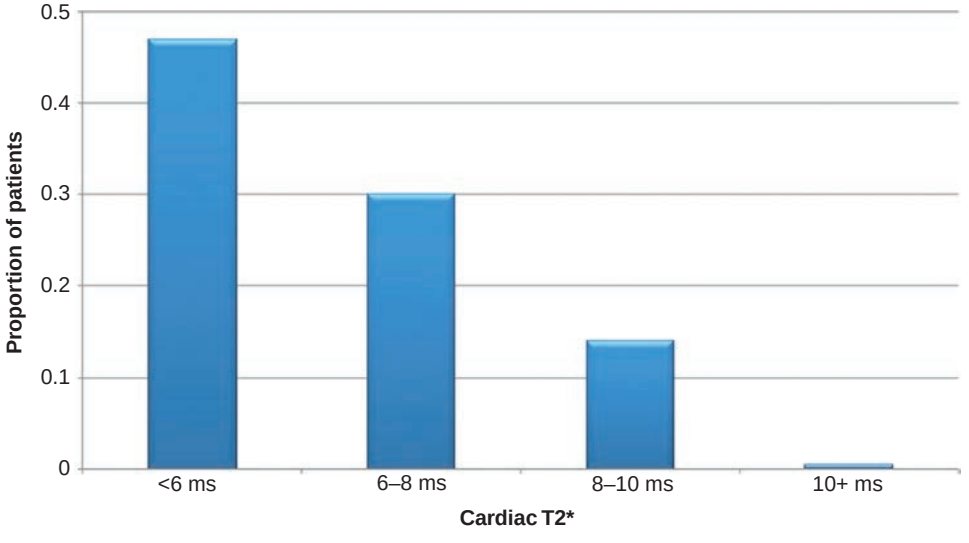

FIGURE 34.11. Proportion of patients developing heart failure after 1 year, according to different baseline cardiac T2* values. (Adapted from Kirk P, Roughton M, Porter JB, et al. Cardiac T2* magnetic resonance for prediction of cardiac complications in thalassemia major. Circulation 2009;120:1961–1968.)

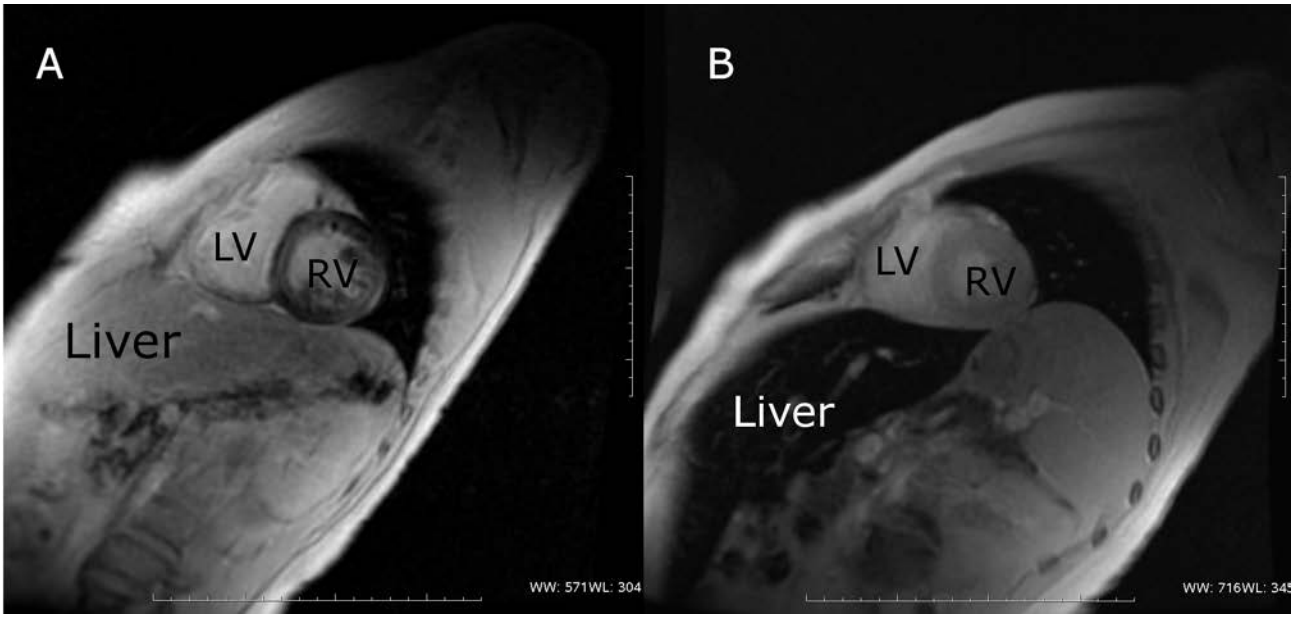

FIGURE 34.12. Heart multislice multi-echo MRI T2* obtained with a 1.5 T scanner. Short axis plane shows discordance of liver and heart iron deposition. A: Heart iron deposition, in contrast with minimal liver iron load. **B:** Severe hepatic iron overload and normal heart iron. (Courtesy of Alessia Pepe, Magnetic Resonance Unit Fondazione G. Monasterio CNR, Tuscany Region, Italy.)

on DFP and 23.6 times greater than for those on the combination of DFP and DFO. For DFX, there was one cardiac event over 269 patient-years.[481]

In addition, the striking reduction in cardiac deaths observed in the United Kingdom in the last decade has been attributed to the combined benefits of T2*, which identifies myocardial siderosis, and of tailored intensification of chelation therapy.[482]

Acute episodes of sterile pericarditis were seen, in the pre-chelation era, in about half of the patients with massive iron overload, but are now uncommon in regularly transfused patients.[483]

Diabetes represents a risk of cardiac complications even when other variables have been accounted for. The presence of iron overload in the pancreas predicts heart siderosis.[459]

Pulmonary hypertension is a possible concomitant cause.[484] An elevated tricuspid regurgitant jet velocity has been described in one-third of transfusion-dependent thalassemia patients, both adults and children. Age, splenectomy, hepatitis C, and smoking were significant univariate risk factors.[485]

However, the use of tricuspid regurgitant jet velocity as a surrogate marker of pulmonary hypertension could be inadequate in patients with chronic anemia and hyperdynamic cardiac activity.[486]

A recent review of Italian patients by means of a shared Internet database, found that approximately 19% of regularly transfused and chelated thalassemia major patients needed cardiovascular drug therapy. This subgroup was characterized by a dilated and mildly hypokinetic left ventricle when compared with the majority of thalassemia major patients, who did not need cardioactive drugs.[487] Management of cardiac complications in patients with thalassemia major has been described.[488] In asymptomatic or minimally symptomatic patients with left ventricular dysfunction, the angiotensin-converting enzyme inhibitor enalapril produced significant improvement in systolic and diastolic function as demonstrated by echocardiography.[489] The treatment of arrhythmias is difficult and the risk of pro-arrhythmic effects of antiarrhythmic drugs is high. The help of a cardiac electrophysiologist is often necessary. Heart transplantation has been attempted with variable results. This kind of treatment, however, should no longer be necessary, except for older patients who could not benefit from the effective chelation and supportive therapy available nowadays.[490,491]

Liver

Liver disease is a major complication of thalassemia major and is due to the damage produced by iron overload and, in a large proportion of older patients, to the effects of transfusion-transmitted viral infections. Liver iron can be assessed by different methods. Today the method of choice is the MRI R2 or its reciprocal T2. A correlation between T2* and liver iron concentration, as measured by biopsy, has been observed with a relatively good sensitivity and specificity for levels above 3.2 mg Fe/g dry tissue. Sensitivity and specificity for higher liver iron concentrations are less satisfactory (e.g., at 7 mg Fe/g, dry tissue sensitivity and specificity are 70% and 88%, respectively. The R2 (1/T2) technique (Ferriscan®) has been registered in the European Union, and can be done on a standard MRI scanner, with data sent electronically to a commercial organization for analysis.[450,492]

Hepatic siderosis in the absence of chelation is present from the very early stages of iron loading and progresses to fibrosis and cirrhosis.[493]

The mechanisms responsible for the effects of iron are not completely clear. Data in rats suggest that peroxidation of intracellular organelles (lysosomes and mitochondria) and membrane components by reactive oxygen species is the major cause of tissue toxicity and organ damage. Iron mediated oxidation, and the consequent loss of integrity of RNA is considered an important contributing factor to disease development.[494]

Also, an interplay between iron and calcium has been demonstrated in isolated rat liver in a laboratory setting and could be considered as an important mechanism of iron toxicity in liver cells.

Liver biopsy is still considered the gold standard to assess liver inflammation and fibrosis. The degree of liver fibrosis is best documented histologically by the Ishak score.[495,496]

However, liver biopsy is an invasive procedure associated with some discomfort, and its accuracy for the evaluation of liver fibrosis is questionable in relation to inadequate tissue sampling and

intraobserver and interobserver variability.[497] Transient elastography, a technique that uses both ultrasound and low-frequency elastic waves whose propagation velocity is directly related to the elasticity of the liver tissue, is widely used to measure liver stiffness in chronic hepatitis C and appears to be a reasonably accurate method for detection of cirrhosis in thalassemia patients, regardless of the degree of iron overload.[495,498,499,500]

Fibrosis of the liver directly correlates with age, number of units of blood transfused, and liver iron concentration.[501]

HCV infection is widely diffused among thalassemia patients who had been transfused before 1989 when the virus was identified and before a systematic screening of blood units was performed.[502] The most common genotype is the genotype 1b.[409,503,504,505] In the United States, a third of the transfusion-dependent thalassemia patients were found to have antibodies against HCV. Of these, one-third were RNA positive.[407] The residual risk of transfusion-transmitted infections associated with the window-period donations is extremely low in industrialized countries, especially after the introduction of NAT technology to screen blood donations, but it remains significant where the prevalence of infection in the population is high.[506–508] Other hepatotropic viruses, such as GB virus C and transfusion-transmitted (TT) virus, are also common among thalassemia patients but have not been found to contribute to chronic hepatocellular damage. HCV hepatitis becomes chronic in 70% to 80% of infected individuals. It has been calculated that 20% of HCV chronically infected patients will develop cirrhosis within 10 years and that their risk of developing hepatocellular carcinoma is increased.[509] Transaminase levels typically fluctuate between normal and slightly elevated values, with a good correlation being demonstrated between transaminase levels and viral load measured by quantitative polymerase chain reaction.[502]

Recommendations on the management of chronic hepatitis in patients with thalassemia have recently been published.[503]

According to these recommendations, the standard of care for the treatment of chronic hepatitis C and compensated cirrhosis is the combination of a pegylated interferon (Peg-interferonα_2a or Peg-interferonα_2b) and ribavirin. Treatment should be administered for 48 weeks to patients infected by genotype 1 or 4, and for 24 weeks to patients infected by genotype 2 or 3. International guidelines recommend stopping antiviral therapy after 12 weeks in patients infected with genotype 1 or 4 if serum HCV-RNA levels have not decreased by at least two log units compared with baseline, on the basis of strong evidence that such patients have a small likelihood of achieving sustained viral response after 48 weeks of treatment.[510] Small series have also been reported from the US Thalassemia Clinical Research Network.[511]

Also, direct-acting antiviral (DAA) agents are becoming available for the optimal treatment regimen of genotype 1 chronic HCV infection.[512]

Single nucleotide polymorphisms (SNPs) associated with IL28B influence the outcome of peginterferon-alfa±/ribavirin therapy of chronic HCV infection. Polymorphisms in IL28B are strongly associated with the first phase viral decline during peginterferon-α±/ribavirin therapy of chronic HCV infection, irrespective of HCV genotype.[513]

Hepatocellular carcinoma represents the first cause of death in patients with genetic hemochromatosis in whom liver cirrhosis has already developed at the time of diagnosis, and it frequently complicates the course of cirrhosis due to chronic HCV and HBV hepatitis. As a consequence of the numerous risk factors present in multitransfused patients, the development of the tumor is to be expected with advancing age of the thalassemia patients. In fact, several such cases have been reported.[514]

Surveillance is of great importance. Because α-fetoprotein determination lacks adequate sensitivity and specificity for effective surveillance and for diagnosis, all patients with chronic HBV hepatitis and patients with HCV and cirrhosis should undergo liver ultrasound every 6 months. Diagnosis of hepatocellular carcinoma should then be based on imaging techniques and/or biopsy.[515] In fact, when diagnosed and treated early this once invariably fatal tumor can be effectively treated.

Kidney

Renal function has not been extensively studied until recently. Renal failure had been described in association with toxicity due to very high doses of deferoxamine.[516] In a small series, 40% of the patients on subcutaneous deferoxamine developed a clinically significant decrease in glomerular filtration rate.[517]

The advent of novel measures of renal function facilitating early detection of kidney disease, in addition to the introduction of a chelator that can induce nephrotoxicity,[518,519] have produced a flurry of interest in the subject. In a study from the US Thalassemia Clinical Research Network, regular transfusions were associated with a decrease in creatinine clearance and almost one-third of the patients had hypercalciuria. Albuminuria was found in over half of patients, but was not consistently associated with transfusion therapy.[520] Other studies have shown impaired renal function with elevated cystatin C levels, glomerular dysfunction with proteinuria, and tubulopathy with hypercalciuria increasing with age and duration of blood transfusion. In a study, most adults with thalassemia major followed for 10 years maintained the estimated glomerular filtration rate within the normal range. However, some patients with tubular dysfunction secondary to either thalassemia major or its treatment developed an abnormal estimated glomerular filtration rate.[521] Renal tubular dysfunction may be related to the disease itself, to the effects of iron overload or to the chelator (see below). Some patients demonstrated an increased creatinine clearance leading to hyperfiltration.[522]

Iron can be demonstrated in kidneys. Nevertheless, kidney MRI T2* correlates weakly with liver and cardiac T2*.[462]

Endocrine Glands

Iron deposition is the main cause of damage to the endocrine glands, directly or through the hypothalamic-pituitary axis. Direct damage to almost all endocrine glands has been demonstrated histologically and by MRI. High ferritin levels, poor compliance with chelation, and splenectomy increase the risk of being affected by all endocrinopathies.[442,443,525]

Intensive iron chelation can normalize the iron load and thereby prevent or even reverse multiple endocrine complications.[526]

Growth Retardation. Stunted growth is common in thalassemia and it is typically characterized by normal growth during childhood, decreased growth velocity at the end of the first decade of life, and evident growth failure at the expected age of puberty in those patients who lack sexual maturation. Poor pubertal growth, however, was found to be present also in a group of thalassemic patients regardless of hypogonadism.[527]

Sitting height is reduced as a consequence of spinal growth abnormalities. A recent survey from the US found that approximately 25% of patients with a thalassemia syndrome[328] had short stature. In children, however, growth was mildly affected and final height was close to midparental height. A report from India, where the majority of adult patients reached a height below 150 cm, highlights the importance of adequate hemoglobin levels and regular transfusion from childhood for normal growth,[528] confirming observations made in the United States and Europe before the introduction of hypertransfusion.[387]

Between 12% and 54% of short children with thalassemia major have been found to have growth hormone (GH) deficiency.[328,529] Dysfunction of the GH–IGF-1 axis, hypothyroidism and hypogonadism, chronic liver disease, and in some patients zinc deficiency, undernutrition, and psychosocial stress can contribute to the growth disturbance. In clinical practice, regular

growth assessment in both standing and sitting positions every 4 to 6 months, annual determination of bone age, and annual pubertal staging should be performed from the age of 11 years. Treatment with recombinant human GH improves height velocity, but most patients remain below their target height.[530]

Adults with GH deficiency have a decreased life expectancy. Therefore the role of treatment with GH in selected deficient adults who present with cardiomyopathy or severe bone disease needs to be evaluated.[531] Desferrioxamine (DFO) toxicity is responsible in some cases of reduced or absent growth velocity, platyspondyly with short trunk, metaphyseal irregularity of long bones, and widened growth plates, in particular of the wrist and knee.[532,533] These abnormalities were first reported in patients who had started high-dose subcutaneous DFO before the age of 3 years, but were later confirmed also in patients on a standard dose of DFO.[534] A negative correlation between the maximum dose of DFO received and height was later described in a group of adolescent patients.[535]

Hypogonadism. Hypogonadism is very common, affecting in all series more than 50% of the patients.[407] It ranges from complete lack of sexual maturation to arrested or delayed puberty. Secondary amenorrhea affects 65% of the women who had had spontaneous menarche.[536] Significant improvement in spontaneous sexual maturation has been observed in patients born after 1975, suggesting a crucial role for adequate chelation.[442] A quarter of sexually mature men go on to develop impotence.[536] Hypogonadism is hypogonadotropic in origin and is probably due to the free radical oxidative damage caused by iron deposition in the anterior pituitary and/or in the hypothalamus.[537] Investigations for the diagnosis of pubertal hypogonadism include bone age measured by x-ray of the wrist and hand, study of the hypothalamic–pituitary–gonadal axis (GnRH test), dosage of sex steroids, and pelvic ultrasound in females.

Hormonal replacement therapy consists in the administration of small doses of oral conjugated estrogens or transdermal 17β-estradiol, plus cyclic or continuous gestagen administration and progesterone to females; testosterone enanthate in males. Therapy is initially given for a period of 3 to 6 months. If puberty does not develop spontaneously within 6 months after the end of treatment, sex steroids are reintroduced at increasing doses. Hormone replacement, in addition to inducing the secondary sexual characters, enhances height velocity, contributes to the prevention of osteoporosis, and has enormous psychological benefits. Fertility is normal in female patients with normal menstrual function, or it can be induced with human menopausal gonadotropin or FSH.[538] In men with thalassemia major, sperm count, sperm motility, and proportion of sperm with normal morphology are significantly lower than in control individuals.[539]

Gonadotropin treatment, using human chorionic gonadotropin plus human FSH or Gn-RH, is given to stimulate spermatogenesis and induce fertility.[540,541]

Pregnancy. In women with hypogonadotropic hypogonadism, gonadal function is usually intact and fertility is therefore retrievable. Hundreds of pregnancies have now taken place and severe obstetric complications have been quite rare.[542–544] Ninety-one percent of the pregnancies recently reported by an Italian cooperative group resulted in successful delivery, and no secondary complications of iron overload developed or worsened during pregnancy.[545] Anemia should be avoided to protect the fetus from hypoxia (Hb levels suggested 10 g/dl), and chelation therapy should be discontinued because of concerns regarding teratogenicity. However, over 80 cases have been reported in which desferrioxamine was given in various periods of gestation without evidence of teratogenic effects.[546]

Preexisting cardiomyopathy, expanded plasma volume, increased cardiac output, continuous iron accumulation in the absence of chelation, and reduced glucose tolerance can deteriorate maternal health in the course of pregnancy. A few cases of cardiac failure, even fatal, have been observed, but care by an expert multidisciplinary team should now be able to prevent serious complications. Delivery has been performed by elective Cesarean section in approximately half of the cases reported. As a consequence of gonadotropin-induced ovulation, multiple pregnancies and preterm births are not rare.[547] To decrease the risk of thromboembolic events, the use of low molecular weight heparin is recommended peripartum, especially in splenectomized women with thrombocytosis. Low-dose aspirin is indicated during the entire pregnancy for women with high platelet counts. Genetic counseling is mandatory before conception.

Hypothyroidism. Hypothyroidism is the second most common endocrine disorder after hypogonadism, having been reported in 5.6% to 17% of patients.[407,442,443]

The majority of patients have subclinical or mild forms, while approximately one-third have the overt form. Central hypothyroidism is less frequent. No difference in the mean level of serum ferritin concentration was found between patients with or without hypothyroidism. Regular assessment of FT4 and TSH is recommended after the first decade of life. Thyroid ultrasonography can show irregular echo pattern and thickening of the capsule. Abnormal thyroid function has been reversed to normal by means of intensive chelation therapy with DFO alone or in combination with deferiprone.[526]

Hypoparathyroidism. Hypoparathyroidism affects 3% to 10% of thalassemia patients and it is attributed to iron deposition in the parathyroids.[407] Males seem to be affected more often than females.

Early detection requires periodic estimation of calcium homeostasis. Serum calcium levels below 8 mg/dl (2 mmol/L), phosphorus above 7 mg/dl (2.6 mmol/L), and low 1,25-dihydroxy vitamin D are suggestive of hypoparathyroidism. Symptoms are usually mild and include paresthesias, muscle pain, and, when severe, tetany and even convulsions. Extreme hypocalcemia is a late event. Intracranial calcifications have been reported in 40% of patients with hypoparathyroidism in the absence of symptoms and independently from the severity of the hormonal deficit.[547] In mild forms the treatment of choice to normalize calcium and phosphate is calcitriol at a dosage of 0.25 to 1 μg twice daily, carefully monitoring serum calcium.

Adrenal. No clinically symptomatic adrenal insufficiency has been reported,[548,549] but dynamic hormonal testing has given conflicting results. Some authors found integrity of the pituitary adrenal axis,[549] while others found subclinical hypoadrenalism, which might become clinically relevant in case of major stressful events, in up to 46% of patients.[550,551]

Diabetes. Diabetes mellitus has been reported with a frequency variable between 4.9%[552] and 14%,[328] with a mean age at diagnosis of 18 to 22 years. The reported prevalence of insulin-dependent diabetes and of impaired glucose tolerance is significantly lower in patients born after 1975, probably as a result of chelation therapy.[553,554] The peak incidence of diabetes was observed in 1986 (3.9%), decreasing to 0.8% in 2007 in parallel with the progressive decrease of the annual mean serum ferritin levels.[555] Patients with a serum ferritin level >2,500 μg/L were 3.5 times more likely to have diabetes mellitus.[443] Iron deposition in the pancreas resulting in excess collagen deposition, fibrosis, and fatty degeneration with progressive β cell destruction can be demonstrated histologically.[556] Pancreatic iron, as evaluated by MRI, is the strongest predictor of β cell toxicity, but total body iron burden, age, and body habitus also influence glucose regulation.[557]

It has been suggested that liver damage could contribute to the impairment of islet cells' function.[558] HCV infection may induce insulin resistance by a direct effect on insulin-signaling pathways and may cause a direct cytopathic effect at the islet cell level, reducing insulin release.[559] In a survey, 36% of HCV positive patients had either a diagnosis of diabetes or an abnormal fasting blood glucose, a percentage significantly higher than in HCV negative patients.[328] Impaired glucose tolerance characterized by insulin resistance can precede the appearance of symptoms by a few months to several years and can be followed by progressive insulin deficiency leading to overt diabetes.[560] Impaired β cell function, as reflected by a reduction in the insulin secretion index, can be found in normoglycemic patients.[561]

Asymptomatic hyperglycemia is the presenting sign in the overwhelming majority of patients. Ketoacidosis is uncommon, and retinopathy develops in a quarter of patients, a percentage that is approximately half that of age- and sex-matched diabetic controls without thalassemia.[562] Intensive chelation may reverse glucose intolerance and postpone the onset of insulin-dependent diabetes.[526]

Impaired glucose tolerance is often responsive to oral hypoglycemic drugs. In the insulin-dependent form, therapy needs to be closely monitored, as glucose control is often difficult.

Exocrine Glands

Low serum levels of chymotrypsin and lipase have been described in patients with thalassemia, and have been attributed to hemosiderosis of the pancreatic acinar tissue.[563] An ultrasonographic study demonstrated hyperechogenicity of the pancreas and significantly decreased size of the gland when compared to controls, both of which were significantly correlated with patient's age and duration of transfusion therapy. Serum concentrations of trypsin and lipase were significantly lower in patients than in controls.[564]

Eye

Ocular involvement is not rare, but it is usually of moderate severity. In a recent report from India, more than half of the patients had some eye problems. Lenticular opacities were the most common ocular finding (44%).[565] It has been known for a long time that retinal pigmentary changes may complicate hemochromatosis. Accordingly, retinal hyperpigmentation detected in a group of thalassemia patients was attributed to iron overload. Also reported were abnormal electroretinographic potentials, similar to those observed in experimental siderosis bulbi.[566] Their severity was directly correlated with iron overload. The presence of retinal angioid streaks should raise the suspicion of pseudoxanthoma elasticum.[367,567] Nevertheless, most eye problems in patients with thalassemia major are a consequence of DFO toxicity and will be discussed below.

Pulmonary Problems

Pulmonary problems, mainly due to ventilatory restrictive impairment, have been reported in patients with thalassemia major. Iron deposition in the respiratory system has been proposed as a potential cause.[568] However, no correlation was found between restrictive impairment and iron deposition in the respiratory system evaluated by MRI.[569]

Chelation

To prevent hemosiderosis, iron needs to be chelated and excreted. Iron balance is obtained when the daily excretion is sufficient to eliminate the iron introduced by transfusion. This amount approximates, in most patients, 0.3 to 0.5 mg/Kg. The two main sources of chelatable iron are (1) the intracellular labile pool, derived from lysosomal catabolism of ferritin and from transferrin- and nontransferrin-bound iron, and (2) the iron derived from red cell catabolism in macrophages.[434,570] The first contributes chiefly to the hepatocellular load and is excreted as fecal iron, while the second is the major source of urinary iron. Ferric iron has six coordination sites, which need to be chelated completely, for the generation of harmful free radicals to be prevented. Three chelators are presently in use: deferoxamine (DFO), deferiprone, and deferasirox. (Fig. 34.13) DFO is hexadentate and therefore forms stable iron-chelate complexes using a single molecule, while the molecules of deferiprone and deferasirox, being bidentate and tridentate, respectively, could, in theory, dissociate from iron at suboptimal concentrations and promote, rather than prevent, iron toxicity.[571]

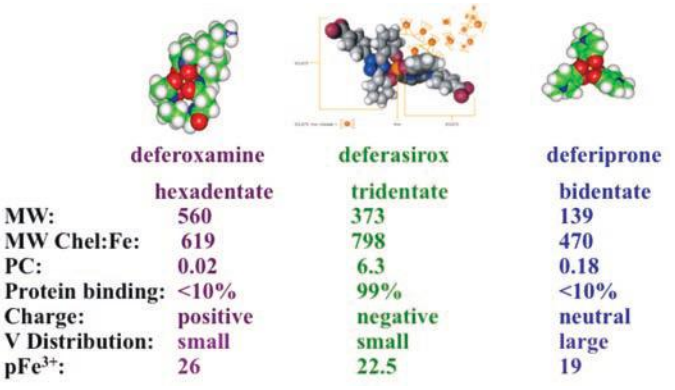

FIGURE 34.13. Molecular structure and chemical properties of the three chelators presently available.

Adherence to chelation therapy and persistence with it is challenging, as the benefits of therapy are not perceived immediately. Children are the most compliant (not being directly responsible for the drug administration), followed by adolescents and adults. Compliance appears to be better with oral chelation (deferasirox in a study), but switching from one chelator to another increases adherence.[572,573] A strict relationship between the patient and the health team is necessary to maintain or improve adherence.[573]

Deferoxamine B

DFO, a trihydroxamic acid produced by *Streptomyces pilosus* was first used for the treatment of transfusional hemosiderosis in 1962.[574] Because of its large molecular weight, it is not efficiently absorbed from the gut and it cannot, therefore, be administered orally. At the beginning, the drug was given by intramuscular injection, but, because of its short half-life and the finite chelatable iron pool available at any given time, negative iron balance was not obtained.[575] In a seminal study performed in the United Kingdom, it was found that patients treated with DFO had, after 7 years, lower ferritin levels and lower liver iron concentration than those not chelated.[576,577] It was only with the administration of prolonged parenteral infusions, however, intravenous at first, and then subcutaneous, that negative iron balance was achieved.[578,579] Today, DFO is most frequently administered subcutaneously, by means of a portable battery-operated pump (Fig. 34.14), at a dose ranging between 20 and 60 mg/kg/day over 8 to 12 hours at night.

Pharmacokinetic studies have shown that a plateau is reached within 4 to 8 hours after starting the infusion and that, at the end of it, plasma levels fall rapidly.[580] Nontransferrin-bound iron (NTBI) is efficiently bound by DFO, so that the effects of free radical formation and lipid peroxidation are prevented.[581] The efficacy of DFO in reducing the iron burden, in improving organ function, and in improving survival has been repeatedly demonstrated.[442,582]

In order to avoid severe effects on growth and bone metabolism, DFO should be started when ferritin levels reach 1,000 ng/ml, or after 10 to 15 units of blood have been given.[583,584]

FIGURE 34.14. Deferoxamine needs to be administered by subcutaneous infusion by means of a pump. The available models are different in technical characteristics, size, and price.

A discrete variability was demonstrated between patients, but the mean liver iron concentration after 1.3 years of transfusions was found to be 8.5 mg/g, slightly above the limit of 7 mg/g, which, in patients with idiopathic hemochromatosis, is considered compatible with a normal life expectancy.[585] Decreasing growth velocity is an indication to lower the dose of the chelator. The adequacy of therapy is monitored by repeated measurements of serum ferritin and by more direct quantification of heart and liver iron, usually by magnetic resonance.

In the case of cardiac dysfunction and gross iron overload, continuous 24-hour deferoxamine infusion, delivered via an intravenous catheter implanted in a large vein, has been used with good results,[586] although the drug is more efficient on the liver than on the heart.[587] Improvement of cardiac performance can usually be demonstrated even before the total iron load is significantly reduced, probably as an effect of the binding of the toxic labile plasma iron. The more frequent catheter-related complications are infection and thromboembolism at a rate of 1.15 and 0.48 per 1,000 catheter days, respectively.[588] In heart cell cultures, studies have demonstrated that DFO removes the iron directly from iron-loaded heart cells, inhibits lipid peroxidation, and reverses the abnormalities in cellular contractility and rhythmicity induced by the iron.[589,590] Recently, the efficacy of DFO on the heart has been found to be insufficient. In fact, myocardial iron loading (T2* < 20 ms), was demonstrated in 65% of patients treated by subcutaneous deferoxamine therapy investigated by MRI. In 13% the iron overload was severe (T2* < 8 ms)[469] (Fig. 34.15).

The administration of DFO by twice daily subcutaneous bolus injection has been demonstrated to induce the same urinary iron excretion as the slow, pump-mediated infusion and to be well accepted, especially by older patients.[352,591,592] The main limit of DFO is the inconvenience of parenteral administration. The patients' adherence therefore, is often erratic, especially during the teenage years.

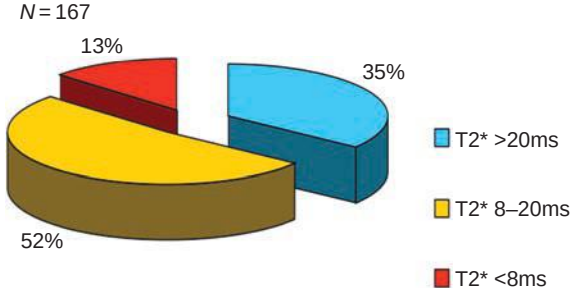

FIGURE 34.15. Myocardial iron loading in patients on long-term deferoxamine treatment.

Deferoxamine B Toxicity. The most common side effects of DFO are represented by local redness and soreness at the site of infusion. Inflammation, necrosis, and even ulceration can be caused by the intradermal insertion of the needle. If the reaction persists after appropriate needle placement in the subcutaneous tissue, hydrocortisone (5 to 10 mg) can be added in the syringe. The direct and rapid injection of DFO in a vessel can cause brief episodes of nausea, hypotension, and collapse. Systemic allergic reactions and, occasionally, anaphylaxis require desensitization or changing chelator.[593,594]

Retinal and optic nerve disturbances, manifesting as loss of central vision, night blindness, and finally amaurosis, were reported in patients treated with high-dose intravenous or subcutaneous DFO.[595,596] All the cases reported were reversible upon discontinuation of therapy and the resumption of treatment was well tolerated. High frequency sensorineural hearing loss was observed in a large percentage of patients during intensive DFO therapy. The defect was correlated with the total monthly dose of DFO received, and it was more frequent in younger patients with low serum ferritin levels.[597] Auditory toxicity can often be prevented by keeping a therapeutic index devised for that purpose (mean daily dose of DFO [mg/kg] divided by the serum ferritin [ng/L]) below 0.025.[598] The hearing defect should be detected early, by performing an audiogram at least yearly, or whenever symptoms, even subtle, are reported. In fact, significant improvement has been observed after reduction of the DFO dose in patients with a mild defect, whereas only a small benefit has been gained by those severely affected.[599]

Stunted growth and rickets-like bone abnormalities have been described when treatment was initiated early, at a dosage higher than 40 mg/kg, or when the iron burden was not severe.[533,600] Sitting height is more often affected than standing height, as a consequence of vertebral growth impairment or flatness of vertebral bodies. Cupping of the ulnar, radial, and tibial metaphyses, which are poorly ossified and with irregular sclerotic margins, can be demonstrated radiographically and, when more advanced, can produce severe deformity of the knees and elbows (Fig. 34.16). Reduction of the DFO dose is sufficient to reestablish normal growth velocity, but orthopedic surgery has sometimes been required for correction of advanced varus and valgus deformities of the knees.[534] An acute, often lethal, pulmonary infiltration syndrome has been observed in patients treated intensively with very high doses of DFO (10 to 20 mg/kg/h).[601,602] Renal failure has also been reported in this context.[516,517] Infection with *Yersinia enterocolitica* is a well-known complication of hemosiderosis. The presence of DFO in plasma and tissues facilitates the growth of the organism, which uses the drug as a siderophore.[603] Fever and gastrointestinal symptoms are an indication to temporarily discontinue DFO. Antibiotic therapy is indicated as *Yersinia* infection can be severe and even life-threatening.[604] *Klebsiella,* whose growth is only moderately favored by DFO,[426] is becoming more frequent in thalassemia, especially in tropical and subtropical countries.

Deferiprone

Deferiprone (DFP) is a member of the family of the hydroxypyridin-4-one chelators that have been intensively studied during the past two decades in order to find an orally active alternative to DFO for the treatment of transfusional iron overload. Because each molecule provides two coordination sites, three molecules of deferiprone are required to fully bind the six coordination sites of an iron atom. The iron-chelate complex that is formed has a lower stability than the one formed by DFO. The sources of chelatable iron are both parenchymal and reticulo-endothelial cells. In addition, iron is mobilized from transferrin, lactoferrin, and hemosiderin. The drug is excreted in the urine within 3 to 4 hours after having been glucuronidated in the liver. Three doses a day are therefore necessary. The recommended dosage is

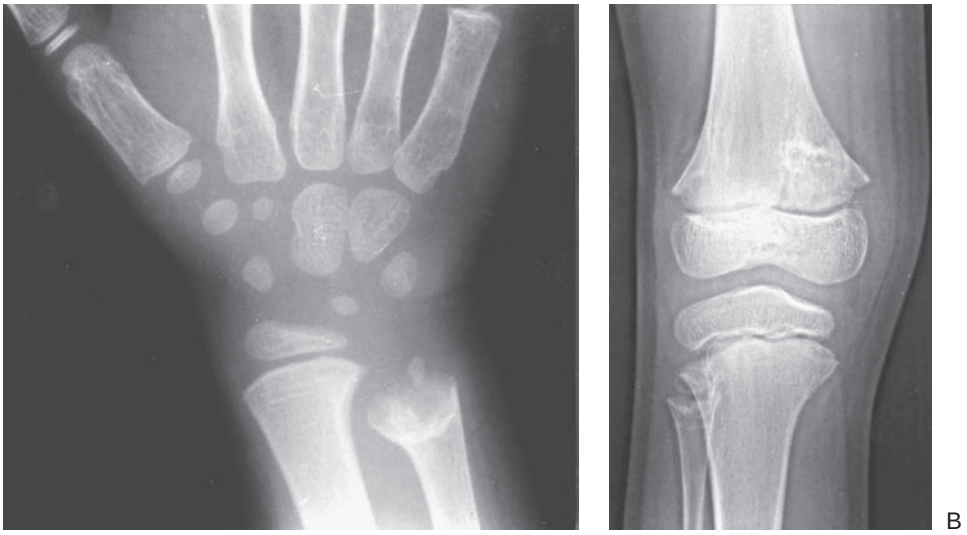

FIGURE 34.16. A: Desferrioxamine toxicity. The growth plate of the distal ulna is wide, and the metaphysis exhibits a cuplike deformity with sclerotic and irregular borders. **B:** A similar picture is present in the metaphyses of the femur and fibula. (Courtesy of Dr. C. Orzincolo.)

75 mg/kg/day in three subdoses given 1 hour before meals. DFP is easily absorbed from the gut and a peak concentration is reached in the plasma 45 minutes after ingestion.[605,606] Food reduces the rate of absorption but not the total amount absorbed. DFP is available as film coated, immediate-release tablets containing either 500 or 1,000 mg of the active agent and as a liquid formulation containing 100 mg/ml. The majority of iron is excreted in the urine, while fecal excretion ranges between 5% and 20%. The dose of 75 mg/kg/day has been shown to induce a urinary iron excretion equivalent to that achieved with 40 mg/kg/day of DFO.[445] Greater excretion can be obtained with a dose of 100 mg/kg/day, and no more side effects occur at this dose.[607] Ascorbic acid has no effect on iron excretion in response to deferiprone. A decrease in NTBI was demonstrated in a small series of patients.[608] Deferiprone, as well as the other oral chelator, deferasirox, were found to be efficient scavengers of the labile iron pools of cardiomyocytes, and to restore contractility impaired by iron overload.[609]

Deferiprone was licensed for clinical use in India in 1995 and in Europe in 1999. The FDA approved the drug in the United States in 2011. In a randomized trial comparing the efficacy over 1 year of DFO and deferiprone, the latter was found to be significantly more effective than deferoxamine in improving asymptomatic myocardial siderosis. Left ventricular ejection fraction also increased significantly more with deferiprone than with DFO.[610] The efficacy of deferiprone in removing iron from the heart has been suggested also by a recent MRI study.[611]

Finally, in the setting of a large natural history study involving all the thalassemia major patients treated in seven Italian centers over 9 years, deferiprone therapy was associated with significantly greater cardiac protection than DFO.[444]

Numerous experiences around the world have been reported on the effectiveness of combining deferiprone and DFO therapy.[612] Results have usually demonstrated an additive effect of combination therapy because the two drugs access different pools of iron. It has been suggested that deferiprone, being able to pass through membranes, could "shuttle" tissue iron to DFO in the bloodstream and then be reused.[613] Combination therapy is now being widely used.[479,614,615] A randomized, placebo-controlled clinical trial demonstrated that, in comparison to the standard chelation monotherapy of DFO, combination treatment with additional deferiprone reduced myocardial iron and improved ejection fraction and endothelial function in thalassemia major patients with mild to moderate cardiac iron loading.[616]

A small non-randomized study and several case reports have confirmed the efficacy of combined therapy in the context of severe cardiac iron overload.[617–619]

Several studies have documented the efficacy of such therapy to rapidly decrease ferritin levels and cardiac iron, as measured by T2*, at the same time improving cardiac function in severely iron-overloaded patients. Reversal of some endocrinopathies was observed after normalization of iron stores with intensive combined iron chelation.[526]

In Cyprus, mortality due to cardiac causes decreased sharply after combined therapy was implemented in the majority of thalassemia patients.[479,480]

Alternating deferiprone and DFO can improve adherence and, in a long-term prospective study, decreased mortality in comparison to DFO alone.[612,620]

Deferiprone Toxicity. The most frequent adverse effects are gastrointestinal discomfort or nausea, reported by 33% of the patients in the first year and decreasing to 3% thereafter. The intensity is usually mild to moderate and few patients have abandoned the treatment because of that. The new liquid formulation seems to cause a lower incidence of gastrointestinal side effects. The most severe adverse effects observed with deferiprone are agranulocytosis and neutropenia. In a prospective multicenter study the overall frequency of agranulocytosis was 0.5% and the incidence was 0.2 per 100 patient-years. Milder neutropenia occurred in 8.5% of patients.[621]

Neutropenia occurred more frequently in non-splenectomized patients.[622] The complication usually appears shortly after inception of therapy, but a case has been reported after 9 years. Rechallenge with the drug can produce relapse of the agranulocytosis and is contraindicated.[623] The concomitant administration of drugs that can induce neutropenia (e.g., interferon, hydroxyurea) should be avoided.

Arthropathy, particularly of the knee, occurs in 6% to 39% of patients and it appears to be more frequent in patients who have more severe iron overload.[621,622,624] It has been hypothesized that the formation of 1:1 or 1:2 deferiprone iron complexes can induce inflammatory changes, possibly mediated by free radicals. Other, less severe, unwanted effects include excessive appetite, zinc deficiency, and fluctuation in liver enzymes, affecting 7% of the patients, more commonly if HCV positive.[625] Progressive liver fibrosis was reported in 5 out of 14 patients treated with deferiprone for over 2 years.[626] However, a large multicenter study, involving 56 patients over 3.5 years, whose

liver biopsies were evaluated in blinded fashion, did not confirm an effect of deferiprone on hepatic fibrosis.[627] Reversible neurologic symptoms were elicited in 2 patients when a dose three times higher than suggested was mistakenly given for over 2 years.

Deferasirox

This compound is a member of a new class of tridentate iron-selective synthetic chelators, the bis-hydroxyphenyl-triazoles. As a tridentate chelator, two molecules of deferasirox bind one molecule of iron. The plasma half-life is 8 to 16 hours.

Deferasirox (Exjade) is available as tablets for oral suspension containing 125 mg, 250 mg, or 500 mg. It should be administered orally once daily on an empty stomach (≥30 minutes before eating), preferably at the same time each day. It should not be administered with aluminum-containing antacid preparations, since the absorption of deferasirox may be decreased. In a large randomized trial comparing the two drugs, deferasirox was shown to be as effective as deferoxamine when administered at doses of 20 and 30 mg/kg. The rate of transfusional iron intake, however, strongly influences the effectiveness of deferasirox. For most patients with transfusional iron intake averaging <0.3 mg/kg/day, a dose of 20 mg/kg of deferasirox is effective in reducing liver iron concentration, while an iron intake of >0.5 mg/kg/day requires doses >30 mg/kg/day.[397]

Careful assessment of the patient's blood consumption, of ferritin trends and liver iron content during treatment is important to regulate the dose of deferasirox to be administered. Currently, doses of deferasirox of up to 40 mg/kg/day are approved for use.

Cardiac iron removal is crucial to reduce morbidity and mortality in thalassemia. Clinical data suggest that deferasirox is able to remove cardiac iron. Myocardial T2*, assessed by cardiovascular magnetic resonance, was measured in patients on a mean deferasirox dose of 33.6 ± 9.8 mg/kg per day. After 3 years, 68% of patients with baseline T2* from 10 to <20 ms normalized their value, and 50% of patients with baseline T2* >5 to <10 ms improved to 10 to <20 ms. Left ventricular ejection fraction did not vary significantly throughout.[477]

The safety and efficacy of deferasirox in pediatric patients reported in a study[519] was similar to that of adult patients, and younger pediatric patients responded similarly to older pediatric patients. The recommended starting dose and dosing modifications are the same for children and adults. A recent study reporting on 111 children concluded that deferasirox is at least as effective as DFO in maintaining safe serum ferritin levels and normal growth progression. The height and weight standard deviation scores in children treated with deferasirox did not differ from those of patients treated with DFO. Fluctuations in liver enzymes and non-progressive increases in serum creatinine were the most common adverse events.[628] Deferasirox was approved in 2005 by the Food and Drug Administration in the United States, and in 2006 in Europe, for use in patients 2 years of age and older.

Deferasirox Toxicity. The most common adverse effects are related to gastrointestinal discomfort, including nausea, vomiting, and abdominal pain.[629,630]

Because lactose monohydrate is among the inactive ingredients of the tablet, some cases of diarrhea can be attributed to coexistence in the patient of congenital or acquired lactose intolerance.

A skin rash can develop, usually within the first month of treatment (Fig. 34.17). For rashes of mild to moderate severity, the drug may be continued without dose adjustment, since the rash often resolves spontaneously. In severe cases, it may be interrupted and reintroduced at a lower dose with escalation, in combination with a short period of oral steroid administration.

Approximately one-third of patients are reported to develop increases in serum creatinine >33% above baseline on two separate occasions.[519] In two-thirds of cases the creatinine level returns to normal without dose adjustment. Therapy should not be started in patients with a creatinine clearance below 40 ml/min or with a serum creatinine >2 times the age-appropriate upper limit of normal.

FIGURE 34.17. Typical rash appearing in patients on deferasirox therapy.

Several cases of Fanconi syndrome have been reported with the use of deferasirox.[518,631–633]

Fanconi syndrome is secondary to generalized dysfunction of the renal proximal tubule and results in renal losses of phosphate, amino acids, bicarbonate, glucose, urate, and other molecules.

Although no conclusive pathogenetic explanation to deferasirox-related serum creatinine increase and proximal tubulopathy has been found, careful monitoring of renal function and serum ferritin levels in patients receiving deferasirox is mandatory. Regarding hepatic toxicity, in the original phase 3 study, 6% of patients treated with deferasirox developed elevations in ALT levels >5 times the upper limit of normal at two consecutive occasions. Of these, two patients had drug-induced hepatitis, proven by liver biopsy.[629]

Increased ALT levels >10 times above the upper limits of normal were reported in 1.0% of patients.[519]

There have been postmarketing reports (both spontaneous and from clinical trials) of cytopenias, including agranulocytosis, neutropenia, and thrombocytopenia.[634] The relationship of these episodes to treatment with deferasirox is uncertain. Interruption of treatment should be considered in patients who develop unexplained cytopenia. Reintroduction of therapy with deferasirox may be considered, once the cause of the cytopenia has been elucidated. Non-fatal upper gastrointestinal tract irritation, ulceration, and gastrointestinal bleeding have been reported in patients, including children and adolescents, receiving deferasirox. Caution should be used when the drug is prescribed in association with non-steroidal anti-inflammatory drugs, corticosteroids, oral bisphosphonates, or anticoagulants. Gastrointestinal symptoms, increases in serum creatinine, and skin rash are dose related, while increases in transaminases are not. Alternating deferasirox with deferiprone has been used successfully to overcome intolerance to both drugs.[635] Combining the two drugs is also a promising alternative for the treatment of severe cardiac iron overload.[636,637]

New Chelators

Despite the availability of three iron chelators, morbidity and mortality are still a major problem for transfusion-dependent patients. Iron chelators in current use (see above) are efficacious in many

patients, but each has limitations relating to safety, ease of administration, patient acceptance, and compliance.[638] FBS0701 is a novel, orally available iron chelator, a member of the desazadesferriothicin class of siderophore-related tridentate chelators. The results of a multicenter phase-2 study designed to assess safety, tolerability, and pharmacodynamics of FBS0701 have been published. The compound seems promising, having a good chelating efficacy and a safety and tolerability profile at therapeutic doses that compare favorably to other oral chelators.[638]

Vitamin Supplementation

Vitamins and trace minerals represent key buffers against the oxidative stress due to iron overload. Chronic demands on oxidative buffering capacity may produce deficiencies in key amino acids and enzymatic cofactors.[639] Siderosis of the exocrine pancreas sometimes causes a decrease in circulating pancreatic trypsin and stool elastase levels[640,641] that results in vitamin malabsorption. In addition, liver damage may play a role in the depletion of lipid-soluble antioxidants, such as vitamins E and A.[642]

A large cooperative survey of dietary habits revealed dietary inadequacy, that increased with increasing age for vitamins A, C, E, B-6, folate, thiamin, calcium, magnesium and zinc. Also, circulating levels of serum 25-OH vitamin D remained insufficient in the majority of subjects despite daily supplementation.[639]

Vitamin D is essential for intestinal calcium absorption and plays a critical role in global calcium homeostasis and bone metabolism.[643] Nevertheless, its receptors are found in nearly all tissues and therefore the vitamin is now believed to play a systemic role. Cardiac iron loading was found to be more common in thalassemia patients with vitamin D deficiency and secondary PTH elevation, but the association of this deficit with left ventricular dysfunction is still unproven.[664]

Vitamin D deficiency is also inversely related to hepatic iron concentration and ferritin, as previously described in hereditary hemochromatosis, because of inhibition of hepatic 25-hydroxylation by excess iron.[645]

In conclusion, chronically transfused thalassemia major patients have broad spectrum nutritional deficiencies of both water- and fat-soluble nutrients. It is therefore advisable to perform periodic nutritional evaluation and supplement as necessary.[639]

Hemosiderotic patients are often ascorbate deficient and a case of frank scurvy has been reported.[438,439]

DFO-induced iron excretion is enhanced by ascorbic acid supplementation because of the expansion of the chelatable iron pool which DFO can access.[434,646]

However, ascorbate, a natural reducing agent, accelerates iron-induced lipid peroxidation in biologic systems at low concentrations and it has been shown to alter the function of rat myocardial cells in culture. In addition, anecdotal echocardiographic observations have in the past suggested cardiotoxicity.[647]

Vitamin C supplementation is therefore recommended only for patients not affected by myocardiopathy, with unsatisfactory iron excretion and demonstrated ascorbate deficiency. When necessary, 50 mg per day of ascorbate in children up to 10 years and 100 mg per day thereafter should be sufficient. Vitamin C should be given when DFO infusion is already under way. Alfa-tocopherol, a lipid-soluble antioxidant, is able to interrupt the membrane lipid peroxidation process. Supplementation with Vitamin E is therefore often suggested, but data demonstrating its efficacy are lacking. Folic acid deficiency was reported in early studies from Thailand.[648] Folate supplementation is advised for patients with a hyperactive bone marrow, like those with thalassemia intermedia, and during pregnancy. Zinc has been found to be low in patients with thalassemia major. Nevertheless, these patients have a normal zinc binding capacity, which is generally increased in nutritional zinc deficiency.[649,650] Zinc supplementation can become necessary when desferrioxamine and deferiprone are given in combination.[615]

Splenectomy

Splenectomy, associated with sporadic blood transfusions, has for many years represented the mainstay of therapy in thalassemia. It was often performed shortly after diagnosis because the spleen soon reached an enormous size and caused severe hypersplenism, frequently leading to profound neutropenia and thrombocytopenia. A cooperative observational study involving 872 regularly transfused thalassemia patients born between 1960 and 1999 found that, overall, 67% of the patients had not been splenectomized, but the probability of having undergone the procedure was strongly influenced by the date of birth[651] (Fig. 34.18). For patients born in 1960 and in 1980 the probability of being splenectomized was 57% and 7%, respectively. No patient younger than 5 years was splenectomized after 1987. This trend toward a delay in, spleen removal is likely due to the improvement in global management of thalassemia, and may represent an important protection against the risks associated with the splenectomy, e.g., infections, thromboembolic complications, and pulmonary hypertension (see below). Rational criteria for splenectomy were first indicated by Modell.[652] She suggested that surgery should be performed when blood consumption increased over 50% above the average consumption of the splenectomized population—in practice, when more than 200 to 250 ml/kg/year of pure red cells are required to maintain a pre-transfusional Hb of 9 to 9.5 g/dl. Splenectomy reduces the transfusion requirement to approximately 150 ml/kg/year, with some variation from patient to patient, and the effect has been demonstrated to be long-lasting.[653]

Attempts at recognizing the appropriate time for splenectomy by the study of Tc-99 sulfur colloid or Tc-99 red blood cell uptake have not proven of great practical use. Cytopenias and physical encumbrances remain strong indications. Risks associated with splenectomy include an increased susceptibility to infections with encapsulated bacteria and an increase in thromboembolic events. Laparoscopic splenectomy, when possible, avoids the disfiguring scar created by laparotomy, reduces the hospital stay, and, in the end, does not seem to have a higher financial cost.[654] However, the large size of the spleen when splenectomy is considered

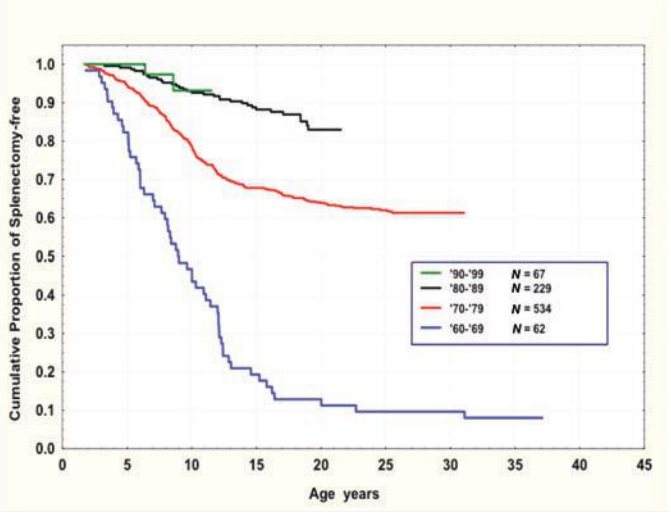

FIGURE 34.18. Cumulative proportion of splenectomy-free survival in different birth cohorts (1960–1969, 1970–1979, 1980–1989, and 1990–1999). During the period of observation, 284 patients (32.6%) were splenectomized, whereas 588 patients (67.4%) still had their spleen in at the end of the study ($P < 0.0001$).

necessary, makes laparoscopic surgery difficult. In addition, the risk of thrombosis of the portal vein seems to be higher.[655,656]

The problem of postsplenectomy sepsis with encapsulated organisms has been recognized for many years.[657–659] These infections are often abrupt in onset and rapidly fatal. The clinical spectrum of serious bacterial postsplenectomy infections among patients with hemoglobinopathies includes sepsis (the most common and severe complication), bacteremia, pneumonia, skin and liver abscesses, and urinary tract infections.[424,660] Overwhelming postsplenectomy sepsis (OPSI) results from the removal of a major site of antibody production (in particular the splenic marginal zone) and, possibly, the long-term decrease of T cell subsets of functional relevance for primary immune responses. Splenic macrophages are critical in clearing opsonized encapsulated bacteria and intraerythrocytic parasites such as those causing malaria and babesiosis, which explains the fulminant nature of these infections in persons with anatomic or functional asplenia.[661–664]

The most frequently responsible bacteria are *Streptococcus pneumoniae, Hemophilus influenzae,* and *Neisseria meningitidis,* but cases have been reported in which *E. coli* and *Staphylococcus aureus* were the causative agents.[665] A recent study from Israel reported that 35% of splenectomized patients with hemoglobinopathies, despite being vaccinated against *Streptococcus pneumoniae* and on prophylactic penicillin, developed serious infections, two of which were fatal. The most common germ involved was *E. coli*, followed by *Streptococcus pneumoniae* and *Campylobacter*.[424]

Klebsiella appears to be an increasingly common cause of infection, particularly in Asia.[666,667]

Capnocytophaga canimorsus, a Gram-negative rod, present as a commensal organism in the saliva of cats and dogs, has also caused severe infections in asplenic and splenectomized individuals.[668]

The risk of severe infections is greatest in younger children and in the first years after splenectomy, but it never disappears. It has been suggested that thalassemia patients are exposed to a higher risk than other non-immunodeficient patients splenectomized for different causes.[669] From a review of the literature, Singer found that 25% of patients undergoing splenectomy for thalassemia developed postsplenectomy sepsis.[670] Later, however, in Thai patients, the frequency was found to be 4%, but the mortality associated was 89%. Guidelines for the prevention of postsplenectomy infections were published by the British Committee for Standards in Haematology in 1996 and updated in 2011.[671]

The guidelines recommend antibiotic prophylaxis with penicillin, amoxicillin, or erythromycin for the first 2 years after surgery, and for children until age 16 years. Compliance with penicillin prophylaxis can be a problem and requires continuous reinforcement.[672,673] Polysaccharidic antipneumococcal immunization (PPSV23) should be given 2 weeks before the procedure, or whenever possible after it. Re-immunization of asplenic patients is currently recommended every 5 years. According to these guidelines, for older children and adults who may or may not have received previous pneumococcal conjugate vaccine (PCV), there is insufficient evidence to recommend a change in policy from PPSV to PCV either for primary immunization or for boosting. On the contrary, the American Academy of Pediatrics recommends that children 6 through 18 years of age who are at increased risk of invasive pneumococcal disease because of anatomic or functional asplenia, should receive a single dose of the recently developed, 13 valent conjugated antipneumococcal vaccine regardless of whether they have previously received the seven valent conjugated vaccine or PPSV23.[674]

The efficacy of antipneumococcal immunization in conjunction with early antibiotic therapy has been demonstrated in children, but infection by serotypes not included in the vaccine or poorly immunogenic has been reported.[675]

Immunization against *Haemophilus influenzae* is also recommended.[676] Previous recommendations did not include meningococcal vaccination, but the revised guidelines recommend meningococcal four-valent conjugated vaccine against serogroups A, C, Y e W135 for unimmunized patients. Patients should also be offered annual influenza vaccination. The risk, already increased, of thrombotic events, can be exacerbated by splenectomy.[353]

Thrombocytosis, due at least in part to the presence in the circulation of platelets previously marginated in the spleen, develops in 75% of the splenectomized patients, and in 15% it reaches 1,000,000/mm^3 or more, peaking between 8 days and 4 months after surgery.[677,678] A correlation between splenectomy and pulmonary hypertension has been suggested on the basis of the high prevalence of asplenia found among patients with unexplained pulmonary hypertension, and confirmed by case series reports.[679] Recurrent lung thromboembolism could be responsible for the phenomenon.[680]

In the attempt to avoid the above mentioned complications of surgical splenectomy, several alternatives have been proposed, with mixed results. Partial splenectomy and partial dearterialization of the spleen have been reported to have an immediate beneficial effect, but of short duration.[681] Partial embolization of the spleen has been successfully performed with long-lasting results, but it has sometimes led to complications.[682,683] It has the advantage of not requiring general anesthesia and not leaving a scar. The procedure is followed by severe pain lasting a few days and requiring spinal anesthesia. The theory that a residual portion of spleen protects the patient from infections and thrombotic events is tempting, but still unproven. It has been hypothesized that the spleen could represent a reservoir for the transfused iron and that splenectomy would, therefore, expose the patient to the risk of more massive siderosis of the liver.[684] However, the iron content of the spleen at splenectomy is low, amounting to no more than one-fifth to one-tenth of the liver iron content.[685] As demonstrated by modern MRI techniques, splenic iron content plateaus at 1 to 1.5 g, even as hepatic content continues to grow.[686] In addition, no difference has been observed, in terms of liver fibrosis, between splenectomized and non-splenectomized patients.[687]

Prognosis with Conventional Therapy

The improved survival of patients with thalassemia major has been reported in several countries and has been attributed to better transfusion therapy, more adequate chelation, the availability of magnetic resonance for the evaluation of cardiac iron overload, and the referral of patients to centers of excellence. Between 1949 and 1957, in Ferrara, only 9% of the patients reached age 6 years, and at the end of the 1970s half of the Italian patients had already died at age 12. A review of the fate of patients followed between 1960 and 1976 at Cornell Medical Center reported a median survival of 17.1 years for patients transfused at low hemoglobin level and not chelated, while for hypertranfused and well-chelated ones, median survival was 31 years. Today, at least in developed countries, most patients will reach the age of employment and marriage.[688,689]

A large cooperative Italian study, including 977 uniformly treated patients, demonstrated significantly better survival for patients born in more recent years and for females (Fig. 34.19), but mortality remains increased compared to the general population. In 2010, 68% of the patients were alive at the age of 35 years, with 67% of the deaths being due to heart disease. Infections represented the second cause of death, being responsible for 15% of the deaths, followed by liver disease and thromboembolic events, both at 4%. Similar data are reported from most world centers. In a report of 1,044 Greek patients, the overall survival at the age of 50 years was 65%. The standardized mortality ratio compared to the general population improved significantly from 28.9 in 1990–1999, to 13.5 in 2000–2008, while the standardized cardiac mortality ratio decreased from 323 to 107, respectively.[690]

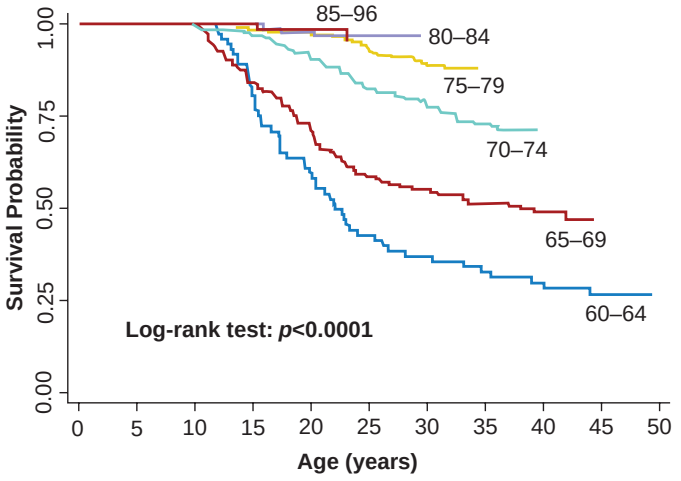

FIGURE 34.19. Kaplan-Meier survival curve after the first decade of life, subdivided by cohort of birth of patients from an Italian cooperative study. The survival data were collected in 2009. The role of the cohort of birth is evident.

The importance of good chelation in improving life expectancy has been repeatedly demonstrated. In fact, lower ferritin levels are associated with a lower probability of heart failure and with prolonged survival, using a cut-off as low as 1,000 ng/ml.[444] Both in the Italian and in the Greek series, birth cohort had a significant effect on survival ($P < 0.001$). In Cyprus, where mortality of thalassemia patients had been high, a marked improvement in survival was noted for patients of all ages since 2000,[479] an observation also made in the United Kingdom[476,482] and in Italy (Fig. 34.20). The use of MRI and the introduction of oral iron chelation have produced significant improvement in terms of reduction of iron overload among US patients.[691]

Complications remain frequent and for the most part are due to the oxidative damage mediated by labile iron. Surveillance, prophylaxis, and prompt treatment of infection remain essential, and chronic hepatitis should be managed with the best available current therapies.

With extended survival, new complications are appearing that will change the classical picture of thalassemia and will require new therapeutic approaches.

Several studies investigating the effects of thalassemia on psychosocial adjustment have given contradictory results. According to a survey from Greece, 42% of the patients examined had psychiatric problems, while other authors demonstrated that thalassemic adults have normal psychological development and better social adjustment and self-esteem than their normal peers.[692,693] A study from the Thalassemia Clinical Research Network, comparing health-related quality of life of 264 patients with thalassemia over age 14 to US normals, found that patients reported a statistically significant worse quality of life on five of the eight subscales (physical functioning, role-physical, general health, social functioning, and role-emotional). Women, older patients, and those with more disease complications and side effects from chelation fared worse.[694] Cultural and economic variables probably influence the acceptance of the chronic problems of thalassemia.[695] Psychological support seems appropriate as an adjunct in treatment. However, no randomized controlled trials assessing the effectiveness of specific psychological interventions have so far been performed.[696]

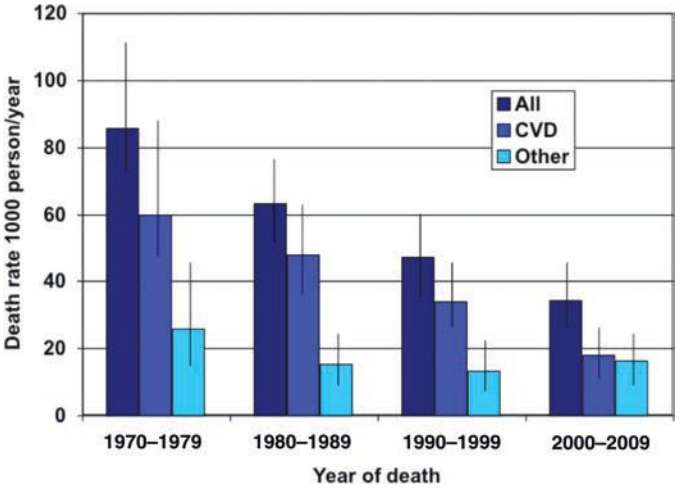

FIGURE 34.20. Decrease in death rate in a multitransfused population of Italian thalassemia patients by year at death. Death constantly decreased, because of the decrease of cardiac causes. (Data collected in 2009 as part of the 7 Centers Study.)

A recent survey of the education and employment status of patients with thalassemia in the United States and Canada revealed that 70% of adults were employed, of whom 67% reported working full-time. Sixty percent had a college degree and 14% had achieved some post-college education. Eighty-two percent of school age children were at expected grade level. Neither transfusion nor chelation was associated with lower employment or educational achievement.[697]

In this chapter we have described the course and therapy of thalassemia major as we see it now in developed countries with adequate economic and health resources. However, the disease is widely diffused in countries where sanitary problems are enormous and the resources required for the management of thalassemia are not available. In third world countries, many thalassemia patients are rarely, if ever, transfused and chelated. Their survival is therefore severely limited and their quality of life poor.[698]

Some countries have adopted a genetic control program according to WHO recommendations, while the poorest and least developed countries have not yet acknowledged the magnitude of the problem.[699,700]

There are countries in Asia, where South-South partnerships are being created to link centers with expertise to centers where competence and expertise need to be developed.[701]

Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) is an accepted approach to the treatment of thalassemia major, and so far the only curative one. The first bone marrow transplant for thalassemia was performed in Seattle in 1981.[702]

Thousands of patients have since received transplants worldwide. The vast majority were affected by thalassemia major, while a few had thalassemia intermedia, HbE/β-thalassemia, or HbH disease. The largest experience has been recorded in Italy by Lucarelli and his group, who, on the basis of their experience, suggested that patients be classified into three levels of transplantation risk, based on the presence or absence of portal fibrosis, hepatomegaly, and regular chelation.[703,704] The lowest risk is present in patients regularly chelated and without liver fibrosis or hepatomegaly. Patients poorly chelated, with hepatomegaly and portal fibrosis, have the highest risk, while the intermediate risk group includes patients with one or two risk factors. The ideal donor is an HLA-identical donor. At present the prognosis for HSCT from an HLA-matched sibling donor is excellent. A recent review by the European Bone Marrow Transplantation Group of 1,061 thalassemia patients of a median age of 7 years, from 28 countries, reported overall survival and thalassemia-free survival of 91% and 83%, respectively. The age threshold for better results was 14 years. In a multicenter study reporting on 179 young thalassemia major patients, 7 years was found to be the age

above which mortality risk was higher.[705] In adult patients, transplant-related mortality remains elevated. Lucarelli and his group transplanted 107 adult patients with a probability of survival, event-free survival, nonrejection mortality, and rejection of 66%, 62%, 37%, and 4%, respectively, with a median follow-up of 12 years.[706] A second group of 15 patients with a median age of 21 years was treated with a reduced-dose intensity-conditioning regimen that produced some improvement in thalassemia-free survival (67%) and lower, but still elevated, transplant-related mortality (27%). In addition, the risk of developing chronic GVHD remained high.[707]

Alternative Donors

An HLA-compatible sibling is available for only 25% to 30% of thalassemia patients. Therefore, alternative donors have been used as a source of hematopoietic cells. HLA-identical relatives can be found in families coming from small ethnic communities or where inbreeding is common. A higher risk of rejection mortality, infection, and GVHD was reported in eight patients transplanted from an HLA-identical parent.[708] While HSCT from HLA mismatched family members has given disappointing results, matched unrelated donors can be considered a viable alternative when a matched sibling is not available. In fact, approximately 30% of Caucasian patients with thalassemia major who started the search found a suitable donor in one of the international hematopoietic stem cell donor registries that now include more than 18 million volunteers worldwide. Initially, these HSCTs were aggravated by high risk of death and GvHD, but more precise characterization of HLA alleles using stringent criteria of compatibility with the recipient (i.e., identity or single allelic disparity for HLA-A, B, C, DRB1, and DQB1 loci) and high-resolution molecular typing for both class I and class II loci can reduce the risk of immune-mediated complications and fatal events.[709] The probability of cure after HSCT was about 85% for children belonging to classes I and II of the Pesaro classification, and 65% for children belonging to class III and for adults.

Additional genetic characteristics have been reported to be of prognostic value in choosing the potential donor more accurately.[710]

Conditioning Regimen

The bone marrow of thalassemia patients is hypercellular. The ideal conditioning regimen should therefore be capable of eradicating the thalassemic marrow and be sufficiently immunosuppressive to permit sustained engraftment. For many years after inception of HSCT for thalassemia, the preparatory regimen included IV dimethyl busulfan or oral busulfan at the dose of 14 mg/kg plus 120 to 200 mg/kg of cyclophosphamide. More recently, the introduction of conditioning regimens including intravenous busulfan or treosulfan associated with thiotepa and fludarabine has improved results. In a study of 60 thalassemia patients (median age 7 years, range 1 to 37) who underwent allogeneic HSCT, a conditioning regimen combining thiotepa/treosulfan/fludarabine proved to be safe and effective. Neither the class of risk nor the donor used influenced outcome.[711]

Reduced-intensity preparative regimens have resulted in minimal toxicity, but in a high percentage of incomplete engraftment and graft rejection, confirming the need for a myeloablative regimen.[712]

GVHD prophylaxis consisting in cyclosporine and short course methotrexate is effective in preventing acute and chronic GvHD. Antithymocyte globulin is often added to reinforce immunosuppression, in particular for transplants from unrelated donors or when an HLA disparity is present.

Rejection can appear in different patterns.[713] The patients can have no take, develop aplasia, or, more often, have autologous reconstitution of the thalassemic marrow after engraftment. The most common transplant-related cause of death is infection, especially in patients who remain aplastic after graft rejection. A few splenectomized patients have died, after transplant, of overwhelming sepsis.

Persistent mixed chimerism was observed, over a period of time varying between 2 and 11 years after BMT, in 11% of patients transplanted for thalassemia.[714,715] Despite the presence of large numbers of residual host cells, these patients no longer required red blood cell transfusions, producing levels of Hb A ranging from 8.3 to14.7 g/dl. The mechanisms underlying this apparent state of immunologic tolerance or education are not clear. However, these observations may be useful in defining optimal strategies for gene therapy and in utero hematopoietic stem cell transplantation.

Cord Blood Transplantation

Umbilical cord blood has rapidly become a valuable alternative stem cell source for allogeneic HSCT. In thalassemia patients, related cord blood transplantation appears to have a probability of success comparable to that offered by bone marrow transplantation; and, in addition to avoiding general anesthesia to the donor, it is associated with lower risks of transplant-related mortality, chronic GVHD, and transmission of viral infections. A large, ongoing international study, retrospectively comparing cord blood to bone marrow recipients, (Locatelli, personal communication) has revealed overall survival and thalassemia-free survival to be very similar in the two groups, in the order of 95% and 88%, respectively, while acute and chronic GVHD were almost double in bone marrow recipients (20% and 12% vs 10%, and 5% for cord blood recipients). The mean age in the two groups were similar, 8 vs. 6 years, and almost all patients belonged to good-risk classes. The main disadvantage of cord blood is represented by the longer time necessary to reach safe platelet and neutrophil counts. Studies have shown that the number of nucleated cells infused is the most significant predictor of success.[716,717]

These results support targeted efforts to bank family cord blood units that can be used for a sibling diagnosed with thalassemia or other diseases which can be cured by allogeneic hematopoietic stem cell transplantation.[718]

Umbilical Cord Blood Transplantation

Umbilical cord blood is less restricted with regards to HLA matching, so that a mismatch at 1 or 2 loci is usually tolerated without a significant increase in GVHD or impaired survival.

The use of unrelated cord blood as a source of stem cells for thalassemia patients has not been explored in well-designed clinical trials. In a recent report of 35 unrelated transplants, the 5-year overall survival and thalassemia-free survival were 88% and 74%, respectively. However, 40% of the patients developed chronic skin GVHD.[719]

Other reports have been less favorable,[720] suggesting that unrelated cord blood transplantation in thalassemia is still an experimental, high-risk approach.

Peripheral blood stem cell transplantation has been tried in patients with thalassemia.[705,721] The results showed that major outcomes obtained with this source of hematopoietic cells are not statistically different from those obtained with bone marrow in terms of rejection and disease-free survival. However, an increased risk of chronic graft-versus-host disease was observed.

Side Effects of Stem Cell Transplantation

Chronic Graft-versus-Host Disease. Chronic graft-versus-host disease (cGVHD) a multiorgan disorder with features of an autoimmune disease, is particular feared when transplanting patients, such as those with thalassemia, who undergo transplantation more to improve their quality of life than to avoid an impending risk of death. In an historic series the incidence of cGVHD was 27%.[722] Among Middle Eastern patients transplanted in Italy, the incidence

of chronic GVHD was 18%,[723] In a group of patients treated with reduced-toxicity conditioning regimen, only one out of 56 patients at risk developed chronic GVHD.[711] The risk of GVHD is lower after cord blood transplantation. After grafting from an unrelated donor chosen according to stringent criteria of HLA-compatibility, the risk of GVHD is not higher.[724]

Growth, Development, and Fertility. Short stature is present in a significant percentage of children transplanted for thalassemia. There appears to be a strict correlation between age at the time of transplant and final adult height. In a study, the patients whose age at transplant was <7 years reached their genetic target for height, while those who were >7 years did not.[725] This is in contrast with most studies in children transplanted for hematologic malignancies that have demonstrated that the younger the patient was at the time of HSCT, the greater the loss in height. Probably the deleterious effects on growth of iron and desferrioxamine, at an early age, are even more profound than the effects of pretransplant conditioning.[726] Results on pubertal maturation remain unsatisfactory after HSCT. In a series of 50 prepubertal patients with thalassemia major, who had been transplanted during childhood or in the peripubertal period, clinical and hormonal evidence of gonadal dysfunction was found, and normal puberty developed in only 40% of patients. There was no correlation between pubertal maturation and age at HSCT or serum ferritin levels.[727] Sterility from pretransplant conditioning is also considered a possible side effect of the procedure. In fact, the myeloablative conditioning regimen including busulfan and cyclophosphamide may induce gonadal dysfunction in males and females, especially when high doses of busulfan are used. Nevertheless, a few successful cases of spontaneous pregnancy and paternity have been reported in patients transplanted for thalassemia.[728]

Counseling is mandatory, as artificial reproductive techniques are available.[729] In postpubertal male patients, sperm can be stored, while for prepubertal males, immature testicular tissue cryopreservation is still an experimental procedure.[730]

Cryopreservation of ovary tissue collected before transplantation is feasible and can maintain fertility even after a long period of time. Several pregnancies have been recorded following autologous reimplantation of frozen ovarian tissue harvested after puberty.[731]

Malignancies. A few solid tumors and several cases of early and late non-Hodgkin lymphoma have been observed in patients transplanted for thalassemia. The overall frequency has been calculated to be less than 7/100,000 per year.[732–734]

Regular screening for oral squamous cell carcinoma should be performed in patients experiencing chronic graft-versus-host disease secondary to HSCT, as malignant lesions of the buccal mucosa can appear decades after the transplant.[735]

Iron Depletion

The hemochromatosis present at the time of grafting will not disappear after transplantation without some kind of intervention. After HSCT, ferritin increases, reaching a peak around the third month after the procedure, probably as a consequence of bone marrow aplasia and shifting of iron to the storage compartment.

The conditioning regimen can contribute to the increase in NTBI levels. In one study, NTBI peaked as early as 4 days prior to transplantation, and was detectable for 6 to 18 days in all patients.[736]

Normally, endogenous antioxidants play a role in scavenging toxic free radicals and preventing cell damage.[737] However, in patients undergoing HSCT, chemotherapy-based conditioning regimens can result in a pro-oxidant status, as indicated by a reduced total radical antioxidant parameter of plasma.[738,739]

After transplant, ferritin usually returns to pretransplant levels. In the absence of therapy, the iron content of the body remains stable, potentially for many years. One study demonstrated that ferritin levels normalized only in moderate-to-severely iron-overloaded pediatric patients as a result of the use of storage iron for growth.[740] The effects of persistent iron overload on the long-term morbidity of HSCT recipients (particularly as it relates to late organ dysfunction) have not been investigated.

Considering the damage that iron induces in non-transplanted thalassemia patients, phlebotomy is indicated for patients with high ferritin levels and/or high parenchymal iron concentration measured before transplant. Bimonthly venesections should be performed starting at least 18 months after grafting. Their effectiveness in reducing ferritin level, median liver iron concentration, and liver enzymes has been repeatedly demonstrated.[449]

Monthly erythrocytaphereses are equally effective. This technique has the advantage of saving plasma and mononucleated cells, but it is more costly and time consuming. Cirrhosis of the liver can be reversed after iron depletion by phlebotomy.[741]

In one report deferasirox was used in seven patients transplanted for thalassemia without negative effects on donor chimerism or liver function. Serum ferritin levels decreased while serum creatinine significantly increased, but it remained within normal limits in all patients.[742]

Deferoxamine can also be used to reduce the iron burden in patients in whom low levels of hemoglobin after transplantation or difficult venous access prevent phlebotomy.[743] Chelation with deferoxamine should not be started too soon after transplant, because this chelator has been reported to interfere with grafting. Deferiprone is contraindicated in this setting for its potential toxicity on the myeloid cell line.

Quality of Life after Hematopoietic Stem Cell Transplantation

The long-term prognosis of thalassemia patients who are treated according to modern criteria is satisfactory and continuously improving. Therefore the choice to undergo HCST must be motivated by serious arguments. On one hand, the freedom from transfusion and chelation, and, if the transplant is done early enough, from the consequences of iron overload; on the other, the immediate risks of death and of acute and chronic GVHD and possibly of the long-term effects of toxic conditioning regimens need to be considered.

Not many data are available in this regard. In a report of 28 children with β-thalassemia from Middle Eastern countries who underwent allogeneic HSCT in Italy, child-self and parent-proxy reports were collected to prospectively evaluate health-related quality of life The study demonstrated that physical functioning declined significantly from the time of transplant to 3 months after it but then increased significantly up to 18 months after the procedure. As expected, chronic GVHD was significantly associated with lower scores.[723]

The results of this study, however, collected in poorly treated patients, may not be applicable to a population of patients enjoying adequate conventional therapy.

Hemoglobin F Reactivation

For patients with homozygous β-thalassemia, an increased γ-globin chain production would result in a more balanced α/non-α ratio and an amelioration of the severity of the anemia. In fact, γ-chains can neutralize the harmful excess of α-chains and allow a better survival of erythroid precursors in the bone marrow and of the red cells in the peripheral blood. Effective procedures to enhance red cell production could reduce or even eliminate the need for transfusions and would represent a major advance in the treatment of homozygous β-thalassemia. Toward this aim, many efforts in the last decades have focused on the pharmacologic induction of fetal hemoglobin in patients with hemoglobinopathies. Three different therapeutic classes of

γ-globin inducers have been investigated, including cytostatic-hypomethylating agents (e.g., hydroxyurea, 5-azacytidine, and decitabine); short-chain fatty acid derivatives, some of which are histone deacetylase inhibitors (e.g., sodium phenylbutyrate, arginine butyrate, and isobutyrate); and recombinant erythropoietin.[744,745,746] These classes of compounds act through complex distinct mechanisms, only partially clarified. Cytostatic-hypomethylating compounds, preferentially killing dividing cells, alter the kinetics of erythropoiesis and induce γ-globin gene hypomethylation. Accelerated erythropoiesis is associated with the emergence of primitive erythroid progenitors, which are more committed to HbF synthesis.[747] Because heavily methylated genes, as are γ-globin genes in the adult, cannot be transcribed and are therefore effectively silenced, demethylation results in transcriptional activation.[748] Small clinical trials have been conducted with 5-azacytidine with some apparent clinical benefit, but the carcinogenic risk of the drug has discouraged its use.[749,750] Recent clinical trials with a more tolerable deoxycytidine analog, decitabine, have shown a modest but significant increase in total hemoglobin and in absolute fetal hemoglobin.[751,752] The largest experience has been reported with hydroxyurea (HU), a potent inhibitor of ribonucleotide reductase that interferes with DNA synthesis and promotes cell death, resulting in perturbation of the kinetics of erythroid differentiation. Several studies suggested that HU may induce HbF synthesis through the guanosine 3′,5′-cyclic monophosphate (CGMP) signaling pathway.[753] HU has been given in many different regimens and doses, alone or in combination with other drugs, including erythropoietin. In some patients with thalassemia intermedia and HbE/β-thalassemia, there has been a modest to moderate effect on total hemoglobin concentration and HbF, but not in all patients.[754–756] A 13-year experience in a large group of Iranian patients with β-thalassemia showed that HU at a dose of 8 to 15 mg/kg/day was effective in decreasing or determining cessation of the need for regular blood transfusions without any major side effects.[757] HU has also been used effectively in thalassemia intermedia to reduce the size of extramedullary erythropoietic masses when these compress vital organs or tissues.[316,758] Recombinant human erythropoietin (Epo) and the new synthetic form, darbepoetin, with a longer half-life, have been used to stimulate erythropoiesis and promote erythroid cell survival. The results have been modest and variable among the patients.[759–761]

The use of compounds that further stimulate erythropoietic expansion is questionable. Combined use of agents that counterbalance their effects (e.g., Epo and HU) may offer a better therapeutic potential.

Butyrate and its analogs, including short-chain fatty acid derivatives, have been used to induce HbF production in hemoglobinopathies, with variable responses.[762,763] This class of compounds increases γ-globin gene expression by promoting histone acetylation (through histone deacetylase inhibition), which is associated with transcriptional activation and increased mRNA translation.[745,764,765] Butyrate and other histone deacetylase inhibitors have shown other epigenetic mechanisms, namely, decreased DNA methylation, signaling activation through the soluble guanylate cyclase and p38MAP kinase pathway as well as ERKMAP kinase inhibition (for review, see Ref. 745). Clinical trials with these agents in patients with β-thalassemia have shown a modest effectiveness and a variability in response among patients.[762,766–769] Moreover, the inconveniently frequent administration of high doses makes this treatment intolerable for many patients. In general, the small-scale studies of the induction of fetal hemoglobin in thalassemia major have been unsuccessful, probably because the magnitude of activation of the γ-globin genes is not sufficient to correct the severe chain imbalance characteristic of the disease.[770] Moreover, there are concerns about the potential for serious side effects from the long-term use of chemotherapeutic agents like 5-azacytidine and HU. Therefore, the use of HbF inducers remains experimental and cannot be recommended outside of clinical trials.

Recent discoveries using new technologies of DNA analysis have further elucidated the mechanism of human fetal hemoglobin regulation.[771,772,773] Physical interactions between the β-LCR and the downstream γ- and β-globin genes with transcription factors and chromatin-remodeling complexes have been shown to play a role in globin gene switching. These insights might lead to the design of new therapeutic approaches to enhance fetal hemoglobin expression in adult erythroid cells.

Gene Therapy

β-Thalassemias were among the first diseases to be considered for gene therapy. In principle, the tissue to be corrected (i.e., the bone marrow) can be removed, treated, and reinfused into the patient. Moreover, the gene and the molecular lesions responsible for the disease are well known. Therefore, genetically based strategies, aimed to insert a normal copy of the human β-globin gene, along with key regulatory sequences into autologous hematopoietic stem cells (HSCs), represent a feasible alternative to bone marrow transplantation to definitively cure β-thalassemia. However, this approach has been impeded over the last decade by challenging obstacles, including the extremely complex regulation of the globin genes, the isolation and the biology of the optimal target cell (i.e., the pluripotent self-renewing hematopoietic stem cell), a safe and efficient transduction, and a stable and effective transgene expression.

For at least two decades gene transfer vectors based on the Moloney murine leukemia retrovirus (MLV) have been used to transfect HSCs, but the transfection was at a very low rate and the transfused globin genes were unstable and only rarely integrated intact into the genome, thus losing any therapeutic efficacy.[774,775] The main problems associated with the use of retroviral vectors for gene therapy include the inability of these vectors to target non-dividing HSCs, the possibility of accommodating only small segments of DNA, and the risk of insertional activation of proto-oncogenes.

To obtain gene therapy for the hemoglobinopathies, vectors must target HSCs because these are the only cells capable of self-maintenance as well as erythroid differentiation. Because of the complexity of globin gene regulation, relatively large segments of DNA need to be integrated into the genome of gene-transduced target human HSCs, if good levels of globin expression have to be attained. The corrective construct should contain the structural human β-globin gene as well as its promoter and critical elements of the human β-LCR (locus control region). Experience from treating X-linked severe combined immunodeficiency (X-SCID) showed that several patients, cured of their disease, developed leukemia as a result of insertional mutagenesis.[776]

Results from trials performed in Paris and London reported in 5 out of 20 patients with X-SCID treated with specific gene therapy, the occurrence of leukemia, which was associated with oncogene transactivation by the vector's transcriptional control elements.[776,777]

To solve these problems, the use of lentiviral vectors was first introduced in the early 2000s.[778–780] The major advantages of these vectors were the ability to infect quiescent hematopoietic stem cells at higher rates and to export unspliced the vector RNA from nuclei, thereby ensuring the integrity of the expression cassette. In the year 2000, the group led by Sadelain published the first study in which a murine model of thalassemia intermedia was efficiently cured with a lentiviral globin vector.[780] Soon after, therapeutic efficacy was demonstrated in a murine model of sickle cell disease,[781] and even in a murine model of thalassemia major.[782] In the following years different laboratories confirmed and extended these initial results, demonstrating the efficacy of lentiviral gene therapy with xenotransplants of

genetically corrected human thalassemic HCSs into recipient SCID mice.[783]

After many animal experiments, the first human gene therapy trial for β-thalassemia and sickle cell anemia began in France in 2006.[784] Two patients with thalassemia were treated. In the first patient, the gene-corrected bone marrow failed to reconstitute and the patient required a rescue with untransduced back-up bone marrow. The second patient had recently been reported to be free of transfusion for more than 3 years of post-gene therapy follow-up, maintaining a hemoglobin level between 9 and 10 g/dl.[784] However, further analysis of the patient discovered a dominant cell clone with integration site into the HMGA2 gene, a potential oncogene.[785,786] The patient continues to be strictly monitored to anticipate a potential evolution into a leukemic state. A more extended follow-up and larger numbers of patients are needed to confirm the initial positive results, as well as to insure that the globin lentiviral vectors are sufficiently safe and offer to thalassemia patients a better option than the traditional transfusion and chelation therapy. In recent years, a new, highly promising technology has been developed that allows derivation of patient-specific embryonic-like stem cells from adult differentiated cells (e.g., skin fibroblast). These reprogrammed cells, produced by transduction with the transcription factors Sox2, Oct3/4, Myc, and Klf4, are called induced pluripotent stem cells (iPS) because they have the ability to differentiate into all embryonic tissues. iPS can be easily obtained and have the great advantage of being expandable in large amounts and indefinitely. Moreover, the possibility of making them amenable to gene correction by homologous recombination renders these cells highly attractive for gene therapy. A proof of principle of this use has recently been provided by employing iPS to correct a murine model of sickle cell anemia.[787] The field is very exciting and rapidly developing, and in the near future has the potential to completely revolutionize the field of gene therapy and regenerative medicine. However, some major challenges need to be overcome before iPS can be considered for clinical use, including the improvement of the efficiency with which somatic cells are reprogrammed and the demonstration that genetically engineered iPS have no potential to undergo subsequent malignant transformation.[788]

THALASSEMIA MINOR

Classical Form: Clinical Picture

The classical heterozygous carrier of β-thalassemia is usually asymptomatic, and the diagnosis is made by chance, because of positive family history or during population screening. Several series have been published on the clinical and hematologic features of people with thalassemia minor.[789,790] Anemia is mild or absent. In pregnancy, anemia can be more severe than in normal women, and folate supplementation, at the dose of 5 mg daily, is recommended.[791,792] Iron absorption is increased, and frank iron overload has been reported. Inappropriate administration of iron has been proposed as a possible cause in some of the patients.[793] In addition, it has been observed that the β-thalassemia trait aggravates the clinical picture of hemochromatosis in individuals homozygous for the mutations C282Y and H63D, favoring higher rates of iron accumulation and the possible development of iron-related complications.[793] On the other hand, the H63D mutation has been reported to increase iron overload in β-thalassemia carriers.[794] Iron deficiency anemia occurs less frequently in children heterozygous for β-thalassemia as compared to normal controls, but its clinical expression, at similar levels of iron depletion, is more severe. The hemoglobin nadir at the end of the first trimester of life is also deeper and more prolonged in carriers of the trait.[795] Serum bilirubin levels present considerable variation. Homozygosity for the mutation typical of Gilbert syndrome is one of the factors determining hyperbilirubinemia in these individuals.[796] Increased risk of gallstones has also been observed in women with the β-thalassemia trait as compared to controls.[797] Data from Sicily seem to indicate that heterozygotes for β-thalassemia have a longer life expectancy.[798] Men have a lower risk of myocardial infarction than the general population.[799] A partially improved cardiovascular risk profile has been observed in terms of low hematocrit, low-density lipoprotein (LDL) cholesterol, and apo-B in carriers of β-thalassemia.[800] The LDL lowering effect of the thalassemia trait is evident even in patients with familial hypercholesterolemia.[801]

Laboratory Features

The reported mean hemoglobin concentration in affected Italian men and women was 12.7 and 10.9 g/dl, respectively; in Greek men, 13.9 g/dl[802]; and in Oriental men and women, 12.1 and 10.8 g/dl, respectively.[790,791,793,803] A slightly lower hemoglobin concentration was noted in Jamaicans with heterozygous β^0-thalassemia (11.3 g/dl) compared with those having heterozygous β^+-thalassemia (12.5 g/dl).[804] Hemoglobin is less markedly decreased in Africans than in Mediterraneans.[805] The red cell count is elevated, and the MCV and MCH values are reduced. The mean cell hemoglobin concentration (MCHC) is normal or only slightly decreased. In one series of 244 cases of β^0-thalassemia carriers, the MCV was 67 ± 4.6 fl (mean ± 1 SD), the MCH was 22.4 ± 1.6 pg, and the MCHC was 32.9 ± 0.8 g/dl red blood cells.[791] The degree of reduction in the MCV is directly related to the degree of reduction in β-globin production.[806] The MCVs produced by β^0 mutations are lower than those produced by β^+ mutations.[807] Heterozygotes for mild β-thalassemia mutations, as a group, have higher MCV and MCH as compared to the severe β^0 and β^+ alleles. Microcytosis and hypochromia, associated with variation in size and shape of the erythrocytes, are commonly observed in the peripheral blood smear. Basophilic stippling is frequently found in heterozygous individuals from the Mediterranean, but not in Africans or Orientals.[808,809] Reticulocytes are generally increased to twice the normal numbers and have been found to correlate with the hemoglobin level.[793] In children, the MCV is lower than in adults and normally increases with age; in thalassemia carriers, the correlation with age is less evident.[810] The evolution of hematologic parameters in children at various ages is reported in Table 34.4.[811] Free erythrocyte protoporphyrin is normal or slightly increased. Osmotic fragility is decreased. Red cell survival, measured by 51Cr, shows mild ineffective erythropoiesis,

TABLE 34.4

MAIN HEMATOLOGIC PARAMETERS OF β-THALASSEMIA CARRIERS ACCORDING TO AGE

Age	Hb (g/dl)	MCV (fl)	HbA_2 (%)	HbF (%)
At birth	18.3 ± 2.3	99 ± 8	0.5 ± 0.2	73.8 ± 10.1
4 mo	10.1 ± 1.1	70 ± 6	3.2 ± 0.7	27.0 ± 10.5
7 mo	10.5 ± 0.8	59 ± 4	4.8 ± 0.7	8.2 ± 4.0
9–10 mo	11.1 ± 0.9	59 ± 2	5.1 ± 0.5	4.4 ± 2.1
2 y	11.2 ± 0.9	58 ± 2	4.8 ± 0.4	4.1 ± 2.1

rather than peripheral hemolysis.[812] HbA2 is constantly elevated in heterozygous carriers of β-thalassemia in all the ethnic groups studied. The values range from 3.5% to 7% with a mean of 5%.[15] This increase appears to be determined by an increased output of δ-chains from both loci, in cis and in trans, to the thalassemia gene. HbF is increased in half of the patients, but the values observed are generally in the range of 1% to 3%. The distribution within the red cells is usually heterogeneous.[813,814] A minority of carriers show unusually high levels of HbA2 (>6.5%) associated with a variable increase of HbF. The molecular basis of these forms is large deletions of the β-globin gene, which remove its 5′ promoter region. Globin chain synthesis analysis in heterozygous β-thalassemia shows variable imbalance correlated to the severity of the β-globin chain defect.[15] The physiologic decrease of HbF in the first weeks of life is slower in β-thalassemia heterozygotes (Table 34.4).

Atypical Carriers

The typical phenotype of the β-thalassemia trait, essentially characterized by reduced MCV and MCH, and increased HbA2, may be modified by several genetic and acquired factors, causing problems in carrier identification. The coinheritance of heterozygous β-thalassemia with homozygous α^+-thalassemia (-α/-α) or heterozygous α^0-thalassemia (–/αα) has a substantial effect on MCV and MCH, which increase sometimes up to normal values (Fig. 34.21).[815] However, the HbA2 in these double heterozygotes remains in the carrier range, thus allowing their identification. Atypical carriers with reduced MCV and MCH and normal or borderline HbA2 include double heterozygotes for δ- and β-thalassemia and carriers of some mild mutation, such as the –87 C→G, the –29 A→G, and IVS-1–6 T→C (Table 34.5). The differential diagnosis includes iron deficiency and α-thalassemia trait. Specific tests and sometimes family studies allow correct identification (see below).[699,816] A third group of atypical β-thalassemia carriers is represented by heterozygotes for very mild or silent β-thalassemia mutations (Table 34.5). As a result of minimal deficiency of β-globin production, these carriers have normal MCV and MCH and normal or borderline HbA2.[816,817] The α- to β-globin chain synthesis ratio is normal or slightly higher than 1, confirming that these mutations cause only a very mild reduction in the expression of the β-globin gene. In this group also, the carriers of the triple α-globin gene arrangement (ααα/αα), which for the excess of α-globin chain produced may be considered a very mild β-thalassemia allele, should be included.[77,818] Identification of these silent carriers is usually retrospective in parents of patients with mild thalassemia intermedia. An extreme, although rare, instance of complex thalassemia gene combination that may lead to an almost silent phenotype is the coinheritance of α-, δ-, and β-thalassemia.[818] Acquired factors able to modify the typical phenotype of β-thalassemia trait are iron deficiency anemia and folate deficiency. Iron deficiency anemia, when severe, may decrease the high HbA2 levels typical of heterozygous β-thalassemia, and folate deficiency may increase the MCV up to normal values.[819] When these deficiency anemias are present, other tests, such as DNA analysis to identify the β-globin gene mutation or retesting after correction of the anemia, are warranted to make a correct diagnosis.

Iron deficiency, diagnosed on the basis of serum ferritin and mild anemia, has been reported to cause mild reduction of HbA2, hence reducing its reliability for β-thalassemia carrier identification.[820,821]

TABLE 34.5

GENOTYPE AND PHENOTYPE OF ATYPICAL β-THALASSEMIA CARRIERS

Phenotype	Genotype
Normal MCV and MCH, high HbA_2	Coinheritance of α-thalassemia
Reduced MCV and MCH, borderline/normal HbA_2	Some mild β-thalassemia alleles Coinheritance of δ-thalassemia ε-γ-δ-β-thalassemia Corfu δ-β-thalassemia
Normal MCV-MCH, and borderline/normal HbA_2	Very mild/silent alleles Triplicated α-globin gene KLF1 mutations
Significant clinical phenotype	Coinheritance of α-globin gene defects: triple alpha locus and HbH disease genotype (-/-α) Hyperunstable globins

Hb, Hemoglobin; MCH, mean cell hemoglobin; MCV, mean cell volume.

δβ and Hereditary Persistence of Fetal Hemoglobin Carriers

$δβ^0$-Thalassemia carriers show red blood cell changes milder than those observed in β-thalassemia trait. Overall, MCV and MCH are around 70 fl and 24 pg, respectively. HbA2 is normal or reduced, and HbF is increased (5% to 20%) and heterogeneously distributed among red cells. The degree of globin chain imbalance is mild (α to non-α ratio around 1.5). Heterozygotes for deletional HPFH are characterized mostly by normal MCV, MCH, and HbA2. Only in some cases is there a mild reduction of red cell indices and

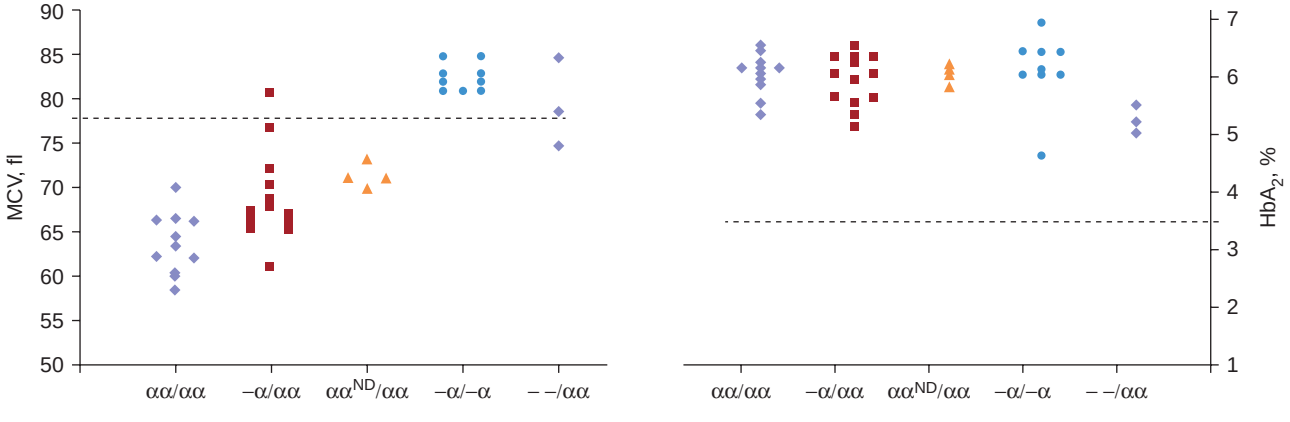

FIGURE 34.21. Effect of coinheritance of different α-thalassemia alleles in β-thalassemia carriers. Hb, hemoglobin; MCV, mean cell volume.

HbA2. HbF ranges from 15% to 30% with pancellular distribution. α-/n-α–globin synthesis is normal or mildly unbalanced.[822] Nondeletional HPFH heterozygotes have red cell indices, HbA2, and α- to non-α ratios similar to those of deletional HPFH carriers, while mean HbF levels vary from 1.5% to 27%.

Carrier Detection

β-Thalassemia and δβ-Thalassemia

Carrier detection methods should be able to identify typical and atypical heterozygous β-thalassemia as well as δβ-thalassemia and the hemoglobin variants, such as HbS and HbE, which, by interacting with β-thalassemia, may result in the production of clinically significant syndromes. As compared to most genetic diseases, carrier detection in hemoglobinopathies is relatively easy because it may be achieved through hematologic examination rather than DNA analysis. However, DNA analysis is needed for the identification of globin gene mutation, which is essential for prenatal diagnosis. Basic hematology methods for carrier detection consist of red blood cell indices determination and hemoglobin pattern analysis. More specialized tests (including iron status determination and globin chain synthesis analysis) and eventually DNA analysis are required in some cases for definitive diagnosis.[384,386,823]

The recommended method for blood count is the electronic measurement of red cell indices. All red cell indices are important in the evaluation, but the most useful for thalassemia carrier identification are MCV and MCH, with cut-off values of <78 fl and 27 pg, respectively. Hemoglobin pattern analysis can be obtained in a single step by high-pressure liquid chromatography (HPLC). This method gives an accurate quantitation of HbA2 and HbF and detects the large majority of Hb variants.[824,825] Several automatic devices for hemoglobin separation and quantitation are available, and a comparative study has shown that all provide reliable detection of hemoglobin variants and good HbA2 quantification.[826] Alternatively, cellulose acetate electrophoresis or isoelectric focusing can be used for detecting Hb variants, but quantitation of HbA2 and HbF should be performed, respectively, by microchromatography and alkali denaturation. Elution of HbA2 and HbF bands after electrophoresis is an accurate but time-consuming method. Appropriate tests for iron status determination and globin chain synthesis analysis are supplementary hematologic methods useful in carrier detection procedures.[823] Family studies may be helpful in some atypical cases, particularly in genetic compounds for two different alleles. The carrier detection procedure should be designed in order not to miss any carrier or couple at risk. Based on the frequency and heterogeneity of thalassemia types present in a population, appropriate screening programs are set out. The most used flow chart in Mediterranean populations, where thalassemias are common and heterogeneous, is reported in Figure 34.22.[11] In addition to MCV and MCH, the first set of tests includes HbA2 quantitation to avoid missing double heterozygotes for α- and β-thalassemia with normal MCV and MCH. Globin chain synthesis analysis is performed to differentiate α-thalassemia trait from δ-+ β-thalassemia or mild β-thalassemia alleles. With this relatively complex flow chart, only the truly silent β-thalassemia carrier and the triple α-globin gene arrangement may be missed.

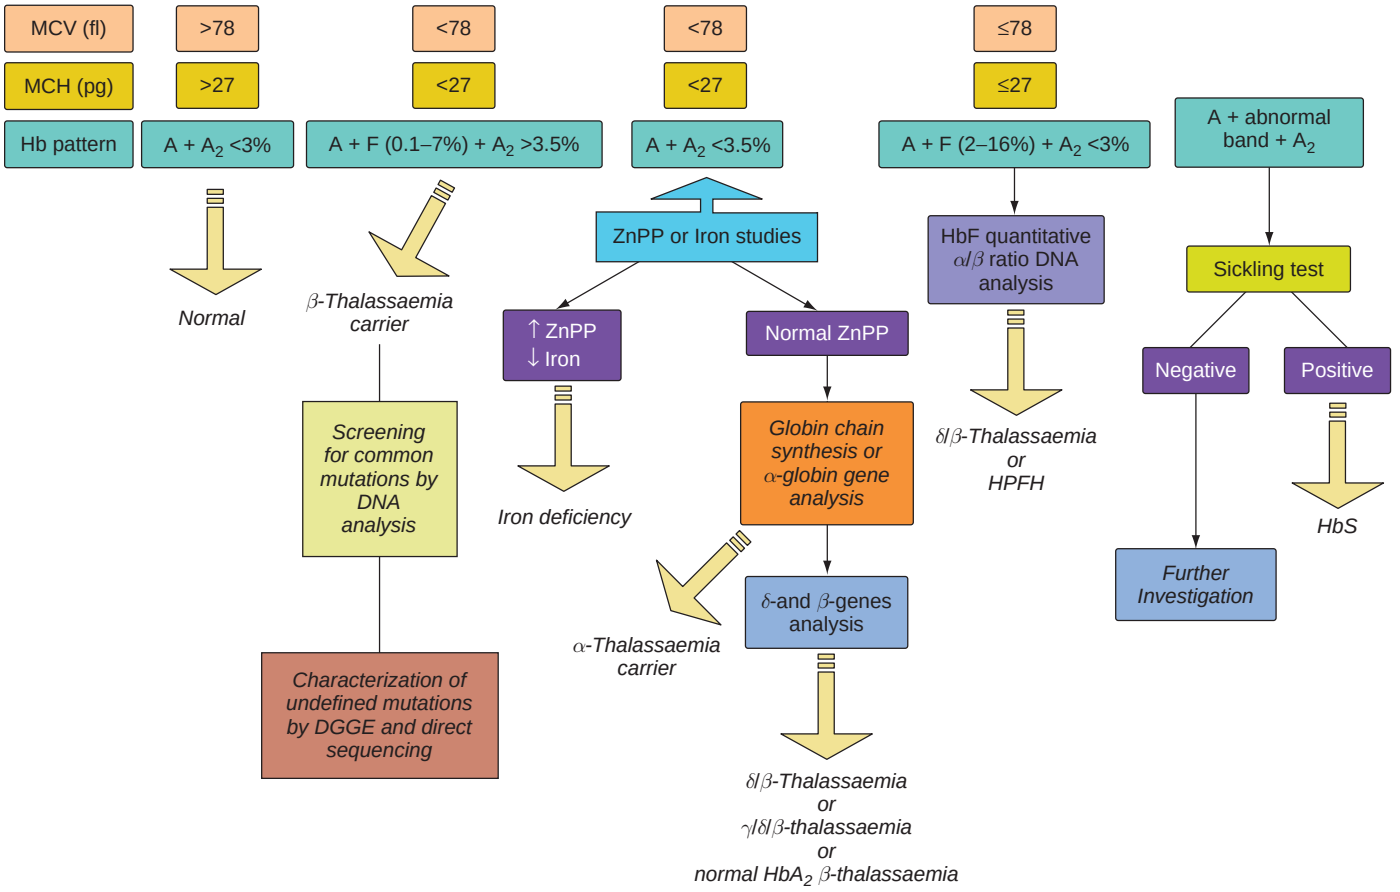

FIGURE 34.22. Flow chart for the diagnosis of thalassemia syndromes. Thalassaemia and glucose-6-phosphate dehydrogenase screening in 13- to 14-year-old students of the Sardinian population: preliminary findings. Community Genet 2008;11:121–128.)

In populations with low frequency of thalassemia the initial screening IVS-1–6 T→C Poly A site AACCCC AATGAA cd, codon; UTR, untranslated region can be performed by the evaluation of red cell indices modification, followed by the hemoglobin pattern analysis to confirm the presence of a thalassemic allele. The osmotic fragility test, less expensive than MCV and MCH determination, is a simple approach to screening for thalassemia.[827] However, this test is sensitive but not specific, is difficult to standardize, and does give false negative results. Several mathematical indices derived from red cell parameters, measured using electronic counters, have been proposed to identify β-thalassemia carriers, discriminating thalassemia trait from iron deficiency (Mentzer, England and Fraser, Shine and Lal). However, these indices turned out to be inaccurate, particularly in pregnant women, in children, and in α- thalassemia–β-thalassemia interaction, predicting the correct diagnosis only in 80% to 90% of the patients.[828] Therefore, their use is not appropriate, particularly in populations with a high frequency of β-thalassemia, where missing a carrier may have serious consequences.

Two common problems in screening for β-thalassemia are the presence of borderline HbA2 values (i.e., HbA2 = 3.2% to 3.8%) and the differential diagnosis of microcytosis with normal to borderline HbA2.[816,818] Borderline HbA2 may be associated with low or normal MCV and MCH. Several β-thalassemia genotypes have been associated with borderline HbA2 including mild β^+ thalassemia mutations (i.e., HBB c.92+6 TC), coinherited δ- and β-thalassemia, and β promoter mutations (i.e., HBB c.-142 CT).[829] However, all these determinants explain only a limited proportion of borderline HbA2 levels, and the unexplained cases pose relevant screening and genetic counseling problems. Recently, mutations of the *KLF1* gene have been described in a consistent proportion of subjects with borderline HbA2, and this facilitates carrier detection and genetic counseling.[830] A phenotype characterized by microcytosis, hypochromia, normal or borderline HbA2, and normal HbF may result from iron deficiency, α-thalassemia, δ-+ β-thalassemia interaction, mild β-thalassemia, or, very rarely, εγδβ-thalassemia. After exclusion of iron deficiency by erythrocyte zinc protoporphyrin determination and/or evaluation of transferrin saturation, the different thalassemia determinants leading to this phenotype are discriminated by globin chain synthesis analysis and eventually by α-, δ-, and β-globin gene analysis.

$\delta\beta^0$-thalassemia carriers and HPFH heterozygotes, both characterized by increased HbF levels, can be clearly differentiated by globin chain synthesis analysis, showing an α/non-α imbalance in the former. Identification of the molecular defect by globin gene DNA analysis may be requested to confirm the diagnosis.

The presence of the Hb Lepore can be suspected in the presence of an abnormal slow Hb band on the electrophoretic pattern associated with reduced MCV, MCH, and HbA2 and usually a mild increase (~2% to 5%) of HbF. The diagnosis is confirmed by DNA analysis of the β-globin gene cluster. In couples at risk identified by the carrier detection procedures described above, the specific mutation is defined by globin gene DNA analysis using polymerase chain reaction (PCR)-based methods. There are now many different PCR-based techniques that can be used to detect globin gene mutations, including dot blot analysis, reverse dot blot analysis, the amplification refractory mutation system (ARMS), denaturing gradient gel electrophoresis (DGGE), mutagenically separated polymerase chain reaction, gap-PCR, restriction endonuclease (RE) analysis, real-time PCR, Sanger sequencing, pyrosequencing, multiplex ligation-dependent probe amplification (MLPA), and gene array systems.[831,832,833,834] Each method has advantages and disadvantages and the choice depends not only on the technical expertise of the laboratory, but also on the type and variety of the mutations likely to be encountered in the populations being tested. In fact, despite the marked heterogeneity of thalassemia mutations, a limited number of molecular defects are prevalent in each population (Table 34.6). This information is very useful in practice because the most appropriate probes or primers can be selected according to the carriers' ethnic origin. It is advisable for any diagnostic laboratory to have at least two alternative methods for detecting mutations.

α-Thalassemia

α-Thalassemia carriers are more difficult to identify than β- or δβ-thalassemia carriers because they do not have typical changes in HbA2 or HbF levels. MCV and MCH are always reduced in carriers of –α/-α and –/αα genotypes, while –α/αα carriers often have normal or sometimes a mild reduction of MCV and MCH values. The hemoglobin pattern in adult α-thalassemia carriers is normal, although as a group they have slightly lower levels of HbA2. In the newborn the electrophoretic detection of Hb Bart (γ4), a fast-moving band, is useful for diagnosis of α-thalassemia trait. α^+-Thalassemia carriers usually show up to 3% of Hb Bart, and α^0-thalassemia carriers (–/αα) and α^+-thalassemia homozygotes (-α/-α) may have 3% to 8%. However, in some carriers Hb Bart may be undetectable.[244,246]

A simple test for detecting α-thalassemia carriers is the incubation of the peripheral blood with brilliant cresyl blue; the smear examination may show rare red blood cells with HbH inclusion bodies, although their absence does not exclude α-thalassemia carrier status.[246] Globin chain synthesis is used to identify α-thalassemia carriers that show an α:β ratio lower than 0.9. This test is helpful in the presence of microcytosis with normal HbA2 to differentiate the α-thalassemia trait from the δ-+ β-thalassemia interaction (see β-Thalassemia Carrier Detection). Definitive diagnosis of α-thalassemia carriers can also be achieved with DNA analysis of the α-globin genes. The methods used depend upon the type of mutations expected in each population and are divided into those that detect deletions (gap-PCR and sometimes Southern blotting) and those that detect point mutations, that is,

nondeletion α-thalassemia (direct detection by restriction enzyme analysis, allele-specific oligonucleotide hybridization, DGGE, and DNA sequencing).[391,835,836] The α^0-thalassemia phenotype can be detected with an anti-ζ globin monoclonal antibody, since small amounts of embryonic ζ globin are produced in adult life by chromosomes lacking both α-globin genes.[837] Detection of α^0-thalassemia carriers is important for prevention of Hb Bart hydrops fetalis syndrome, for which prenatal diagnosis is always indicated, also to avoid the severe toxemic maternal complications during pregnancy. HbH disease is not considered to be among the hemoglobinopathies targeted for prevention.

Hemoglobin E

The diagnosis of heterozygous HbE is based on the hemoglobin pattern analysis by electrophoresis or HPLC separation. At alkaline pH (8.4), HbE moves at the same position as HbA2 and can be distinguished by its high concentration; usually 25% to 30% HbE has the same elution time of HbA2 atHPLC.[838] Lower proportions of HbE in carriers indicate the presence of coinheritance α-thalassemia or of iron deficiency anemia. The blue dye dichlorophenolindophenol (DCIP) can be used as a screening test for HbE, which will dissociate and precipitate at the bottom of the tube upon incubation with this dye at 37°C.[839]

Prenatal Diagnosis

The availability of prenatal diagnosis added a new option to couples at risk for a major hemoglobinopathy, leading to a significant change in the effectiveness of screening and counseling in hemoglobinopathy prevention.[840] Prenatal diagnosis of both α- and β-thalassemia was carried out for the first time in the 1970s using globin chain synthesis analysis in fetal blood, obtained by fetoscopy or placental aspiration around the 19th week of gestation.[841] The advent of DNA analysis and the introduction of chorionic villus sampling resulted in a notable improvement in prenatal diagnosis that can now be performed within the first trimester of pregnancy, generally at 10 to 12 weeks of gestation.[842,843] Fetal DNA can be obtained also from amniocytes at 15 to 17 weeks of pregnancy. Chorionic villus sampling is carried out transcervically or transabdominally and the risk of fetal loss with this procedure has given contrasting results, ranging from 0.5% to 4.5%.[844,845] However, in experienced hands, the fetal loss rate appears to be 0.5% to 1%, similar to natural wastage for pregnancies of this duration.[846] After sampling, fetal DNA analysis is performed by the PCR-based methods. Methods aimed at identifying the mutations are traditionally separated into direct (those designed to interrogate samples for the presence/absence of specific candidate mutations known to be present in the population) or indirect methods (those that screen regions of genes to identify/exclude sequence variation of genes within each gene region (for review see 832). As a consequence of recent immigrations and the admixture of different ethnic groups, the spectrum of mutations, particularly in western countries, has increased. In this context, more generic methods such as DNA sequencing, are more appropriate. In general, the mutation to be detected in the fetus is first identified in the parents. The results of DNA analysis are very accurate, but misdiagnosis may occur for several reasons (e.g., failure to amplify the target DNA fragment, mispaternity, maternal contamination, and sample exchange). However, the risk of misdiagnosis can be significantly reduced using a number of precautionary measures, such as the fetal DNA analysis for selected polymorphic markers.[844,847] The advent of DNA amplification has made it possible to define the genotype of a single cell biopsied from cleaving embryos (preimplantation diagnosis), and to analyze the polar body obtained during the maturation of the oocyte (preconception diagnosis).[848,849] These procedures avoid the need to terminate affected pregnancies through identification and transfer only of healthy embryos, established from in vitro fertilization. Successful experiences in many couples with this approach have been reported in hemoglobinopathies.[850–852] However, preimplantation genetic diagnosis (PGD) is a technically challenging, intensive procedure, which requires the close collaboration of a team of specialists. PGD is now an established reproductive alternative to prenatal diagnosis, offered in several specialized centers throughout the world (http://www.eshre.com).[832] PDG requires close collaboration between experts in assisted reproductive techniques and DNA-experienced laboratories. Hemoglobinopathies are the monogenic disease for which PGD has been used more frequently.[853] PGD performed in combination with HLA typing for selecting unaffected and histocompatible embryos to facilitate bone marrow transplantation raises relevant bioethical problems. The ultimate success (an unaffected baby suitable as a bone marrow donor), based on genetic combinations, success of implantation, and frequency of delivery rate, is very limited in practice, rarely surpassing about 10% for any cycle.[854–856] In the last decades there have been efforts in developing noninvasive methods for prenatal diagnosis, analyzing fetal cells or fetal free DNA present in maternal blood during pregnancy.[857,858] The rarity of fetal erythroblasts in the maternal circulation has limited the practicality of this approach, while the use of fetal DNA holds promise for the noninvasive prenatal diagnosis of various hemoglobinopathies.[859,860]

β-thalassemia prevention programs adapted to meet the need of different communities have been implemented in several at-risk countries across the world.[861] These programs are based on education, carrier screening, and genetic counseling associated, in most but not all countries, with prenatal diagnosis. As for the timing, carrier screening can be premarital, preconceptual, or antenatal, each one offering different options to the carrier couples at risk.[11,862–865]

Hemoglobinopathy screening programs are mostly offered on a voluntary basis, but in some countries, including Saudi Arabia and Palestinian territories laws in place make premarital screening mandatory.[865,866]

The incidence of thalassemia major has decreased significantly after the introduction of prevention programs in several areas, including Sardinia, Cyprus, Taiwan, Iran, India, and Guangdong (China) (Fig. 34.23).[271,863,867–870]

THALASSEMIA INTERMEDIA

Genetic Determinants

The remarkable clinical diversity of thalassemia intermedia may be produced by a great variety of genotypes. Thalassemia intermedia most commonly is associated with a homozygous or compound heterozygous state for two β-thalassemia alleles.[15,871–873] However, several patients with this mild clinical picture have only a single β-globin gene affected and are considered heterozygotes for β-thalassemia. It has been clearly established that the severity of the β-thalassemias is related to the degree of globin chain imbalance. Therefore, in homozygous β-thalassemia, any inherited or acquired factor able to reduce the degree of globin imbalance may produce milder clinical forms (Fig. 34.24). On the other hand, in simple β-thalassemia heterozygotes, the worsening of globin chain imbalance may turn the asymptomatic carrier state into a significant clinical phenotype (Table 34.5).

Homozygotes or compound heterozygotes for mild β-thalassemia mutations, characterized by a residual high β-globin chain production, usually have thalassemia intermedia. Examples are the homozygous state for –29 A→G in black patients and the IVS-1–6 T→C in Mediterranean

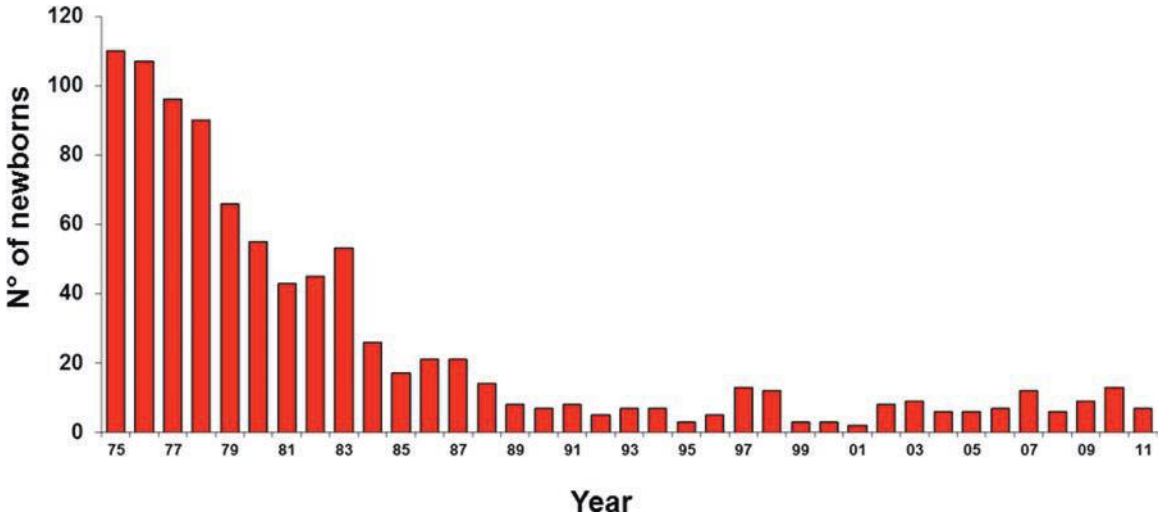

FIGURE 34.23. Fall in the birth rate of infants with homozygous β-thalassemia in Sardinia.

patients.[114,874,875] Compound heterozygotes for a mild and a severe mutation may cover a remarkably broad clinical spectrum of severity.[227,815] This variability can be related to the presence of α-thalassemia or of genetic determinants able to increase the γ-chain production.[227] Few homozygotes for silent mutations have been reported (e.g., β CAP + 1 ASC, IVS-2–844 C→G); they have the hematologic and clinical characteristics of β-thalassemia trait.[110,876] Compound heterozygotes for a silent and a severe mutation usually have a very mild thalassemia intermedia, but exceptions with a severe phenotype have been reported.[108,236,817,818,877–879] Coinheritance of α-thalassemia with homozygous β-thalassemia leads to a reduction in the excess of the α-chain pool and in the imbalance of the globin chain (Fig. 34.24A). Interacting α-thalassemia has been reported in patients with β-thalassemia intermedia from the Mediterranean and Southeast Asia.[880–883] However, the ameliorating effect depends both on the type of coinherited α-thalassemia (the presence of two α genes deleted being more effective) and on the severity of the β-thalassemia allele (α-thalassemia being less effective in ameliorating the homozygous β^0-thalassemia). Genetic determinants maintaining a high γ-chain synthesis after birth result in a reduction of the α/non-α-chain imbalance, thus producing a mild phenotype when coinherited with homozygous severe β-thalassemia. Moreover, a high γ-chain synthesis produces a net increase in total hemoglobin synthesis. Rarely, the increase of γ-chain output depends on the type of thalassemia mutations per se, as it occurs in δβ-thalassemias, caused by deletions of variable extent in the β-globin gene cluster, or in deletions removing the β-globin gene promoter. Most commonly the persistence of HbF production depends on the co-transmission of specific determinants associated with quantitative trait loci linked or unlinked to the β-globin cluster. The most common of these loci is –158 C→T Gγ promoter substitution, which is in linkage disequilibrium with several β^0-thalassemia mutations (cd 6 [-A], cd 8 [-AA], IVS-2–1 G→A).[871,884] This mutation leads to enhanced γ-chain production under conditions of erythropoietic stress and partially compensates for the absence of β-chain synthesis with consequent amelioration of the α/non-α imbalance and of the clinical phenotype. The –158 Gγ C→T substitution has been

found occasionally in patients with β^+ IVS-1–6 T→C and with the severe β^0 39 C→T mutation.[885] Genetic determinants capable of sustaining a continuous increased production of HbF in adult life and mapping outside the β-globin gene cluster have been identified on chromosome 2p16 (BCL11A gene) and on chromosome 6q23 (HBS1L-MYB intergenic region).[44,45,159] Several polymorphisms at these loci have been associated with increased HbF levels in patients with different hemoglobinopathies (e.g., β-thalassemia, sickle cell anemia, HbE/β-thalassemia) belonging to different populations (Sardinians, Chinese, Thais, African-Americans).[45,160,886] Coinheritance of these determinants and α-thalassemia contributes to the amelioration of the phenotype of homozygous β-thalassemia, resulting in a thalassemia intermedia phenotype.[163,164] However, in some patients with thalassemia intermedia homozygotes or compound heterozygotes for severe β-thalassemia mutations, even of the β^0 type, the inherited modifying factors able to ameliorate the clinical features are still unknown. Less commonly, the phenotype of thalassemia intermedia has been reported in subjects carrying only one β-globin gene defect. The worsening of the globin chain imbalance which converts the asymptomatic carrier state into a significant clinical phenotype depends on several mechanisms (Fig. 34.24B). Among them, five groups have been defined: (1) the dominantly inherited β-thalassemia mutations (also reported as hyperunstable globins or inclusion body thalassemias);[887,888] (2) compound heterozygosity for severe β-thalassemia with both deletion and nondeletion pancellular HPFH; (3) compound heterozygosity for β-thalassemia and some structural β-chain variants (HbD-Los Angeles β 121 GluSGln, HbC β 6 Glu→Lys, HbO-Arab β 121 Glu→Lys);[889] (4) coexistence of somatic deletions of a region of chromosome 11 p15;[169,170] and (5) coinheritance of triplicated α-globin gene with excessive α-globin production.[76,890,891] This is the most common group. Recently, cases have also been reported of simple β-thalassemia heterozygosity presenting with an intermediate to severe phenotype because of duplication of the complete α-globin gene cluster, including the upstream regulatory element HS-40, resulting in α-globin gene quadruplication.[892,893] However, it should be pointed out that several patients, heterozygotes for β-thalassemia with the typical thalassemia intermedia clinical picture, have been reported in whom extensive analysis of β- and α-globin gene cluster and family studies fail to identify any other associated molecular defect.[894,895] Recently, a new protein has been identified that binds to α-globin, preventing its precipitation.[187] This protein belongs to the group of molecular chaperones and is referred to as AHSP. Transgenic mice, lacking functional AHSP, showed red blood cell changes consistent with damage caused by excess α-chains. Unexplained cases of thalassemia intermedia in β-thalassemia heterozygotes might result from mutations in AHSP that would cause the α-chain excess to be more detrimental.[896] However, few and discordant results have been reported.[892,893]

Clinical Features

The clinical spectrum of thalassemia intermedia is heterogenous and variable in severity, ranging from mild anemia and jaundice to a thalassemia major–like clinical picture. It is usually diagnosed later compared to thalassemia major. Modell and Berdoukas reported that only 11% of patients with thalassemia intermedia presented in the first year of life, 30% in the second year, and 59% later in life.[310]

Conventionally, thalassemia intermedia is considered transfusion-independent if hemoglobin is spontaneously maintained at or above 7 to 7.5 g/dl.[897]

However, regular transfusions often become necessary with advancing age, while in other cases they are required only occasionally (infections, hypersplenism, and pregnancy).[898] It is not easy to predict which patients will become transfusion-dependent and when. Age at presentation seems to represent a good indicator of future transfusion independency. Cao et al., describing a group of 34 patients with thalassemia intermedia, observed that those who became transfusion-dependent were diagnosed at a mean age of 8.5 ± 1.8 months, while those who remained transfusion-independent were diagnosed at 17.4 ± 11.8 months.[899]

Patients with truly transfusion-independent forms may be completely asymptomatic until adulthood, experiencing anemia of various degrees and mild jaundice, while growth and development are not impaired. In severely affected patients, thalassemia intermedia generally presents between the ages of 2 and 6 years, and although many are able to survive without regular transfusions, growth and development can be delayed.

The spleen is palpable in the majority of the patients and its size increases with time. Hypersplenism may develop, causing a decrease in hemoglobin levels and sometimes thrombocytopenia and neutropenia.

Bone deformities are common and include frontal bossing, prominence of the zygomatic bones, depression of the base of the nose, shortening of long bones, cortical thinning, and dilatation of the medullary cavities, as described for thalassemia major.[897] The more severe skeletal abnormalities indicate excessive marrow activity secondary to anemia and are an indication to begin transfusions.

Osteoporosis is frequently found in thalassemia intermedia and along with cortical thinning is responsible for pathologic fractures of long bones and vertebrae. The pathophysiology of bone disease is complex and is due to bone marrow expansion, endocrine dysfunction, genetic factors, direct iron toxicity to osteoblasts, and increased osteoclast activity.[327] Vitamin D deficiency has an important role.[900] The development of osteoporosis in some patients has been associated with specific polymorphisms in candidate genes (vitamin D receptor, estrogen receptor, calcitonin receptor, and collagen type 1 α_1), but the hypothesis has not been confirmed.[321] Bone and joint pains are also frequently reported.

Extramedullary erythropoiesis is common in thalassemia intermedia and can produce all sorts of bizarre symptoms.[902,903] It is found in up to 65% of patients with thalassemia intermedia, compared to thalassemia major patients on regular transfusions, where the prevalence remains below 1%.[897]

Symptoms are usually reported during the third and fourth decades of life; however, there have been reports in children.[904,905]

Ectopic erythropoietic masses may be found in various body sites, including spleen, liver, lymph nodes, and kidneys, but also in paravertebral, intrathoracic, pelvic, and intracranial locations.[316,906]

Most cases remain asymptomatic and are usually diagnosed incidentally by radiologic techniques, while others lead to compression of adjacent structures as tumor-like masses.

Paraspinal involvement occurs in 11% to 15% of cases and may present with a variety of neurologic symptoms, including back pain, paraparesis, paraplegia, urinary urgency, and bowel incontinence.[906,907] (Fig. 34.26) Spinal cord compression causing paraparesis and cauda equina syndrome requires urgent treatment.

The intrathoracic location is often asymptomatic; however, it may present with pleural effusion or mediastinal syndrome.[908–910] (Fig. 34.25)

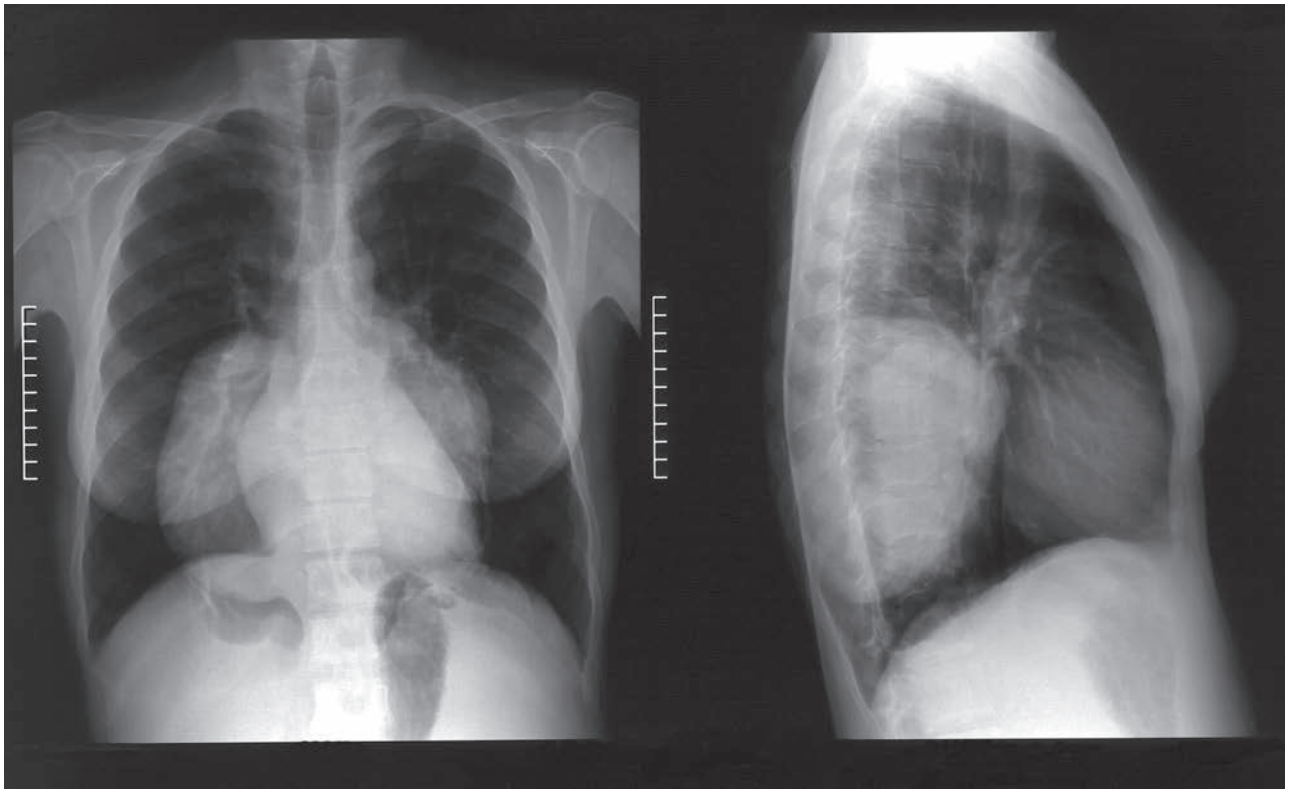
There is currently no consensus on the best treatment strategy for extramedullary erythropoiesis. Hydroxyurea and transfusions have proven to be effective,[908,911] but when rapid regression is required, surgical treatment and/or radiotherapy may be indicated.[912–914]

Magnetic resonance imaging (MRI) is considered the method of choice for the diagnosis and follow-up of extramedullary erythropoiesis, especially for paraspinal localizations.[907,908,915]

Transfusion Therapy

Thalassemia intermedia, is, by definition, transfusion-independent. However, at some time during the life of a patient the decision to initiate transfusion therapy may need to be made. In general, transfusion becomes necessary when the sense of well-being of the patient decreases to a level inadequate to the activities of a normal life. This usually occurs at levels of hemoglobin below 7 g/dl. In children, in addition to the level of hemoglobin, the main indicators are stunted growth, poor general condition, and skeletal deformities.

Also, it is important to consider the consequences of withholding transfusions in terms of medullary and extramedullary hyperplasia. Other circumstances that may require transfusion therapy include infections, hypersplenism, periods of rapid growth, and



A B

pregnancy. Parvovirus B19 infections can cause aplastic crises, characterized by peripheral reticulocytopenia and giant and bizarre pronormoblasts in the bone marrow and, sometimes, transient pancytopenia. Anemia is often severe enough to require blood transfusion.

In adult patients who have been transfusion-independent for decades, transfusions can become necessary because of reduced marrow activity and development of severe anemia. This phenomenon has been attributed by some authors to a decreased production of erythropoietin, but further research is necessary to confirm this hypothesis. When the decision to transfuse is made, the transfusion regimen should be similar to the one generally adopted for thalassemia major. A level of pretransfusional Hb around 9.5 to 10 mg/dl is usually sufficient to adequately suppress the bone marrow activity, promoting better growth and decreasing iron absorption from the gut. Several authors believe that patients with more severe forms of thalassemia intermedia, mimicking thalassemia major, should be transfused immediately following diagnosis.[898]

In the OPTIMAL CARE study, a large cooperative effort including heterogeneous patients from the Middle East, Iran, and Italy, and in several observational studies, transfused thalassemia intermedia patients experienced fewer complications related to chronic anemia, ineffective erythropoiesis, and hemolysis (extramedullary hematopoiesis, pulmonary hypertension, and thromboembolic events), while suffering higher rates of iron overload–related endocrinopathy.[900]

The introduction of transfusions earlier in life will probably increase iron accumulation overload, that can, however, be controlled by effective iron-chelating drugs.[916]

Another reason to start transfusion early is that the risks of alloimmunization and autoimmunization seem to be lower if transfusions are initiated early in life. In a report, 34% of 139 patients with thalassemia intermedia developed this complication,[917] and a Greek study reported a frequency of alloimmunization of 21% versus 47.5% in patients transfused before and after the age of 3 years.[223]

The consequences can be dramatic when the autoimmune hemolytic anemia develops during pregnancy, causing severe anemia incompatible with survival of the fetus.[545]

The pathogenesis of allo- and autoimmunization is unclear, and it has been attributed to "hidden" antigens from peripheral red blood cell fragmentation. Transfusion of blood phenotypically matched at least for the ABO, Rh, and Kell systems is necessary and can prevent alloimmunization in many cases.[918]

Therapy with immune suppressants, intravenous immunoglobulins, hydroxyurea, and even splenectomy can be attempted. Remission of the hemolytic process has been reported with allogeneic bone marrow transplantation.[919] Hypersplenism is an almost inevitable complication of thalassemia intermedia, often leading to transfusion dependency that is usually reversed by splenectomy. An exception is represented by the association of duplication of α genes plus heterozygous β-thalassemia, in which splenectomy can aggravate the hemolytic process.[920]

In any case, the risks of postsplenectomy infection and thrombosis should always be kept in mind.

Iron Overload

Iron overload in thalassemia intermedia can be caused by two mechanisms: increased intestinal absorption and, more rarely, transfusions. In non-transfused patients iron overload develops more slowly and accumulates in different sites. The role of hepcidin in this process is being unveiled. Hepcidin is a 25–amino acid peptide synthesized in the hepatocytes that controls the concentration of ferroportin on the intestinal epithelium. Low levels of hepcidin correlate with higher levels of ferroportin, resulting in increased intestinal iron absorption that for the most part is stored in the liver (Fig. 34.27). The lack of hepcidin results in hyperabsorption of dietary iron, but also in iron depletion of macrophages, lowering their secretion of ferritin and, consequently, serum ferritin levels. Therefore, reliance on serum ferritin alone may delay adequate treatment[195,428,429] (Fig. 34.10).

In thalassemia intermedia, the high erythropoietic drive induces hepcidin deficiency, in large part mediated by growth differentiation factor 15 (GDF15). GDF15, identified as a hepcidin suppressor factor, is expressed at high levels in patients with ineffective erythropoiesis.[430] Data suggesting that Janus kinase-2 (Jak2) may affect iron metabolism, regulating ferroportin degradation,[192] have not been confirmed.[458,921]

Iron Chelation

Studies performed by magnetic resonance have shown that, in thalassemia intermedia, iron tends to accumulate in the liver, while the heart is usually spared.

Iron assessment in thalassemia intermedia should include direct liver iron concentration by MRI or, if necessary, by biopsy.[922–924]

The decision to start iron chelation in patients with thalassemia intermedia depends on several factors: degree of iron overload, rate of iron accumulation, duration of exposure to excess iron, and various other factors, including compliance.[906] In a study, elevated liver iron concentration was associated with an increased rate of morbidity in patients with phenotypes of any severity. An increase in 1 mg Fe/g dry weight in liver iron concentration was independently and significantly associated with higher odds of thrombosis, pulmonary hypertension, hypothyroidism, osteoporosis, and hypogonadism.[925]

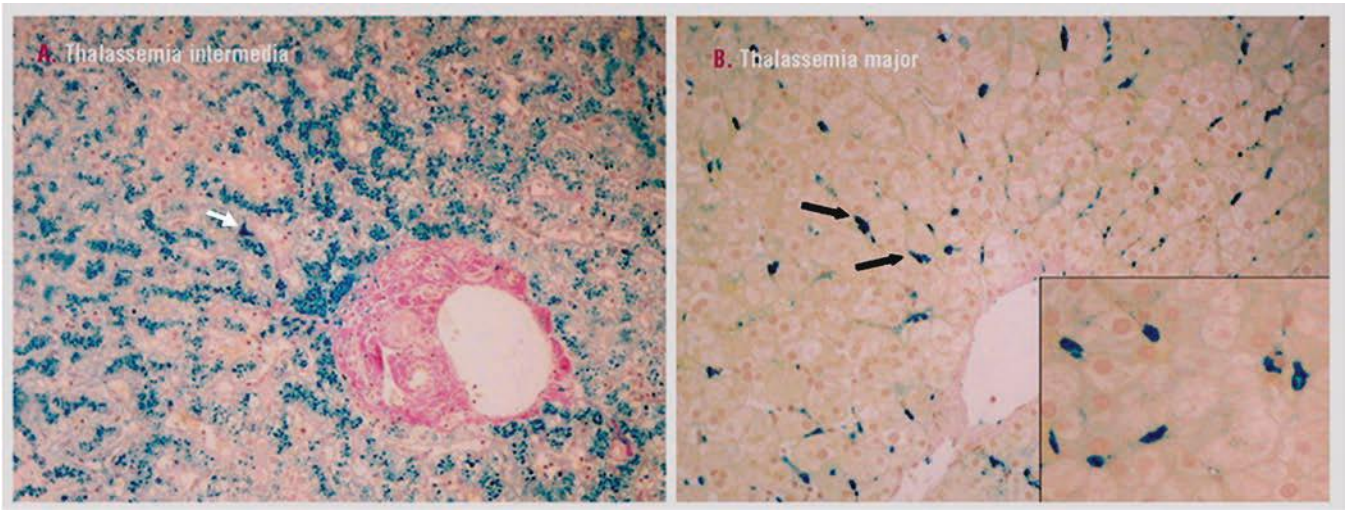

FIGURE 34.27. Iron distribution in the liver of thalassemia intermedia (A) and major (B) patients. **A:** Stored iron is found mainly at the biliary pole of hepatocytes. Only sporadic iron-loaded hypertrophic Küpffer cells are observed (*arrow*) (Perls' stain, original magnification is ×250). **B:** Stored iron is observed mainly in hypertrophic Küpffer cells (*arrows*) (Perls' stain, original magnification is ×250). At higher magnification (×400, insert), fine hemosiderin granules are also seen in the cytoplasm of hepatocytes. (Reprinted with permission of Origa R, Galanello R, Ganz T, et al. Liver iron concentrations and urinary hepcidin in β-thalassemia. Haematologica 2007;92:583–588.)

It is suggested that chelation therapy should be initiated if liver iron concentration exceeds 7 mg/g dry weight of liver tissue.[926] However, lower levels of liver iron concentration for initiation of chelation therapy may also be considered, especially if oral chelators are available.[906]

Three chelating agents are currently available: desferrioxamine (DFO), deferiprone (DFP), and deferasirox (DFX).

Deferoxamine has demonstrated significant benefits in terms of morbidity and mortality in iron-overloaded thalassemia major patients.[442,690] However, data on safety and efficacy in thalassemia intermedia are limited. In the past, in a small study of ten transfusion-independent patients treated with DFO for 6 months, a significant reduction of serum ferritin, accompanied by iron excretion, was seen.[927]

Data on the use of the first available oral iron chelator, DFP, in thalassemia intermedia are also limited. A small clinical trial using deferiprone in nine intermittently transfused thalassemia intermedia patients demonstrated significant reductions in mean serum ferritin, hepatic iron, red cell membrane iron, and serum nontransferrin-bound iron levels. Adverse events were mostly mild and included gastrointestinal symptoms and joint pain.[928]

Deferiprone is known to be more effective than desferrioxamine in removing cardiac iron,[444,610] and these two agents in combination are used for intensive chelation in the presence of severe iron overload.[480,526] However, data for thalassemia intermedia patients are not yet available and, considering that cardiac iron overload is virtually absent in thalassemia intermedia, intensive combination treatment may rarely be necessary.[924,929,930]

A recent, randomized, double-blind, placebo-controlled study of 1 year duration assessed the efficacy and safety of deferasirox in 166 thalassemia intermedia patients. Liver iron concentration and serum ferritin decreased and the frequency of adverse events compared favorably with placebo.[931]

In the rare patients with sufficiently high hemoglobin levels, phlebotomy could be used to decrease the iron overload accumulated with previous transfusions or through the gastrointestinal tract.[932] A few patients have been treated by bone marrow transplantation.[728,919]

Endocrine Complications

Endocrine complications are rare in patients with thalassemia intermedia, but hypogonadism, diabetes, and hypothyroidism have been reported.[925] Although patients generally experience delayed puberty, they have normal sexual development, and fertility is usually preserved. Hundreds of children have been born to women and men with thalassemia intermedia, mostly after spontaneous conception. However, pregnancy may be complicated by miscarriage, preterm delivery, intrauterine growth restriction, and thromboembolic events.[538,545,933] In some series, miscarriages seem to be more frequent than in the normal population, especially if severe anemia is present.[543]

Anemia becomes more severe during pregnancy, especially during the first and second trimester and, in order to prevent fetal growth restriction due to hypoxia, blood transfusion is often required.[906,916]

However, transfusions in previously untransfused women may induce alloimmunization, which contributes to worsening of anemia.[495,897] Alternative approaches, such as erythropoietin administration, have been suggested.[934]

Sometimes splenomegaly can interfere with uterus enlargement and splenectomy can become necessary.

The risk of thrombosis is high enough to warrant antithrombotic therapy before and after delivery.[356,933]

Folic acid deficiency, a risk factor for neural tube defects, is common in thalassemia intermedia. Therefore, oral folic acid supplementation is recommended during pregnancy. Caesarean section is often chosen as a method of delivery, especially when a fetopelvic disproportion, not rare in these women, is present.

Leg Ulcers

Trophic leg ulcers developing above the medial malleolus are a common and distressing finding in older patients with thalassemia intermedia (Fig. 34.28). The pathophysiology is still unclear, but it seems that the low hemoglobin levels associated with abnormal red cell rheology and increased hemoglobin F levels that cause reduced oxygen release determine tissue hypoxia. This promotes thinning of the skin and subcutaneous fragility, which in turn increase the risk of lesions both spontaneous and from minimal trauma.[935,936] Hemolysis-induced low arginine and nitric oxide bioavailability, associated with oxidative stress and hypercoagulability have been demonstrated in patients with thalassemia intermedia. These factors contribute to endothelial dysfunction and development of vasculopathy, which have been implicated in the pathogenesis of pulmonary hypertension, stroke, priapism, and also leg ulcers.[680,937,938]

FIGURE 34.28. Large malleolar ulcer in a patient with thalassemia intermedia. After numerous unsuccessful attempts the lesion was cured with compressive bandages.

Treatment is often unsatisfactory, as leg ulcers are difficult to heal and frequently recur. It may include simple measures, like pressure dressing[939] and elevation of legs and feet for a few hours during the day or at night, or, in more complicated cases, skin grafting.[935] Regular blood transfusion, associated with hydroxyurea, may be useful in persistent cases.[940] In one report, a transfusion-independent patient suffering from persistent leg ulcerations responded to 1-year therapy with exchange transfusions, which reduced the percentage of HbF from 70% to 35%.[941] Other reported treatments include topical G-CSF, as well as platelet growth factor, zinc supplementation, and local hyperbaric oxygen sessions.[942]

Thromboembolic Disease

Hypercoagulability and thromboembolic events have been reported in all thalassemia syndromes. However, they appear to be more common in thalassemia intermedia compared to a normal age- and sex-matched population and to thalassemia major patients.[200] In a report on 8,860 thalassemia patients from the Mediterranean countries and Iran, thromboembolism occurred in 4% of 2,190 patients with thalassemia intermedia compared to 0.9% of 6,670 patients with thalassemia major. In the thalassemia intermedia group, these events primarily occurred in the venous system and included deep vein thrombosis (40%), portal vein thrombosis (19%), stroke (9%), pulmonary embolism (12%), and others (20%).[354]

In an Italian multicenter study, the prevalence of thromboembolic events was found to be 9.6% in patients with thalassemia intermedia as compared to 4% in patients with thalassemia major.[943]

In a large cooperative study thrombosis was the fifth most common complication, affecting 14% of the patient population. On multivariate analysis, splenectomy, age above 35 years, and a serum ferritin level $\geq$ 1,000 μg/l were associated with a higher risk for thrombosis. Conversely, a positive history of transfusion and a hemoglobin level $\geq$ 9 g/dl were found to be protective against thrombosis.[900]

Thrombosis of the portal vein after splenectomy has been reported.[944]

In addition, a magnetic resonance imaging study described the presence of silent white matter lesions in the brains of as many as 60% of splenectomized adults. The occurrence and multiplicity of the lesions were associated with older age and transfusion naivety (83% of lesion-positive patients had never had a transfusion vs. 25% of lesion negative patients).[945]

The pathogenesis of the chronic hypercoagulable state is complex. Circulating damaged red cells and erythroid precursors and red cell remnants expose negatively charged phosphatidyl-serine through the "flip-flop" phenomenon and subsequently activate thrombosis. Splenectomy favors the persistence of these damaged red cells in the circulation, especially in non-transfused patients.[946] Endothelial cells are also activated and damaged by the oxidative stress due to hemolysis and iron overload, leading to increased expression of adhesion molecules and impaired nitric oxide production. Furthermore, increased platelet numbers and aggregation are common in thalassemia.[200] Higher plasma levels of markers of coagulation and of fibrinolysis activation are present in splenectomized thalassemia intermedia patients compared to thalassemia major and to healthy individuals.[356] Also, splenectomy, as well as liver dysfunction, cause deficiency of natural anticoagulants, such as protein C and protein S and increased levels of thrombin-ATIII complex.[198]

It has been suggested, on the basis of data from a large multicenter study, that splenectomized patients who will develop thromboembolic events may be identified early on by the high number of circulating nucleated red blood cells and platelet counts, evidence of pulmonary hypertension, and transfusion naivety.[947]

In a subanalysis of a large cooperative study, platelet counts over 500×10^9/l were an independent and significant predictor of thrombosis in splenectomized thalassemia intermedia patients.[916] Therefore, platelet antiaggregants should be given early in the disease, particularly in splenectomized patients. High counts of nucleated red blood cells and evidence of pulmonary hypertension were also predictive of development of thromboembolic events in splenectomized thalassemia intermedia patients.[947]

Finally, a model for assessing the risk of thrombosis in thalassemia has been proposed to estimate the thrombotic risk as a function of intrinsic (thalassemia type and number of circulating red blood cells) and extrinsic (infection, surgery, and splenectomy) factors.[197]

Recommended treatment options include platelet anti-aggregants, such as aspirin, in patients with thrombocytosis or anticoagulant agents, such as low molecular weight heparin, in patients undergoing surgery, and in the peripartum period. Heparin therapy, followed by long-term oral anticoagulants or antiplatelet agents is indicated after thromboembolic events. Although reasonable and widely applied, these recommendations are not supported by compelling evidence from the literature.[897,906]

Liver Disease

Hepatocellular carcinoma has been reported in adult patients with thalassemia intermedia as a consequence of iron overload and chronic viral infection.[948]

Gallstones are more common in thalassemia intermedia than in thalassemia major because of greater ineffective erythropoiesis and peripheral hemolysis, in the absence of regular transfusions. Coinheritance of the Gilbert's syndrome (mutation of the A[TA]nTAA motif of the promoter of the bilirubin in UDP-glucuronosyltransferase gene) increases the indirect bilirubin level and the risk of gallstones in thalassemia syndromes.[373] The effect is even more evident in thalassemia intermedia patients, in whom the prevalence of gallstones seems to be related to allele dosage: 27% in patients with normal (TA)6/(TA)6 genotype, 68% in heterozygous patients for the mutated (TA)7, and 80% in homozygotes (TA)7/(TA)7.[229]

Pronounced jaundice is a frequent consequence of hemolysis, especially in patients with coexistent Gilbert's syndrome, and is often found disturbing for esthetical reasons.

Cardiac Disease

While heart disease, as a consequence of iron overload, is the first cause of death in thalassemia major, patients with thalassemia

intermedia are usually not affected by severe hemosiderosis and are therefore less prone to cardiac problems. MRI data have demonstrated that in patients with thalassemia intermedia cardiac iron overload is virtually absent.[924,929,930] Nevertheless, a large multicenter study of 110 Greek patients found that 5.4% had congestive heart failure, 8% acute pericarditis, 34% chronic pericardial changes, and more than half had some kind of valvular defect.[373]

Chronically high cardiac output in non-transfused patients has an important role in left ventricular remodeling, which has been demonstrated to be more pronounced than in regularly transfused thalassemia major patients.[949] Regular transfusions seem to be protective toward the development of heart failure.[900] However, pulmonary hypertension is known to be the leading cause of cardiac failure in thalassemia intermedia.

Pulmonary Hypertension

Pulmonary hypertension is defined as systolic pulmonary artery pressure >25 mmHg at rest and >30 mmHg during exercise with a normal pulmonary artery wedge pressure <15 mmHg and an increased pulmonary vascular resistance greater than three Wood units. It is now considered the leading cause of cardiac failure in thalassemia intermedia.

In the previously mentioned Greek study, pulmonary hypertension was found in 59% of cases and all the patients with congestive heart failure had severe pulmonary hypertension with normal systolic left ventricular function.[373] Risk factors for pulmonary hypertension have been identified as being splenectomized, having high nucleated red blood cell counts, not being transfused, and not being treated with hydroxyurea or iron chelation. In addition, a risk factor is a previous history of thromboembolism.[950]

The mechanisms underlying pulmonary hypertension in thalassemia intermedia are unclear. There is evidence that chronic hemolysis, through the induction of nitric oxide and arginine depletion, may lead to vasoconstriction, vessel wall hypertrophy, hypercoagulability, local thrombosis, and increase of thromboxane and endothelin, resulting in chronic organ damage and endothelial dysfunction.[951]

Platelet activation has been shown to be significantly higher in thalassemia intermedia compared to thalassemia major.[952] Complex interactions between platelets, coagulation factors, erythrocytes, and endothelial cells with inflammatory and vascular mediators may also contribute to the endothelial dysfunction and subsequent pulmonary vascular remodeling.[952,953]

For all the above mentioned reasons, screening for pulmonary hypertension is an essential part of the diagnostic follow-up in patients with thalassemia intermedia.

Regular transfusions associated with adequate iron chelation reduce tissue hypoxia, ineffective erythropoiesis, and circulation of damaged erythrocytes, therefore preventing hemolysis and hypercoagulability, which contribute to the development of pulmonary hypertension.[637]

However, the preventive role of transfusion is still controversial. Pulmonary hypertension has been described also among transfused thalassemia major patients, mostly after splenectomy, implying that in some cases regular transfusions do not prevent the disease.

Many authors recommend regular transfusions and iron chelation in thalassemia intermedia patients when early signs of pulmonary hypertension appear.[373,906,954]

Hydroxyurea prevents hemolysis and hypercoagulability by increasing hemoglobin F synthesis and reducing thrombocytosis. A retrospective study found no pulmonary hypertension in 50 thalassemia intermedia patients treated with hydroxyurea for 7 years.[900,955]

Specific treatments for pulmonary hypertension are being studied. New agents, like prostacyclin analogs (epoprostenol, iloprost, oral beraprost), endothelin receptor antagonists (bosentan, sitaxsentan), and phosphodiesterase 5 inhibitors (sildenafil) have been successfully used to treat pulmonary hypertension. Some of these have been used in patients with hemoglobinopathies.

Bosentan is often used with good results, but it sometimes needs to be discontinued because of hepatotoxicity or inadequate efficacy.

Sildenafil citrate was first successfully used in a 34-year-old transfusion-dependent man with thalassemia intermedia[956] and, more recently, in four patients who during therapy experienced reduction of pulmonary pressure, improvement of cardiovascular function, and better exercise tolerance.[957]

Unfortunately, there are no randomized, controlled trials demonstrating the long-term safety and efficacy of these new treatments in patients with hemoglobinopathies. Two randomized trials in sickle cell disease, one using sildenafil and the other bosentan, were discontinued because of the increase of painful crises in one and lack of beneficial effects in both.[958,959]

Further studies including larger groups of patients are necessary to establish the long-term safety and efficacy of these new agents in patients with thalassemia intermedia.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is an autosomal recessive, multisystem disorder affecting elastic tissues, because of a mutation on chromosome 16p13.1. The gene encodes the membrane transport protein ABCC6 and more than 300 mutations have been described. Clinically it is characterized by typical lesions of the skin (small yellowish papules or larger coalescent plaques), eyes (breaks of the elastic lamina of Brush membrane named angioid streaks), and arteries (degeneration of the elastic lamina of the arterial wall often accompanied by arterial calcification). Acquired PXE-like syndromes have been described in several hemolytic disorders.

Typical skin lesions, angioid streaks in the retina, calcified arterial walls, and aortic valve disease resembling PXE have been reported in patients affected by thalassemia.[367,367]

It appears to be age-dependent and it is more common in thalassemia intermedia than in thalassemia major. In a study published in 1998 and including patients affected by thalassemia intermedia older than 30 years, arterial calcifications were found in 55%, skin lesions in 20%, and ocular alterations in 52%. Eighty-five percent had at least one of the three typical lesions.[368]

The presence of PXE is usually suspected because of the characteristic skin lesions.

The typical histopathologic features of PXE both in the inherited and the acquired form are the abnormal, mineralized, and fragmented elastic fibers (elastorrhexia) in skin, eyes, and arterial blood vessels; however, the genetic mutations of the inherited form are not present in patients with PXE and thalassemia.[369]

The pathophysiology remains unclear and it is attributed to iron-induced oxidative tissue damage, caused by hemolysis and iron overload.

Thrombotic events and gastrointestinal and intracranial bleeding, which preclude the use of platelet antiaggregants, can complicate the clinical course.[376]

Although no effective therapy is available, phosphate binders, a group of drugs given in the attempt to limit the intestinal absorption of phosphate and consequently normalizing the serum calcium phosphate product, could offer a means of reducing the calcium/phosphate load in patients with PXE. Histopathologic regression of skin calcifications was demonstrated in 3 out of six patients treated with aluminum hydroxide for 1 year and in all six no progression of the ocular angioid streaks was observed.[377]

In a knock-out mouse model of PXE, obtained by silencing the Abcc6 gene, a magnesium carbonate–enriched diet completely prevented mineralization of the vibrissae, an early biomarker of the mineralization process. These results suggest that phosphate binders may offer a potential treatment modality for this so far intractable disease.[378]

Other Complications

Folic acid deficiency can be present[960,961] because of increased folate utilization by the hyperactive bone marrow. Daily supplementation with 1 mg of folic acid is advised for patients with thalassemia intermedia.[962]

β-THALASSEMIA IN ASSOCIATION WITH β-CHAIN STRUCTURAL VARIANTS

Hemoglobin S Thalassemia Syndromes

The term sickle cell disease refers, not only to homozygous HbSS, but also to all genotypes in which HbS interacts with other globin gene mutations, including β°-thalassemia, β^{+}-thalassemia, $\delta\beta$-thalassemia, HPFH, and HbLepore. The clinical course of these phenotypes is extremely variable; however, the thalassemia gene is expressed with some degree of microcytosis, hypochromia, and variation in the relative proportions of HbA2 and HbF. Sickling symptoms, if present, are often milder than those noted in patients with homozygous sickle cell anemia.

Hemoglobin S–β-Thalassemia

The double heterozygous state for HbS and β-thalassemia is the most common variant of sickle cell disease in individuals of Mediterranean ancestry and the second most common sickling disorder. In the U.S. it is estimated to affect about 1 in 1667 Americans at birth.[963] HbS/β^{0}-thalassemia occurs approximately once in every 23,000 Afro-Americans[964] and in Jamaica has a frequency of one in 6,750.[965]

HbS/β-thalassemia is clinically more similar to sickle cell disease than to thalassemia major or intermedia. The severity depends on the type of β-thalassemia mutation. Patients who inherit a β° gene are clinically indistinguishable from those with homozygous sickle cell anemia and have very low levels of HbA, while patients with β^{+} genes present milder phenotypes and may even be asymptomatic because of the higher levels of HbA.[966,967]

Hematologically HbS/β-thalassemia presents with higher red blood cell counts and HbA2 levels and lower MCV and MCH values (mean 68 fl and 20 pg, respectively) compared to HbSS.[968]

The risk of stroke in patients with HbS/β°-thalassemia is considered high and therefore transcranial Doppler screening is recommended, as in homozygous HbSS.[969]

Complications of both diseases are frequently seen, including delayed growth and puberty, vaso-occlusive events, and acute chest syndrome.

Splenomegaly is more common in patients with HbS/β-thalassemia, compared to HbSS, and the spleen tends to remain enlarged and functional in adulthood. As a consequence, several cases of fatal splenic sequestration have been reported in patients with HbS-β^{+}-thalassemia.[970–972]

Avascular necrosis of the femoral head is more frequent and appears earlier in sickling disorders with higher hematocrits, like HbS/β^{+}-thalassemia.[973]

Proliferative sickle retinopathy also seems to be more common and severe in sickle-thalassemia than in homozygous HbSS.[974,975]

While antibiotic prophylaxis is highly recommended in HbSS and HbS/β°-thalassemia, in patients with HbS/β^{+}-thalassemia its use is controversial, because their splenic function is not usually impaired and they are not considered at high risk of having pneumococcal septicemia.[976]

Various phenotypes of sickle cell disease may have a milder course when associated with a concomitant α-thalassemia trait as a result of a decrease in the MCHC, which lowers HbS polymer formation.[977]

Other genetic modifiers can influence the phenotype, as hypothesized on the basis of the discordance of symptoms in affected members of a single family.[978]

In particular, the relative amount of HbF plays an important role in disease severity.[979]

Precise diagnosis is important to predict the clinical course and prognosis, and to perform correct genetic counseling.

In HbS/β-thalassemia, HbS is the most abundant hemoglobin, HbA2 is increased, and HbF may be normal or variably increased. HbA accounts for less than 30% of the total amount of hemoglobin in patients with β^{+} gene mutations, while it is virtually absent in HbS-β°-thalassemia.[968,980]

The electrophoretic picture of HbS/β^{+}-thalassemia and sickle cell trait may be similar, but usually the relative proportions of HbS and HbA allow a correct diagnosis. On the other hand, HbS-β°-thalassemia and homozygous sickle cell anemia may be indistinguishable.

Although consistently elevated by 1 year of age, HbA2 may be difficult to measure accurately with electrophoresis because of its proximity to the HbS band, and with HPLC because of co-elution of minor components with HbA2 (secondary to post-translational modifications of HbS).[824,981]

Hemoglobin S–δβ-Thalassemia

δβ-thalassemia is a condition characterized by high levels of HbF. The coinheritance with sickle cell disease has been described in African-Americans, Indians, and individuals of Mediterranean origin.[982–985]

Patients are usually asymptomatic and may show signs only of mild anemia or hematologic alterations, which include microcytosis, presence of target cells, and rare sickled cells. The electrophoretic pattern is characterized by the prevalence of HbS and elevated HbF (15% to 40%), associated with the absence of HbA and decreased HbA2. Some patients however may present with a severe clinical course, because of heterogenous distribution of HbF among peripheral red blood.[985]

Hemoglobin S-Hereditary Persistence of Fetal Hemoglobin

Compound heterozygosity for HbS and HPFH is characterized by a relatively benign clinical picture. A recent study demonstrated that, in patients with HbS-HPFH, HbF levels are 50% to 90% during infancy and tend to decline steeply within the first few years of life, stabilizing at approximately 30% between ages 3 and 5 years. Furthermore, hematologic parameters are nearly normal, with average hemoglobin concentration being 13 ± 1 g/dl and average MCV 75 ± 4 fl.[986]

In adults the electrophoretic pattern is similar to that of homozygous sickle cell anemia: HbS 70% to 80% of the total hemoglobin, Hb F 20% to 30%, decreased HbA2, and absent HbA.

In HbS-HPFH patients, all red blood cells contain uniformly distributed HbF in sufficient concentration to dilute HbS and inhibit its polymerization despite the high percentage of HbS.

A correct diagnosis is necessary in order to allow appropriate counseling and alleviate anxiety associated with the diagnosis of sickle cell disease. Therefore, in sickle cell patients with elevated HbF levels after the age of 1 year, molecular testing should be performed.

Hemoglobin S Hemoglobin Lepore

The double heterozygosity for sickle hemoglobin with Lepore hemoglobin is a relatively rare condition. The Hb Lepore gene alone or in combination with the HbS gene manifests as microcythemia; therefore the Hb S/Hb Lepore is similar to microdrepanocytosis. This syndrome is usually characterized by a disorder of

moderate severity, with chronic hemolytic anemia, splenomegaly, and few painful crises.[987–990]

The electrophoretic mobility of HbLepore at an alkaline pH is identical to that of HbS; therefore the condition can be confused with sickle cell anemia. At an acid pH, however, Hb Lepore migrates with HbA. HbS accounts for 60% to 80% of the hemoglobin, Hb Lepore for approximately 10%, and HbF for 9% to 25%. HbA2 is decreased and HbA is absent.

Hemoglobin C Thalassemia

The association of HbC with β-thalassemia, especially with β^+-thalassemia in Africans (more common than β°-thalassemia in this ethnic group) results in a clinical picture similar to homozygous HbCC, with mild hemolytic anemia, splenomegaly, and a benign clinical course.[991] However, unlike the homozygous state, Hb C/β-thalassemia is a microcythemic condition. The diagnosis is based on the presence of target cells, specific intraerythrocytic Hb C crystals in blood smear and Hb C level at 100%.

In Italian, North African, and Turkish individuals HbC may be coinherited with β°-thalassemia, resulting in a more severe clinical course, similar to thalassemia intermedia.[992]

Hb C-Hb Lepore has been described in an African-American and in an Algerian family.[993,994]

Hemoglobin E Syndromes

HbE is the most common abnormal hemoglobin of Southeast Asia, but it has recently been reported from other Asian regions, like Pakistan[995] and India.[996]

In southern China thousands of patients are affected.[1] It is estimated that 30 million people are heterozygous for HbE and that one million are homozygous.[997]

As a consequence of migratory fluxes, the epidemiology of thalassemia has changed in most industrialized countries. In North America hemoglobin E-β-thalassemia affects 13% of patients with a hemoglobinopathy and it is more common in the Western states.[998]

HbE is a thalassemic hemoglobinopathy because the nucleotide substitution G→A at codon 26 of the β gene changes the encoded aminoacid (Lys→Glu) and creates a new alternative splice site in exon 1.[117] This results in the synthesis of structurally abnormal variant hemoglobin HbE by the normally spliced β-mRNA and in a β^+-thalassemia phenotype because of the use of the new splice site. Its molecular and clinical features have been reviewed.[999,1000] When HbE is present, alone or in different combinations with α- and β-thalassemia or with other abnormal hemoglobins, many different HbE syndromes are observed, which can be divided into asymptomatic and symptomatic forms.

Asymptomatic Forms

HbE heterozygotes are clinically normal with only minimal hematologic changes. Red blood cells are normocytic or slightly microcytic with minor morphologic changes, such as target cell morphology. HbE constitutes 25% to 30% of the total hemoglobin and this amount is reduced by the coexistence of α-thalassemia.[839]

Patients homozygous for HbE are usually asymptomatic and have normal hemoglobin levels, although in some cases mild anemia may be present. They show microcytosis and 20% to 80% of target red cells at peripheral blood smear examination. Hemoglobin analysis reveals 85% to 95% of HbE with the remainder being HbF. The α/non-α–globin chain synthesis ratio is around 2.0.[1001]

Symptomatic Forms

The clinical spectrum of the disease is very heterogeneous, ranging from a mild phenotype to a severe transfusion-dependent anemia.[1002–1004] This heterogeneity depends only in part on the different interacting β-thalassemia alleles.[1005] HbE-β°-thalassemia is characterized by HbE and F, only while in Hb-β^+-thalassemia, some HbA is detected in addition to HbE and HbF. HbE in association with β-thalassemia is considered to represent one-half of all the severe thalassemia syndromes worldwide.

A large study has been going on since 1997 in Sri Lanka, attempting to define the genetic and environmental factors that modify the severity of HbE thalassemia.[1006] Considerable phenotypic heterogeneity occurred within a relatively narrow range of hemoglobin values. Major genetic factors included the type of β-thalassemia mutation, the coinheritance of α-thalassemia, and polymorphisms associated with increased synthesis of fetal hemoglobin. The presence of the *Xmn*-1 polymorphism in the promoter region of the Gγ gene explained the variation of Hb F production. Among the environmental factors, coinfection with the malaria parasite, previous splenectomy, a variable increase in response to erythropoietin, and attenuation of this response with time appear to be important. The remarkable variation and instability of clinical phenotypes requires periodic reassessment of the need for transfusion therapy.[1004,1006]

As a consequence of the interaction of HbE with HbH disease and Hb Constant Spring, three symptomatic syndromes have been identified:[1007,1008]

(a) HbAE Bart's disease, resulting from the interaction of HbH disease with heterozygous HbE;
(b) HbEF Bart's disease, which is due to the interaction of HbH disease with homozygous HbE or HbE-β-thalassemia;
(c) homozygous HbE with homozygous Hb Constant Spring syndrome.

The anemia in these forms is moderate to severe and the various genotypes can be suspected on the basis of the hemoglobin pattern and/or family studies, but DNA analysis is required for the definition of the exact genotype. Phenotypes similar to thalassemia major can be predicted from the early onset of clinical symptoms and the requirement of regular blood transfusion from infancy.

Clinical Picture

Most HbE β-thalassemia patients are not transfused or are transfused very little, and iron chelation is rarely administered. Erythropoiesis is markedly increased, and extramedullary masses are common.[911] As is the case in other forms of sporadically transfused thalassemias, allo- and autoimmune hemolytic anemia develops frequently.[1009]

Infections, mostly due to gram-negative bacteria, are a major complication and cause of death in patients with Hb E β-thalassemia, especially after splenectomy.[1004] Prospective studies indicate increased susceptibility to bacterial, fungal, and viral infections.[1010,1011] *Pythium insidiosum* (a type of water mold which is now classified within the kingdom Chromista together with algae) has been reported to have caused arterial occlusion and gangrene of the legs.[406] Gallstones are present in 50% of the patients and are strongly associated with the 7/7 genotype of the *UGTA1A* promoter.[1004,1012] The clinical syndrome of hypertension, convulsions, and cerebral hemorrhage occurring immediately or as late as 2 weeks after multiple blood transfusions in Hb E β-thalassemia is a possible complication.[1013] Monitoring blood pressure during and after blood transfusion is, therefore, necessary, as prompt therapy with anti-hypertensive drugs will reduce mortality from cerebral hemorrhage. In a group of nontransfusion-dependent β-thalassemia/HbE patients, nontransferrin–bound iron (labile plasma iron and directly chelatable iron) was found to be increased and to respond to treatment with deferiprone.[1014] An increased risk of thrombosis reported in these patients, especially after splenectomy, can be explained by chronic low-grade coagulation and platelet activation, chronic low-grade

inflammation, endothelial cell injury, impaired fibrinolysis, and decreased naturally occurring anticoagulants.[1015] Hypoxemia is observed in the majority of splenectomized patients.[1016] The underlying mechanism is unknown, but it has been attributed to increased aggregation of platelets in the pulmonary vessels, based on the autoptic finding of pulmonary arterial occlusion in a large number of such patients.[1017] Accordingly, the administration of aspirin can ameliorate the degree of hypoxemia in the majority of cases. Stem cell transplantation, be it bone marrow or cord blood, has proven effective.[1018,1019] Some, but not all, β-thalassemia/HbE patients respond to hydroxyurea treatment.[1020] In an Indian trial, patients who responded showed an increase in hemoglobin, mean corpuscular volume, mean cell hemoglobin content, fetal hemoglobin, and F cells.[1021] In a study, membrane deformability and cell hydration, whose improvement is important for extending the life span of erythrocytes, did not change significantly, except in splenectomized patients.[1022]

Pregnancy in women affected by β-thal/HbE disease is possible, but the cases reported were significantly associated with an increased risk of fetal growth restriction, preterm birth, and low birth weight.[1023]

Survival of patients with β-thalassemia/HbE in Thailand has been reported to be 30 years, significantly longer than the 10 years reported for homozygous β-thalassemia.[1024]

CHAPTER 35

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY, UNSTABLE HEMOGLOBINS, M-HEMOGLOBINS, AND DYSHEMOGLOBINEMIAS

Martin H. Steinberg

More than 1,100 mutations affecting the globin subunits of hemoglobin have been described (http://globin.cse.psu.edu/), and among these, sickle cell disease along with hemoglobinopathies associated with HbE, HbC, and the β- and α-thalassemias are mankind's most common single-gene disorders (see Chapters 33 and 34). Much less common are hemoglobin mutations discussed in this chapter that affect the ability of the molecule to bind and release oxygen, that reduce its stability, and that allow its heme iron to be oxidized. Exogenous agents can also oxidize hemoglobin, interfering with oxygen transport.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

The affinity of hemoglobin for oxygen is characterized by the amount of oxygen bound at any given oxygen tension. Oxygen affinity is usually designated by the P_{50}, which is the partial pressure of oxygen at which hemoglobin is 50% saturated. Oxygen affinity can be modified by pH, temperature, and organic phosphates. The normal co-operativity of hemoglobin, or heme–heme interactions in the hemoglobin tetramer, determines the sigmoidal shape of the hemoglobin–oxygen dissociation curve. This is a result of the fact that the deoxygenated T (tense) form of hemoglobin has a lower affinity for oxygen than the oxygenated R (relaxed) form (see Chapter 6). Consequently, globin gene mutations that alter areas of the molecule involved with T–R interactions can lead to alterations in oxygen affinity. Both high- and low-oxygen–affinity hemoglobin variants are encountered and all globin genes have been affected.

High-oxygen–Affinity Hemoglobins

Globin gene mutations can increase the affinity of the hemoglobin molecule for oxygen and cause erythrocytosis. More than 90 high-oxygen–affinity variants have been reported in http://globin.cse.psu.edu/ and Wajcman and Galacteros.[1] Familial erythrocytosis is a valuable clue to the presence of a high-oxygen–affinity hemoglobin variant; isolated cases are caused by new mutations. These α- or β-globin chain mutations are dominant disorders, expressed clinically in the heterozygote. They may be lethal in homozygotes if they affect the α-globin chain and are expressed in utero. One γ-globin variant (HbF-Monserrato-Sassari, *HBG2* cys93arg) in a normal newborn and a possible δ-globin variant (Hb Noah Mehmet Oesteurk, *HBD* his143tyr) have been described. Several homozygotes for β-globin high-oxygen–affinity variants have been described and these individuals can have more severe disease.[2–5] Compound heterozygotes with a high-oxygen–affinity hemoglobin and β^0-thalassemia have also been described, mimicking the homozygous state as normal adult hemoglobin A (HbA) is not present.

Pathophysiology

Stabilization of the R state of the hemoglobin tetramer ($\alpha_2\beta_2$), with its high affinity for oxygen, or destabilization of the low-oxygen–affinity T state is caused by globin gene mutations in critical areas that can effect the R→T transition (Table 35.1).[6] The increased avidity for oxygen (low P_{50}) of these variants reduces oxygen delivery to tissues, thereby stimulating erythropoietin production and increasing red cell mass. Patients with high-oxygen–affinity hemoglobins with erythrocytosis usually have normal urine erythropoietin levels. However, erythropoietin levels increase when they are phlebotomized to a normal red cell mass.[7,8] Individuals with these hemoglobin variants appear to be reasonably compensated for the low P_{50} by the increased red cell mass. Oxygen consumption and arterial pO_2 are normal, but in some cases there is reduced mixed venous pO_2 and decreased resting cardiac output.

Not unexpectedly, the *JAK2* V617F mutation found in some individuals with polycythemia vera is absent in patients with high-oxygen–affinity hemoglobin variant induced erythropoiesis.[9]

Diagnosis

The differential diagnosis of increased red cell mass is discussed in Chapter 44. The diagnosis of high-oxygen–affinity hemoglobins is suspected by finding isolated erythrocytosis without accompanying leukocytosis, thrombocytosis, and splenomegaly, as might be expected in cases of polycythemia vera. A family history of erythrocytosis is also suggestive of a high-oxygen–affinity hemoglobin variant. Other disorders expressed in the erythrocyte that cause isolated erythrocytosis include 2,3-diphosphoglycerate (2,3-DPG) mutase mutations that reduce the synthesis of this modulator of hemoglobin–oxygen affinity, some instances of methemoglobinemia, and chronic carbon monoxide (CO) poisoning.

Determination of the red cell oxygen equilibrium curve is the benchmark for the diagnosis of erythrocytosis due to high-oxygen–affinity hemoglobins. The oxygen-binding characteristics of hybrid tetramers ($\alpha_2\beta^A\beta^{var}$) are likely to be intermediate between purified HbA and purified variant, and the shape of the hemoglobin–oxygen dissociation curve can at times be biphasic. Measurement of blood P_{50} confirms the shift in the hemoglobin–oxygen dissociation curve. Rarely, the whole-blood P_{50} is normal, requiring study of dialyzed purified hemoglobin. An accurate P_{50} value is difficult to "calculate" from pO_2 data, and it is best to measure the pO_2 and hemoglobin saturation directly. P_{50} measurements are not widely available but can be done with several instruments.

High oxygen affinity is observed in both erythrocytes and purified dialyzed hemoglobin. The concentration of 2,3-DPG is normal, indicating that altered oxygen affinity is not caused by reduced levels of this modulator of hemoglobin function. This is in contrast to what is seen in the rare instance of red cell 2,3-DPG mutase deficiency, where both erythrocytes and whole blood have high oxygen affinity, and the oxygen affinity of the purified hemolysate stripped of 2,3-DPG is normal.[10]

High-performance liquid chromatography (HPLC) studies may reveal an abnormal hemoglobin, but normal studies do not exclude the possibility of a high-affinity hemoglobin that migrates with normal HbA. As with all evaluations for abnormal hemoglobins, determining the DNA sequence of the globin genes provides the definitive information.

Examples of high-oxygen–affinity hemoglobins that illustrate the varying mechanisms and heterogeneous clinical findings seen with these variants are discussed in the following. A detailed

TABLE 35.1

SITES OF GLOBIN MUTATION ASSOCIATED WITH INCREASED OXYGEN AFFINITY[a]

$\alpha_1\beta_2$ interface contacts (sliding contact) connecting $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers
$\alpha_1\beta_1$, $\alpha_2\beta_2$ interface
Mutations that reduce 2,3-diphosphoglycerate (2,3-DPG) binding
Heme pocket mutations
Miscellaneous

[a]Other than single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains.

understanding of the structure of hemoglobin and the importance of each residue in determining function allows a molecular explanation of most of the clinical abnormalities observed.

α-Globin Chain Variants

Because there are four α-globin genes, most stable α-globin variants form 25% or less of the total hemoglobin, compared with 40% to 50% for β-globin variants. As a result, the clinical effects of α-globin variants are less striking than those of β-globin variants. However, the coincident inheritance of a β-thalassemia gene can modulate the concentration of high-affinity α-variant hemoglobins and homozygosity for a high-oxygen–affinity variant affecting α-globin chains has been described.

Hb Chesapeake (*HBA* arg92leu) was the first reported high-affinity hemoglobin variant.[11] It was discovered in an 81-year-old patient with erythrocytosis, an abnormal hemoglobin detected by hemoglobin electrophoresis, and erythrocytes with increased oxygen affinity. Fifteen members of the proband's family were similarly affected. Hb Chesapeake represented ~20% of the total hemoglobin. With a P_{50} of 19 mm Hg (normal ~26 mm Hg), Hb Chesapeake produced moderate erythrocytosis. The mutation affected an invariant residue that stabilizes the R state at the $\alpha_1\beta_2$ area of contact, making the T conformer less favored.

Hb Nunobiki (*HBA1* arg141cys), is one of four mutations of this invariant residue, all of which exhibit high oxygen affinity and moderate to mild erythrocytosis.[12] This group of mutations represents an interesting cluster of variants that illustrates the effects of different mutations at the same amino acid residue. As a mutant of the 3′-*HBA1* gene that is expressed to a lesser extent than the 5′-*HBA2* gene, Hb Nunobiki makes up ~13% of the hemolysate and is accompanied by only mild erythrocytosis. High oxygen affinity is a result of the breaking of the C terminal-to-C terminal salt bridge that is indispensable for the stabilization of the T state, favoring the R state.

β-Globin Chain Variants

All possible single-base mutations of the β99 site disturbing the $\alpha_1\beta_2$ area of contact have been described and include Hb Kempsey (*HBB* αsp99asn), Hb Yakima (asp99his), Hb Radcliffe (asp99ala), Hb Ypsilanti (asp99tyr), Hb Hotel-Dieu (asp99gly), Hb Chemilly (asp99val), and Hb Coimbra (asp99glu). As expected for stable β-globin chain variants, all are present at 40% to 50% of the hemolysate, exhibit moderately high oxygen affinity, and are characterized clinically by erythrocytosis. Hbs Kempsey, Radcliffe, and Hotel Dieu have a decreased response to 2,3-DPG. Hbs Ypsilanti and Radcliffe form stable hybrid tetramers in the hemolysates in which the abnormal β chains coexist with normal β chains.

Six of the possible seven mutations of the C-terminal CAC (tyr) codon have also been described. One of them, Hb Cochin-Port Royal (tyr146arg), has nearly normal oxygen affinity but decreased 2,3-DPG interaction and Bohr effect.[13]

Three mutations of β82 lys have been described: Hb Rahere (lys82thr), Hb Helsinki (lys82met), and Hb Providence (lys82asn). All have moderately high oxygen affinity and moderate erythrocytosis. These mutants have drastically reduced 2,3-DPG binding as a result of the elimination of one of the normal binding sites for this allosteric effector. Hb Porto Alegre (*HBB* ser9cys) has high oxygen affinity and a tendency to aggregate, but erythrocytosis is not present.[14] Polymerization of Hb Porto Alegre is based on the formation of disulfide bonds in oxygenated samples and is different from HbS polymerization. Polymerization of this mutant diminishes heme–heme interaction and increases the oxygen affinity.

Hb Tak (*HBB* 147(+AC), modified C-terminal sequence: 147thr-lys-leu-ala-phe-leu-leu-ser-asn-phe-157tyr-COOH), is elongated by 11 amino acid residues.[15,16] It forms 40% of the hemolysate, has a very high oxygen affinity with no co-operativity, and no allosteric interaction with pH or 2,3-DPG. The C terminus of the β-globin chain is actively involved in the conformational changes of the hemoglobin molecule by stabilizing the T state. By having these stabilizing interactions disrupted, Hb Tak is totally frozen in the R state. Hb Tak is also slightly unstable. In spite of these severe functional abnormalities, a heterozygous patient did not have erythrocytosis. The extreme biphasic nature of the hemoglobin–oxygen affinity curve observed in mixtures of Hb Tak and HbA suggests that hybrid tetramer ($\alpha_2\beta^A\beta^{Tak}$) formation is absent. The top portion of the oxygen equilibrium curve is normal, and it begins to be abnormal only at <40% saturation. Because physiologic oxygen exchange occurs most commonly above that level of saturation, the tissues may not be hypoxic, removing the stimulus for increased erythropoiesis.

Clinical Features

Patients with high-affinity hemoglobins and erythrocytosis have a benign clinical course and rarely have complications, apart from a ruddy complexion. Splenomegaly is typically absent. Hemoglobin concentration and hematocrit are increased variably, and usually only moderately, suggesting that modulation by variations in other genes might affect the physiologic response to hypoxia. Some patients with Hb Malmo (*HBB* his97gln) have been reported to be symptomatic and to benefit from phlebotomy and the transfusion of normal blood, but this clinical course is an exception.[17]

Many cases of high-oxygen–affinity hemoglobins are diagnosed during a routine hematologic examination or when the family of a proband known to have erythrocytosis is examined. In very limited studies, exercise capacity in the laboratory and the indices of working capacity and cardiac tolerance were similar in patients with high-oxygen–affinity hemoglobins and in controls.[18] It has been suspected that carriers of these variants may have enhanced athletic performance under some circumstances, and this has led to the unfortunate and sometimes fatal use of erythropoietin or transfusion to enhance performance in competitive athletics.

In a population-based study of erythrocytosis, high-oxygen–affinity variants accounted for 3% of all cases.[19] By early diagnosis of high-affinity hemoglobins, unnecessary invasive diagnostic procedures and inappropriate therapeutic interventions, such as cardiac catheterization, can be avoided. Patients have received ^{32}P treatment based on a mistaken diagnosis of polycythemia vera.

Increased morbidity or mortality in mothers with high-oxygen–affinity hemoglobins or their offspring has not been observed, suggesting that the affinity of the mother's hemoglobin is irrelevant with respect to oxygen delivery to the fetus.[18] Low ambient pO_2, as in unpressurized airplanes and ascent to altitude, do not represent a risk, because high-affinity hemoglobins are avid for oxygen. Hypothetically, carriers should be less prone to "the bends" during deep sea diving, because of slower oxygen release during ascension.

Treatment

Patients with high-oxygen–affinity hemoglobins have reasonable compensation for their abnormality, with adequate tissue oxygen delivery despite increases in blood viscosity. Intervention is therefore rarely required. Exercise studies before and after phlebotomy in patients with Hb Osler (*HBB* tyr145asn), a variant with a P_{50} of 10 to 11 mm Hg and a hemoglobin concentration of ~22 g/dl, did not show an impairment after phlebotomy.[18] Limited studies have suggested that phlebotomy generally does not improve exercise performance. However, rare individuals appear to have benefited from phlebotomy, and thus other unknown factors may be interfering with their normal compensation for high hemoglobin–oxygen affinity, and increased blood viscosity may have become a burden. Prudence dictates that before embarking on a regimen of chronic phlebotomy, one should be conservative and review the hematologic and physiologic findings at 6-month intervals during the first few years after diagnosis. In older patients, special attention should be directed to blood flow to the heart and central nervous system. Thrombosis has been reported in individuals with high-oxygen–affinity variants but a causal relationship has not been established. In an example of a patient with a high-oxygen–affinity hemoglobin with concurrent β-thalassemia, treatment with hydroxyurea reduced the PCV from 61% to 39%, increased HbF from 3.6% to 30%, and P_{50} from 6 to 10 mm Hg.[20] This case should not be a recommendation for routine treatment of erythrocytosis due to high-oxygen–affinity hemoglobins with cytostatic agents.

Low-oxygen–Affinity Hemoglobins

Hemoglobin variants with reduced affinity for oxygen are in many respects the converse of high-oxygen–affinity variants. About half as many low-oxygen–affinity variants have been described compared to high-oxygen–affinity variants. They are expressed in the heterozygote, with homozygosity likely to be embryonic lethal. A major clinical feature is anemia that, at times, is accompanied by cyanosis.

Pathophysiology

Alterations of critical molecular regions involved directly in the R–T transition result in the stabilization of the deoxy T state or destabilization of the oxy R state. Low-oxygen–affinity hemoglobins deliver more O_2 to the tissues per gram of hemoglobin, and this is reflected by an oxygen–hemoglobin dissociation curve shifted toward the right of normal and an increase in P_{50}. When hemoglobin has a right-shifted or low-affinity curve, the difference between oxygen binding in the lungs at PO_2 levels of 100 mm Hg and unloading in the tissues at 40 mm Hg can be twice as great as the differences in a hemoglobin with a normal oxygen equilibrium curve. Patients with a moderately right-shifted oxygen equilibrium curve (P_{50} between 35 and 55 mm Hg) may be mildly anemic, but some individuals with very right-shifted oxygen equilibrium curves (P_{50} ~80) are not anemic. A right-shifted oxygen equilibrium curve leads to an increase in the synthesis of 2,3-DPG and a decrease in its destruction.

Diagnosis

The first report of a low-oxygen–affinity hemoglobin was Hb Kansas (*HBB* asn102thr), which presented with asymptomatic cyanosis without anemia or hemolysis.[21] Detection of a low-oxygen–affinity hemoglobin is part of the differential diagnosis of patients with cyanosis (see later). Before undertaking extensive diagnostic procedures in cases of cyanosis that are not clearly the result of cardiovascular or pulmonary disease, fractionating hemoglobin by HPLC and measuring blood P_{50} is advisable. A search for low-affinity hemoglobins as an explanation for anemia without cyanosis is less compelling, but if other investigations prove fruitless, unexplained normocytic anemia without reticulocytosis might be evaluated by measuring P_{50}.

A simple bedside test can distinguish cyanosis resulting from low-oxygen–affinity hemoglobins or cardiopulmonary cyanosis from that occurring with methemoglobinemia, M hemoglobins, or sulfhemoglobinemia. When blood from carriers of low-oxygen–affinity hemoglobins or patients with cardiopulmonary disease is exposed to ambient oxygen, it will turn from purple-greenish to bright red. In contrast, blood of patients with methemoglobinemia, sulfhemoglobinemia, or M hemoglobins will remain abnormally colored.

Clinically apparent cyanosis is observed only in carriers of low-oxygen–affinity variants with greatly right-shifted curves and where the variant comprises a substantial portion of the hemolysate. Cyanosis is present from birth in some low-oxygen–affinity hemoglobins due to α-globin chain mutants. In carriers of β-globin chain mutants, cyanosis may appear from the middle to the end of the first year of life as γ-globin gene expression and HbF synthesis wanes and is replaced by β-globin gene expression and HbA. Neonatal cyanosis has been associated with γ-globin variants that have low oxygen affinity.[22] Globin gene sequencing is the sole means of definitive diagnosis.

Clinical Features

Three low-oxygen–affinity variants have been described at β102. Hb Kansas, the best-studied variant, has a whole-blood P_{50} of ~70 mm Hg, decreased co-operativity, and a normal Bohr effect.[21] The β102 asn residue is invariant among β-globin chains and participates in the only hydrogen bond between asn 102 and asp 94 across the $\alpha_1\beta_2$ interface in oxyhemoglobin. This bond is broken when the molecule assumes the T state. The new thr residue is incapable of forming this bond, and low oxygen affinity results from destabilization of the R conformer. The changes induced by this substitution at the $\alpha_1\beta_2$ interface allow Hb Kansas to dissociate into $\alpha\beta$ dimers, the near opposite of the high-oxygen–affinity Hb Chesapeake.

Hb Beth Israel (*HBB* asn102ser) was found in a patient with cyanosis of the fingers, lips, and nail beds.[23] The P_{50} was 88 mm Hg, and arterial blood was only 63% saturated despite a normal pO_2. The hemolysate also had a low oxygen affinity and a normal Bohr effect. Erythrocyte 2,3-DPG was mildly elevated. The molecular mechanism of reduced oxygen affinity is the same as for Hb Kansas, although the defect may be more disruptive locally, because the serine side chain is shorter than that of threonine.

Hb Bologna (*HBB* lys61met) is informative because it was present as a compound heterozygote with β^0-thalassemia and comprised 90% of the hemolysate.[24] Adults were neither cyanotic nor anemic despite having a P_{50} of 37.6 mm Hg. During gestation, the high concentration of HbF makes it doubtful that this mutation would have an effect on fetal development.

Hb Bruxelles (*HBB* phe42del) is a deletion of the most conserved amino acid residue of hemoglobin.[25,26] Phenylalanine residues at β41 and β42 are conserved in all normal mammalian non-α–globin chains and are indispensable for the structural integrity and oxygen-binding functions of the molecule. From age 4 years, the index case of Hb Bruxelles had severe hemolytic anemia and cyanosis, requiring blood transfusion once. Later in life, her hemoglobin concentration stabilized at 10 g/dL. Reasons for this "switch" of phenotype are unknown. Other mutations of β41 and β42, which are predominately unstable hemoglobins, are discussed later.

Treatment

Treatment is not needed for these variants. The importance of early diagnosis is to avoid unnecessary work-up and to alleviate concern for the patient and family.

UNSTABLE HEMOGLOBINS

The unstable hemoglobins result from globin chain mutations that cause hemoglobin tetramer instability and intracellular precipitation of its globin subunits. These intraerythrocytic precipitates are detectable by supravital staining and appear as globular aggregates called Heinz bodies. These inclusions reduce the life of the erythrocyte by binding to the membrane, decreasing cell deformability, and increasing membrane permeability. The resultant hemolytic disorder is sometimes called congenital Heinz body hemolytic anemia. Heinz bodies and hemolysis also occur with certain hereditary erythrocyte enzyme deficiencies (see Chapter 28). More than 140 unstable variants of both the β- and α-globin chains with widely varying clinical severity have been reported, almost always as heterozygotes for the mutation, although some homozygous cases have been reported. The major clinical features are anemia, reticulocytosis, pigmenturia, and splenomegaly.

Pathophysiology

The pathophysiology of unstable hemoglobins relates to the specific mutations leading to altered heme–globin interaction, the process of Heinz body formation, and destruction of red cells containing denatured hemoglobin.

Mutations That Alter Heme–Globin Interaction

Mutations that change the primary structure (amino acid sequence) of globin, depending on the substitution and its location, can alter the secondary structure (α-helical), the tertiary structure (folding of the globin chain), or the quaternary structure (interactions within the hemoglobin tetramer). The mechanisms that can lead to this hemoglobin instability are listed in Table 35.2.

Heme–globin interactions are vital for oxygen delivery but also contribute to molecular stability and intracellular solubility. For example, introduction of a charged amino acid residue into the heme pocket, a site normally formed by residues with nonpolar side chains, results in hemoglobin instability (e.g., Hb Bristol). Mutations involving residues that interact directly with heme, such as those near the (F8) proximal histidine that reacts with heme-iron (e.g., Hb Köln), are associated with hemoglobin instability. Also, mutations associated with nontyrosine substitutions of the (E7) distal histidine (e.g., Hb Zürich) cause molecular instability. An interesting effect of this is that the ligand-binding properties of iron are changed, and Hb Zürich has a much higher affinity for CO.[27,28]

Disruption of the secondary structure reduces subunit solubility and is often a result of the introduction of proline residue that cannot be accommodated into the α-helix except in its first two positions. α-Helices comprise ~70% of a globin subunit and must be folded into a globin motif. Introduction of water into the molecule destroys its stability, and this can be caused by substitution of a charged residue, for example, alanine, for a nonpolar residue, such as proline (e.g., Hb Brockton).[29]

Loss of intersubunit contact hydrogen bonds or salt bridges in the $\alpha_1\beta_1$ contact area will interfere with hemoglobin quaternary structure and also reduce stability. Dissociation of $\alpha_1\beta_1$ contacts normally does not occur in red cells, whereas dissociation of $\alpha_1\beta_2$ contact does take place. Dissociation of $\alpha_1\beta_1$ dimers into monomers is normally minimal, as it generates methemoglobin and consequent instability. Dissociation of chains along the $\alpha_1\beta_1$ contact generates α- and β-globin chains that uncoil, loosening their heme–globin interaction and favoring methemoglobin formation. Mutations affecting the $\alpha_1\beta_1$ interface tend to be more unstable than those affecting the $\alpha_1\beta_2$ contact. Examples of unstable hemoglobin mutations that are due to decreased $\alpha_1\beta_1$ contact include Hb Philly,[30] Hb Peterborough,[31] and Hb Stanmore.[32]

α-Hemoglobin–stabilizing protein (AHSP) binds free α-globin chains, protecting them from precipitation (see Chapter 6). In vitro studies suggest that the impaired interaction of AHSP with α-globin variants when the mutation lies in the molecular sites where ASHP binds α-globin might affect the stability of the variant. In these studies, recombinant Hb Groen Hart (*HBA* pro119ser), Hb Diamant (*HBA* pro119leu), and α-globin termination mutants had impaired interactions with AHSP. These observations suggest an additional mechanism for unstable α-globin variants.[33,34]

Heinz Body Formation

Heme loss is inhibited by maintaining heme iron in the reduced ferrous (Fe^{2+}) state by the action of methemoglobin reductases and detoxification of oxygen radicals. Therefore, dimerization and the dispersion and precipitation of free heme is minimized. Hemoglobin dimers autoxidize and lose heme more readily than tetramers. Generation of methemoglobin increases the thermoinstability of hemoglobin, suggesting that the pathways and events accompanying the conversion of ferrous to ferric heme are important for hemoglobin stability.

Heinz bodies are the product of hemoglobin denaturation. First suggested to be heme-depleted globin chains, these inclusions were subsequently identified as hemichromes, derivatives of ferric hemoglobin that have the sixth coordination position occupied by a ligand provided by the globin. Hemichromes are generated when heme is dissociated from the heme pocket and rebinds elsewhere in the globin after the α- or the β-chains have denatured. Irreversible hemichromes are a stage in the formation of Heinz bodies (also see Chapter 6). Membranes prepared from the red cells of patients with Hb Köln (*HBB* val98met) who have had splenectomies contain aggregates composed of disulfide-linked spectrin, Band 3, globin, and high-molecular-weight complexes composed in part of denatured spectrin.

Red Cell Destruction

Red blood cells containing Heinz bodies have a shortened lifespan. Hemichrome can bind to Band 3 of the erythrocyte membrane. Decreased deformability of the erythrocyte leads to preferential trapping in the spleen, where Heinz bodies are removed. The coincident loss of small amounts of membrane gradually converts discoid cells into spherocytes that are eventually removed from the circulation. Membrane damage might also result from lipid peroxidation and protein cross-linking because of free-radical formation that is a result of Fenton chemistry.

Hyperunstable hemoglobins are an uncommon class of variants in which the mutation, usually in the third exon of the globin gene, leads often to a truncated globin that is barely detectable or is undetectable.[35,36] These hemoglobins, presumably synthesized normally, are rapidly destroyed, creating the phenotype of dominantly inherited thalassemia.

TABLE 35.2

SITES OF GLOBIN MUTATION ASSOCIATED WITH UNSTABLE HEMOGLOBINS[a]

Weakening or modification heme–globin interactions
Interference with the secondary structure of a globin subunit
Interference with the tertiary structure of the subunit
Altered subunit interactions interfering with the quaternary structure

[a]Other than single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains.

Diagnosis

Patients with unstable hemoglobins may have characteristically dark urine or pigmenturia. This is a result of the presence of dipyrroles that are also present in Heinz bodies. The absence of pigmenturia does not exclude the diagnosis of unstable hemoglobin, and the severity of the hemolysis is unrelated to pigmenturia. For example, carriers of Hb Köln and Hb Zürich (*HBB* his63arg) both can have pigmenturia, but hemolysis with Hb Köln can be severe whereas it is usually very mild with Hb Zürich. The P_{50} of unstable hemoglobins is variable and can be normal, low, or high. This is a result of different mutations variously affecting heme–globin interaction, and the tertiary and quaternary structures of the molecule.

Blood Smear

Abnormalities of the blood smear are nonspecific. They can include anisocytosis, basophilic stippling, Howell-Jolly bodies, nucleated red blood cells, and microspherocytes. Fragmented cells appear to have had a "bite" taken from them and are thought to result from the phagocytosis of Heinz bodies during passage of the cell through the spleen. The mean corpuscular hemoglobin concentration may be as low as 25 g/dl because of heme loss or Heinz body formation. Some reported values for reticulocytes may be factitiously high, as inclusion bodies are mistaken for reticulocytes.

Heinz Body Preparation

Heinz bodies in circulating red cells are usually seen only after splenectomy or during an acute hemolytic episode. Under such circumstances, >50% of the cells typically contain one or more large, spherical inclusions. Heinz body detection requires the incubation of erythrocytes with a supravital stain such as new methylene blue or crystal violet. The Heinz bodies appear as single or multiple inclusions of 2 μm in diameter or less and often appear attached to the membrane. Heinz bodies may be found in fresh blood, but usually, incubation for 24 hours without glucose is required for their formation. A normal control should always be run simultaneously.

Hemoglobin Stability Tests

The isopropanol test is a good screening test for unstable hemoglobins, but it can give false-positive results when the sample contains >5% HbF.[37] In the heat denaturation test, a hemolysate is incubated for 1 or 2 hours at 50°C, and hemoglobin instability is suggested by the development of a visible precipitate.[38] Although the test is simple, the results can vary because of different concentrations of the abnormal variant and different temperatures needed for denaturation. Controls with a normal stable hemolysate must be run simultaneously.

Hemoglobin High-performance Liquid Chromatography

When the mutation is such that heme dissociates from the abnormal globin chain, as in the example of Hb Köln, the partially heme-deficient molecule is susceptible to reversible and irreversible hemichrome formation with subsequent denaturation. Precipitates tend to be pale, and the pattern found during hemoglobin separation is characterized by lack of discrete peaks and multiple diffuse bands when electrophoresis is used, unless stabilized by the addition of hemin. Dipyrroluria is present, suggesting that free heme was converted to dipyrroles rather than bilirubin.

About a quarter of unstable hemoglobins are not detectable by commonly used methods of hemoglobin separation. On HPLC, some unstable hemoglobins such as Hb Köln, Hb Zurich, and Hb Hasharon demonstrate characteristic elution times.

Detection of the Variant Hemoglobin and Mutation Analysis

If clinical and hematologic studies suggest an unstable variant, the determination of the molecular defect becomes the final step in diagnosis. DNA analysis is the ultimate approach to defining the globin mutation. New mutations are common, so a family history need not be present.

Clinical Features

The presence of an unstable hemoglobin should always be considered when hemolytic anemia is present and its cause is not clearly defined. Chronic hemolysis as a result of unstable hemoglobins can be associated with all of the known complications of hemolysis, including aplastic crisis, jaundice with cholelithiasis, leg ulcers, splenomegaly, and hypersplenism and pulmonary hypertension.[39] A special feature of unstable hemoglobins is pigmenturia. Similar to glucose-6-phosphate dehydrogenase (G6PD) deficiency, increased hemolysis often is associated with fever, infections, and ingestion of certain drugs (see Chapter 28). Dusky cyanosis has been described in some patients with unstable hemoglobins predisposed to methemoglobin formation. In one case in which the γ-globin chain of HbF was affected (HbF-Poole; *HBG2* trp130gly), hemolytic anemia was present in the newborn but disappeared as the γ- to β-globin switch was completed.[40] Sometimes the disease is seen in early childhood; it can be found in adults incidentally, or when fever or drug treatment induces hemolysis.

Many unstable hemoglobin variants produce mild hemolytic disease with minimal or no anemia. In the steady state, reticulocyte counts range between 4% and 10%. Splenomegaly may be present. Most patients with mild disease are first seen during a hemolytic crisis induced by drugs or infection. More than one half of the unstable variants are associated with no hematologic abnormality and are detected through screening programs (http://globin.cse.psu.edu).

Just as in all other chronic hemolytic anemias, B19 parvovirus infection can temporarily shut down erythropoiesis, rapidly worsening the anemia and resulting in an aplastic crisis. Anemia may also increase during infection and after treatment with oxidant drugs such as sulfonamides. The intensity of hemolysis is variable and is dependent on the mutation and fraction of abnormal hemoglobin present.

Hb Köln, described in multiple kindreds, is the most common unstable hemoglobin and is characterized by anemia, reticulocytosis, splenomegaly, and 10% to 25% Hb Köln.[41] It is not associated with oxidant-drug–induced hemolysis. The independent occurrence of this variant in so many apparently unrelated individuals suggests that the Hb Köln mutation, located at a methylated CpG dinucleotide sequence of the β-globin gene, can act as a "hotspot" for mutation through the deamination of the methylcytosine nucleotide to form thymine.

Hb Zürich has also been reported on multiple occasions.[42] This variant, forming ~25% of the hemolysate, is accompanied by mild anemia exacerbated by oxidant drugs, pigmenturia, and, as discussed previously, an increased affinity for CO. The latter protects the β-globin heme group from oxidation and increased instability. Carriers have a special susceptibility to sulfonamide-induced hemolytic crisis. Investigation of the basis for variation in drug-related hemolysis of family members with Hb Zürich disease suggested that tobacco smoking ameliorated hemolysis, probably because the high affinity of Hb Zürich for CO stabilized the hemoglobin tetramer.[43,44]

Hb Hasharon (*HBA2* asp47his) is another more common variant affecting the α-globin chain, found in Ashkenazi Jews and

causing hemolysis in newborns but not in most adults.[45,46] This variant comprises 15% to 20% of the hemolysate, and inclusion bodies are not found.

Some unstable hemoglobins are linked to α- or β-thalassemia genes: the α-chain mutants Hb Suan-Dok (*HBA2* leu109arg) and Hb Petah Tikva (*HBA* ala110asp) coexist in *cis* with α-thalassemia and some β-chain mutants such as Hb Leiden (*HBB* glu6 or 7del), Hb Duarte (*HBB* ala62pro), and HbG-Ferrara (*HBB* asn57lys) coexist with a β^0-thalassemia mutation in *trans*.

Pulmonary Hypertension

Altered nitric oxide (NO) bioavailability has become recognized as a common occurrence in hemolytic anemia and might account for a commonality of clinical findings in what are very different pathophysiologic entities.[47,48] Because a variable fraction of hemolysis occurs within the vasculature, heme and arginase released from the erythrocyte into blood consume NO and deplete supplies of arginine, the substrate of the NO synthases. Pulmonary hypertension and priapism, common complications of hemolytic anemia, have been described in patients with unstable hemoglobins.[49,50]

Miscellaneous

In a case of hemolytic anemia resulting from Hb Bristol-Alesha (*HBB* val68met), moyamoya and transient ischemic attacks occurred in a 10-year-old girl.[51] The authors suggested that chronic hypoxemia may be the cause of occlusive moyamoya in unstable hemoglobinopathies or in hemoglobins with altered oxygen affinity.

Hyperunstable Hemoglobin

Some uncommon globin mutations are hyperunstable. Although these mutants are synthesized in normal amounts, they are unable to form stable tetramers or even dimers and are rapidly catabolized. These variants therefore have features of both unstable hemoglobins and thalassemias, and they have been called thalassemic hemoglobinopathies. The phenotype is that of severe, dominantly inherited β-thalassemia rather than unstable hemoglobin disease, because the affected globin chain fails to accumulate and participate in tetramer formation. In the first recognized example of this phenotype, three generations of a family had a dominantly transmitted hemolytic anemia with splenomegaly, gross abnormalities of the erythrocytes, dyserythropoiesis, and large inclusion bodies in bone marrow erythroblasts and in nucleated red cells of the peripheral blood.[35,36]

Dominantly inherited β-thalassemias (sometimes the α-globin chain is similarly affected) have been identified in many ethnic groups and are caused by missense mutations, deletions or insertions of intact codons, single-base substitutions leading to premature termination of translation (nonsense mutations), and mutations causing frameshifts or aberrant splicing. Most of the mutations are in exon 3 of the affected gene, and this location might permit globin mRNA to escape nonsense-mediated decay and allow enough denatured protein, along with the uninvolved globin chain, to accumulate and damage the developing erythroblast.

Treatment

Unstable hemoglobinopathies are generally mild disorders and do not require therapy except supportive and preventive measures. As with other hemolytic anemias, Parvovirus B19 infections can cause the development of severe acute anemia. Administration of folic acid to prevent megaloblastic arrest of erythropoiesis might be warranted, although access to a nutritious diet is probably satisfactory. The possibility of fever-associated hemolysis should be recognized, and avoidance of oxidant drugs, including acetaminophen and sulfonamides, are other management considerations. Chronic hemolysis is associated with a high incidence of cholelithiasis.

Severe hemolysis raises the question of splenectomy because the spleen undoubtedly plays an important pathophysiologic role in the destruction of Heinz-body–containing red cells. As in other chronic hemolytic anemias, the decision to perform a splenectomy must be balanced with the role of the spleen as a defense against pneumococcal infections early in life and the need for antipneumococcal vaccines and prophylactic penicillin in cases where splenectomy is performed in childhood. On balance, splenectomy might be beneficial for individuals with severe unstable hemoglobinopathies, and partial correction of the anemia is sometimes achieved. Nevertheless, predicting the response to splenectomy is difficult. Hydroxyurea has been used to stimulate HbF production and help repair anemia in two cases of unstable hemoglobin disease.[52]

M HEMOGLOBINS

The M (met) hemoglobins are characterized by heme-iron oxidation. Heme iron is more stable in the ferric than the ferrous state. Erythrocyte methemoglobin reductive capacity cannot effectively compensate for this instability of ferrous heme. The major clinical feature of these disorders is cyanosis. They are not noted for clinical severity. The misdiagnosis of other causes of cyanosis and unneeded treatment are the major hazards of these rare variants.

Pathophysiology

In the M hemoglobins, the mutant globin chain creates an abnormal microenvironment for the heme iron, displacing the equilibrium toward the oxidized or ferric (Fe^{3+}) state. A combination of Fe^{3+} and its abnormal coordination with the substituted amino acid generates a visible spectrum that resembles, but is clearly different from, methemoglobin that is not due to a globin gene mutation, in which the heme iron is oxidized but there is no associated amino acid substitution.

In the Iwate prefecture of Japan, "black children" had been observed for more than 160 years, and this was associated with a brownish-colored hemoglobin in the hemolysate of a patient that was eventually characterized as HbM Iwate (*HBA* his87tyr).[53] Six β-, two α-, and two γ-globin HbM variants have been reported. In five of the eight described HbM variants, the mutation involves the substitution of the distal (E7) or proximal (F8) histidine interacting with the heme iron via tyrosine (http://globin.cse.psu.edu). With HbM Milwaukee (*HBB* val67glu), the longer side chain of the glutamic acid residue can reach and perturb the heme iron. In two novel variants that form methemoglobin, an amino acid deletion was suspected to alter the orientations of the distal and proximal histidine residues.[54] Properties of some M hemoglobins are shown in Table 35.3. The strength of attachment of ferric heme to globins differs among M hemoglobins.

HbM Milwaukee is an example of an M hemoglobin that is not caused by mutation of the proximal or distal histidine residues, but by the nearby β67 (E11) val (http://globin.cse.psu.edu). When this residue is replaced by a glutaminyl residue, it perturbs the heme iron and generates an M hemoglobin. Of interest, other mutations of that site, such as Hb Bristol (val67asp) or Hb Sidney (val67ala), are unstable or have low affinity but do not lead to heme–iron oxidation. X-ray crystallography shows that the carboxylic group of the new glutaminyl residue in Hb Milwaukee occupies the sixth coordination position of the iron, and that the proximal histidine maintains its role as the tenant of the fifth coordinating position, stabilizing the abnormal ferric state of HbM Milwaukee.

TABLE 35.3

HEMATOLOGIC FEATURES OF SOME HβM VARIANTS OF THE α- AND β-GLOBIN GENES

Variant	Percent	Hb (g/dl)	Reticulocytes (%)	P_{50}	Bohr Effect
HbM Hyde Park (Milwaukee-2)(β)	23–32	10–13	4–6	Normal	Present
HbM Iwate (α)	19	17	—	Decreased	Decreased
HbM Boston (α)	20–30	—	—	Decreased	Decreased
HbM Milwaukee (β)	50	14–15	1–2	Decreased	Present
HbM Saskatoon (β)	35	13–16	0.8–3.2	Normal	Present
HbM Chile (β)	17	13.2	1.2	—	—

Oxygen-binding Properties and the R→T Transition of M Hemoglobins

HbM Milwaukee, HbM Hyde Park (*HBB* his92tyr), and HbM Boston (*HBA* his58tyr) all adopt deoxy or deoxylike conformation upon the deoxygenation of the two normal chains, although the abnormal chains cannot off-load oxygen. This, and crystallographic, electron paramagnetic resonance, and nuclear magnetic resonance (NMR) spectroscopy, and 2,3-DPG–binding studies affirm that after two heme groups become deoxygenated, the entire molecule adopts the deoxy T conformation.

With HbM Milwaukee, Hb M Saskatoon (*HBB* his63tyr), and HbM Hyde Park, a normal Bohr effect and P_{50} strongly suggest that the hemoglobin adopts the R state when the two normal chains are oxygenated. NMR studies of HbM Milwaukee support the notion that the conformational changes take place when the normal heme groups are oxygenated. In contrast, HbM Iwate is in the crystallographic T configuration when its normal heme groups are in the ferric state, explaining its decreased oxygen affinity; the molecule does not shift to the R state when the normal heme groups are liganded and remains in the low-affinity T state. A similar situation probably exists in HbM Boston, as the habit of the deoxy crystal remains intact after oxygenation, suggesting that no conformational change has occurred that would require a different crystal structure.

HbM Saskatoon and HbM Boston have different properties despite the common substitution of the distal histidine. This occurs because HbM Saskatoon does not change its conformation when oxygenated, whereas the latter variant does. Why properties of the β-globin chains differ from those of the α-globin chain when their distal histidine is substituted is unresolved.

Iron Oxidation and Spectral Characteristics

In M hemoglobins, the affected heme groups are stabilized in the ferric state and have an abnormal microenvironment. They exhibit an abnormal visible absorption spectrum that is easily distinguished from methemoglobin. This characteristic separates these variants from some unstable hemoglobin mutants that also have a tendency to form methemoglobin.

Heme iron in the abnormal subunits of the M hemoglobin exhibit abnormally low redox potential. They are oxidized more rapidly by molecular oxygen and are resistant, to a variable degree, to reduction by dithionite. Differences also exist in the rate of reduction of the five M hemoglobins with NADH-cytochrome b_5 reductase (*CYB5R3*). HbM Iwate, HbM Hyde Park, and HbM Boston are not reduced at all, whereas HbM Milwaukee is reduced slowly and HbM Saskatoon is reduced normally by this reductase. These last two variants might be less oxidized in vivo than expected. Full ferric conversion might occur only in vitro, because of the high autoxidation rate of these abnormal hemoglobins. Older red cells might, nevertheless, have fully oxidized abnormal chains consistent with the presence of clinically apparent cyanosis.

Clinical Features and Diagnosis

Clinically, the skin and mucous membranes of HbM carriers have an appearance similar to, but not identical with, cyanosis, sometimes called pseudocyanosis. Pseudocyanosis is not associated with dyspnea or clubbing. Skin and mucosal surfaces are brownish/slate-colored, more like methemoglobinemia, but not as slate blue-purple as true cyanosis. This distinction is subtle and might not be apparent without comparing the two conditions at the same time. Skin reflects hemoglobin molecules with an abnormal ferric heme and abnormal spectrum, whereas cyanosis is caused by the presence of more than 5 g/dl of deoxyhemoglobin. Pseudocyanosis is present from birth in α-globin–chain abnormalities and from the middle of the first year of life in the β-chain mutants. The γ-globin gene HbM variants, HbF-M Osaka (*HBG2* his63tyr) and HbF-M Fort Ripley (*HBG* his92tyr), have been associated with neonatal "cyanosis" that disappears as γ-globin–chain synthesis wanes.[55,56] A mixture of the abnormal pigment and true cyanosis, resulting from hemoglobin desaturation of the normal chains, is observed in the low-oxygen–affinity HbM Boston and HbM Hb Iwate.

A mild hemolytic anemia and reticulocytosis have been observed in HbM Hyde Park and can be explained by the instability of the hemoglobin induced by partial heme loss.

HbM should be considered in all patients with abnormal homogeneous coloration of the skin and mucosa, particularly if pulmonary and cardiac functions are normal. The diagnosis can be suspected by observing an abnormal brown coloration of the blood in a tube. To distinguish this coloration from methemoglobin, the addition of KCN to the hemolysate is useful. KCN will turn blood containing methemoglobin red but has little if any effect on HbM-containing hemolysates. Lack of color conversion with KCN is diagnostic of HbM.

A spectrophotometric recording of the visible spectrum of the hemolysate is critical for the diagnosis, and the mutation is confirmed by DNA analysis. M hemoglobins do not have an absorbance peak at 630 to 635 nm which is typical of methemoglobin. In the presence of HbM, accurate measurement of oxygen saturation and CO hemoglobin is difficult with most instruments. Absorption maxima at different wavelengths of all hemoglobin M variants have been reported.

Treatment

Treatment for individuals with HbM is neither necessary nor possible. A correct diagnosis is most important, because this will forestall therapeutic and diagnostic misadventures.

METHEMOGLOBINEMIA UNRELATED TO GLOBIN GENE MUTATIONS

Normally, small amounts of hemoglobin are continually being oxidized by endogenous agents, including oxygen itself (auto-oxidation). When oxygen reacts with deoxygenated hemoglobin to produce oxyhemoglobin, one electron from heme-iron (Fe^{2+}) is transferred to the bound oxygen, thereby forming a ferric–superoxide anion complex (Fe^{3+}–O_2^-). Subsequently, when hemoglobin is deoxygenated, most oxygen is released as O_2, but a small amount leaves as superoxide anion (O_2^-). The partially transferred electron is not returned to iron, leaving the heme-iron as Fe^{3+} (methemoglobin). Increased temperature and low pH promote auto-oxidation.[6] Usually, methemoglobin levels are <1% of the total hemoglobin, because erythrocytes contain cytochrome b5 reductase that catalyzes its reduction (see Chapter 6). Genetically determined methemoglobinemia, unrelated to globin gene mutations, occurs in individuals with hereditary deficiency of cytochrome b5 reductase. Acquired methemoglobinemia occurs in normal individuals exposed to drugs and chemicals that oxidize hemoglobin iron at a rate that exceeds the capacity for enzymatic reduction.

Cyanosis

Cyanosis most often is due to cardiac or pulmonary disease, but genetic and acquired disorders of hemoglobin can result in significant arterial desaturation. In the M hemoglobins and with sulfhemoglobin and methemoglobin, the altered visible spectrum of the abnormal pigments is responsible for the brownish/slate skin color. The spectral properties of sulfhemoglobin versus methemoglobin are such that patients can be markedly "cyanotic," with 0.5 g/dl of sulfhemoglobin; 1.5 g/dl of methemoglobin is required to produce "cyanosis"; true cyanosis requires 10 times this concentration of deoxyhemoglobin.

Although dyspnea is not a feature of M hemoglobins, it can be present even with relatively low levels of methemoglobinemia. Because the altered hemes in HbM, sulfhemoglobin, and methemoglobin do not transport oxygen, affected individuals with all three conditions may have normal hemoglobin concentrations but are functionally anemic, simply because of insufficient operational heme groups. This effect is clinically significant only in extreme cases of methemoglobinemia and sulfhemoglobinemia or when the overall hemoglobin level is low. With HbM, the proportion of normal to abnormal heme is genetically determined and fixed, so that decreased oxygen delivery is problematical only when superimposed on underlying anemia.

The clinical effects of nonfunctional heme groups are not limited to an inability to transport oxygen. Small amounts of nonfunctional heme can have clinical significance if their presence produces a physiologically dysfunctional shift in the oxygenation of neighboring unmodified subunits. This is the molecular basis of the left-shifted oxygenation curve, the impaired oxygen delivery to the tissues, and the resulting respiratory distress seen in relatively mild degrees of methemoglobinemia. This phenomenon, called the Darling-Roughton effect, occurs as oxidized subunits in partially oxidized tetramers are held in an R-like conformation, increasing the oxygen affinity of the remaining subunits. Although mixed venous blood is unusually saturated, the abnormal spectrum of the methemoglobin dominates this effect, causing cyanosis. An analogous left shift in the oxygenation curve, but to a more pronounced degree, is present with CO poisoning and impaired oxygen delivery exacerbates dyspnea.

Cytochrome b5 Reductase Deficiency

Mutations of the cytochrome b5 reductase 3 gene (*CYB5R3*; 22q13) cause decreased activity of the soluble form of this erythrocyte enzyme and hereditary methemoglobinemia. *CYB5R3* is a transferase that facilitates electron transfer from NADH to cytochrome b5, which then directly reduces methemoglobin. A second erythrocyte enzyme is NADPH-methemoglobin reductase, which by itself is unable to reduce methemoglobin effectively, and individuals lacking this enzyme do not have methemoglobinemia. However, in the presence of redox compounds such as methylene blue, NADPH methemoglobin reductase rapidly reduces methemoglobin. Thus this agent is useful in treating methemoglobinemia.

Cytochrome b5 reductase enzyme deficiency is a recessive trait, and only homozygotes or individuals who are compound heterozygotes for two different gene mutations express the disease. Of interest, however, heterozygotes can be at risk for acquired methemoglobinemia when exposed to oxidant drugs.[57,58] Two forms of cytochrome b5 reductase deficiency are recognized, types I and II.

Type I deficiency is limited to erythrocytes and is manifested by methemoglobinemia only. Patients are more cyanotic than sick, in the worst cases complaining of fatigue with strenuous exercise. They have normal survival and have normal pregnancies. Methemoglobin levels vary from 20% to 40%. When exposed to methemoglobin-inducing drugs or chemicals, these patients are at risk for developing further methemoglobinemia symptoms. Enzymatic activity of the NADH-dependent methemoglobin reductase system is reduced in the erythrocyte.

Type II deficiency is a generalized form cytochrome b5 reductase deficiency, affecting 10% to 15% of patients. It is a severe and lethal disease, with a strong neurologic component. Although the methemoglobinemia can be treated, the neurologic syndrome is refractory. The disease is secondary to homozygosity or compound heterozygosity for defective cytochrome b5 reductase in all tissues.

At least 33 mutations of *CYB5R3* have been associated with methemoglobinemia.[62] Seventeen exon mutations were associated with type 1 disease, 15 with type II, and 1 with both types of disease. Missense, nonsense, deletions, and other classes of mutation have been described.

A high incidence of hereditary methemoglobinemia is found among Alaskan Eskimos, Northwest Indians, Navajo Indians, and natives of Yakusk, Siberia, groups that might have common ancestry. In one report from Alaska, the gene frequency was 0.07, but these results were based on enzyme assay and not detection of the gene. Cytochrome b5 reductase deficiency has also been observed sporadically among Puerto Ricans and in Mediterranean populations.

Acquired (Toxic) Methemoglobinemia

Many chemical agents and drugs can induce methemoglobinemia in normal people (Table 35.4). Dapsone- and primaquine-induced methemoglobinemia, at levels of 15% to 33%, have been reported in human immunodeficiency virus (HIV)-infected patients. Nitrites also are common offenders, and recreational use of amyl, butyl, or isobutyl nitrites is a cause of acquired methemoglobinemia. Infections that release toxins (including nitrites) can produce methemoglobin. Aniline dyes and aniline reduce molecular oxygen and generate methemoglobin. Phenylhydroxylamine, after reducing oxyhemoglobin, can generate nitrosobenzene, which is reduced again to phenylhydroxylamine by red cell enzymes. The cycle can then, in turn, generate more methemoglobin. Henna, a natural product used worldwide as a hair dye and to stain skin and nails, contains a chemical, 2-hydroxy-1,4-naphthoquinone, that can increase methemoglobin production, especially in G6PD-deficient individuals. Use of benzocaine as a topical anesthetic is often associated with methemoglobinemia. Certain medications used to treat diaper rash that contain benzocaine and resorcinol have been reported to produce methemoglobin levels as high as 35%.[57–64]

TABLE 35.4

DRUGS AND AGENTS THAT CAN CAUSE METHEMOGLOBINEMIA

Local anesthetics
Benzocaine
Lidocaine
Procaine
Prilocaine
Analine dyes
Chlorates
Dapsone
Diarylsulfonylureas (sulofenur)
Primaquine
Rasburicase
Nitrates and nitrites
Nitroglycerine
Cerium nitrate
Amyl nitrate
Isobutyl
Nitrobenzines
Nitrofurans
Pyridium
Primaquine
Sulfonamides
Acetaminophen/phenacetin

Newborn infants are at increased risk for methemoglobinemia because of a transient decrease in NADH cytochrome reductase activity during the neonatal period; normal adult enzyme activity is present by 3 to 4 months of age. Infantile methemoglobinemia has occurred in association with nitrate contamination of the water supply.[60] Children with septic shock also can have methemoglobinemia, presumably because of increased circulating nitrite/nitrate levels. In children with *Plasmodium falciparum* malaria, mean methemoglobin levels are increased, and this is related to disease and anemia severity.[61] Because malaria itself produces hypoxia, the additional reduction in oxygen-carrying capacity because of the presence of methemoglobinemia might be particularly critical for the subgroup of patients who are anemic or acidotic.

Diagnosis

The possibility of acquired methemoglobinemia should be considered in anyone with recent or sudden apparent cyanosis who is unresponsive to 100% oxygen and without cardiopulmonary pathology. Sulfhemoglobinemia (see later) should also be considered in these cases. Acquired methemoglobinemia is not rare; it is much more common than any of the genetic causes of methemoglobinemia. In a retrospective study of acquired methemoglobinemia (methemoglobin level >2%), 138 cases were encountered over a period of 28 months.[64] Patients' ages ranged from 4 days to 86 years, and there was one fatality and three near-fatalities. Dapsone was the most common etiology of acquired methemoglobinemia, accounting for 42% of all cases. The mean peak methemoglobin level among these individuals was 7.6%. In five of the patients with the most severely elevated levels, 20% benzocaine spray was the causative agent and was associated with a mean peak methemoglobin level of 44%. Eleven pediatric patients developed methemoglobinemia either from exogenous exposure, such as drugs, or because of serious illness, such as gastrointestinal infections with dehydration. Ninety-four percent of patients with methemoglobinemia were anemic.

Long-standing symptoms, or symptoms in siblings, is suggestive of a hereditary methemoglobinemia. Because the enzyme deficiency is inherited as a recessive trait, clinical disease is not expected in the parents. The differential diagnosis includes the HbM variants and low-oxygen–affinity hemoglobins. Because of the "dominance" of the HbM genes, one parent often has the same symptoms.

The diagnosis of cytochrome b5 reductase deficiency is made by direct assay of the enzyme. Genetic ascertainment is available for the known mutations. Pre-natal diagnosis is available for type II congenital methemoglobinemia.

Treatment

Acquired methemoglobin is treated by stopping the offending agent once it is identified. Direct drug intervention with intravenous methylene blue is indicated in patients with 40% to 60% methemoglobin, particularly when symptoms are present. Methemoglobin levels of 70% can be fatal. The usual dose of methylene blue is 1 to 2 mg/kg, and the maximum dose is 7 mg/kg. It can be given intravenously in acute methemoglobinemia. For intravenous administration, it should be given slowly over 35 minutes to avoid high concentrations and paradoxical methemoglobin production. Rapid improvement in cyanosis and normalization of methemoglobin level usually occurs 30 to 60 minutes after methylene blue injection. If there is coexistent G6PD deficiency, methylene blue is not effective, because of the lack of NADPH production, and its use may result in hemolysis. A transient drop of pulse oximeter arterial oxygen saturation can be seen following methylene blue injection, a result of interference by methylene blue with the light-wave emission of the pulse oximeter. Methemoglobin levels can increase again following successful treatment.[65] In type I cytochrome b5 reductase deficiency, treatment is mainly for cosmetic purposes. Oral methylene blue, 100 to 300 mg daily, can maintain methemoglobin levels of 5% to 10%. Ascorbic acid, 200 to 500 mg daily, also can reverse cyanosis in patients with type I methemoglobinemia.

In aniline-induced methemoglobinemia, methylene blue can couple with oxyhemoglobin to generate free radicals and has sometimes produced hemolysis. In these cases, dosing should be limited.

Automated red blood cell exchange has been used successfully when methylene blue is ineffective and may be superior to manual exchange transfusion.[66]

PULSE OXIMETRY

Virtually all of the classes of hemoglobin variants and methemoglobinemia discussed above have been associated with unexpected low oxygen saturations when this is measured by pulse oximetry. Some low-oxygen–affinity variants have both a low pulse oximeter measured oxygen saturation and a low arterial oxygen saturation although the arterial oxygen pressure was normal.[67–70] These anomalies are due to the altered absorption spectrum of the hemoglobin variant that confounds the settings of the pulse oximeter which uses set wavelengths of light to calculate oxygen saturation. Attention should be paid to measurement of blood oxygen saturation when any hemoglobin variant is present. Blood oxygen saturation can be measured using an arterial blood gas analyzer, by pulse oximetry, or by using a CO-oximeter. The first method measures blood partial pressure of dissolved oxygen and provides the PaO_2 and SaO_2. The convenient pulse oximeter provides a transcutaneous measure of absorbance at two wavelengths (660 and 940 nm) but is inaccurate when dyshemoglobins, such as methemoglobin (hemoglobin with oxidized [Fe^{3+}] heme iron), carboxyhemoglobin, and sulfhemoglobin, are present. CO-oximetry, the most accurate of all the methods, can be inaccurate in cases of M hemoglobins.

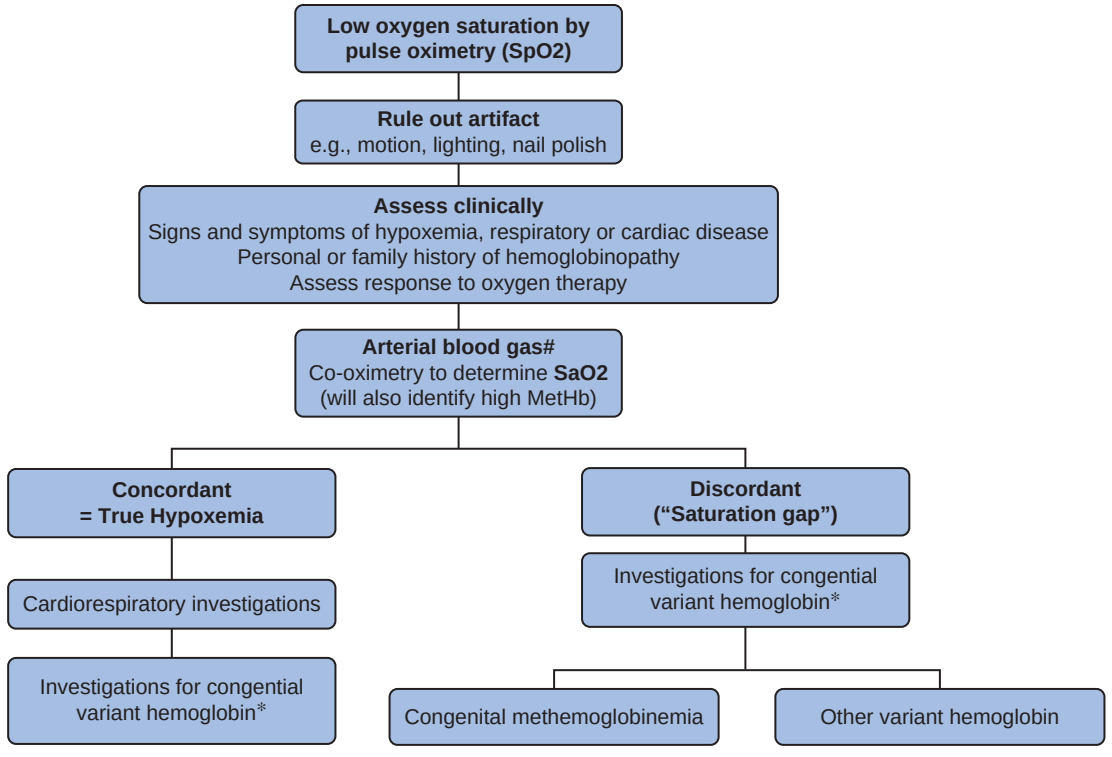

FIGURE 35.1. An algorithm for evaluation of low SpO2. Arterial blood gas should be done on room air and with simultaneous SpO2 measurement. (Redrawn from Ref. 70.)

Oxygen saturation calculated from pH and PO_2 should be interpreted with caution, because the algorithms used assume normal hemoglobin oxygen affinity, normal 2,3-DPG concentrations, and no dyshemoglobins such as methemoglobin or hemoglobinopathies. CO-oximeter reports should include the dyshemoglobin fractions in addition to the oxyhemoglobin fraction. In cases of increased methemoglobin fraction, pulse oximeter values trend toward 85%, underestimating the actual oxygen saturation. Hemoglobin M variants may yield normal methemoglobin levels and increased carboxyhemoglobin or sulfhemoglobin fractions measured by CO-oximetry.

In a systematic review, 25 publications and 4 unpublished reports representing 45 patients with low SpO2 and a confirmed variant hemoglobin were identified.[70] Fifty-seven family members of patients had a confirmed or suspected variant hemoglobin. Three low-oxygen–affinity variant hemoglobins had concordantly low SpO2 and SaO2. Eleven variant hemoglobins were associated with unexpectedly low SpO2 measurements but normal SaO2. Most variant hemoglobins were associated with spuriously low SpO2. The differential diagnosis of possible variant hemoglobin should be considered in asymptomatic patients found to have unexpectedly low SpO2. Otherwise these patients might be subjected to unneeded extensive cardiopulmonary investigations in search of the cause of their "hypoxemia." A approach to the evaluation of low oxygen saturation is shown in Figure 35.1.

DYSHEMOGLOBINEMIAS: CARBOXY-, SULF-, AND NITROSOHEMOGLOBINS

CO and NO are present in normal red cells in very low concentrations, and both can bind to hemoglobin to form carboxyhemoglobin (CO hemoglobin) and nitrosohemoglobin (NO hemoglobin), respectively. Carboxyhemoglobin avidly binds oxygen and cannot release it to the tissues. Nitrosohemoglobin may have critical physiologic functions. In addition to these normally occurring liganded hemoglobins, sulfur compounds can bind to the pyrrole ring of heme, forming a thiochlorin, referred to as sulfhemoglobin (see Chapter 6). Mutations or environmental conditions can increase the concentrations of all these liganded or oxidized hemoglobins, thereby producing dyshemoglobinemias. Sometimes, increased levels of dyshemoglobins are life-threatening, and because effective treatments are available, their presence should be identified promptly.

Carbon Monoxide Poisoning: Carboxyhemoglobinemia

CO, a toxic gas, is odorless, colorless, and tasteless, has a low solubility in water, and is relatively inert. It combines with hemoglobin heme with high affinity and with lesser affinities to myoglobin and cytochrome heme. Under physiologic conditions, its affinity for hemoglobin is ~240 times greater than that of oxygen. Once CO is bound to heme, its "off" rate is very slow, producing a very high affinity constant of CO for heme and a life-threatening danger for organisms exposed to high levels of CO.

Further endangering those exposed to CO, once two molecules of CO are bound to hemoglobin, the molecule switches to the R state, and the two globin chains that can bind oxygen will be in their high-affinity conformation. This high ligand affinity makes the delivery of oxygen to the tissues by the remaining oxygen-binding sites more difficult (Darling-Roughton effect). Consequently, the oxygen equilibrium curve of blood is shifted to the left with increasing CO levels.

In the absence of increased environmental CO, the blood of adults contains ~1% to 2% CO hemoglobin. This endogenous CO is derived from heme catabolism, specifically, the first enzymatic reaction catalyzed by heme oxygenase (see Chapter 6). Caloric restriction, dehydration, and Japanese

and Amerindians seem to generate higher endogenous levels of CO. Hemolytic anemia, hematomas, and infection tend to increase CO production up to threefold. Fetuses and newborns have double the normal adult levels of CO hemoglobin, and this increases further in the presence of neonatal hemolysis. Exogenous sources of CO include atmospheric CO, which is a product of incomplete combustion and oxidation of hydrocarbons, and natural sources.

The most commonly used instrument for the detection and quantification of carboxyhemoglobins is the CO-oximeter, which also provides the levels of oxy-, deoxy-, and methemoglobin.

Chronic CO Intoxication

It has been estimated that CO intoxication is responsible for upward of 50,000 emergency room visits yearly.[71] Symptoms of CO hemoglobinemia can include irritability, nausea, lethargy, headache, and sometimes a flulike condition. A study of more than 1,000 CO-poisoned patients suggested that symptoms might not correlate well with blood levels of CO hemoglobin.[72] Higher CO hemoglobin levels produce somnolence, palpitations, cardiomegaly, and hypertension, and might contribute to atherosclerosis. Long-term neuropsychological symptoms can persist and even be permanent.[71] Chronic CO poisoning can produce erythrocytosis, the magnitude of which varies with the level of CO hemoglobin. By increasing red cell production, chronic CO poisoning can mask the mild anemia of thalassemia trait or other acquired or genetic hemolytic disorders.

The most frequent exogenous source of CO is cigarette smoking, which can increase carboxyhemoglobin to 15%. Waterpipes have also been associated with CO hemoglobinemia. Pregnant women, fetuses, neonates, and infants are particularly susceptible to CO poisoning from smoking. Because CO hemoglobin increases hemoglobin-O_2 affinity, this may cause erythrocytosis, especially in smokers. The second most common cause of chronic CO exposure is defective heating exhaust systems and vehicles that leak CO into the passenger compartment. Occupational exposure is seen in garage workers, toll booth attendants, tunnel workers and other situations and occupations with poor ventilation, firefighters, and workers with industrial exposure.

Acute CO Intoxication

Carboxyhemoglobin levels >20% are usually required before symptoms appear. Accidental exposures to high environmental levels of CO or suicide attempts by deliberate exposure to a CO source are the most frequent causes of acute poisoning in the United States, responsible for ~4,000 adult deaths a year. Acute CO intoxication in children is responsible for ~400 deaths a year, is more severe, and sometimes has unique symptomatology. Children are more likely to have severe sequelae such as leukoencephalopathy, white-matter destruction, and severe myocardial ischemia. Carboxyhemoglobinemia has been associated with high doses of sodium nitroprusside in children, with levels of 5.5% to 7.7%.[73] The mechanism is unclear but is hypothesized to be the induction of heme oxygenase, the first enzyme in heme catabolism that generates CO.[74]

CO rapidly affects the central and peripheral nervous system and cardiopulmonary functions. Cerebral edema is common, as are alterations of sensory and peripheral nerve function. CO induces increased permeability in the lung, resulting in acute pulmonary edema. Cardiac arrhythmia, generalized hypoxemia, and respiratory failure are the common causes of CO-related death. Carboxyhemoglobin levels >40% are present in these cases. In survivors, considerable neurologic deficits may remain.

Less severe acute cases present with the same types of symptoms as patients with chronic intoxication. Arrhythmias, myocardial ischemia, lactic acidosis, convulsions, and coma also can occur. An interesting complication observed several days after the exposure to CO are patches of necrotic skin induced by localized hypoxia. The levels of carboxyhemoglobin that can elicit any of these symptoms vary widely among patients.

Treatment

Treatment of chronic exposure is principally rapid removal of the patient from the source of environmental CO and if needed, breathing 100% O_2 will increase the rate of CO removal. Hyperbaric oxygen, whose efficacy is unproven,[71,74] perhaps because of the almost inevitable delay in its institution, should be reserved for exceptional cases of CO intoxication.[74] In acute exposure, after identification and removal of the source of CO, 100% O_2 should be administered.

Sulfhemoglobinemia

Sulfhemoglobin is a green-pigmented protein with a sulfur atom incorporated into the heme ring. It is first suspected in a cyanotic patient with near-normal oxygen tension who is felt to have methemoglobinemia but does not respond to therapy with methylene blue. Although it shares a similar absorption peak with methemoglobin, the absorption peak of methemoglobin, unlike that of sulfhemoglobin, is abolished by cyanide. At low concentrations, sulfurated tetramers are shifted toward the deoxy or T form, producing a right shift of the oxygen equilibrium curve. This shift in the hemoglobin–oxygen dissociation curve reduces the likelihood of dyspnea unless the concentrations of sulfhemoglobin are exceptionally high.

Sulfhemoglobin has been associated with the use of certain "oxidant" medications, although mostly when used in doses higher than recommended, during drug abuse, with occupational exposure to sulfur compounds and with exposure to polluted air.[75] Sulfhemoglobin and methemoglobin have been reported to coexist in some cases of drug-induced hemoglobinopathy, and chemicals and drugs reported to produce these syndromes are similar. Congenital sulfhemoglobinemia is rare and has been described with an unstable hemoglobin. It is likely, that, because of drug-related and industrial exposure to sulfur, this condition is underdiagnosed. For equivalent amounts of abnormal pigment, the patient with sulfhemoglobinemia appears bluer than the patient with methemoglobinemia, and concentrations of 0.5 g/dl can produce cyanosis. These individuals are less symptomatic than those with methemoglobinemia, as cyanosis occurs at a sulfhemoglobin concentration 10 times lower than the methemoglobin level needed to cause cyanosis. Treatment is rarely required in addition to withdrawal from the putative offending agent. Exchange transfusion is the sole therapeutic option for symptomatic cases.

Nitrosohemoglobins

NO is generated from l-arginine by nitric oxide synthases (see Chapter 6). NO diffuses out of the originating cells and into nearby target cells, where it binds the heme groups of enzymes and hemoglobin. The reaction of free NO with erythrocytes is diffusion-limited. It has been proposed that *S*-nitrosylhemoglobin is formed in the lungs, whereas in tissues NO is liberated from hemoglobin leading to vasodilation. It is hypothesized that by sensing the physiologic oxygen gradient in tissues, hemoglobin exploits conformation-associated changes in the position of β93 cys to bring local blood flow into line with oxygen requirements.[76–81] This hypothesis is controversial, however, and there is little direct evidence that NO is liberated from the β93 cys site as hemoglobin assumes the T state.

CHAPTER 36

MEGALOBLASTIC ANEMIAS: DISORDERS OF IMPAIRED DNA SYNTHESIS

Ralph Carmel

HISTORICAL BACKGROUND

The story of megaloblastic anemia, its causes, and how they were decoded is a wonderfully instructive chapter of medicine. Clinical observations set the stage for a series of insightful clinical investigations that converted a dreaded "pernicious" condition into one that is now easily treated.

A puzzling illness with anemia, debilitation, languor, and, finally, torpor and death was described by Addison[1] in 1849. Although possibly similar cases were reported earlier and Addison believed the anemia to be related to adrenal dysfunction, this is generally taken as the first description of pernicious anemia. Neuropathy was noted by Osler and Gardner in 1877, and Lichtheim associated it with myelopathy 10 years later. In 1880, Ehrlich identified megaloblasts and proposed them as the precursors of the "giant blood corpuscles" described in the peripheral blood by Hayem.

The clinical breakthrough occurred in 1926 when Minot and Murphy,[2] using the then new technique of reticulocyte assessment, showed that the manifestations could be reversed and held in abeyance by eating prodigious amounts of liver; for this, they shared the Nobel Prize. Three years later, Castle,[3] building on earlier descriptions of achylia gastrica, demonstrated that gastric juice contains an "intrinsic factor" (IF) that combines with an "extrinsic factor" in meat and allows it to be absorbed. Several decades later, the extrinsic factor, vitamin B_{12}, was synthesized,[4,5] and its structure was demonstrated by Hodgkin,[6] who was awarded a Nobel Prize for her crystallographic work.

Studies by Wills,[7] who treated macrocytic anemia with yeast, and by many others defined the need for folate, which was isolated and characterized by 1948.[8] The ability of nutritional folate deficiency to cause megaloblastic anemia was proven in a notable self-experiment by Herbert.[9] The stories of these and other discoveries are available in several highly readable books and articles.[10–13]

Cure is so simple now that the once deadly diseases are considered domesticated. That gratifying development has been so successful that the potential for clinical neglect has emerged,[14–16] even as major metabolic and molecular advances continue. The definitions of insufficiency have expanded,[17] and accurate and accessible biochemical tools have facilitated exploration of potential impact on public health. This has not been free of controversy.

NORMAL PHYSIOLOGY AND PATHOPHYSIOLOGY

Megaloblastic anemia is, most often, a product of folate or cobalamin (vitamin B_{12}) deficiency. These metabolically intertwined vitamins, whose disorders are sometimes difficult to differentiate, require very distinct diagnostic and therapeutic approaches. The two are discussed separately throughout this chapter, which signals the need to always differentiate between them.

Biochemistry and Metabolism

Folate

Folate, or pteroylglutamate, consists of a pteridine ring, paraminobenzoate, and one or more glutamate side chains (Fig. 36.1). Folates vary in their reduction states, one-carbon moieties, and glutamation states. Polyglutamated folates, with three or more γ-carboxyl–linked glutamate residues, predominate intracellularly; they are better retained in cells than monoglutamated forms, which traverse membranes more easily.[18] Polyglutamated forms are also more effective participants in enzymatic reactions, although N5-methyltetrahydrofolate (methylTHF), the major folate in the body, tends to be a poor substrate for polyglutamation.

Folic acid is pharmacologically stable but must be reduced to be active. Folates reduced to tetrahydrofolate (THF) at positions N5 through N8 (Fig. 36.1) function as one-carbon group donors, acceptors, or modifiers. THFs with varying one-carbon moieties at the N5, N10, or both positions, attach to enzymes and serve as co-substrates in cytoplasmic or mitochondrial one-carbon group transfers involving amino acids (Fig. 36.2, reactions 4, 5, and 7),

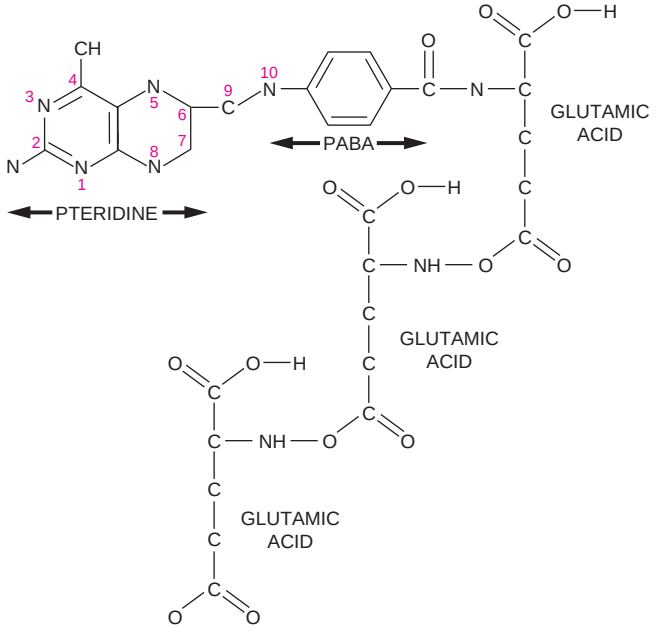

FIGURE 36.1. Folate structure. The constituents are, from left to right, pteridine and *p*-aminobenzoic acid (PABA), which constitute the pteroyl moiety, and one or more glutamates that are attached by γ-carboxyl linkage (in this diagram, three glutamates are linked). Metabolic activity requires reduction to tetrahydrofolate at positions 5, 6, 7, and 8. Various one-carbon moieties are attached to the nitrogen at position 5 (N5-methyl, N5-formyl, or N5-formimino) or 10 (N10-formyl), or bridging 5 and 10 (N5,10-methylene or N5,10-methenyl). Each folate participates in specific reactions by transferring, accepting, or transforming its one-carbon moiety.

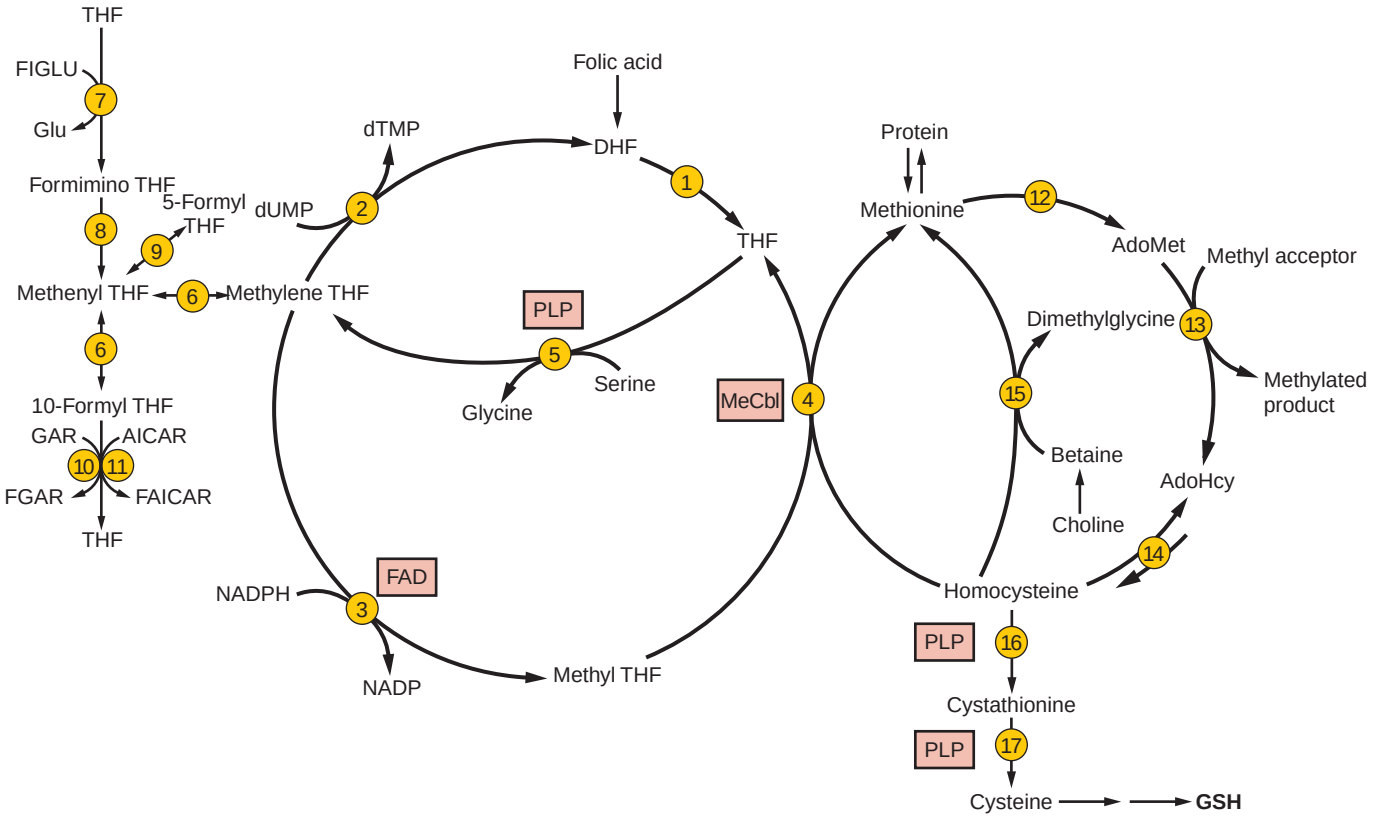

FIGURE 36.2. Folate metabolism and its linkage with cobalamin (*reaction 4*) to homocysteine and methionine metabolism (*right*). Vitamin co-factors are highlighted in boxes. Not all bidirectional reactions are noted as such, but the unidirectional nature of reaction 3 is the basis for the methyltetrahydrofolate trap hypothesis. The enzymes for the reactions include the following: *(1)* dihydrofolate (DHF) reductase; *(2)* thymidylate synthase; *(3)* methylene tetrahydrofolate (THF) reductase; *(4)* methionine synthase (maintained by a reductive system mediated by methionine synthase reductase); *(5)* serine hydroxymethyltransferase; *(6)* two sequential reactions mediated by two enzymatic activities of a single protein (methyleneTHF dehydrogenase and methenylTHF cyclohydrolase); *(7)* glutamate formiminotransferase; *(8)* formiminoTHF cyclodeaminase; *(9)* methenylTHF synthase; *(10)* glycinamide ribonucleotide (GAR) transformylase; *(11)* 5-aminoimidazole-4carboxamide ribonucleotide (AICAR) transformylase; *(12)* methionine adenosyltransferase; *(13)* diverse *S*-adenosylmethionine (AdoMet)–dependent methyltransferases; *(14)* *S*-adenosylhomocysteine (AdoHcy) hydrolase (kinetics usually favor synthesis of AdoHcy); *(15)* betaine:homocysteine methyltransferase; *(16)* cystathionine β-synthase;*(17)* cystathionine γ-lyase. *dTMP*, deoxythymidine monophosphate; *dUMP*, deoxyuridine monophosphate; *FAD*, flavin adenine dinucleotide (riboflavin); *FAICAR*, formylAICAR; *FGAR*, formylGAR; *FIGLU*, formiminoglutamic acid; *Glu*, glutamic acid; *MeCbl*, methylcobalamin; *PLP*, pyridoxal 5′-phosphate.

purines (reactions 10 and 11), and pyrimidines (reaction 2). By indirectly contributing to *S*-adenosylmethionine (AdoMet) generation, folate is linked to important methylations, including methylation of DNA cytosine (Fig. 36.2, reaction 13). Cellular folate metabolism and its compartments are reviewed elsewhere.[18,19]

Cobalamin

Cobalamin, a 1,355-Da member of the corrin family, is an organometallic co-factor. Four nitrogens of its planar tetrapyrrole anchor a central cobalt atom linked with a nucleotide (5,6-dimethylbenzimidazole) below and a variable prosthetic moiety above the pyrrole plane (Fig. 36.3). Specific cobalamins are named for their prosthetic moiety: methylcobalamin, which predominates in plasma and cytoplasm, and 5′-deoxyadenosylcobalamin, which predominates in mitochondria. *Vitamin* B_{12}, used popularly as a synonym for cobalamin, was the name given to cyanocobalamin,[4] a stable pharmacologic preparation that must be converted to other forms for utilization. Noncobalamin corrinoids, often with major structural changes or deletions, are ubiquitous in microbial metabolism, but cannot be used by humans. Some noncobalamin analogs are nevertheless bound avidly by transcobalamin (TC) I (also called haptocorrin) [20,21] and are found in the gut, plasma, and, much less often, tissues.[22]

To serve as an active co-enzyme, cobalamin requires reduction of its cobalt to the monovalent cob(I)alamin or divalent cob(II)alamin.[23] Reduced cobalamin has two known roles in humans. Attached to methionine synthase, it accepts the methyl group from methylTHF as methylcobalamin and transfers it to homocysteine (Fig. 36.2, reaction 4). Cobalamin activity for this reaction is maintained by methionine synthase reductase[24] and requires AdoMet. In cobalamin's other role, reduced mitochondrial cobalamin accepts 5′-deoxyadenosyl from adenosine triphosphate and binds to methylmalonyl coenzyme A (CoA) mutase. This mutase mediates an intramolecular rearrangement of L-methylmalonyl CoA to succinyl CoA in propionate metabolism.[25]

Cobalamin deficiency has a major impact on folate, homocysteine, and methionine metabolism by impairing the methionine synthase reaction. Most evidence supports the concept that cobalamin deficiency thereby "traps" methylTHF, which has no alternative metabolic role or route.[26,27] Feedback mechanisms activate methyleneTHF reductase (Fig. 36.2, reaction 3) in an effort to mobilize more methylTHF but only end up diverting even more methyleneTHF from its other roles and into the trap. A paralysis of folate metabolism spreads as THF and other active folates decrease. An alternative to the trap hypothesis emphasizes that the failure of methionine synthesis ultimately leads to formate "starvation,"[28] with depletion of formylTHF, methenylTHF, and methyleneTHF.

Homocysteine and Methionine

Folate and cobalamin participate intimately in homocysteine and methionine metabolism. The eventual generation of AdoMet (Fig. 36.2, reaction 12) serves several major functions. AdoMet helps regulate the metabolism of folate and disposition of homocysteine

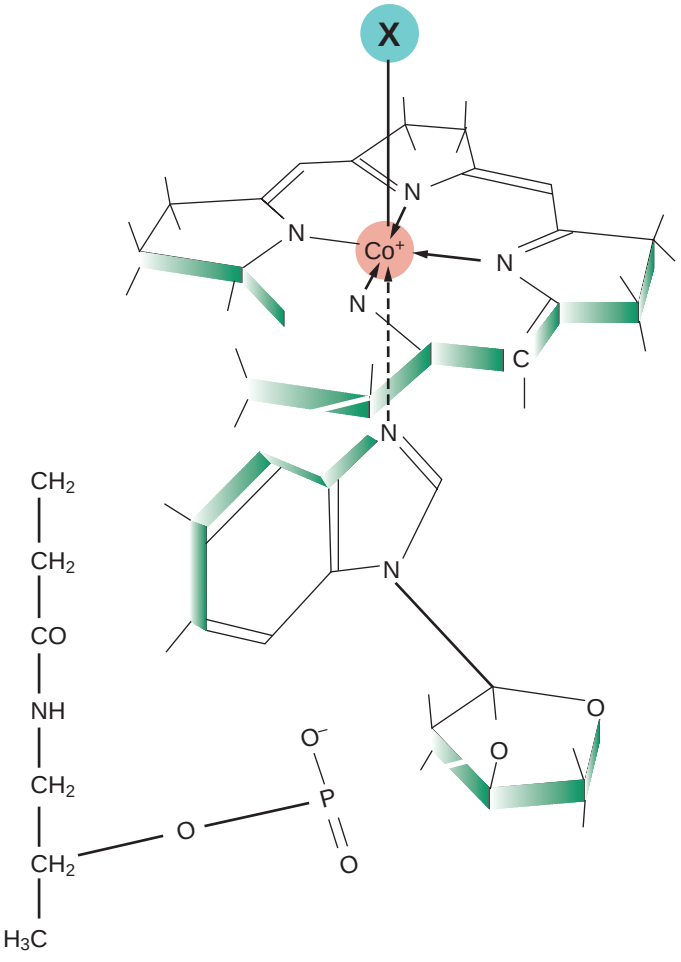

FIGURE 36.3. Cobalamin structure. Attached to the central cobalt atom of the corrin tetrapyrrole and to one of the pyrrole rings is the α-ligand, the 5,6-dimethylbenzimidazole nucleotide, extending below the corrin plane. The β-ligand (marked as *X* in the diagram) above the plane can be any one of several moieties, such as methyl, 5′-deoxyadenosyl, hydroxyl, or cyanide.

by inhibiting both methyleneTHF reductase (reaction 3) and betaine hydroxymethyltransferase (an alternate remethylator of homocysteine [reaction 15] confined to liver and perhaps kidney and lens), and by activating cystathionine β-synthase (reaction 16).[29]

Even more importantly, AdoMet is the methyl donor for most cellular methylation reactions affecting proteins, nucleic acids, histones, phospholipids, and neurotransmitters, all mediated by various methyltransferases (Fig. 36.2, reaction 13).[30] DNA hypomethylation, which contributes to neoplasia, can result from AdoMet deficiency. In the methylation reactions, *S*-adenosylhomocysteine (AdoHcy) is formed. AdoHcy, which in excess inhibits AdoMet activity, can be hydrolyzed to homocysteine; under normal conditions, however, the direction of this reaction favors AdoHcy synthesis (reaction 14).

An alternate fate of homocysteine is its transsulfuration to cystathionine and then to cysteine; both of these steps require pyridoxal 5′-phosphate (reactions 16 and 17). This is the major catabolic pathway for homocysteine, which is cytotoxic in concentrations normal for other amino acids. The pathway also influences redox activity by generating glutathione, a major intracellular reducing agent.

Normal Folate Physiology

Nutritional Characteristics

Folate, named for green leafy vegetables, exists in nearly all classes of foods. Organ meats (e.g., liver and kidney) and yeast are particularly rich, although not frequently eaten, sources. More common sources are other meats, nuts, beans, orange juice, dairy products, grains, and cereals. However, food folate, mostly methylTHF and formylTHF, is labile. Large losses occur with storage and some cooking processes,[31] especially when the water is discarded.[9]

Fortification of the American food supply in 1998 with 140 μg folic acid/100 g in grain and cereal products was mandated to lower the risk of neural tube defect births. Many food producers exceeded that amount, increasing the average folate intake by 190 μg/day.[32] Folate levels have risen sharply, reducing the frequency of subnormal red cell folate from 37.6% to 4.5% in young women.[33] Supplement use has also grown in Western societies, especially among women and the aged.[34] However, overall folate intake remains poor in other countries.

Dietary recommendations[35] take into account folate bioavailability, which is highest for synthetic folic acid and lower for food folate, which tends to be polyglutamated and requires conversion to monoglutamate for optimal absorption. Recommended intake is therefore expressed in dietary folate equivalents, in which 0.5 μg of folic acid supplement or 0.85 μg folic-acid–fortified food delivers the dietary equivalent of 1 μg of food folate. The recommended dietary folate equivalent intake is 400 μg daily for adults, 600 μg for pregnant women, 500 μg for lactating women, and lesser amounts scaled for age in children. Women of reproductive age are advised to take 400 μg of folic acid as an additional supplement to prevent neural tube defect births.

Physiologic Cycle of Assimilation

Folate Absorption

The absorption combines specific saturable processes that tend to predominate in the upper small intestine and nonsaturable ones that predominate in the ileum.[36] Luminal binding proteins appear not to be involved. The saturable process allows absorption of all folates, usually after the polyglutamated forms are hydrolyzed to monoglutamated ones by glutamate carboxypeptidase II in the jejunal brush borders. Two transmembrane, high-affinity members of the solute carrier superfamily mediate the saturable absorption of reduced folates in the upper small intestine. The main one, the proton-coupled folate transporter, has optimal affinity for folate at the duodenal pH of 5.5.[36,37,38] The reduced folate carrier has a higher affinity at pH 7.4 and thus has a lesser duodenal role.[36] Both these carriers exist in other tissues also. Conversion of absorbed folate to methylTHF appears to occur in the intestinal cell, which then exports the methylTHF into portal blood via carrier-mediated basolateral membrane transport, but some have proposed later hepatic conversion instead.[39] The liver either polyglutamates and stores the folate, secretes it for biliary enterohepatic recycling, or exports it for delivery elsewhere. Folate achieves peak levels in the blood 1 hour after ingestion.

Nonsaturable ileal absorption of folate assumes a dominant role whenever more than 200 μg of folate, which exceeds the capacity of the jejunal process, is ingested.[35] Such absorption of nearly unlimited amounts of unreduced monoglutamates may explain why oral folic acid is effective even when the more specific jejunal mechanisms fail in some malabsorptive disorders.

Folate Binders and Receptors

The various specific and nonspecific folate binders are incompletely understood and may not be mandatory for cellular uptake of folate. Specific binding proteins in the blood bind only a small fraction of circulating folate. Secretions, especially milk, also contain specific binding protein whose role is unclear but may withhold folate from bacteria.

The reduced folate carrier belongs to the SLC19 family of transporters, some members of which transport thiamine, and transports reduced folates (and methotrexate) into cells by a process linked to organic anions.[36] With its high activity at neutral

pH and operating at higher concentrations of folate, reduced folate carrier assumes major responsibility for folate uptake from the blood by the liver, kidney, leukocytes, placenta, and parts of the brain.

Folate receptor-α (FR-α or FR1) and FR-β (or FR2), are specific, partially homologous receptors in epithelial cells, placenta, hematopoietic cells, renal tubular cells, and malignant cells.[36,40] Their related genes lie on chromosome 11q13. FR-α and FR-β are covalently linked to glycosylphosphatidyl inositol anchors on cell membranes, bind and internalize methylTHF by endocytosis via clathrin-coated pits, and are recycled.[41] FR-γ is confined to hematopoietic cells but lacks glycosylphosphatidyl inositol anchoring and is therefore readily secreted.[42] The roles of these FR isoforms are not known, but FRα is active in renal tubular reabsorption of excreted folates. Some FR is found intracellularly, and some circulating folate-binding proteins appear to derive from FR. FRs are being explored as enhancers of drug delivery and cellular imaging because of their high expression in malignant and inflammatory cells. FR-α is also a co-factor for entry of Marburg and Ebola viruses into cells.[43]

Folate Transport and Cellular Utilization

Dietary folate and reabsorbed biliary folate enter the bloodstream and are rapidly cleared to tissues.[44] The rapid flux probably explains why plasma folate declines within 3 weeks when intake is reduced. Plasma folate, which is mostly methylTHF, is bound nonspecifically and with low affinity to proteins such as albumin, but approximately one third circulates unbound and a tiny fraction is bound specifically by the previously discussed FR-derived binding proteins. None of the circulating proteins plays any obvious role in cell uptake of folates.

Cellular uptake of monoglutamated folate occurs via either membrane FR or reduced folate carrier, the details varying among cell types and conditions.[18,36] Passive diffusion also occurs. In the cell, folates are rapidly polyglutamated by folylpoly-γ-glutamate synthetase, which enhances cellular retention and promotes attachment to enzymes. The folate is transported by saturable mechanisms into organelles; 35% of intracellular folate is in mitochondria.

Folate Stores and Turnover

A classic depletion study in one volunteer suggests that body stores of folate can be depleted in a few months to levels that do not support normal hematopoiesis,[9] but precise data are scarce. Old data estimate that normal liver folate content exceeds 7.5 mg.[45] The liver concentrates much of the body's folate and is a major site of one-carbon metabolism. Several folate pools exist, with different turnover rates ranging up to 100 days.[46] Enterohepatic recycling involves as much as 100 μg of folate daily.[44]

Approximately 200 μg of folate is excreted fecally every day. However, that amount includes not only the endogenous losses via sloughed intestinal cells and nonreabsorbed biliary folate but also external folates, such as unabsorbed food folate and folate synthesized by intestinal bacteria.[46] Approximately 1 mg of folate is filtered daily in the glomerulus but is largely reabsorbed as its folate-binding protein attaches to megalin, the multiligand receptor in proximal tubules.[47] Oxidatively degraded folate is lost, primarily in urine. Daily losses thus approximate 1% to 2% of body stores, which is compatible with the folate depletion rate reported in a normal person after 2 to 3 months of dietary restriction.[9]

Normal Cobalamin Physiology

Nutritional Characteristics

Humans obtain their cobalamin secondhand from animals and fish, which ingested the bacteria that synthesize cobalamin, or from animal products, such as milk.[45,48] The more prodigious bacteria ingestors, such as ruminants and oysters, are rich sources. Plants do not contain cobalamin. Bioavailability varies with different foods[45,48,49,50] and is at least as important as content. Cereals, fortified with cobalamin, dairy products, and fish provide better cobalamin bioavailability than meat.[49,50] Cobalamin supplement use, often as part of a multivitamin, has grown.[49,51]

When absorption is normal, the recommended daily requirement of 2.4 μg in adults[52] provides more than 1 μg cobalamin to compensate for the approximate daily loss. In children, recommended daily intake rises from 0.4 μg in infancy to 1.8 μg in preadolescence. A survey in 1995 indicated that typical daily intake of cobalamin in the United States is 4.0 to 6.2 μg.[53] European surveys suggested that metabolic sufficiency plateaus at intakes of 4.2 μg or higher, depending on the population surveyed.[50,54,55]

Physiologic Cycle of Assimilation

Intestinal absorption and tissue uptake (Fig. 36.4) are designed to internalize and concentrate available cobalamin efficiently while excluding possibly harmful nonfunctional analogs. The process is tightly regulated by a system of binding proteins and receptors.[56,57,58] Whether food-bound or as a free supplement, cobalamin that exceeds the capacity of IF-mediated uptake is poorly absorbed,[59] unlike the ready absorption of excess, free folic acid. IF mediates the absorption of more than 75% of the typically small cobalamin load in a meal but can accommodate little more than a total of 1 to 2 μg at a time.[45]

Cobalamin-binding Proteins

Three proteins with nonoverlapping roles bind cobalamin with high affinity[56,57,58,60] (Table 36.1). IF and TC II (called TC by authors who eschew TC I and TC II terminology) share moderate structural homology but their genes are located on different chromosomes.[61,62] Crystallographic analysis of TC II has defined key functional regions[63] that may be shared by IF. Each protein binds cobalamin specifically and ferries it into cells by endocytosis via its specific receptor; neither protein binds nonfunctional corrinoid analogs avidly.[20] IF, which originates in parietal cells although chief cells may synthesize it ectopically in patients with gastritis,[64] is confined to the gastrointestinal tract. TC II is synthesized by endothelial and other cells and is found in plasma and other fluids (Table 36.1). Holo-TC II (TC II with bound cobalamin) is cleared quickly by cellular uptake; its half-life in plasma is 90 minutes.[65] Plasma levels of total TC II tend to rise in inflammatory and other disorders, suggesting an acute-phase reactant character unrelated to cobalamin status,[56,66,67] but correlation with C-reactive protein levels is poor.[68] A common missense polymorphism of the *TCN2* gene, C776G, displays no consistent phenotypic impact,[69,70,71] but the less common A67G mutation was associated with lower holo-TC II without affecting metabolic cobalamin status.[71]

TC I (also called *haptocorrin*, *R binder*, or *cobalophilin*) is heavily glycosylated.[56] Its carbohydrate variability is prominent and affects major physicochemical characteristics.[56,72] Some carbohydrate variations led to ill-advised isoelectric point demarcation of a "TC III" subset of TC I, but others may substantively alter TC I clearance from plasma. TC I is synthesized in the specific granules of late myeloid precursors[73] and in exocrine gland epithelium.[56] TC I has only 33% to 36% homology to IF and TC II.[62,74] It also differs from them in two important ways: it binds nonfunctional corrinoid analogs as avidly as cobalamin, and it lacks specific receptors for cellular delivery. As a result, plasma TC I exists largely saturated with cobalamin (i.e., holo-TC I) and has a half-life of 9 to 10 days.[65] Thus, TC I carries more than 70% of cobalamin[75,76] and virtually 100% of analogs in plasma,[20,77] whose concentrations are nearly equal. Only 10% to 30% of plasma cobalamin is holo-TC II at any moment, which greatly underestimates the heavy but rapidly turning over holo-TC II traffic.

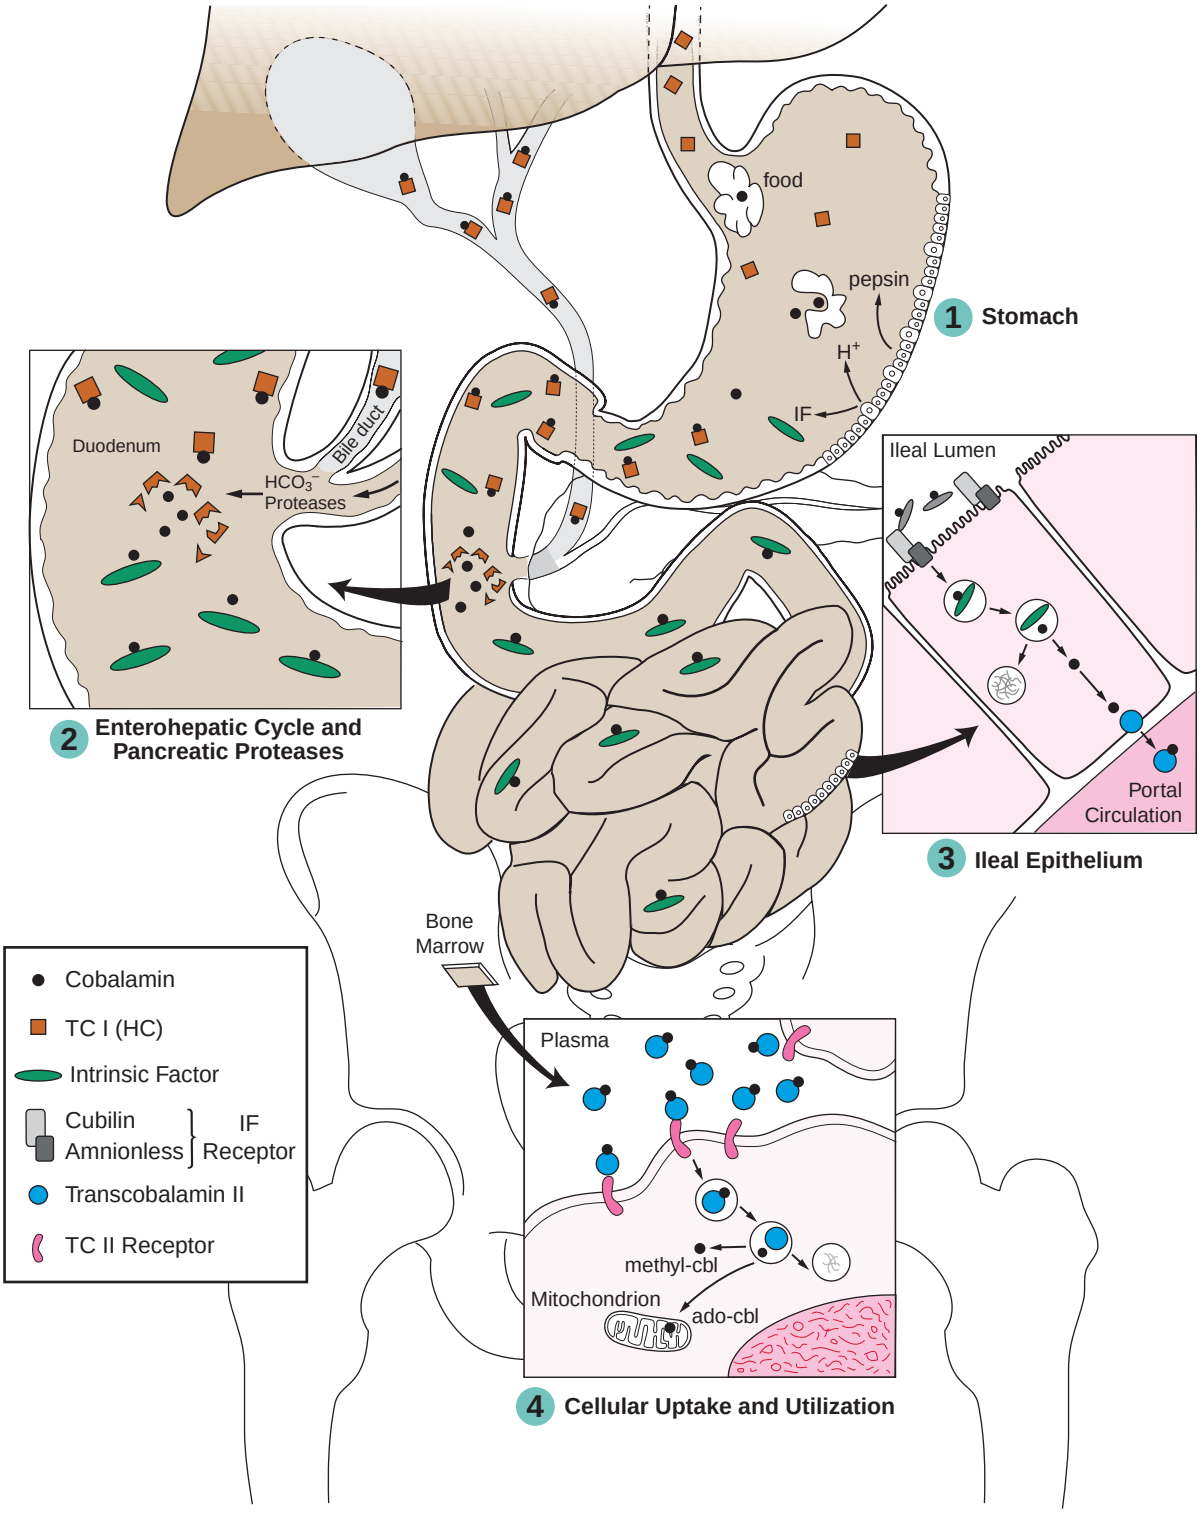

FIGURE 36.4. Assimilation and utilization of cobalamin. *ado-cbl*, 5′-deoxyadenosylcobalamin; *IF*, intrinsic factor; *methyl-cbl*, methylcobalamin; *TC I (HC)*, transcobalamin I (haptocorrin); *TC II*, transcobalamin II. (Modified from Carmel R. Cobalamin deficiency. In Carmel R, Jacobsen DW, eds. Homocysteine in health and disease. Cambridge, MA: Cambridge University Press, 2001:289–305, with permission.)

Holoprotein proportions can vary widely in some disorders, and the reason is not always known.[76,78] Desialylated TC I is cleared nonspecifically by hepatic receptors for asialoglycoproteins,[79] whereby some of its cobalamin is cleared in bile.

TC I concentrations in all secretions exceed plasma levels manyfold.[56] TC I carries nearly all the cobalamin in breast milk, salivary TC I is the first protein to bind ingested cobalamin, and biliary TC I is involved in enterohepatic recycling of cobalamin. These facts suggest that much of the TC I role lies outside the bloodstream. It is plausible to suggest that TC I, whose role is considered unknown, is the primary "withholder"of excess cobalamin and, perhaps more important, all analogs that are used by

TABLE 36.1

COBALAMIN-BINDING PROTEINS

	Intrinsic Factor	TC II (TC)	TC I (Haptocorrin)
Gene	*GIF* (chr. 11q13)	*TCN2* (chr. 22q12.2)	*TCN1* (chr. 11q11-q12.3)
Cbl-related role	Promotes ileal uptake	Promotes uptake by all cells	Sequesters Cbl and nonfunctional corrinoids, withholding them from cellular uptake; carries all Cbl in milk and bile and most Cbl in blood; initial acceptor of Cbl in stomach
Cbl binding	High affinity and specificity for Cbl; low affinity for corrinoid analogs	High affinity and specificity for Cbl; low affinity for corrinoid analogs	High affinity for Cbl; high affinity for corrinoid analogs
Cells of origin	Gastric parietal cell[a]	Endothelial cell; fibroblast; ?ileal cell; ?hepatocyte	Neutrophil; exocrine gland epithelial and ductal cells
Distribution in fluids	Gastric juice	Plasma, CSF, semen, amniotic fluid	Plasma, all exocrine secretions,[b] CSF, semen
Protein structure	48-kDa glycoprotein (15% carbohydrate)	43-kDa polypeptide	66-kDa glycoprotein (33–40% carbohydrate)
Receptors	Cubilin-amnionless complex ("cubam")	TC II receptor;[c] Megalin[d]	None identified[e]
Consequence of binder deficiency	Cbl malabsorption	Severe cellular Cbl deficiency	Low serum Cbl level without Cbl deficiency

Cbl, cobalamin; chr., chromosome; CSF, cerebrospinal fluid; TC, transcobalamin.
[a]Ectopic production of intrinsic factor by chief cells occurs in patients with gastritis.
[b]Secretions include saliva, breast milk, bronchial secretions, and tears.
[c]This specific receptor is ubiquitous and internalizes holo-TC II for cobalamin utilization. Its gene is TCblR/*CD320*.
[d]Multiligand receptor in proximal renal tubule, intestine, choroid plexus, type 2 pneumocyte, and yolk sac; renal role involves cobalamin salvage but roles elsewhere are uncertain. Its gene is *LRP2*.
[e]Desialylated TC I may undergo nonspecific clearance by asialoglycoprotein receptors in the liver.

the vast human microbiome in the gut and elsewhere, as well as withholding unusable analogs from human cells.[80] The subject requires careful study. Several minor cobalamin-binding proteins and complexes have also been described in plasma, but their roles are unknown.[56,79,81–83]

Cobalamin Absorption

Cobalamin is released from food by pepsin at an acid pH in the stomach and binds preferentially to salivary TC I rather than IF at this pH (Fig. 36.4, panel 1). Pancreatic secretions entering the duodenum neutralize the pH and provide proteases to degrade TC I.[84] The released cobalamin, including biliary cobalamin,[21] thus becomes available to IF (Fig. 36.4, panel 2).

The IF–cobalamin complex eventually attaches to the cubilin receptor for IF in the ileum (Fig. 36.4, panel 3). Cubilin is a 460-kDa glycoprotein whose 27 CUB domains provide binding sites for many other ligands, such as vitamin-D–binding protein, transferrin, immunoglobulin light chain, albumin, and apolipoprotein A1;[47] it also exists in yolk sac, renal proximal tubules, and elsewhere. Cubilin lacks a transmembrane domain but is anchored by amnionless, a 45-kDa transmembrane protein that provides cell signaling for the "cubam" receptor complex.[85–87] After endocytosis, the cubilin–IF–cobalamin complex is split, and cobalamin exits the ileal cell into the bloodstream several hours after its oral ingestion. Whether the exit is mediated by TC II or multidrug resistance protein-1[88] is unclear.

Plasma Transport and Cellular Utilization

Some of the portal blood holo-TC II is internalized by hepatocytes via TC II receptors.[21] The remainder finds its way to other tissues for calcium-dependent, TC II receptor-mediated cellular endocytosis[89,90] (Fig. 36.4, panel 4). After lysosomal degradation of the TC II, its cobalamin is released for attachment to cytoplasmic methionine synthase and conversion to methylcobalamin and to mitochondria for conversion to adenosylcobalamin.

Specific uptake of holo-TC II also occurs in yolk sac, gut, and especially in the proximal renal tubule by a second receptor, megalin, a 600-kDa glycoprotein member of the low-density lipoprotein receptor family.[47] As is cubilin, with which it sometimes co-localizes, megalin is a multiligand receptor, but it has a considerably greater clientele of ligands; these include additional vitamin-binding proteins (such as folate-binding protein and retinol-binding protein), several lipoproteins, carrier proteins (such as albumin, lactoferrin, and transthyretin), hormones, enzymes, hemoglobin, and myoglobin. Most information on megalin derives from studies in the proximal renal tubule, which is rich in the protein, and in knockout mice. Megalin prevents the urinary loss of many filtered proteins, and virtually completely reabsorbs the 1.5-μg cobalamin load in the holo-TC II that is filtered by the glomerulus daily.

Body Stores and Turnover

Cobalamin stores exceed daily requirement more than 1,000-fold. This contrast with the much smaller ratio for folate explains why cobalamin depletion takes years whereas folate depletion takes weeks to months. The total body content of cobalamin approximates 2.5 mg (2,500 μg) in adults[91] and only approximately 1 μg is lost daily. Some of the loss occurs by biliary excretion of 1.4 μg daily, but two thirds of that is reabsorbed via the IF mechanism.[21] If the IF mechanism fails, as in pernicious anemia, biliary reabsorption ceases. Urinary loss of cobalamin is minor because of reabsorption by megalin (however, if plasma cobalamin exceeds TC II capacity, as happens after cobalamin injection, the free cobalamin escapes renal reabsorption).

It bears mention that corrinoid analogs outnumber cobalamin 98-fold in the colon,[92] whereas they approximately equal cobalamin content in the plasma.[77] The extent of cobalamin conversion to analog in the body is unknown.

CLINICAL AND LABORATORY FEATURES

The hematologic consequences are identical in folate and cobalamin deficiency. So are many nonhematologic manifestations, with the notable exception of neurologic dysfunction. Some clinical variations reflect the ways in which the two deficiencies arise. Folate deficiency typically evolves rapidly, and it is often

associated with broad malnutrition and with alcohol abuse. In contrast, the evolution of cobalamin deficiency is usually measured in years, and it tends to be a purer deficiency state because malabsorption is often restricted to cobalamin alone.

Megaloblastic Anemia in Cobalamin and Folate Deficiency

Biochemistry

Deficiency of folate compromises the methylation of deoxyuridylate to deoxythymidylate (Fig. 36.2, reaction 2), and deficiency of cobalamin does so indirectly. However, impaired de novo thymidylate synthesis only partially explains megaloblastic anemia. Observations in nonanemic patients with cobalamin deficiency[93–95,96] and animal models[97] show that thymidylate synthase impairment alone need not lead to anemia. Other steps contribute.[98] The excess uracil from deoxyuridylate is misincorporated into DNA in place of thymine and active excision repair produces many single-strand breaks.[99] When excisions coincide at opposing DNA strand sites, double-stranded breaks result, which may explain the nuclear defects of megaloblastic anemia. The end result appears to be an arrest at various stages of interphase in hematopoietic precursors.[100] Even so, the details are incomplete and megaloblastic anemia is not restricted to cobalamin or folate deficiency.

Hematopathology

Megaloblastic anemia is a panmyelosis, even though its name suggests a disorder limited to red cells and erythroid hyperplasia is a prominent feature. Indeed, the immature appearance of megaloblastic nuclei and the occasionally intense myeloid proliferation in the marrow have led to a misdiagnosis of leukemia in rare cases. The morphologic hallmark is nuclear-cytoplasmic dissociation, which is best appreciated in precursor cells in the bone marrow aspirate (Fig. 36.5). Megaloblastic nuclei are larger than normoblastic nuclei, and their chromatin appears abnormally dispersed due to its retarded condensation. Random chromosomal abnormalities are seen, including centromere spreading,[101] but nonrandom changes may also occur.[102,103] Cytoplasmic maturation appears unremarkable.

Giant band cells and metamyelocytes with large and often misshapen nuclei are typical. Neutrophils with characteristic hypersegmented nuclei (Fig. 36.6) appear in the blood early in the course,[9,104] but they do not arise directly from the giant metamyelocytes.[98] The mechanism of hypersegmentation and why it persists in the blood for more than a week after therapy[105] are unknown. As megaloblastic anemia worsens, neutropenia and thrombocytopenia develop. These can be severe in advanced cases but are uncommon when anemia is mild.[45] Platelets are often functionally impaired,[106] although megakaryocytes do not show definable morphologic changes. The same may apply to lymphocytes.[107]
