ALK expression subdivides ALCL into at least 3 clinical subtypes of ALCL: 1) ALK-positive systemic ALCL, 2) ALK-negative systemic ALCL, and 3) primary cutaneous ALCL (also, ALK-negative). ALK-positive ALCL occurs at a younger median age (15 to 30 years) than ALK-negative (45 to 65 years), has a male predominance (male:female = 2–6:1), and usually has advanced stage disease with frequent B symptoms (40% to 75%) and extranodal involvement (50% to 80%).[258,312,313] Skin (21% to 35%) (Fig. 88.18), soft tissue (17%), and bone (8% to 17%) are common extranodal sites, while the gastrointestinal tract and central nervous system are rarely involved.[258] Bone marrow involvement in ALK-positive ALCL is identified in 10% to 15% with hematoxylin and eosin stains, but up to 30% if immunohistochemistry stains are used to identify isolated ALCL cells.[258,564]

ALK-positive ALCL is more chemosensitive than ALK-negative ALCL with CR rates >75% for ALK-positive and 50% to 75% in ALK-negative.[312,313,565,566] Better responses have resulted in a twofold or higher increase in survival for ALK-positive ALCL (60% to 93% at 5 years) compared to ALK-negative ALCL (15% to 46%) in retrospective series (Fig. 88.19).[3121,313,542,565,567–569] A worse prognosis can be seen in ALK-positive patients with B symptoms, a high IPI, small cell variant histology, and expression of CD56 or survivin (a member of the inhibitor of apoptosis family).[570,571]

A problem comparing ALK-positive ALCL to ALK-negative ALCL is the fact that the latter represents a heterogeneous group of diseases. Translocations affecting 6p25.3 which target *DUSP22* and/or *IFD4* have been identified in a subset of ALK-negative ALCL with predominant skin involvement.[572] ALK-negative ALCL may be considered as secondary ALCL when it follows mycosis fungoides, lymphomatoid papulosis, or HL.[258] Hodgkin-like ALCL is formally a provisional diagnosis of the WHO classification, but is probably a variant of HL.[573] ALK-negative ALCL can rarely be of B cell origin, either with an aggressive course or in the setting of AIDS.[258,573] Differences in gene expression may further define ALCL with overexpression of genes encoding signal transduction and underexpression of transcription factor genes in ALK-positive compared to ALK-negative ALCL.[574,575]

Primary cutaneous ALCL is another ALK-negative ALCL, is part of the spectrum of CD30+ cutaneous lymphoproliferative disease, and clinically overlaps with lymphomatoid papulosis (Chapter 92).[576,577] It usually arises in the skin in an older patient (median age ~60 years) as an isolated reddish-violet tumor, which may be ulcerated. Less commonly, it may present as multiple nodules in a circumscribed area, or rarely with disseminated skin lesions. Treatment of localized lesions may be watchful waiting (because approximately one-quarter of patients regress), local excision ± radiation, or radiation alone.[258,577] Combination chemotherapy may be warranted with widespread skin disease or localized skin disease with adjacent nodal involvement, but these patients tend to relapse.[577,578]

Two proteins provide unique therapeutic targets in ALCL. Brentuximab vedotin (SGN-35;Adcetris, Seattle Genetics, Botnell, WA) is an antibody-drug complex that combines an anti-CD30 antibody with the antimicrotubule agent, monomethylauristatin E. In a phase II trial in 58 patients with relapsed/refractory ALCL, the ORR was 86% with 57% CR. The median duration of objective response was 12.6 months for all patients and 13.2 months for CR patients. Crizotinib (PR-02341066; Xalkori, Pfizer, San Diego, CA)

The aggressive peripheral T cell lymphomas: 2012 update on diagnosis, risk stratification, and management. Am J Hematol 2012;87:511–519, with permission.

is an oral small-molecule inhibitor of ALK tyrosine kinase that was first used in non-small cell lung cancer with a rearrangement involving *ALK* in 2% of cases. A phase I trial reported 7 CRs in 8 relapsed pediatric ALK-positive ALCL.[579] A subsequent report confirmed CRs in adults.[580] Both agents are being incorporated into phase III trials.[581]

Nodal Peripheral T Cell Lymphoma

Problems in management of PTCL include the fact that, unlike B cell NHL, cell size does not correlate with prognosis, and there is sparse data regarding the impact of cytogenetics on diagnosis other than ALK expression in ALCL. The IPI does correlate with prognosis in PTCL-not otherwise specified (NOS), but only the low-risk (0,1) has prolonged survival over 45%.[346,5676,568,582] A new prognostic model has added bone marrow involvement to some of the IPI factors (age, PS LDH).[307] Elevated levels of serological markers, nm23-H1 (involved in regulation of metastasis), IL-2 receptor, and soluble CD44 may enhance the IPI.[583]

PTCL-NOS represented the largest group (29.5%) in the international T cell Lymphoma Project.[582] The median age was 60 years with a male predominance. Most patients presented with nodal disease (87%) and had advanced stage (69%); extranodal involvement occurred in 49%. The 5-year OS was 32% and FFS was 20%.

Tumor-specific features under evaluation to assess prognosis include expression of cytotoxic molecules, Ki-67, TP53, chemokine receptors, and gene profiles.[584] Cytotoxic molecules (CM), TIA-1, and granzyme B in PTCL-NOS, are associated with B symptoms, a higher IPI, an inferior CR rate, and a worse overall survival when compared to a CM-negative group.[585] The proliferation-associated antigen, Ki67, was additive to IPI factors (age, PS, LDH) in a series of PTCL-NOS.[586] Immunohistochemistry detection of TP53 overexpression was detected in a minority (29%) of nodal PTCL cases; was associated with Ki-67, BCL-2, and P-glycoprotein; and was a better predictor of poor survival than IPI.[328] Preliminary data indicate chemokine receptor expression that distinguishes subsets of T helper cells, Th_1 and Th_2, and correlates with histology and prognosis.[587]

Gene expression profiles are under investigation as a method to subdivide PTCL.[588] Three molecular profiles have been identified in PTCL-NOS: 1) Overexpression of genes with an aggressive course, including *CYCLIN D2; 2*) genes involved in T cell activation and apoptosis, *NFKB1* and *BCL-2*; and 3) overexpression of genes in the interferon γ/JAK/STAT pathway.[589] Another study reported that reduced expression of *NF-κB* pathway genes had an inferior survival to those with increased NF-κB expression.[590] Two different profiles, a large group corresponding to activated $CD4^+$ cells and a smaller group of $CD8^+$ cells, also subdivided PTCL-NOS.[591]

AILT is difficult to diagnose and treat because there may be the presence of both B and T clones, as well as EBV; and it has a variable clinical course with autoimmune features.[543,592,593,594] AITL was the second most common type (18.5%) in the IPTL usually occurs in the elderly (median age, 57 to 68 years) as a systemic disease with diffuse adenopathy (84% to 100%), B symptoms (52% to 86%), a pruritic rash (38% to 58%), arthritis (16% to 18%), eosinophilia (32% to 50%), and immunologic abnormalities (Coombs' positive hemolytic anemia [32% to 75%], cold agglutinins, cryoglobulinemia, polyclonal hypergammaglobulinemia [50% to 83%], antinuclear antibodies and rheumatoid factors). Most patients have extranodal disease and are advanced stage (68% to 94%).

There is clonal evolution over time in AILT and EBV may participate in lymphomagenesis.[595] The cell of origin is a T-follicular helper cell (TFH); and there is cytoplasmic expression of the cytokine CXCL13.[596] TCR gene rearrangements occur early in the course of AILT, indicating a clonal T cell population. Nearly all patients have EBV-positive B cells and approximately one-third have also had IG gene rearrangements.[597]As with post-transplant lymphoproliferation but unlike other NHL, unrelated or oligoclonal clones are commonly found in AILT. The most common cytogenetic abnormalities are trisomy 3, trisomy 5, and an additional X chromosome, but patients who develop complex aberrant clones and structural abnormalities in the short arm of chromosome 1 progress rapidly.[598] EBV can be identified in both B cells and T cells of AILT, and it may participate in the occasional B-immunoblastic lymphoma as well as the more common PTCL.[592,597,599] Gene expression profile found overexpression of genes characteristic of TFH cells and genes deregulating vascular endothelial growth factor.[600,601]

AILT may spontaneously regress in up to 10% of patients; and it can respond to single agents, including steroids, cyclosporine, methotrexate, interferon, nucleoside analogs, bortezomib denileukin diftitox, and rituximab. Combination chemotherapy is usually warranted once a diagnosis is made with a CR rate of 50% to 70% following anthracycline-based therapy, but patients have frequent and early relapses or deaths due to infections, with 5-year survival at 10% to 30%.[543,593]

Extranodal T Cell and Natural Killer-Cell Lymphomas

Hepatosplenic γ/δ T cell lymphoma (HSTL) was first described in 1990 as an aggressive illness with B symptoms and organomegaly in young adult males.[602,603] Up to 20% of HSTLs arise in patients with solid organ transplants and Crohn disease.[541] The median age is 25 to 35 years with a male/female ratio of 9:1. Patients have splenomegaly (98%), hepatomegaly (80%), minimal to no lymphadenopathy, anemia (84%) and severe thrombocytopenia (85%).[233,604] The bone marrow is involved in 72% of patients and erythrophagocytosis may occur.[604] Isochrome 7q, often associated with trisomy 8, is a common cytogenetic abnormality.[605] Most patients are refractory to anthracycline-based therapy or have brief responses and have a median survival less than 1 year.[233,549,604] There is an α/β variant with similar features and prognosis.[606] A similar gene expression profile involving genes implicated in cytotoxic T and NK cell function is present in both γ/δ and α/β variants.[607]

Subcutaneous panniculitis-like T cell lymphoma (SPTL) presents with subcutaneous nodules, usually on the extremities, and is often associated with systemic symptoms and erythrophagocytosis.[608–610] The 2008 WHO classification recognizes only the $\alpha\beta$ subtype as SPTL and distinguishes it from cutaneous $\gamma\delta$T cell lymphoma, which may have a panniculitis-like presentation.[611] The $\alpha\beta$ subtype occurs at a younger median age (36 years) with a female predominance. The skin lesions tend to be self-healing subcutaneous plaques and nodules without ulceration. Disseminated disease and hemophagocytosis (17%) are rare. These patients may be controlled with single agent steroids and/or methotrexate and have a 5-year OS of 82%.[611] The $\gamma\delta$type occurs in an older population (median age, 59 years) with a roughly equal male:female ratio. Skin lesions may involve the epidermis and ulcerate. B symptoms, nodal disease, and hemophagocytosis are associated with a poor prognosis and a 5-year OS of 11% despite combination chemotherapy.[611]

Enteropathy-associated T cell lymphoma (EATL) has an association with celiac disease but has occurred without it as well.[612–616] There are two types of EATL.[616] Type 1 has a large cell or pleomorphic cytology, has chromosome 9q31.3 gain or 16q12.1 deletion, is associated with the HLA-DQ2 haplotype, is strongly associated with celiac disease, and is common in Europe. Type 2 is characterized by monomorphic cells often with CD56 expression, has chromosome 8q24 gain and less commonly 1q and 5q gains, is less associated with sprue, and is found in Asia. The median age is 50 to 64 years and males predominate in most series.[614,615] Abdominal pain and weight loss occur in over four-fifths of patients at presentation followed by diarrhea or vomiting in one-third of patients.[614] Small bowel obstruction or perforation is common, and the diagnosis of EATL is usually made at laparotomy. Prognosis is poor, with median survival of 7.5 months and 1 year failure-free survival less than 20%.[614–616]

Nasal and nasal-type NK/T lymphomas are characterized by angiocentric and angiodestructive proliferation;large granular lymphocyte morphology; $CD2^+$, $CD3^-$, $CD16^{-/+}$, $CD56^+$, $CD57^-$ phenotype; and an aggressive course.[617,618] Only 10% express surface CD3+ and have clonal TCR rearrangement and have a similar course.[618] EBV is consistently detected in tumor cells and elevated levels of EBV DNA in tumor tissue or serum have correlated with a poor prognosis.[619,620] NK neoplasms are prevalent in Asia and Latin America. Nasal NK/T lymphoma may present with facial swelling or midfacial destruction and was formerly called lethal midline granuloma or polymorphic reticulosis. The disease occurs more commonly in males with a median age of 50 to 55 years.[617,618]

Nasal NK/T lymphoma is localized stage I/II in 80% of patients at diagnosis but can disseminate early to skin, gastrointestinal tract, testis, orbit, and CNS (Fig. 88.20). Although radiation alone can achieve CR in two-thirds of localized disease, local relapse occurs in half the patients and disseminated disease develops in one-quarter of patients.[617] Combined modality with early radiation and chemotherapy is recommended. Patients with disease confined to the nasal cavity, larynx, pharynx, or oral cavity had 54% 5-year survival compared to 20% ($P = 0.0068$) with more advanced disease.[621]

Nasal-type NK/T cell lymphoma is essentially disseminated nasal disease without obvious nasal involvement.[622] Only one-fifth of patients have stage I disease.[622] Despite anthracycline therapy, median survival is less than 1 year. L-asparaginase has been shown to be effective as a single agent in patients who failed CHOP.[623] Because of high expression in P-glycoprotein, regimens containing multidrug resistant-independent agents, such

FIGURE 88.20. Nasal NK/T lymphoma: Patient presented with facial edema, proptosis, and dysconjugate gaze (A) and an ulcerated lesion in the hard palate (B).

as SMILE (steroids, methotrexate, ifosfamide, L-asparaginase, etoposide) have been formulated to treat nasal-type NK/T cell lymphoma.[624] Patients with cutaneous only involvement have a better survival.[625] A disseminated, leukemic form is usually fatal within weeks.[626]

Mature T Cell and Natural Killer-Cell Leukemias

The differential diagnosis of CLL in Chapter 90 includes the mature T/NK leukemias. Large granular lymphocyte (LGL) leukemia was associated with chronic neutropenia in 1977, recognized as a clonal disorder in 1985, and classified into T ($CD3^+$) and NK (CD3-) types in 1993(Fig. 88.21A).[204,627,628] The median age is 55 to 60 years, and there is an association with rheumatoid arthritis (20%) and autoimmune features.[204,629] Lymphocytosis is usually between 2 and 20 $\times$ 10^9/L and mild splenomegaly (25% to 50%) may be present, but the usual clinical presentation is neutropenia or anemia. Recurrent infections are usually respiratory or mucocutaneous and occur in 15% to 56% of patients.[204] Pure red cell aplasia, autoimmune hemolytic anemia, aplastic anemia, ITP, and MDS may occur in LGL leukemia. LGL cells express high levels of both FAS and FAS ligand, but the cells are resistant to FAS-mediated death due to STAT 3 activation which upregulates an antiapoptotic protein.[629,630] LGL leukemia is an indolent disease with median survival over 10 years.[204] Immunosuppressant drugs which have been used in LGL leukemia include methotrexate, cyclosporine, prednisone, cyclophosphamide, nucleoside analogs, and alemtuzumab.[204,627,631,632]

Aggressive NK leukemia is a rare disorder more common in Asia, is associated with EBV, and represents the leukemic phase of nasal-type NK lymphoma (Fig. 88.21B).[633–635] Patients are young (median age, 30 to 40 years) with slight male predominance and present with a fulminant illness characterized by B symptoms, diffuse adenopathy, organomegaly, and circulating LGL cells which can have a blastic appearance.[634,635] Patients are chemoresistant and have a median survival of less than 3 months.[634,635] Another neoplasm of possible NK cell lineage is myeloid/NK cell precursor acute leukemia.[636,637] Blastic plasmacytoid dendritic cell neoplasm, formerly mislabeled as $CD4^+$/$CD56^+$ hematodermic neoplasm or blastic NK cell lymphoma, has a predilection for cutaneous involvement and probably should receive therapy for acute myeloid leukemia.[638]

T-prolymphocytic leukemia (T-PLL) represents approximately 2% of small lymphocytic leukemia in adults (Fig. 88.21C).[639,640,641] Median age is 57 to 69 years and the male:female ratio is 1.5:1.[642,643] Patients usually have a marked lymphocytosis (>100 $\times$ 10^9/L in 75% of patients), splenomegaly (73%) and lymphadenopathy (53%); and approximately 20% of patients have

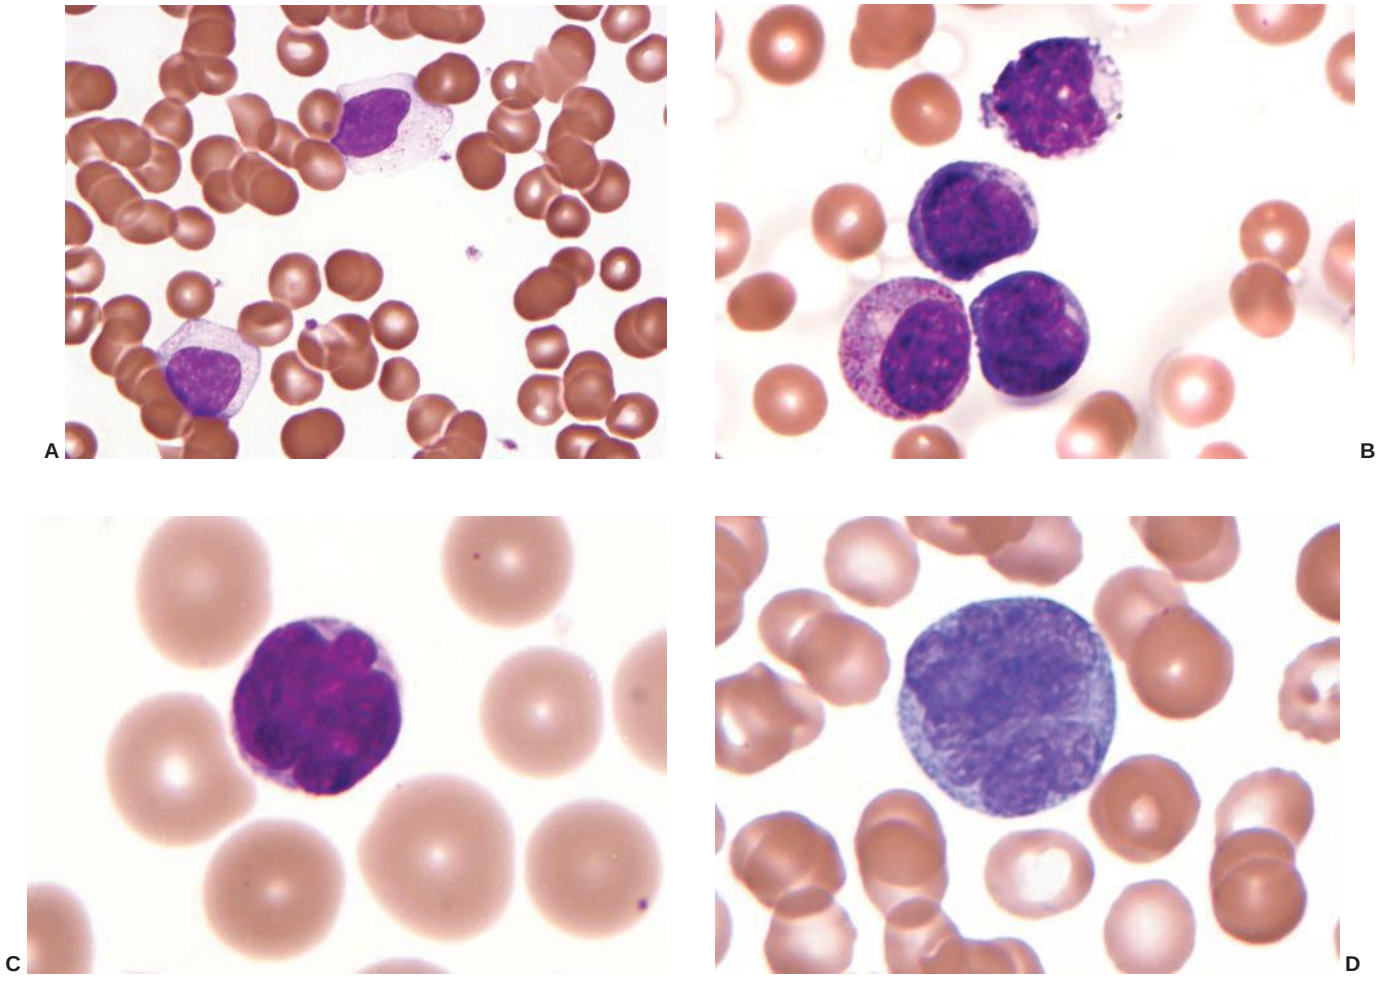

FIGURE 88.21. Mature T/NK leukemias: **A:** T cell large granular lymphocytic leukemia: The lymphocytes are enlarged with dense nuclear chromatin and abundant cytoplasm with fine azurophilic granules. **B:** Natural killer/T cell leukemia: Three leukemic cells and one myelocyte are present. The leukemia cells have blastic, fine nuclear chromatin with irregular nuclei and basophilic cytoplasm. Some cases may show cytoplasmic granules. **C:** T cell prolymphocytic leukemia: The lymphocyte has clumped nuclear chromatin with irregular nuclear contours, sometimes referred to as "knobby cells." Nucleoli may be inconspicuous, in contrast to B cell prolymphocytic leukemia, which has prominent nucleoli. **D:** Abnormal T lymphocyte in the peripheral blood of a patient with adult T cell leukemia. The cell is enlarged with a multilobated nucleus. These "flower cells" are usually easily found with this disorder. Images provided by Dr. Dan Arber, Stanford University, Palo Alto, CA.

skin infiltration.[639,640,642] Cell morphology is variable; the nuclei are irregular, include a "knobby" variant, and usually have prominent nucleoli; cytoplasmic protrusions are characteristic. Sixty per cent of patients are $CD4^+/CD8^-$; 25% coexpress $CD4^+/CD8^+$; and 15% are $CD4^-/CD8^+$ [639,640,642].

The most common cytogenetic abnormality occurring in 80% of patients is an inversion of chromosome 14 with break points in q11 and q32; 10% have a reciprocal translocation t(14;14)(q11;q32).[639,644] These translocations juxtapose the locus of the TCR α/β gene with the TCL1 and TCL1b genes at 14q32.[645] Deletions at 11q23, the locus for the ATM gene, and at 12p13, and abnormalities of chromosome 8 are other common cytogenetic findings in T-PLL.[639,646]

Response rates in T-PLL are 10% to 48% with few complete remissions utilizing chemotherapy, including CHOP or nucleoside analogs.[642,643] Median survival is usually 1 year although up to one-third of patients can have an indolent phase.[642,643,647]Alemtuzumab (Campath 1H) is the most active single agent in T-PLL with a 74% and 91% response rate in previously treated and untreated patients, respectively.[641,648] Preliminary data suggest the best survival occurs in patients treated with intravenous alemtuzumab followed by an allogeneic HCT. Nucleoside analogs, particularly pentostatin, can be effective in slow responders.[641]

The clinical course of ATL, which follows infection by HTLV1, is variable and takes 4 basic forms: 1) acute (leukemic) (60%), 2) lymphoma (20%), 3) chronic (20%), and 4) smoldering (5%). The male to female ratio is 1.3–2.2:1, and the median age is 47 to 65 years.[59] The acute form is characterized by lymphadenopathy, organomegaly, skin lesions, elevated white count with multilobed lymphocytes, often referred to as "cloverleaf" or "flower" cells (Fig. 88.21D), hypercalcemia, elevated lactate dehydrogenase (LDH) level, and usually a rapidly fatal course. The cutaneous lesions have a diverse appearance, including papules, nodules, plaques, tumors, and ulcers. Histologically, dermal invasion predominates, although the lesions of ATL may resemble primary cutaneous T cell lymphoma with epidermotropism and Pautrier's microabscesses. Anemia and thrombocytopenia are infrequent findings because of a low degree of marrow infiltration. Central nervous system involvement may develop in as many as 10% of patients with ATL.[649]

Lymphoma is distinguished by prominent adenopathy without significant peripheral blood involvement. Primary extranodal lymphoma occurs in approximately 5% of lymphomatous presentations and has involved skin, Waldeyer's ring, gastrointestinal tract, sinuses, and pleura.[650] The chronic type is associated with an increased white blood cell count and occasionally with slight adenopathy and organomegaly. Patients with smoldering ATL have few ATL cells (0.5% to 3%) in the peripheral blood, and may have skin lesions as well as slight adenopathy, organomegaly, and marrow infiltration. Chronic and/or smoldering ATL may evolve into an acute form after many years of indolent disease.[651]

No consistent cytogenetic abnormality has been identified in ATL. The most common abnormalities are gains at chromosomes 14q, 7q, and 3p and losses at 6q and 13q.[652,653] Aneuploidy, multiple chromosomal breaks, and loss of tumor suppressor genes are associated with an aggressive course.[653,654]

Despite combination chemotherapy, which can yield brief and low responses, median survivals in the acute and lymphomatous forms of ATL are usually less than 1 year.[59,655,656,657] Chemotherapy with a complex regimen, the LSG15 protocol, is marginally superior to CHOP and has higher response rates in the lymphoma form compared to acute.[658] Overexpression of *MDR* (*ABCB1*) and *TP53* contribute to chemoresistance.[659,660] Poor performance status, high LDH, age above 40 years, tumor bulk, and hypercalcemia are adverse prognostic factors.[655] The chronic and smoldering forms have a longer survival rate regardless of therapy. The major causes of death in ATL are opportunistic pulmonary infections and progressive disease, often in association with hypercalcemia.[661,662]

Because of its chemoresistance and its HTLV-1 viral leukemogenesis, ATL has been a unique disease for investigating therapy. Interferon α (IFN) plus zidovudine (AZT) has had a higher response rate (67% to 92%) than chemotherapy regimens in ATLL.[663] The current recommendation is to first initiate antiviral therapy for the acute, chronic, and smoldering forms.[657] Others advocate debulking with chemotherapy followed by antiviral therapy or concomitant treatment, particularly for the lymphoma form. NF-κB inhibition has been proposed as a therapeutic target in ATL. Arsenic trioxide synergizes with IFN, has been shown to shut down the NF-κB pathway, and has been effective in phase II trials.[664] Conjugated and unconjugated monoclonal antibodies directed at the IL-2 receptor (CD25), CD52 (alemtuzumab), chemokine receptor 4(KW-0761), and CD2 (Siplizumab) have activity in ATL and are being evaluated in conjunction with other therapy.

Allogeneic hematopoietic cell transplantation (alloHCT) was first reported as a curative option in ATL in 1996. Although the median survival with alloHCT (9.9 months in a review of 586 patients) does not appear superior to other therapy, the 3-year estimated overall survival of 36% suggests HCT may offer the best chance for long-term survival.[665]

Despite the new therapies under investigation in ATL, the ultimate goal is prevention of the disease. Avoiding breast-feeding in mothers infected with HTLV-1 can reduce infection in the newborn by 80%.[59] Other proposed methods to prevent ATL are antiretroviral therapy and a TAX-targeted vaccine.

THERAPY FOR LOCALIZED LARGE CELL LYMPHOMA

Localized disease is defined by either stage I or II disease which is nonbulky (no tumor mass $\geq$ 10 cm; no mediastinal mass $>$ one-third the chest diameter). Radiation therapy alone has resulted in 20% to 85% cure rates for limited stage large cell lymphomas, with the best results in patients who have stage I disease after undergoing pathologic staging.[18,666] With clinical staging, cure rates with radiation alone have usually been less than 50%; therefore, most investigators are advocating chemotherapy, usually CHOP-type regimens, often followed by radiation, with cure rates of 70% to 90%.[667] Using a stage-modified IPI for localized disease, patients with no adverse risk factors (stage I, age $\leq$60, $<$2 performance status, normal LDH) have cure rates exceeding 90%.[668]

Clinical trials have addressed the issue of chemotherapy versus combined modality therapy in limited stage large cell lymphoma.[669] In a SWOG study, patients with localized intermediate- or high-grade NHL were randomized to 3 cycles of CHOP followed by involved field radiation therapy (4,000 to 5,500 cGy) versus 8 cycles of CHOP.[670] Better PFS (77% versus 64%, $P = 0.03$) and OS (82% versus 72%, $P = 0.02$) were observed in the combined modality arm and there was a trend toward increased toxicity, particularly cardiac, in the chemotherapy-only arm.[670] A subsequent follow-up report, however, indicates no difference in survival between the two arms.[671] Other concerns of the SWOG study are that 8 cycles of CHOP is probably excessive for localized disease and that radiation will contribute to the risk of long-term toxicities.

An ECOG trial compared low-dose (30 Gy) radiotherapy (RT) with observation in limited stage aggressive lymphoma patients who had achieved CR after CHOP times 8 cycles, and assessed the impact of higher dose (40 Gy) RT in patients in PR.[672] The DFS at 6 years was significantly greater for CR patients who received RT (76% vs. 56%, $P = 0.05$), but there was no improvement in overall survival. Patients who received RT rarely relapsed in previously irradiated sites. PR patients had a 63% FFS at 6 years, indicating

a role for the addition of RT. The efficacy of adding rituximab to CHOP chemotherapy followed by IFRT was evaluated in a SWOG study. The 4-year PFS and OS were 88% and 92%, respectively.[673]

Other randomized trials in children, as well as adults, have shown no benefit to combined modality over chemotherapy alone in limited stage patients.[674,675] A GELA trial compared 4 cycles of CHOP plus RT to 4 cycles of CHOP alone in patients over 60 years of age and found no difference in EFS or OS.[675] Another GELA randomized trial compared an intensive regimen of ACVBP (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone) to 3 cycles of CHOP followed by involved field RT for patients less than 60 years of age with limited stage disease. Although there was more toxicity in the ACVBP arm, there was superiority in both EFS (82% vs. 74%, $P< 0.001$) and 0S (90% vs. 81%, $P = 0.001$) for the intensive regimen over the CHOP plus RT.[676] The major improvement for ACVBP was in the patients with bulky stage II disease.

Thus, although short course chemotherapy (3 to 4 cycles) followed by RT is an accepted treatment for adults with localized large cell NHL, there is data to support chemotherapy alone for many patients. There may be more local relapses when RT is not used, but there are no differences in survival and there is likely to be fewer long-term toxicities with chemotherapy alone. A potential role for RT could be in patients who have a positive interim or postchemotherapy FDG-PET scan.[669] In a series of 59 patients (83% with stage I/II disease), the 3-year PFS for patients with negative scans receiving chemotherapy alone ($n = 39$) and with positive scans receiving consolidative involved field RT ($n = 20$) were 97% and 90%, respectively.[677]

CHEMOTHERAPY

In the early 1970s, DeVita introduced a combination chemotherapy regimen, C-MOPP (cyclophosphamide replacing mechlorethamine, vincristine, procarbazine, and prednisone), which produced a CR rate in excess of 40% in patients with diffuse "histiocytic" lymphoma, a neoplasm generally equivalent to DLCL; approximately one-third of these patients were cured.[678,679] By the middle 1970s, doxorubicin had been added to cyclophosphamide, vincristine, and prednisone to produce the CHOP regimen, which produced CR rates of 50% to 60% and DFS of 30% to 40%.[680,681] CHOP is the most extensively studied and used regimen in the therapy of large cell lymphoma. The addition of rituximab has improved response and survival.[682] Clinical observations have been that rapid achievement of a CR was associated with a good prognosis[680,683] and that relapses after 2 years of DFS were rare. Further follow-up for large cell lymphoma, however, recorded relapses in 6% to 22% of patients after 2 years of CR.[683,684]

Subsequent regimens were developed in part on the concepts of Goldie and Coldman, who proposed that tumors develop drug resistance by spontaneous mutation soon after exposure to chemotherapy;and of Hryniuk and Bush, who proposed that increasing dose intensity could overcome drug resistance.[342,685–692] The CR rates of third-generation regimens were 78% to 88% with DFS of 58% to 69% in studies primarily at single institutions.[686,692–695] Many of these newer regimens had considerable toxicity when used initially, and were associated with mortality rates of 5% to 10%; however, the rate of toxic deaths decreased over time with more experience and with better patient selection.[684] Many of the series in which these regimens were used involved favorable prognostic groups, including patients with limited stage disease and patients with a relatively young median age.

One of the most important clinical trials for lymphoma was performed by an intergroup (SWOG and ECOG) study which compared CHOP with 3 of the newer and reportedly more intensive regimens, m-BACOD (methotrexate, bleomycin, Adriamycin [doxorubicin], cyclophosphamide, Oncovin [vincristine], and dexamethasone), MACOP-B (methotrexate, bleomycin, Adriamycin, cyclophosphamide, Oncovin, and prednisone), and ProMACE-CytaBOM (prednisone, Matulane, Adriamycin, cyclophosphamide, etoposide/cytarabine, bleomycin, Oncovin, methotrexate).[696] There were no differences in CR, PFS, or OS. The percentage of patients alive without progression at 3 years was 41% in the CHOP and MACOP-B groups and 46% in the m-BACOD and ProMACE-CytaBOM groups (Fig. 88.22). The estimated OS was 52% of the entire group: 50% for both ProMACE-CytaBOM and MACOP-B, 52% for m-BACOD, and 54% for CHOP ($P = 0.90$). There were also no differences in fatal toxicities among the regimens: CHOP (1%), ProMACE-CytaBOM (3%), m-BACOD (5%), and MACOP-B (6%)($P = 0.09$).

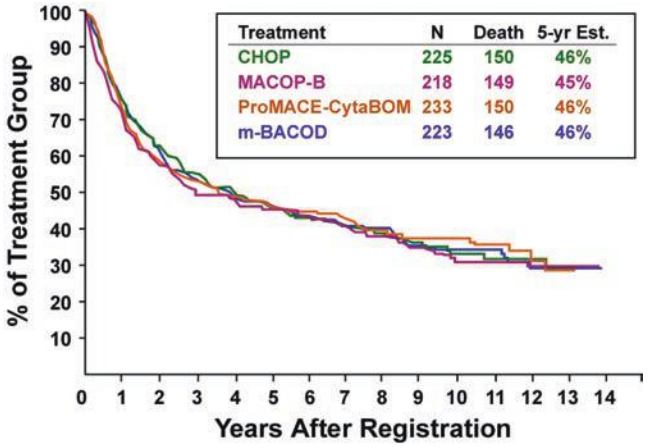

FIGURE 88.22. Intergroup study comparing CHOP, M-BACOD, and ProMACE/CytaBOM in predominantly intermediate grade Working Formulation (WF) lymphomas. There were no differences observed in time to treatment failure in the four groups. Updated and adapted from Fisher RI, Gaynor ER, Dahlberg S, et al. Comparison of a standard regimen (CHOP) with three intensive chemotherapy regimens for advanced non-Hodgkin's lymphoma. N Engl J Med 1993;328:1002–1006, with permission.

While the intergroup study reestablished CHOP as standard therapy for large cell lymphoma, it did not address the issue of dose intensity, and it did not emphasize how poorly these regimens do in patients with adverse prognostic factors. Although the newer regimens supposedly were more dose intensive than CHOP, there are few differences among the regimens with respect to the doses of the most active agents used (i.e., cyclophosphamide and doxorubicin). Although no differences were identified among the regimens in patients with adverse prognostic factors, none of them produced good results. Using these conventional regimens, CR rates of 55% and 44% and 5-year survivals of 43% and 26% were observed in the high-intermediate and high-risk groups, respectively, in the IPI (see section on Prognostic Factors).[283,697]

The intergroup trial was met with praise as well as disappointment because it indicated no improvement in survival for nearly two decades after the establishment of CHOP as an effective regimen. The first study to show an improvement in survival was a randomized GELA comparison of CHOP to rituximab plus CHOP (R-CHOP) in elderly patients (age 60 to 80 years) with DLBCL.[299] The rate of CR/CRu was higher for R-CHOP compared to CHOP alone (75% versus 63%, $P = 0.005$). The 5-year EFS and OS were significantly higher in the R-CHOP arm: 47% versus 29%, $P< 0.001$; and 58% versus 45%, $P = 0.007$.[299,698] The results have held up at 10 years (Fig. 88.23).[699] A similar intergroup trial reported a 3-year FFS of 53% for R-CHOP and 46% for CHOP ($P = 0.04$).[700] A second randomization evaluated the role of maintenance rituximab (MR) and resulted in a 2-year FFS of 76% for MR compared to 61% for observation ($P = 0.009$); however, the major improvement was observed in patients who had not

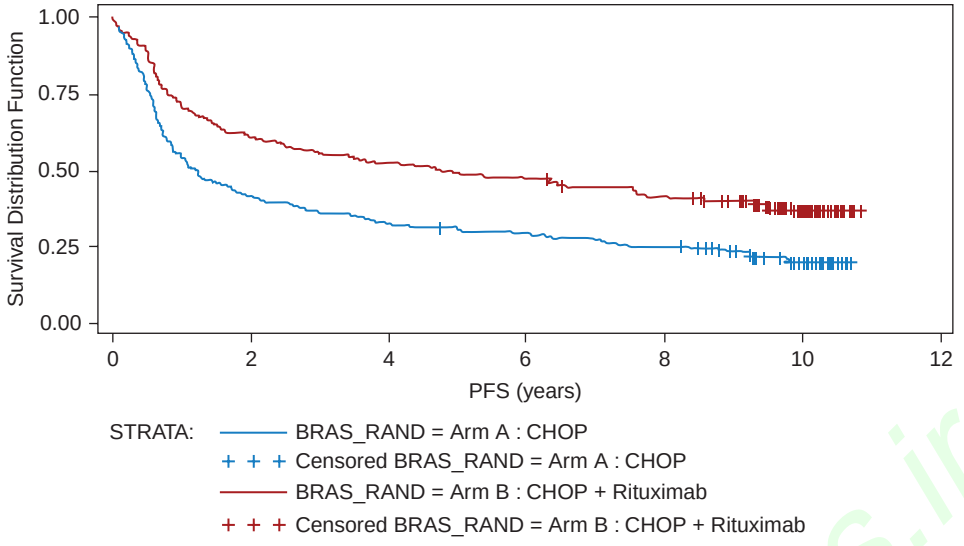

FIGURE 88.23. Progression-free survival (PFS) in elderly patients randomized between CHOP plus rituximab (R-CHOP) and CHOP. The 10-year PFS (median) was 36.5% (4.8 years, 95% CI: 23.7 to 7.6) for R-CHOP versus 20% (1.2 years, 95% CI: 9–1.8) for CHOP ($P < 0.0001$). From Coiffier B, Thieblemont C, Van Den Neste E, et al. Long-term outcome of patients in the LNH-98.5 trial, the first randomized study comparing rituximab-CHOP to standard CHOP chemotherapy in DLBCL patients: a study by the Groupe d'Etudes des Lymphomes de l'Adulte. Blood 2010;116:2040–2045, with permission.

received rituximab with CHOP. The 2-year FFS after the second randomization for the 4 arms were: 77%, 79%, 74%, and 45% for R-CHOP, R-CHOP plus MR, CHOP+MR, and CHOP, respectively. Randomized trials in young patients have shown a superiority to the rituximab arm: 79% versus 59% 3-year EFS ($P < 0.0001$).[701] The addition of rituximab to CHOP may partially overcome the adverse prognosis associated with the nongerminal center (ABC) DLBCL.[702] New prognostic models evaluating biologic markers and/or gene expression are under investigation in the rituximab era, although reproducibility remains a concern.[326,703]

Strategies to improve response and survival in aggressive lymphomas have included using alternating non–cross-resistant regimens, infusional therapy, additional drugs, shorter intervals, modifiers of multidrug resistant genes, and dose intensification, including HCT. Phase II trials of non–cross-resistant regimens such as alternating triple therapy from M.D. Anderson, appeared to overcome adverse prognostic factors, but they were not compared to CHOP in phase III trials.[704,705] Similarly a continuous infusional regimen, EPOCH with dose adjustments (DA-EPOCH) based on an individual's drug clearance, had a CR rate in large B cell NHL of 92%, a 5-year PFS and OS of 70% and 73%, respectively, and overcame the IPI.[536] Other phase II trials evaluating infusional therapy with or without modifiers of MDR (verapamil and quinine) have not shown an advantage over historical trials utilizing CHOP therapy.[706] An intergroup trial is now comparing DA-EPOCH-R to R-CHOP.

German trials have evaluated whether biweekly CHOP (CHOP-14) with or without etoposide (CHOEP) was more effective than the same regimens given on a 21-day cycle. For elderly patients, aged 61 to 75 years, CHOP-14 was superior to CHOP-21 with 43.8% and 53.3% 5-year EFS and OS compared to 32.5% and 40.6%; and the CHOEP regimens were too toxic.[707] Alternatively, for younger patients, aged 18 to 60 years, the CHOEP regimen had better CR (87.6% versus 79.4%, $P = 0.003$) and 5-year EFS (69.2% versus 57.6%; $P = 0.004$) than CHOP.[708] There was no statistical advantage of CHOEP-14 over CHOEP-21. These trials were performed without rituximab which, if added, might lessen differences among the regimens. Randomized trials in the United Kingdom and France have compared R-CHOP 14 to R-CHOP 21 and have shown no differences in responses or survivals.[709,710]

Dose escalation has been advocated as a means to improve response and survival in aggressive lymphomas, but phase III clinical trials have yet to prove the efficacy of dose intensity. Increased doses of doxorubicin in the BACOP regimen failed to show improvement in response or survival when compared in a randomized trial to standard doses.[711] In a small trial of 22 patients treated with high-dose CHOP, the CR rate was 86% with 69% PFS but short follow-up (median of 20 months).[712] In a trial of 70 patients with intermediate- to high-grade lymphoma, a short course (8 weeks), dose intensive therapy, referred to as MEGA, produced an 81% CR rate and 52% 5-year FFS.[713] Another phase II trial evaluating double dose ProMACE-CytaBOM with growth factor support reported a CR of 69%, PFS of 58%, and OS at 73% at 4 years.[714] A dose-escalated trial known as MegaCHOEP with stem cell transplantation on the third and fourth cycles resulted in FFTF of 62.1% and OS of 67.2% at 5 years.[715]

In a phase III trial (LNH87-1) that compared a more intensive regimen, ACVBP (Adriamycin [doxorubicin], cyclophosphamide, vindesine, bleomycin, prednisone) to a standard regimen (m-BACOD) in a group of low-risk aggressive lymphoma patients, there were no differences in FFS and OS (65% and 75% in ACVBP, and 61% and 73% in m-BACOD).[716] In a multivariate analysis, ACVBP was associated with a better FFS in the patients with 2 or 3 age-adjusted IPI risk factors.[716] In another randomized trial, ACVBP was superior to CHOP plus RT for limited stage patients.[676] ACVBP plus rituximab was also superior to R-CHOP in DLBCL patients <60 years with an IPI of 1. Three year EFS was 81% vs. 67% ($P = 0.0035$) and OS was 92% vs. 84% ($P = 0.0071$). Serious adverse events, particularly febrile neutropenia, were more common in R-ACVBP (42%) than in R-CHOP (15%).[717]

Some investigators advocate early autologous HCT for selected DLBCL patients with poor prognostic factors, but large randomized trials have failed to consistently show a benefit for early transplantation.[718,719,720–723] R-CHOP is the standard regimen for DLBCL for adults in the United States. European trials and pediatric studies, however, have indicated a role for more intensive therapy based upon an increasing number of adverse features.[715,716,724] And it is likely that there are patients with such poor survival at diagnosis who should be considered for either dose intensification or early transplantation. Ongoing trials continue to address the issues of dose intensity and transplantation as front-line therapy for aggressive NHL.[725,726]

SALVAGE CHEMOTHERAPY

Chemotherapy regimens at relapse usually involve agents that are non–cross-resistant with, or at least different from, drugs used in initial therapy. Rituximab is usually added to the regimen as long as the lymphoma remains CD20-positive. For example, ifosfamide, an alkylating agent analog, produced a 29% response rate in phase II trials,[727] and has been incorporated into salvage regimens. Investigators at MDACC have developed multiple effective protocols: MIME (methylguazone, ifosfamide, methotrexate, etoposide [VP-16]),[728] DHAP (dexamethasone, high-dose cytarabine [ara-C], and cisplatin [Platinol]),[729] ESHAP (etoposide, solumedrol [methylprednisone], high-dose cytarabine [ara-C], Platinol [cisplatin]),[730] MINE (mesna, ifosfamide, Novantrone [mitoxantrone], etoposide),[731] and MINT (mesna, ifosfamide, Novantrone [mitoxantrone], Taxol [paclitaxel]).[732] The CR and PR rates for a variety of histologic types were 24% and 36% for MIME; 31% and 24% for DHAP; 37% and 27% for etoposide, solumedrol (methylprednisolone), and high-dose cytarabine (ara-C) with or without cisplatin; and 26% and 20% for MINT. However, most of the responses were of short duration with median times to treatment failure usually less than 1 year. Combining regimens such as MINT-ESHAP or MINE-ESHAP has yielded response rates in the 49% to 69% range, but there are no obvious differences in outcome among the combinations.[733,734]

Various doses and schedules of ICE (ifosfamide, carboplatinum, etoposide) have been used in relapsed NHL and to mobilize peripheral blood stem cells prior to transplant.[735,736] The response rate to an ICE regimen developed at Memorial Sloan-Kettering Cancer Center was 66%, with 89% of these patients going on to transplantation.[735] Patients who achieved a CR to ICE prior to transplantation had a superior OS to patients who had PR (65% versus 30%, $P = 0.003$).[735] The addition of rituximab to an ICE regimen improved the CR rate from 27% on a previous study to 53%.[737]

A phase III trial, the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL) study, randomized R-ICE versus R-DHAP in patients with refractory or relapsed $CD20^+$ DLBCL and found similar response rates (63.5% vs. 62.8%).[738] Responding patients failed to mobilize after both regimens and only 50% of patients were able to undergo SCT. There was no difference in 3-year EFS (26% and 35%) or OS (47% and 51%) between the 2 regimens. EFS was adversely affected by initial relapse within 1 year from diagnosis, aaIPI of 2 to 3, and prior rituximab treatment.

Based on the premise that prolonged exposure to therapy may be more effective than bolus, EPOCH was developed at the NCI and produced a 24% CR and 50% PR in relapsed/refractory NHL.[739] With a median follow-up of 76 months, the OS and EFS were 17.5 and 7 months, respectively. In patients with chemosensitive disease with aggressive histologies, the EFS was 19% at 3 years[739] (see section on "DA-EPOCH-R in Chemotherapy"). Investigators at Stanford University developed CEPP(B) (cyclophosphamide, etoposide, procarbazine, prednisone ± bleomycin), which produced 34% CR and 22% PR in previously treated patients with intermediate- or high-grade histologies.[740]

In general, salvage chemotherapy regimens in DLBCL are utilized as a bridge to transplantations because prolonged survivals without transplant are less than 15%. Single agent therapy is rarely used in intermediate- to high-grade lymphoma except in phase I/II trials or as palliation. Because of significant activity in relapsed disease, some of the agents are being used in combination with other drugs earlier in the course of NHL.

Oxaliplatin, a third-generation platinum drug with no renal toxicity and minimal auditory damage, has a 40% response rate in refractory NHL and is used in salvage regimens.[741] Rituximab, dexamethasone, cytarabine, and oxaliplatin (R-DHAX) had an ORR of 75% (57% CR/CRu) in relapsed NHL, primarily DLBCL and FL.[742] Combining gemcitabine with oxaliplatin and rituximab (GEMOX-R) led to an ORR of 43% with 34% CR in refractory/relapsing DLBCL.[743] Both regimens could be used in elderly patients and the best survivals were in patients who were able to go to transplant.

Doxorubicin-related compounds used as single agents and in combination chemotherapy for relapsed NHL include mitoxantrone,[734] amsacrine,[744] idarubicin,[745] epirubicin,[746] aclacinomycin,[747] esorubicin,[748] liposomal doxorubicin,[749] and pixantrone.[750] No drug has had an advantage over doxorubicin, although mitoxantrone produces less alopecia, mucositis, nausea, emesis, and possibly cardiotoxicity. Liposomal doxorubicin also appears to have less cardiotoxicity. CHOP was superior to CNOP (cyclophosphamide, mitoxantrone, vincristine, prednisone) in a randomized trial in elderly patients;[751] however, an argument has been made that the study did not compare equivalent doses of doxorubicin and mitoxantrone.[734] A salvage regimen utilizing mitoxantrone, carboplatin, cytosine arabinoside, and methylprednisolone had a response rate of 70% (26% CR).[752]

Nucleoside analogs have primarily been used in indolent lymphomas, but gemcitabine, a pyrimidine antimetabolite, has had activity in relapsed aggressive lymphomas (see section on "GEMOX"). A response rate of 20% was observed in predominantly large B cell NHL, and higher responses have been observed in PTCL.[753,754] The ORRs in gemcitabine combination regimens with cisplatin and methylprednisolone, and with vinorelbine, have been 79% (21% CR) and 50% (14% CR), respectively.[755,756] The ORR of cisplatin, etoposide, gemcitabine, and methylprednisolone (PEGS) in PTCL was 39% (24% CR/CRu) with 2-year OS of 30% and PFS of 12%.[553] The authors concluded that PEGS was not clearly superior to results for CHOP likely because of the inherent chemoresistance of PTCL, but PEGS could serve as a comparison for non-CHOP regimens in PTCL.

Vinca alkaloids with less neurotoxicity than vincristine have also been evaluated in NHL. Vincristine sulfate liposomes injection had a 25% ORR (5% CR/CRu) in refractory aggressive NHL with twice the dose intensity of standard vincristine.[757] Infusional vinorelbine resulted in 25% response with a median PFS of 6 months in responders.[758] Novel methods of drug delivery including liposomal formulations, pegylation, different schedules of infusions, and oral formulations may also obtain responses in relapsed NHL.[757,759,760]

Taxanes and camptothecins are agents with activity in solid tumors which are being evaluated in the therapy of NHL. Paclitaxel (Taxol) and docetaxel (Taxotere) are tubulin-binding taxanes which have produced responses in 13% to 23% of heavily treated patients.[761–764] Camptothecins, topoisomerase I inhibitors, including hycamptamine (Topotecan), irinotecan (Camptosar), and 9-aminocamptothecin (9-AC) have had responses of 25% to 35%.[765,766] Combinations of paclitaxel plus hycamptamine are synergistic, with a response rate of 48% and a median duration of 6 months.[767]

Bortezomib is a proteasome inhibitor that has shown activity in lymphoma, and response rates vary according to histologic subtypes.[768–770] The best response rates (33% to 56%) have been reported in MCL, the only type of NHL for which bortezomib is approved. Bortezomib plus CHOP-R is in trials for previously untreated DLBCL and MCL and appears to overcome the poor prognosis of nongerminal DLBCL, possibly through inhibition of the NF-KB pathway.[494,769–771]

Understanding mechanisms of drug resistance is an area of investigation for the development of salvage regimens. Although the multidrug resistance (*MDR/ABCB1*) gene and its gene product, P-glycoprotein, are expressed rarely in lymphomas at diagnosis, MDR expression often is detected in lymphoma cells at relapse. The MDR-inhibiting agents include verapamil, cyclosporine, and its analog valspodar (PSC-833), and their use in conjunction with chemotherapy has been inconsistent in patients with relapsed lymphomas.[772,773]

NOVEL AGENTS

Relapse due to chemoresistance remains a major obstacle in improving survival for NHL. Targeting B and T cell receptors with monoclonal antibodies, both unconjugated and conjugated, is an ongoing area of investigation (see section on "Immunotherapy"). The PI3K/AKT/mTOR signaling pathway is critical in cancer development, and aberrant activation of the protein tyrosine kinases has led to the development of novel targeted therapy. Drugs under investigation target protein kinases, oncogenic signaling via the mammalian target of rapamycin complex (mTOR), and the tumor microenvironment (immune modulation) (Fig. 88.24).[774,775,776]

B cell receptor (BCR) signaling can lead to activation of spleen tyrosine kinase (SYK) in B cell lymphomas. Fostamatinib, an oral SYK inhibitor, abrogates BCR signaling, inhibits MYC overexpression, and induces apoptosis. In a phase I/II trial of relapsed B-NHL (n = 68), the ORRs were: 22% for DLBCL, 10% for FL, 55% for SLL/CLL, and 11% for MCL.[777] Side effects included fatigue (41%), diarrhea (41%), cytopenias (24% to 31%), and hypertension (24%).

Ibrutinib (PCI-32765) is an oral, irreversible inhibitor of Bruton tyrosine kinase (BTK) just downstream of SYK; and it inhibits the subsequent pathways, including MAPK, PI3K, and NF-κB signaling.[778] In 26 elderly (median age, 71 years) CLL patients, 73% achieved a response (65% PR and 8% CR) and an additional 12% had a nodal response with lymphocytosis.[779] One year PFS was 93%. Diarrhea, nausea, and fatigue were common (grade $\leq$2) side effects; 10% of patients had > grade 3 cytopenias or infections. In a phase IA study of 56 patients with relapsed B-NHL, the ORR was 62%, including 29% for DLBCL and 78% for MCL.[780]

CAL-101 (GS-1101) is an oral selective inhibitor of PI3K-δ and is active in CLL and other B cell NHL with little toxicity and minimal myelosuppression. In a phase I trial of 55 patients with relapsed B-NHL, PRs occurred in 62% for both indolent NHl and MCL but none in DLBCL.[781] Because CAL-101 inhibits microenvironment signals which can cause drug resistance and enhances cytotoxic agents, it is being investigated in combination regimens.[782] In 18 patients who received CAL-101 with rituximab or bendamustine, the ORRs were 91% in indolent B-NHL (n = 11) and 71% in CLL.[783]

Enzastaurin is an oral inhibitor of protein kinase C beta (PKCβ), an essential component of the vascular endothelial growth factor (VEGF) signaling pathway, which has been linked to a poor prognosis in DLBCL.[784] In a phase II trial of 55 patients with relapsed/refractory DLBCL, 7% had a CR,22% experienced FFP for $\geq$ 2 cycles, and 15% had FFP for $\geq$ 4 cycles.[785] Toxicities were minimal with 4% grade 3 and there was no grade 3 or 4 neutropenia. In a randomized phase II trial of R-CHOP plus enzastaurin versus R-CHOP in high-intermediate or high IPI DLBCL, the CR rates were 36% vs. 26% and the 1 year PFS was 71% vs. 52% with similar toxicity profiles.[786]

Rapamycin and the rapalogs (temsirolimus, everolimus, and deforolimus) are inhibitors of mTOR kinase, a mediator of growth signaling that follows the PI3K pathway and is activated by mutation or amplification of AKT (protein kinase B).[774,787] Temsirolimus has yielded ORR of 22% to 41% in MCL.[787] In a phase III trial comparing temsirolimus to investigator's choice of therapy in relapsed/refractory MCL, the objective RR was higher for temsirolimus (22% vs. 2%) (P = 0.0019); and there was no statistical difference in median OS (12.8 vs. 9.7 months).[788] The grade 3/4 toxicities were thrombocytopenia (59%), anemia (20%), neutropenia (15%), and asthenia (13%). In a phase II trial of everolimus for relapsed B-NHL, the ORR was 30% with no differences among DLBCL (30%), MCL (32%), and FL (38%).[789]

Immunomodulating drugs (IMiDs) have both immunomodulatory and antiangiogenic properties; they can stimulate T cell responses and dendritic cells to recruit natural killer cells and modify the cytokine microenvironment.[774] Lenalidomide, an analog of thalidomide, has been extensively evaluated in CLL. Responses of 31%to 47% were observed in relapsed patients and 58% to 65% in previously untreated CLL.[790] A tumor flare response (painful enlargement of nodes or spleen, fever, and rash) occurs in over half the patients in several series and may be lessened by slow dose escalation and the use of steroids.[790,791] Tumor lysis may occur in up to 5% of CLL patients treated with lenalidomide.[790]

Lenalidomide monotherapy has also been used in aggressive lymphomas. An ORR of 35% (12% CR/CRu) was observed in 49 relapsed/refractory B-NHL, including 19% for DLBCL and 53% for MCL.[792] Grade 4 cytopenias were 8.2%. In an international phase II trial, the ORR was similarly 35% (13% CR): 28% for DLBCL, 42% for MCL, 42% for FL-grade 3, and 45% for transformed lymphoma.[793] The PFS was 3.7 months and the median duration of response for responders was 10.6 months. Grade 4 neutropenia and thrombocytopenia occurred in 17% and 6%, respectively. A higher response and improved survival with lenalidomide has been reported for the nongerminal center DLBCL compared to the germinal center type.[794] An ORR of 30% has been reported in PTCL.[795]

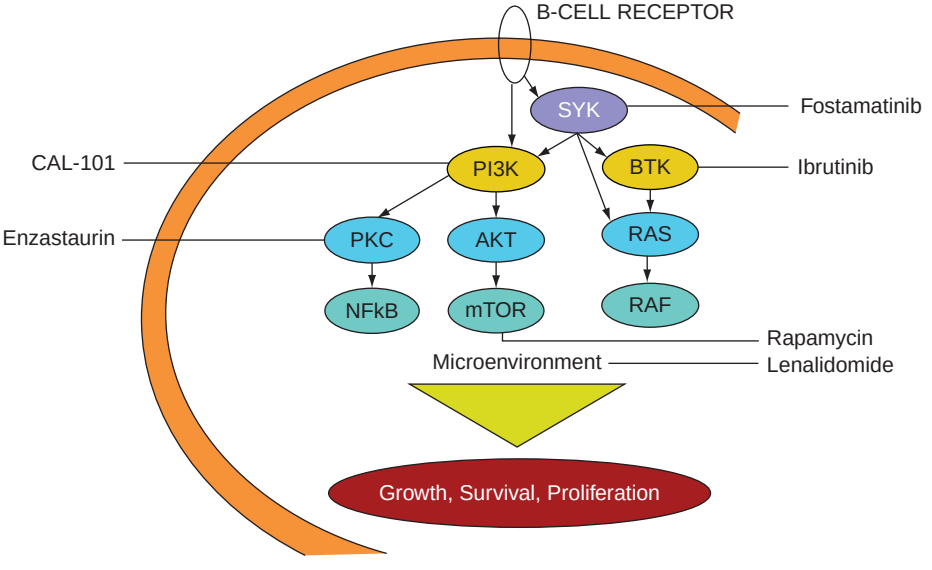

FIGURE 88.24. Targeting B cells: This simplified schematic illustrates relationships between intermediates (see text) in the PI3K/AKT/mTOR pathway and shows points at which selected drugs inhibit B cell growth.

All of the above agents and many more are being investigated in combinations with each other, monoclonal antibodies, and chemotherapy. Trials should be designed with specific targets, preclinical evidence of synergism, and an awareness of the expense.

HIGHLY AGGRESSIVE LYMPHOMAS

BL and lymphoblastic lymphoma (LBL), usually of immature T cell origin, are rare NHLs in adults, each representing less than 3% of NHLs. Since NHL is more common in adults; the absolute number of highly aggressive lymphomas exceeds that in children. Because children are treated primarily on clinical trials unlike adults, at least in the United States, the main advances learned from pediatrics apply to the therapy of highly aggressive lymphoma in adults (Chapter 89). In brief, short course, dose intensive cyclophosphamide therapy is utilized in BL while therapy for ALL is the main approach to LBL. Both types of highly aggressive NHL require CNS prophylaxis, and have clinical overlap with adult ALL (Chapter 74).

Burkitt Lymphoma

BL has a bimodal peak between 0 and 15 years and a later peak over 60 years.[796] SEER data indicates the median age is as high as 45 years with 30% over 60 years of age.[797]

BL is characterized by a high proliferative rate (Ki67 approaching 100%), a germinal center phenotype expressing CD10 and BCL6 and weak BCL2, and a *MYC*/8q24 translocation.[798] B cell lymphoma unclassified with features intermediate between DLBCL and BL (BLU) tend to have slightly deviant morphology and not quite as high a proliferative rate as BL. *MYC* translocations occur in 30% to 50% of BLU, but there are usually more complex genetic abnormalities than BL, including "double hits" where there are *BCL2* translocations or breakpoints in *BCL6*.[515]

GEP is emerging as a technology to distinguish lymphomas with an intermediate morphology between DLBCL and BL. BL can be distinguished from DLBCL by a high level of *MYC* target genes, a subgroup of germinal center B genes, and a low level of expression of major-histocompatibility complex Class I genes and NF-κB target genes.[799] Until GEP becomes more available, detecting *MYC* translocations by fluorescence in situ hybridization along with a high proliferative index can usually distinguish BL from DLBCL.[800]

In the United States, BL tends to occur in younger adults with more gastrointestinal presentations and less marrow involvement than BLU;but they clinically overlap, have a risk for spontaneous tumor lysis, and have been difficult to cure with conventional chemotherapy for adults. Intraabdominal presentations usually involve the small bowel and intraabdominal nodes and may mimic appendicitis or intussusception.[801] Surgery formerly played a role in staging and debulking disease, but now is reserved for the emergency acute abdomen. Early use of rasburicase and nephrology intervention should be considered in patients with elevated levels of LDH and uric acid. Bone marrow and CNS involvement have been reported in 30% to 38% and 13% to 17% of patients, respectively.[801]

Short course, dose intensive regimens have improved results in BL/mature B-ALL.[727,802–809,810,811,812,813–815] Results vary in part due to differences in age, stage, number of HIV-positive patients, and intensity of therapy (Table 88.14). In general, the CR rates are in the range of greater than 80% and survival is approximately 50% for the older adult and in the range of 60% to 90% for young adults. CNS prophylaxis previously involved whole brain and occasionally spinal radiation, but can be accomplished by a combination of intravenous and intrathecal drugs (methotrexate and/or cytarabine). Radiation may still be utilized in patients who have documented CNS disease at diagnosis. Growth factors, either G- or GM-CSF, have decreased the length of myelosuppression and are a part of present-day regimens. Rituximab is incorporated into the regimens and appears to have improved outcome, but there are no comparative trials.[810] Relapses are usually confined to the first year after stopping therapy; there is no role for maintenance.

In pediatric and some adult trials, there is a prephase with low-dose cyclophosphamide- vincristinesteroids to debulk and to lessen tumor lysis, followed by intensive therapy stratified according to prognostic factors.[803] Prephases are probably unnecessary in most patients, particularly with the use of rasburicase. Patients with limited stage disease often require only 2 to 3 cycles of therapy delivered over 2.5 to 4 months.[816] In a retrospective review of adults treated with the pediatric LMB protocols, the CR rate was 89% with a 3-year OS of 74%.[803] The Magrath regimen of CODOX-m/IVAC has been administered to both children and adults and also utilizes risk stratification. The initial reports had a 4-year DFS of 84% but were in a young population with a median age of 25 years.[727] Selected older patients are now given the more intensive regimens but tend to have more treatment-related deaths unless modifications are made.[817]

Intensity of therapy in HIV patients with NHL was previously reduced due to risk of infections and poor survival; however, in the era of HAART and growth factor support, the CR rate with hyper-CVAD in HIV patients with BL/leukemia has reached 92% with a 2-year survival of 48%.[818] Myelosuppression can still be problematic in HIV patients and dose modifications may be required. There is a randomized trial indicating that rituximab does not improve survival if given with chemotherapy in HIV-related NHL.[819] The lack of improvement in the rituximab arm was attributed to increased infectious deaths in HIV patients with CD4(+) counts less than 50/mm^3. Rituximab with concurrent infusional EPOCH achieved a high rate of complete response. At a median follow-up of 5 years the PFS and OS were 84% and 68%, respectively.[820] DA-EPOCH-R is also being used in non-HIV BL/BUL and may be particularly warranted in the elderly due to less toxicity.[815]

Advanced stage patients with CNS or marrow involvement previously had survival less than 30% and were considered candidates for early transplantation;[821] however, with the present-day regimens, DFS is in the 40% to 80% range for BL/B-ALL, obviating the need for early transplantation in most adult patients.[822] At relapse, there is no standard therapy, and there is no clear advantage of allogeneic HCT over autologous, even though many centers favor the former.[823] Transplantation is rarely successful for relapsed patients unless they are chemosensitive and in a second CR (see Chapter 104).

Lymphoblastic Lymphoma

T cell LBL is more common than B-LBL in adults, accounting for up to 90% of cases. T-LBL is seen primarily in adolescents and young adults with a predominance of men (2 to 3:1) who have a bimodal distribution (peaks at age 10 to 30 and 60 to 70 years).[824] T-LBL presents with a mediastinal mass in 60% to 70% of cases.[825] B cell LBL has a slight male predominance, a more even age distribution (median age ~39 years), and rarely has mediastinal or bone marrow involvement. Extranodal sites of disease are common in B-LBL and include skin, bone, and soft tissue.[826,827]

The immature T cell origin of LBL was confirmed by the presence of the intranuclear enzyme, terminal deoxynucleotidyl transferase (TdT), which is not detected in the mature or peripheral T cell neoplasms. Although LBL expresses less TdT and tends to have a more mature phenotype than T-ALL, considerable overlap exists both biologically and clinically between these entities, and they are unified as precursor T cell lymphoblastic leukemia/lymphoma by the WHO classification.[828]

Multiple genes have been identified in the translocations associated with T-LBL/ALL. Approximately one-third of patients with T-LBL have translocations involving the loci of T cell receptor

genes, α and δ at 14q11.2, β at 7q35, and γ at 7p14-5, which produce high levels of transcription factor genes such as *HOX11/TLX1*, *TAL1/SCL, TAL2*, and *LYL*. GEP can subdivide T-LBL into subtypes with differing prognoses.[829–831] Patients with *HOX11* have a pattern of gene expression associated with the early cortical thymocyte and have a better prognosis than patients with TAL1 or LYL1 expression, which correlate with late cortical and early pro-T lymphocytes, respectively.[832] NOTCH1 is a transmembrane receptor and activating mutations occur in 50% to 60% of patients with childhood T-ALL.[833,834] FBXW7 is a ubiquitin ligase that triggers ubiquitination and degradation by the proteasome. Inactivating mutations *FBXW7* have been reported in 11% to 13% of patients. *NOTCH1* and *FBXW7* mutational status together identify a favorable group of lymphoblastic lymphoma.[835] Rarely, T-LBL is associated with eosinophilia, myeloid malignancy, specific cytogenetic translocations t(8;13) (p11;q12), t(8;9)(p11;q32), or t(6;8)(q27;p11), and is known as 8p11 myeloproliferative disorder.[836] Unusual cases of T cell LBL have been associated with prior epipodophyllotoxin chemotherapy and a cytogenetic translocation involving the *MLL* gene, t(11;19)(q23;p23).[837]

Because LBL is rare in adults, only a few series have addressed therapy and some patients have received early transplantation, which compromises the assessment of the impact of chemotherapy.[458] Studies in the 1980s indicated a CR rate of 53% to 95% using CHOP-like induction regimens and high CNS relapse (~40%) if CNS prophylaxis was not given.[838–840]Using predominantly ALL-like regimens with a maintenance phase lasting 12 to 36 months results in 3- to 5-year survivals of 40% to 72%.[838–840] Poor prognostic features included age (> 30 years), bone marrow involvement, elevated white-cell count (>50 $\times$ 10^9/L), CNS disease, elevated LDH, and slow response.[839,840] Coleman reported a 5-year survival of 94% in low-risk patients compared to 19% (P< 0.001) with high-risk features, defined by bone marrow or CNS disease or elevated LDH (>1.5 $\times$ normal).[840] Short course, dose intensive regimens without maintenance have been tried in lymphoblastic lymphoma, but the relapses appear excessive and the numbers are too small to utilize this approach.[841]

Controversial management issues for LBL include the optimal type of CNS prophylaxis, the role of radiation to the mediastinum, the type of maintenance therapy, and the role of transplantation. With present-day ALL regimens, the CR rates are 75% to 90%, with prolonged DFS of 40% to 70% of responders (Table 88.15).[842–853] An option to consider for young adults is to utilize pediatric-based protocols which have had better EFS when compared to adult ALL protocols.[854] A retrospective analysis comparing patients irradiated to those not irradiated showed less mediastinal relapse but no difference in FFP or OS.[855] In the era of intensive ALL regimens, however, routine mediastinal radiation is no longer used in pediatrics and is probably not warranted in most adults. PET imaging may assess residual mediastinal disease, but it has not been well studied in LBL. Because of poor survival with chemotherapy in high-risk patients, there may be a role for early transplantation.[851]

The most significant predictor of survival for patients undergoing HCT is the status of the disease at the time of transplant.[853,856–859] The European Bone Marrow Transplantation Group retrospectively reviewed their experience in 214 patients with LBL who underwent autologous transplantation with 6-year DFS varying according to disease status: 63% in first CR, 31% in second CR, and 15% with resistant disease.[853] Trials that evaluate HCT often fail to include intent to treat analysis and result in a bias favoring the transplant arm. In a randomized trial comparing early autologous HCT to conventional chemotherapy,[858] there was a trend favoring autoHCT (55% versus 24%, P = 0.065) but there was no improvement in OS.[858] Only two-thirds of patients eligible for randomization were actually randomized.

The role of allogeneic transplant in LBL in first CR is even more controversial. In an International Bone Marrow Transplant Registry retrospective review of transplants for LBL, there were fewer relapses with allogeneic HCT compared to autologous HCT, but there was no survival advantage due to higher treatment-related mortality.[859] Recent randomized trials in adult ALL, some of which include LBL, however, are favoring the allogeneic arm.[860,861]

Novel agents are being studied in relapsed LBL. Nelarabine, an analog of AraG, had an ORR of 55% in pediatric patients with T-ALL/LBL in first relapse and 27% in second relapse.[862] An ORR of 46% (36% CR) was reported for adults with relapsed/refractory T-ALL/LBL.[863] Clofarabine, a nucleoside analog that

inhibits ribonucleotide reductase, had an ORR of 30% (24% CR) in relapsed pediatric ALL and 17% in adult ALL.[864] Clofarabine combined with cyclophosphamide and/or etoposide had a 31% CR rate in adults with relapsed ALL/LBL, but had 23% treatment-related deaths.[865] The prevalent *NOTCH1* mutations in T-ALL are targets for inhibition, and mutations of *NUP214-ABL1*, an activated tyrosine kinase in episomal DNA, present in 6% of T-ALL, may respond to tyrosine kinase inhibitors.[866]

MANAGEMENT OF EXTRANODAL LYMPHOMAS

Approximately one-third of NHLs arise from sites other than nodes, spleen, or bone marrow, and have occurred in almost every organ.[867] There is geographic and ethnic variation for sites and types of extranodal lymphomas.[868] The gastrointestinal tract accounts for up to one-third of extranodal NHL in the Western hemisphere.[867,869] If Waldeyer's ring and tonsils are included, head and neck localizations are the second most common site, accounting for one-fifth of cases. SEER data reports stomach, skin, intestine, and brain to be the most common sites of extranodal disease.[35] The sites of extranodal lymphoma reflect the homing mechanisms of lymphocytes and may depend upon antigen-driven lymphoproliferation. Management of extranodal lymphomas does not necessarily follow that of their nodal counterparts.[870]

Site(s) of involvement and histologic type are both important factors in the management of extranodal lymphomas (Table 88.16). It is important to determine whether the disease is localized or disseminated. The Ann Arbor staging system has been used with stage IE, representing localized extranodal lymphoma, and IIE, representing extranodal lymphoma with involvement of adjacent lymph nodes; a subclassification of IIE, which separates involvement into contiguous nodes (II_1E) and noncontiguous nodes (II_2E), has been used in gastric lymphomas; stages III and IV in extranodal lymphomas represent disseminated disease with little advantage in distinguishing the 2 stages. Extranodal lymphomas of the gastrointestinal tract, nasopharynx, and testes are generally more aggressive than those of the lung, orbit, or salivary gland. Therapy, however, depends not only on the site, but also on the histologic characteristics, immunophenotype, epidemiologic factors, size, and stage of the lymphoma.

The stomach accounts for approximately one-half of the gastrointestinal lymphomas; 60% of gastric lymphomas are aggressive, usually DLBCL, sometimes in conjunction with low grade histology, and 40% are indolent, usually of the MALT type. The

TABLE 88.16

MANAGEMENT ISSUES FOR EXTRANODAL LYMPHOMAS

Site	Usual Pathology	Clinical Associations	Suggested Therapy[a]
Stomach	B cell MALToma	*Helicobacter pylori*	Antibiotic trial, serial endoscopy; other therapy if t(11;18), t(1;14), transformation or progressive disease
Intestine Ileum Immunoproliferative small intestinal disease Enteropathy-associated T cell lymphoma	Burkitt B cell MALToma Peripheral T cell lymphoma	Obstruction Malabsorption IgA heavy chain, Middle East Celiac disease, West Obstruction	High-dose cyclophosphamide combination chemotherapy ±surgery Antibiotics, steroids, ± combination chemotherapy Combination chemotherapy ± surgery; nutrition
Waldeyer's ring	Large B cell	Other gastrointestinal disease	Combination chemotherapy or combined modality
Paranasal (sinus)	Large B cell	CNS disease	Combined modality, consider CNS prophylaxis
Nasal	Natural killer/T cell lymphoma	Epstein-Barr virus; angiocentric features, Asia	Combined modality, consider CNS prophylaxis
Salivary gland	B cell MALToma	Sjögren syndrome	Single agent and/or radiation
Thyroid	Large B cell, B cell MALToma	Hashimoto thyroiditis	Radiation or combined modality, depending on histology and stage
Lung	Small B cell, B cell MALToma		Single agent, surgery, or radiation
Orbital	Small B cell, B cell MALTtoma		Radiation
Primary CNS	Large B cell	Ocular involvement Leptomeningeal disease AIDS	Steroids, high-dose methotrexate ± radiation
Testis	Large B cell	Contralateral testicular disease, CNS disease, retroperitoneal spread	Orchiectomy, combination chemotherapy, radiation to contralateral testis, CNS prophylaxis
Breast	Large B cell	Pregnancy	Combination chemotherapy ± radiation
Ovary	Burkitt Large B cell	Bilateral disease	Combination chemotherapy
Bone	Large B cell		Combination chemotherapy ± radiation
Cutaneous	Mycosis Fungoides B cell MALTomas, primary cutaneous follicular lymphoma, primary cutaneous large B cell lymphoma		Skin-directed Radiation if stage IE Combined modality (see Chapter 92)

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; MALToma, lymphoma of mucosa-associated lymphoid tissue.

[a]Combined modality refers to combination chemotherapy and radiation. Combination chemotherapy refers to doxorubicin-based therapy. Rituximab is added to therapy of most B cell (CD20+) lymphomas.

recognition of MALTomas has led to unique therapeutic options. MALTomas were previously called pseudolymphomas, but the latter term is no longer valid because MALTomas are monoclonal, can be associated with a higher grade histology, and have cytogenetic abnormalities.[107–110,871] Clinically, MALTomas are different from other indolent lymphomas in that they tend to remain localized, rarely disseminate, and respond favorably to local therapy.[871,872]

Management of gastric MALToma changed when antibiotic therapy for *H. pylori* resulted in regression of lymphoma.[873–877] Ultrasound endoscopy and biopsies assist in determining the extent of disease and depth of invasion, which correlate with spread to regional lymph nodes and response to antibiotics.[878] CR rates to antibiotics are over 80% when disease is confined to the mucosa and submucosa.[876] Antibiotics are also curative in over half the patients with *H. pylori* associated gastric large B cell lymphoma, with either a mixed marginal zone/DLBCL or pure DLBCL.[101] Infiltration of the muscularis propria or nodal extension and the presence of t(11;18) or t(1:14) predict poor response to antibiotics.[875,876,879] Serial endoscopies are warranted to ensure eradication of *H. pylori* and gradual disappearance of the lymphoma over many months.[873–876] Follow-up endoscopy is recommended 2 months after antibiotic therapy and, subsequently, at least twice a year for 2 years.[878] B cell clonality as detected by PCR may persist after histologic regression, but is of uncertain clinical significance.[104,880] If there is *H. pylori* negative or progressive disease, alternative therapies are usually effective and include radiation, rituximab, and/or single agent or combination chemotherapy.[872,881,882]

With the recognition of MALToma and the effectiveness of other therapies, the role of surgery has diminished in the management of gastrointestinal lymphoma. While early studies advocated surgical resection in gastric and other intestinal lymphomas to cure localized disease, debulk, accurately stage, and/or prevent perforation,[247,883,884] recent reports have achieved good results with either combination chemotherapy or combined modality without surgery, particularly for the aggressive histologies.[869] While a partial or subtotal gastrectomy may be justified in rare cases, more extensive surgery, such as total gastrectomy, should not be routinely performed because of the increased morbidity and the curability with alternative therapies. In a series of 398 patients with localized primary gastric lymphoma (38% MZL and 49% DLBCL) who received radiation and/or chemotherapy, there was no difference in survival at 42 months for those treated with surgery (n = 63; 86% OS) compared to those without surgery (n = 335; 91% OS).[885]

Similar surgical issues pertain to intestinal lymphomas as to gastric lymphomas, particularly if they present with obstruction; however, they usually are less amenable to total resection.[886] Other B cell tumors which can have unique gastrointestinal presentations are Burkitt in the ileocecal region, which is common in the Middle East,[887] mantle cell lymphoma, which can present with lymphomatous polyposis,[250] and FL in the duodenum.[888] Immunoproliferative small intestinal disease (IPSID), also called alpha heavy chain disease or Mediterranean lymphoma, can be considered a subtype of B cell MALToma distinguished by its occurrence in older children and young adults (age range, 10 to 35 years) from low socioeconomic groups in the Middle East and North Africa and its association with the synthesis of an IgA heavy chain and *Campylobacter jejuni*.[114,889] Although the prognosis is usually considered poor in IPSID, a combination of antibiotics (tetracycline), steroids, and/or anthracycline-based chemotherapy, along with aggressive supportive care with hyperalimentation, can achieve complete remissions in two-thirds of patients, with survivals in over half the patients at 3.5 years.[889,890] A unique T cell lymphoma of the small intestine is EATL, which can be associated with celiac disease (type I), may require emergent surgery due to obstruction or perforation, and responds poorly to chemotherapy (see section on "Extranodal Peripheral T Cell Lymphoma").[612,891,892]

Lymphomas involving Waldeyer's ring account for up to one-third of extranodal lymphomas and are second to gastric lymphoma as the most common extranodal site.[893] Prognosis depends upon histology, which is usually a DLBCL, size of the tonsillar mass, and stage.[894] Up to one-half of patients have advanced disease, and simultaneous involvement of the gastrointestinal tract is detected in 10% to 15% of patients with Waldeyer's ring lymphoma.[895,896] Because of the usual DLBCL histology and the advanced stage of many patients, chemotherapy plus rituximab, often in combination with radiation, is usually considered the therapy of choice.[897] With combined modality therapy, 5-year PFS is 70% to 90% for clinical stage IE and 40% to 60% for stage IIE.[898–900]

Lymphomas of the nasal cavity and paranasal sinuses often are evaluated in series that include Waldeyer's ring lymphomas, despite differences in presentation, diagnosis, and therapy. The primary lymphoma is often advanced in nasal lymphomas with invasion of adjacent bones and an increased risk for CNS involvement. Although uncommon, cervical node involvement in nasal lymphomas is associated with a poor prognosis.[898] Using the American Joint Committee TNM staging for carcinoma of the paranasal sinuses, patients with T 1 to 2 lesions had an 89% 5-year DFS compared to 25% for patients with T 3 to 4 lesions.[898] DLBCL is the most common histology in the West; but in series from Asia, NK/T cell lymphomas predominate, present with nasal septal perforation or destruction, and are associated with EBV (see section on "Extranodal PTCL").[617,901] Concurrent chemoradiotherapy or novel chemotherapy using agents which bypass MDR is advocated for most nasal NK/T cell lymphoma.[902] The best therapeutic results in nasal lymphomas have tended to be in those series with combined modality therapy.[901,903] Adding CNS prophylaxis to combined modality therapy resulted in a 5-year OS of 47% and disease-specific survival of 62%.[904]

Although somewhat variable according to series, the majority of salivary gland lymphomas are indolent (MALToma) and localized, most often to the parotid, and have survivals following radiation therapy alone of 80% to 90% at 5 years and 50% to 70% at 10 years.[188,905,906,907] Most patients (approximately 80%) with thyroid lymphomas have localized stage I_E or II_E disease, and the majority are DLBCL, sometimes with a MALToma component.[908,909] Approximately half of the patients have a history of HT.[910] A worse prognosis occurs with penetration of the thyroid capsule, tumor bulk, advanced stage, and intermediate- to high-grade histologic types. Because of the frequency of these factors, many have advocated combined modality therapy for thyroid lymphoma except in the patient with stage I MALToma, who can receive radiation alone.[909,910] Five-year OS for DLBCL of the thyroid ranges from 52% to 90%.[906,911] Five-year DFS for MALToma of the thyroid following radiation is 88% to 100%.[912]

Most primary pulmonary lymphomas are small B lymphocytic with or without plasmacytic differentiation and are considered a part of the spectrum of MALTomas. Two previously diagnosed entities, pseudolymphoma and lymphocytic interstitial pneumonitis, likely represent MALTomas. Therapy options include rituximab;chemotherapy, either single agent or combination; surgical resection; and radiation. The prognosis is good with 94% OS at 5 years without reaching a median survival at 10 years; and there is no advantage for a specific type of therapy.[274,913,914] Other pulmonary lymphomas are heterogeneous, and therapy depends upon pathology and extent of disease. A favorable prognosis has been reported for DLBCL without bulk disease and normal LDH.[915] Lymphomatoid granulomatosis (LYG) is a rare type of EBV lymphoproliferation of B cells which most commonly presents with lung lesions varying from nodules to necrotic cavitary lesions, and which can have associated CNS and skin lesions.[916] Therapy and prognosis depend upon grading with steroids and

interferon used for grades 1/2 and chemotherapy plus rituximab for grade 3 lesions.

Orbital lymphomas usually involve small B lymphocytes with or without plasmacytic differentiation and need to be distinguished from benign lymphoid hyperplasia. Some are associated with *Chlamydia psittaci* and can respond to antibiotics (see section on "Prelymphomatous Conditions"). They tend to be localized (80%+), and 10% to 20% are bilateral. They respond to radiation, with survival of 75% to 95% at 5 years and 70% to 80% at 10 years.[269,917,918] Large B cell lymphomas are less common, tend to involve the lacrimal gland or retro-orbital area, and are treated with (10 to 200) combined modality therapy plus rituximab.[269,919]

CNS lymphomas are predominantly DLBCL and are responsive to steroids, radiation, intrathecal or Ommaya reservoir therapy, and systemic chemotherapy which crosses the blood brain barrier.[920,921] Standard treatment historically for PCNSL was whole brain radiation therapy (WBRT) alone; and the prognosis was poor with survival less than 6 months in AIDS patients and 1 to 2 years in immunocompetent hosts.[922,923] However, recent data utilizing early chemotherapy, particularly high-dose methotrexate or cytosine arabinoside, usually followed by WBRT, have improved results in PCNSL with median survivals from 30 to 60 months.[920,924–926] Severe neurologic toxicity manifested as leukoencephalopathy secondary to radiation is common, particularly in the patient over 60 years of age, and trials with chemotherapy alone and deferred radiation are being conducted.[266,927–929] In a randomized trial of 551 patients with PCNSL, there was no difference in OS when WBRT was omitted from primary chemotherapy.[930] Rituximab has poor penetration into the CNS, but it is being used in protocols with PCNSL and its role is yet to be determined.[920,931] Alkylating agents with good CNS penetration which are a part of chemotherapy combination include thiotepa, ifosfamide, nitrosoureas, procarbazine, and temozolomide.[920] There may be a role for high-dose chemotherapy and autologous transplant for PCNSL in both the relapsed and upfront setting.[932,933]

Testicular lymphoma, representing approximately 5% of testicular neoplasms, is the most common testicular tumor beyond the age of 60 years and the most common bilateral testicular tumor.[934,935,936] It is associated with involvement of the contralateral testis in 20% to 35% of patients, and with involvement of the skin, Waldeyer's ring, and CNS, each in approximately 10% of patients. The predominant histologic type is DLBCL (80% to 90%). In early series, median survivals have been 1 to 2 years, and 5-year survivals have varied from 12% to 48%, depending in part upon the extent of disease.[934,935] Because of the poor prognosis and early systemic spread, anthracycline-based chemotherapy and rituximab are warranted, usually with radiation to the involved testis if unresected, as well as to the contralateral testis. Because of the CNS relapse rate of 15% to 31%, CNS prophylaxis should be considered.[934,937] In an international phase II trial of 53 patients treated with R-CHOP, usually with CNS prophylaxis and testicular radiation, the 5-year PFS and OS were 74% and 85%, respectively; CNS relapse was 6%.[938] Breast lymphomas usually manifest as a rapidly enlarging mass, may be multiple, and involve the opposite breast in 10% to 20% of patients.[273,939,940] The histologic type is variable, but the majority are DLBCL; low grade lesions with MALToma features and an association with lymphocytic lobulitis have been described.[941] Massive bilateral breast involvement with BL has been described in pregnant or lactating women, predominantly from Africa, and is characterized by rapid dissemination with ovarian and CNS disease.[273] After simple biopsy and staging, radiation therapy can be considered for local control of low grade lesions, but combination chemotherapy plus rituximab is warranted for aggressive histologies.

Primary ovarian lymphomas are rare, except in countries where BL is endemic; however, the ovary is the most common site of female genital tract involvement by lymphoma.[942] Ovarian lymphomas may be associated with bilateral involvement in 20% to 50% of patients and have had a poor prognosis, with 5-year survival of less than 25%. Prognosis depends on the extent of disease and the histologic type. DLBCL is the most common type, followed by FL, all grades, and Burkitt. Combination chemotherapy plus rituximab is warranted in most patients because of aggressive histologies.

Primary bone lymphomas are usually DLBCL (85%+), and approximately one-third have more than one bone involved.[271] Prognosis depends on the bones involved, with the femur the best and the spine the worst, histologic type, stage, and the presence of soft tissue involvement.[271,943] Although combined modality has been recommended for aggressive histologies,[944,945] chemotherapy alone has been successful. Because radiologic abnormalities persist after chemotherapy, local radiation is often given to the entire bone with a boost to the tumor bed.[946] For localized bone lymphoma treated with combined modality, FFTF exceeds 80% at 5 years.[947]

Therapy of CTCL and the differential diagnosis of cutaneous lymphomas are addressed in Chapter 92. Local radiation therapy is often adequate for localized (IE) cutaneous MALToma or PCFCL, whereas multiple therapeutic options similar to other indolent lymphomas can be considered for advanced disease. Both the primary cutaneous MALToma, or marginal zone lymphoma (PCMZL), and PCFCL have a good prognosis with 5-year OS exceeding 90%.[948,949] The majority of PCMZL have multifocal skin lesions involving the trunk and extremities, and up to 50% will relapse within 5 years of their initial therapy, but will still have a good prognosis (5-year OS>90%).[948] PCFCLs tend to involve the head and neck and lack BCL-2 expression and the *BCL-2* gene rearrangement. Alternatively, BCL-2 expression is often present in PCBCL of the leg as opposed to other sites, is primarily seen in the elderly, and has a poor prognosis (5-year OS 43% to 63%) despite the use of rituximab and combined modality therapy.[517,949–951]

ROLE OF HEMATOPOIETIC CELL TRANSPLANTATION

Transplantation is addressed in Chapters 102 and 104 and has taken an expanded role in the therapy of NHL; its use has been noted in preceding sections on individual diseases. Outcomes depend upon disease state (type of lymphoma, remission status), patient factors (age, performance status), and source of stem cells, either autologous (auto) or allogeneic (allo). In 1978, Appelbaum reported long-term DFS in 3 of 9 patients with relapsed BL who underwent high-dose chemotherapy and autologous marrow transplantation.[952] Subsequent series reported a 5-year OS rate of 20% to 50% using autoSCT for relapsed NHL.[953,954,956] In the rituximab and RIT era, the OS has improved to 40% to 70%, but is variable depending upon type of lymphoma, prognostic factors, and chemosensitivity.[957,958]

Patient selection determines outcome, with the best results achieved in patients who are either in first CR or have minimal residual disease before the transplant and have a good performance status. Transplants in first CR or in patients with indolent histologies are controversial. Patients with predominantly DLBCL who are in a sensitive relapse—i.e., they are responding to additional chemotherapy—have a 30% to 70% salvage rate with autoHCT, compared to 0% to 15% patients who are in a resistant relapse. There is no superior preparative regimen, which may include various chemotherapy agents with or without total body irradiation. Rituximab and/or RIT are being incorporated into preparative regimens to try to decrease relapses.[957,959] In a randomized trial comparing BEAM (carmustine, etoposide, cytarabine, and melphalan) plus rituximab vs. BEAM plus conventional tositumomab (Bexxar) followed by autoHCT, there was no difference in PFS, OS, or transplant relapsed mortality (TRM).[960]

AlloHCT has been used less than autoHCT because of higher mortality rates, cost, and/or lack of a donor. It was initially reserved for selected young patients (usually less than 50 years of age) with marrow involvement, highly aggressive lymphomas, or after relapse from an autoHCT. Early (day 100) mortality rates previously were 5% to 25% for autoHCT and 15% to 45% for alloHCT, but are now <5% and 5% to 15%, respectively. Relapse is the main reason for failure after autoHCT; and TRM, either regimen-related toxicity or graft-versus-host disease (GVHD), is the main problem with alloHCT. Donor availability has increased with the expansion of unrelated donor registries, the use of umbilical cord transplantation in adults, and immune suppression to allow the use of mismatched donors.

The development of reduced intensity conditioning (RIC) and nonmyeloablative (NMAC) regimens for alloHCT has led to less early mortality and to use in older patients.[959] In a CIBMTR report of 396 alloHCT for DLBCL, there was higher 5-year non-relapse mortality (NRM) with myeloablative conditioning (MAC, n = 165) than RIC (n = 143) and NMAC (n = 88) regimens (56% vs. 47% vs. 36%; P = 0.007).Five-year relapse was lower in MAC than in RIC and NMAC (26% vs. 38% vs. 40%; P= 0.031).[961] There were no differences in GVHD 5-year PFS (15% to 25%) and OS (18% to 26%). Similar findings of less NRM and increased relapse were reported by the CIBMTR comparing RIC to MAC for alloHCT patients with relapsed FL.[962] Chemosensitivity and performance status were better predictors of outcome than intensity of conditioning and have led to a shift in favor of RIC/NMAC for FL. Using a NMAC regimen (fludarabine, cyclophosphamide, and high-dose rituximab), Khouri et al. reported a 5-year OS and PFS rate for FL of 85% and 83%, respectively, with a TRM of 14%; acute GVHD was 11% and chronic GVHD was 60%.[963]

Unresolved issues of HCT for NHL are the optimal timing and the type of transplant. There is agreement that HCT is warranted in relapsed patients with intermediate-grade histology based on the PARMA trial which randomized patients to transplantation versus chemotherapy (Fig. 88.25).[953] Disagreement surrounds which, if any, poor prognostic factors could be used to select patients with NHL for early HCT. While several small series have had DFS over 75% in selected patients with aggressive histologies transplanted in initial PR or first CR,[954–956] most studies comparing autoHCT to chemotherapy in first CR or in slow responders have shown no advantage to early transplantation.[718,719,720,964–969] Retrospective analysis of trials and an occasional prospective trial indicate a survival advantage for HCT in patients with an age-adjusted IPI that is greater than or equal to 2 (high–intermediate or high);[719,968,970] however, the majority of randomized trials have not supported early transplantation over chemotherapy.[971,972] Many centers still offer HCT in first CR for poor prognosis NHL, particularly MCL and PTCL (see sections on these diseases).

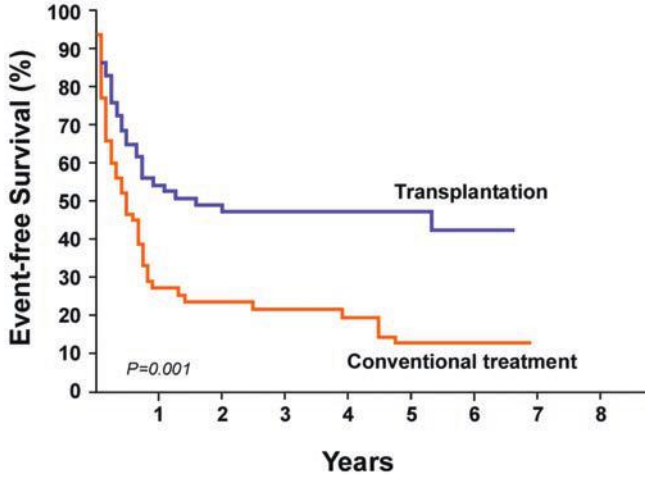

FIGURE 88.25. Kaplan-Meier curves for event-free survival of patients with relapsed intermediate to high grade lymphomas in the transplantation and conventional treatment groups. Data are based on an intention-to-treat analysis. From Philip T, Guglielmi C, Hagenbeck A, et al. Autologous bone marrow transplantation as compared with salvage chemotherapy in relapses of chemotherapy-sensitive non-Hodgkin's lymphoma. N Engl J Med 1995;333:1540–1545, with permission.

The use and timing of HCT and the role of purging are controversial in indolent lymphomas. Various techniques have been used for removal of tumor cells and include in vivo and in vitro monoclonal antibodies, metabolites of cytotoxic agents, and physical methods.[973] There is evidence that indicates an advantage for successfully purging *BCL2*-positive clonal B cells in FL patients undergoing autoHCT.[974] Prognostic models have been developed to select patients with indolent lymphomas for early HCT and include progressive disease within 1 year of initial therapy, extensive marrow involvement, multiple extranodal sites of disease, tumor bulk, transformation, and a high IPI.[424,975–977] Randomized trials comparing chemotherapy to chemotherapy followed by autoHCT are less common in FL than the aggressive histologies, predominantly DLBCL, but similarly have not shown an advantage to early HCT.[975,978] Long follow-up and randomized trials are required to determine the role of HCT and purging in indolent lymphomas.[973,975]

The optimal transplant strategy and stem cell source remain controversial. Peripheral blood stem cells have replaced bone marrow for autografting because of quicker engraftment, but have not consistently improved survival compared to marrow.[979] Peripheral blood tends to also be used over marrow for allografts, but is associated with more chronic GVHD. As many as one-half of patients undergoing autologous peripheral stem cell collection mobilize malignant cells.[979,980] MDS and secondary AML are an increasingly recognized problem after autografts, with an actuarial incidence of 5% to 10% at 10 years. Prior exposure to radiation, 4 or more chemotherapy regimens, and difficulty harvesting stem cells have been associated with a higher risk of MDS/AML.[981–983]

Some investigators have favored allografts because of fewer relapses, a graft-versus-lymphoma effect, a tumor free stem cell source, and less MDS/AML.[984–986] The lack of an available donor and the toxicity of allograft transplantation keep the issue of optimal stem cell source unresolved; however, the availability of alternative donors and the use of nonmyeloablative regimens are expanding the role of alloHCT. Because of higher relapse rates in autografts, trials are evaluating pre- and posttransplant immunotherapy and radioimmunotherapy to eradicate minimal residual disease.[960,987–990] An emerging strategy is to utilize an autograft to achieve minimal residual disease followed by a RIC, or NMAC, allograft.[991,992]

SPECIAL AREAS

Therapy in the Elderly

Lymphomas steadily increase in number with aging as over half the new cases occur in people over 60 years of age.[993] There is an expected increase in lymphomas solely based on the aging population, particularly in developed countries.[994] The prognosis tends to be poor in the older patient; however, survival has improved for older patients with NHL in 2008 to 2012.[995] Factors that contribute to poor prognosis in the elderly include poor performance status, reduced vital organ reserve, comorbid diseases, altered absorption or metabolism of drugs, decreased immunologic integrity, and biologic features of the lymphoma. Lymphomas in the elderly have more frequent extranodal presentations and more often have aggressive histologies. Unique presentations with a predilection for the elderly include primary CNS lymphoma,

primary cutaneous DLBCL of the leg, EBV-positive DLBCL, and intravascular B cell lymphoma.

Randomized clinical trials comparing different regimens to doxorubicin-based therapy have shown inferior results.[751,996–999] The randomized trials that favored CHOP plus rituximab over CHOP established a new standard for therapy of large B cell lymphoma in the elderly.[299,700] Physician biases and reduction of chemotherapy doses may contribute to an inferior prognosis in the elderly.[1000,1001] In a SWOG study with CHOP chemotherapy in which the dosage was reduced by 50% in patients over 65 years of age, CR rates declined with advancing age; however, in a small subset of patients over 65 years of age who did receive full doses, the CR rate approximated that of younger patients.[1002] A relative dose intensity factor of CHOP-based therapy less than 70% is associated with poor long-term outcomes; however, dose reductions for patients over the age of 70 years (R-70%CHOP) and 80 years (R mini-CHOP) have not markedly compromised response or survival.[1003,1004] Elderly patients experience more frequent treatment-related toxicities even with dose reductions and greater utilization of supportive care.[1005–1008]

Novel regimens have been developed for the elderly patient, not only to lessen toxicity but also to maintain curability or control of NHL.[1009–1012] For patients who cannot tolerate anthracyclines, there are numerous alternatives, including bendamustine, gemcitabine, and etoposide, among others (see section on "Salvage Regimens"). Growth factors lessen the neutropenia of various regimens and allow the delivery of adequate doses on schedule.[1010] Age is a continuum, with tolerance to therapy and survival worsening over 70 years of age; however, performance status is the best predictor of treatment-related death.[1013] New clinical assessment tools, such as instrumental activities of daily living, may assist in determining a patient's ability to tolerate therapy.[1004] AutoHCT in the elderly (patients <70 years) can approach similar outcomes as observed in younger patients.[1012] With the use of RIC and NMAC regimens, alloHCT is being utilized in the eligible older patient. Elderly patients should not be excluded from clinical trials or curative therapy solely on the basis of age, but dose reductions or alternative drugs may be warranted in selected patients. Palliative care should be offered to those who are too frail or compromised to receive therapy.

Therapy in Pregnancy

Lymphoma is a rare event during pregnancy, but the estimated coincidence of NHL and HL in pregnancy is 1:1,000 to 1:6,000.[1014] Therapy is based on histologic type and point of gestation at diagnosis.[1015] Staging studies are limited because of concern for radiation exposure to the fetus. MRI can be used, although it is still recommended to avoid it in the first trimester. Ultrasonography and echocardiograms can provide useful information in the pregnant patient. Most women who develop NHL during pregnancy have aggressive histologies and advanced stage disease.[1014] There is an unusually high incidence of breast, ovarian, uterine, and cervix involvement attributed to hormonal influences and increased blood flow to these organs.[1014] Placental involvement is rare, and transmission to the fetus is so uncommon that it is reportable.[1016]

Patients with aggressive lymphomas who present in the first trimester should be considered for a therapeutic abortion unless the lymphoma is localized above the diaphragm and could be treated with involved field radiation plus abdominal shielding.[1017] Radiation should be avoided until the third trimester, or not used at all, whereas combination chemotherapy can be given successfully in the second or third trimester. Although as a general rule chemotherapy is to be avoided in the first trimester, anthracyclines have been given without untoward effects to mother or fetus.[1018] Rituximab with chemotherapy has been given to pregnant patients without evident harm to mother or fetus.[1019] Early delivery (either by induction or caesarean section) can be considered either to avoid myelosuppression of mother and fetus or to initiate intensive chemotherapy. Complete staging should be done after delivery.

The prognosis for mothers has been relatively poor, with DFS of only 40% to 50%, probably because of both the aggressive histologies and the advanced stage.[1014,1016,1017] Although indolent lymphomas constitute a minority of NHL in pregnancy, they generally can be observed until after delivery. If necessary, interferon can be used throughout pregnancy to control indolent hematologic disorders.[1020] Offspring who as fetuses received chemotherapy even in the first trimester have had normal growth and development and no increased risk of cancer.

Long-term Sequelae

The long-term complications of therapy in NHL are not as well described as those in HL, but they appear to be similar and depend on the therapy used, age of the patient, and comorbid illnesses.[1021] These problems include endocrine disorders (infertility, hypothyroidism, panhypopituitarism, growth retardation), vital organ toxicity, psychosocial issues, and second neoplasms.[1022,1023] Radiation is the main cause of endocrine and neurological toxicities and secondary solid neoplasms.[1022] Cardiotoxicity from anthracyclines is the most common chemotherapy-related toxicity and is usually manifested as congestive heart failure. Factors associated with increased cardiomyopathy include older age (>70 years), previous cardiac disease, hypertension, prior mediastinal radiation, and combination with other chemotherapy agents (e.g., cyclophosphamide). The cumulative incidence of cardiovascular disease in patients with NHL treated with anthracyclines was 12% at 5 years and 22% at 10 years.[1024] Cardiomyopathy can occur many years (15 to 20 years) after completion of therapy.[1025] Although previous studies suggested no increase in second neoplasms after therapy for NHL, the NCI's SEER Program identified an increased risk over time for AML;cancers of the bladder, kidney, and lung; malignant melanoma; and HL.[1022,1023] Up to 10% of NHL patients treated with standard chemotherapy regimens or autologous transplantation, particularly using total body irradiation, may develop MDS or AML within 10 years of their initial therapy.[981,983]

FUTURE DEVELOPMENTS

Advances in NHL will involve molecular techniques to refine diagnosis, classification, and therapy. The classification of lymphoma will improve with genomic profiling in conjunction with clinical and pathologic factors. The application of PCR to detect minimal residual disease may identify patients who should be followed more closely or receive additional therapy. The success of monoclonal antibody therapy in NHL has been remarkable; and the development of vaccines may be the ultimate goal of immunotherapy (Chapter 70). New agents are targeting both B and T cell receptors and protein signaling pathways critical to lymphomagenesis. The novel agents are synergistic with other chemotherapy and monoclonal antibodies and will require phase III trials to establish their place in the expanding list of treatments for NHL. Continued trials evaluating the role of dose intensification and the use of different types of transplantation are warranted in NHL.

CHAPTER 89

NON-HODGKIN LYMPHOMA IN CHILDREN

John T. Sandlund Jr., Mihaela Onciu

INTRODUCTION

There have been significant clinical and laboratory advances over the last 25 years in our understanding of the non-Hodgkin lymphomas (NHLs) of childhood. These include the refinement of diagnosis and classification of clinically relevant histologic subtypes, the elucidation of various pathogenic mechanisms, and most importantly, improvements in therapy and supportive care which have resulted in improved event-free and overall survival rates. Increased attention to the reduction and elimination of late effects of therapy such as infertility, cardiotoxicity, and second cancers is another important hallmark of clinical research over recent years. These advances and future directions will be discussed in this chapter.

Malignant lymphomas, which comprise both Hodgkin lymphoma and NHL, are the third most common type of childhood cancer after acute lymphoblastic leukemia (ALL) and brain tumors.[1,2,3–7] Among children <18 years of age, there is a slight predominance of Hodgkin lymphoma, whereas the reverse is true among those <15 years of age.[3,6]

It is important to note the distinction between the NHLs of adults and children.[8,9,10] Children typically present with diffuse extranodal disease in contrast to adults, among whom primary nodal disease is more common. Additionally, the pediatric NHLs are typically high grade tumors,[9] in contrast to the low- and intermediate-grade tumors which are predominant among adults. Age-related differences in the immune system and associated susceptibility to malignant transformation are possible contributing factors to these observed differences in histologic subtype.[7]

EPIDEMIOLOGY

There are at least 500 cases of newly diagnosed pediatric NHL in the United States each year.[3–5]Although there is no clear peak age, the median age in one single institution review was 10 years (range, 7 months to 19 years).[10] This disease occurs uncommonly in very young children (i.e., <3 years of age).[2,10] NHL is two to three times more common in boys than in girls, and more common in black children than in white children.[2,7] The reasons for these differences have yet to be elucidated.

There are geographical differences with respect to frequency and distribution of histologic subtypes of NHL in children.[11] For example, although NHL is very common in equatorial Africa, it is very rare in Japan.[12] Among the NHL cases observed in equatorial Africa, Burkitt lymphoma (BL) is the most common type observed. BL is also the most frequent histologic subtype encountered in northeastern Brazil and in some areas of the Middle East.[13] In contrast, lymphoblastic lymphoma (LBL) is the predominant histologic subtype in southern India.[13]

BL is also of interest with respect to the geographical (i.e., endemic versus sporadic) variances that exist with respect to both clinical and biologic features.[14] Those tumors, which arise in children from equatorial Africa ("endemic subtype"), are characterized clinically by frequent involvement of jaw, abdomen, paraspinal area, and orbit, and by a younger age at diagnosis.[14,15,16] Those Burkitt tumors which arise in children from Western Europe and the United States ("sporadic subtype"), are in contrast characterized by frequent involvement of the abdomen, nasopharynx, and bone marrow and an older age at diagnosis.[14,15,16] The breakpoint in the c-myc proto-oncogene and in the IG heavy chain (*IGH*) genes in BLs has also been reported to vary with respect to geography: in sporadic cases the breakpoints tend to occur within the *MYC* gene and the switch region of *IGH* gene, as compared to upstream of *MYC* and the *VDJ* region of *IGH* in endemic cases.[14,17]

An infectious agent was suspected to play a role in the pathogenesis of BL in equatorial Africa after it was noticed that the malaria belt overlapped with the lymphoma belt. Subsequently, EBV was shown to be associated with BL in this part of the world (i.e., equatorial Africa).[14,16] The association of EBV with BL has been shown, however, to vary with geography. EBV association occurs in approximately 85% of endemic cases, in contrast to the 15% association in Western Europe and the United States.[14,16] An intermediate degree of EBV association has been observed in other parts of the world, such as northeastern Brazil.[18] Although the evidence for a direct role for EBV in BL pathogenesis is relatively lacking, the circumstantial evidence is compelling. It was initially hypothesized that EBV, a B-cell mitogen, increases the target pool of cells that would be susceptible to a malignant transformation.[14] This hypothesis is supported by the observation that the expression of the recombination activating gene (*RAG*) can be induced by EBV, and therefore potentially increases the chance that a chromosomal translocation may occur during IG gene rearrangement.[19]

Children with certain immunodeficiency conditions are at increased risk for the development of NHL.[2,7] Examples of specific populations at risk include those with congenital immunodeficiency disorders such as ataxia-telangiectasia (A-T),[20] X-linked lymphoproliferative syndrome (XLP), and Wiskott-Aldrich syndrome. It is important that these underlying conditions be recognized in children who present with NHL, so that appropriately designed therapy can be delivered. For example, in children with A-T, involved field irradiation and the use of radiomimetics such as bleomycin should be avoided, and the judicious use of x-rays is advised. Children with A-T are also at increased risk for the development of severe late onset hemorrhagic cystitis following the administration of alkylating agents such as cyclophosphamide and ifosfamide; therefore, vigorous hydration and administration of the uroprotectant mesna are recommended whenever these agents are delivered. Boys with XLP are at increased risk for the development of both B-cell lymphomas and fatal infectious mononucleosis, and are potential candidates for allogeneic bone marrow transplantation. Therefore, the diagnosis of XLP should be considered in any boy who presents with a B-cell lymphoma and whose brother has had either B-cell lymphoma or fatal infectious mononucleosis, or in any male who has had two primary B-cell lymphomas. There is also an increased risk for the development of NHL among children with acquired immunodeficiency conditions.[21] Specific populations at risk include those with the acquired immunodeficiency syndrome (AIDS) and those on immunosuppressive therapy following bone marrow or organ transplantation.

PATHOLOGIC SPECIMEN EVALUATION

Most of the NHLs of childhood are very rapidly growing neoplasms. It is therefore imperative that the diagnosis be established as soon as possible so that appropriate therapy can be started. The diagnosis typically requires a comprehensive characterization of the tumor, including histologic, flow cytometric, cytogenetic,

and molecular genetic studies. Ideally, larger fragments of tissue should be obtained by open biopsy of an involved site, but percutaneous image-guided needle biopsy has been increasingly used for diagnosis in the pediatric age group with good results.[22] Bilateral bone marrow aspirates and biopsies should be considered before open biopsy, since this may allow the diagnosis to be established without a more invasive open biopsy. In patients who are not candidates for general anesthesia, such as those with a large anterior mediastinal mass, the diagnosis may be established by examination of pleural fluid obtained by thoracentesis or by parasternal core biopsy of the mass using local anesthesia with an anesthesiologist in attendance.[23]

CLASSIFICATION

The most recent World Health Organization (WHO) Classification of Tumors of Haematopoietic and Lymphoid Tissues[24] designates NHLs, including those predominant in the pediatric age group, according to their clinical, morphologic, immunophenotypic, and genetic features, and also acknowledges difficulties in differentiating some of the clinically significant subtypes of B-cell lymphoma by introducing some borderline ("gray-zone") categories to encompass these issues. Table 89.1 summarizes the pediatric NHLs according to the WHO Classification 2008. Table 89.2 summarizes the main diagnostic immunophenotypic features of the most common subtypes of NHL encountered in this age group.

Lymphoblastic Lymphoma (T and B Lymphoblastic Lymphoma/Leukemia)

ALL and LBL are neoplasms of precursor B-cells or T-cells, characterized by immature (blastic) morphology and immunophenotype.

TABLE 89.1

SUBTYPES OF NON-HODGKIN LYMPHOMA ENCOUNTERED IN CHILDREN ACCORDING TO THE WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION (2008)

Precursor Lymphoid Neoplasms
- **B lymphoblastic lymphoma/leukemia**
- **T lymphoblastic lymphoma/leukemia**

Mature B-cell lymphomas
- **Burkitt lymphoma**
- **Diffuse large B-cell lymphoma (DLBCL)**
- **Primary mediastinal (thymic) large B-cell lymphoma**
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma
- Follicular lymphoma. Variant: Pediatric FL
- Marginal zone lymphoma (nodal and extranodal/MALT lymphoma). Variant: Pediatric nodal marginal zone lymphoma

Mature T and NK cell neoplasms
- **Anaplastic large cell lymphoma, ALK-positive**
- **Peripheral T-cell lymphoma, NOS**
- Hepatosplenic T-cell lymphoma
- Extranodal NK/T cell lymphoma, nasal type
- Subcutaneous panniculitis-like T-cell lymphoma
- Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
- Mycosis fungoides
- Hydroa vacciniforme-like lymphoma[a]

The categories highlighted in bold represent entities common in children; the remainder are rare in this age group.
MALT, mucosa-associated lymphoid tissue; NK, natural killer; NOS, Not Otherwise Specified.
[a]This type of lymphoma is limited to Asia, South and Central America, and Mexico.

At the pathologic and clinical levels, ALL and LBL appear to represent an overlapping continuum, with the distinction between these two processes being largely quantitative and arbitrary: cases involving at least 25% of the marrow cellularity are managed as ALL, while cases with less or no marrow involvement, are designated as LBL.[25–27] More recent studies have identified important differences in gene expression profiles, adhesion molecule expression, and molecular pathways of T-ALL and T-LBL that explain at least partially their distinct dissemination patterns.[28–30] T-LBL is the more common subtype and involves most often the mediastinum, lymph nodes, skin, bone, or soft tissues, and less commonly kidney, lung, or orbit. By contrast, the less common B-LBL more often presents in the lymph nodes, skin, bone, soft tissues, or breast, with mediastinal presentation being very uncommon.[31–35] The most frequent location of skin lesions in children is the scalp.[34,35]

Histologically, B- and T-LBLs show a diffuse growth pattern, with extensive replacement of the underlying normal tissue architecture by sheets of blastic cells. The malignant lymphoblasts are small to intermediate in size, with scant to moderate amounts of basophilic cytoplasm, finely dispersed nuclear chromatin, and small indistinct nucleoli (see Fig. 89.1). In some cases the nuclei may have markedly irregular or convoluted outlines, a feature more common in T-LBL. Mitotic figures may be numerous in some cases, correlating with the presence of a "starry sky" appearance imparted by scattered pale macrophages containing apoptotic nuclear debris. BL should be considered in the differential diagnosis of such cases.

Immunophenotypically, approximately 90% of LBLs are of T lineage and the remaining 10% of B lineage.[36–40] Most T-LBLs resemble cortical thymocytes, a feature that may lead to difficulties in the differential diagnosis with thymoma and residual normal thymus in biopsy samples obtained from mediastinal and cervical lesions. They typically express CD1a, CD10, weak CD79a, BCL2, CD99, and the pan-T-cell antigens CD2, CD3 (mostly cytoplasmic), CD5, and CD7, although these markers may under- or overexpressed when compared to their normal counterparts. Similar to thymocytes, T-LBLs are often $CD4^+$ and $CD8^+$ and usually terminal deoxynucleotidyl transferase (TdT) positive, a marker that can be used to distinguish this neoplastic process from mature T-cell lymphomas.[41,46] Other immature T-cell markers, including CD34 and HLA-DR are also coexpressed in these cases. A more frequent expression of T-cell receptor $\alpha\beta$ than $\gamma\delta$ has been reported in T-cell LBL as compared to precursor T-cell ALL.[47] Some LBLs may aberrantly express myeloid-associated antigens.[37,48,49] Of note, CD45 expression, often used to differentiate blasts by flow cytometry, ranges from dim ("blast-like") to strong ("mature lymphocyte-like") in T-ALL/LBL. A subset of T-LBLs resemble late thymocytes. In these cases TdT expression may be absent. They also express strong surface CD3, lack expression of CD1a, CD10, CD34, and HLA-DR, and are $CD4^+$ *or* $CD8^+$, rendering distinction from mature T-NHL very difficult, especially in small needle biopsy samples. The mediastinal localization and blastic cell morphology are very helpful in such cases.

B-LBLs typically resemble normal progenitor B-cells found primarily in the bone marrow and in lower numbers in blood, lymph nodes, and tonsils.[46,50,51] They express CD10, TdT, CD99, the B lineage antigens PAX-5 and CD79a, and may be negative or only weakly positive for the mature B-cell marker CD20. The neoplastic cells most often lack expression of surface IG and light chain restriction. Most often they express cytoplasmic μ heavy chain without detectable κ or λ IG light chains.[38,52,53] Rare cases of B-LBL may express surface IG with light chain restriction, associated with strong CD20 expression and without detectable TdT; in such cases BL should be considered in the differential diagnosis.[39,54] Of note, a significant proportion of pediatric B-ALL/LBL lack expression of CD45 (leukocyte common antigen), a marker often used to identify hematopoietic neoplasms in tissue

TABLE 89.2

IMMUNOPHENOTYPIC FEATURES OF THE MOST COMMON PEDIATRIC NON-HODGKIN LYMPHOMAS

	TDT	CD20	CD79a	Ig	CD5	CD3	CD30	CD15	ALK	CTA	MUM1[b]	BCL2	BCL6
T-LBL	+(−)	−	−(+)	−	+/−	+[a]	−	−	−	−	−/+	−	+/−

ALCL, anaplastic large cell lymphoma; B-LBL, B lymphoblastic lymphoma; CTA, cytotoxic antigen (e.g.,TIA-1, perforin); DLBCL, diffuse large B cell lymphoma; FL, follicular lymphoma; HSL; hepatosplenic lymphoma; MUM1, interferon regulatory factor-4 (IRF4); PMBL, mediastinal large B-cell lymphoma; PTCL, peripheral T cell lymphoma; T-LBL, T-lymphoblastic lymphoma.
[a]cytoplasmic CD3.
[b]cytoplasmic μ heavy chain only.
[c]ALK restricted to the ALK+ DLBCL subtype.

sections. This feature, combined with the frequent expression of CD99 by these neoplasms may lead to an erroneous diagnosis of Ewing sarcoma, another CD99$^+$ pediatric neoplasm with blastic morphology, unless other markers (e.g., PAX5, TdT) are included in the diagnostic immunohistochemistry panels.

Cytogenetic studies of pediatric LBLs are few and include small numbers of patients (Table 89.3).[55–57] Additionally, some reports of the cytogenetic or molecular genetics of LBL include cases of ALL with extra-medullary spread. T-LBL and T-ALL share similar chromosomal abnormalities. Chromosome abnormalities of the T cell receptor are relatively common and include chromosome abnormalities at 7q34–36, 7p15, and 14q11.[56,57] The t(9;17) translocation appears more commonly in T-LBL than T-ALL.[56,57] These patients often present with a mediastinal mass and have an aggressive disease course. The t(8;13)(p11;q11–14) has been described in rare cases of precursor T-LBL that present with myeloid hyperplasia and eosinophilia.[58–60] The t(10;11)(p13–14;q14–21) is an uncommon but recurring translocation associated with T-ALL, and T-LBL, where it correlates with expression of the γ/δ T-cell receptor by the neoplastic cells.[61–63] Cytogenetic abnormalities have not been shown to be of prognostic significance in LBL. At the molecular level, B-LBLs and T-LBLs contain IG (IG) and T-cell receptor gene (TCR) rearrangements, respectively. The latter should not be used for lineage determination, as B-LBLs (like B-ALL) often contain TCR rearrangements, and T-LBLs may also harbor IG gene rearrangements.

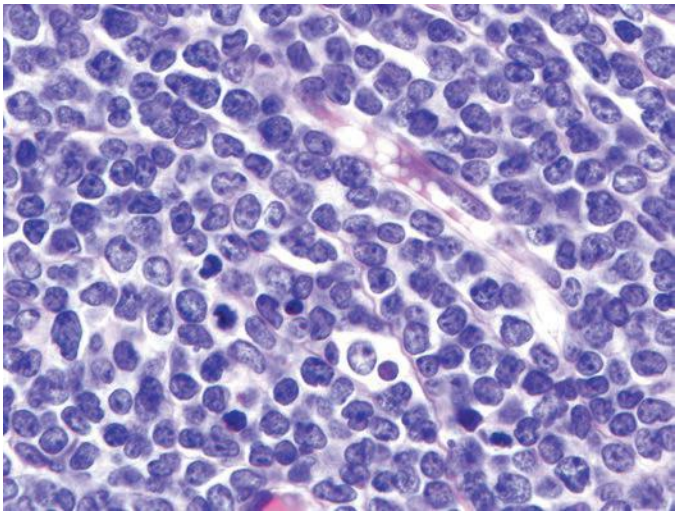

FIGURE 89.1. Lymphoblastic lymphoma. Sheets of small lymphoid cells with fairly uniform chromatin without clearing and scant cytoplasm are present. They show little variation in size and many show mitotic activity.

Burkitt Lymphoma

The WHO Classification replaced "small noncleaved cell lymphoma" of the older NCI Working Formulation with BL (Table 89.1),[9,64,65] and also combined under the same category the ALL-L3 of the French-American-British classification, which corresponded to cases of high-stage BL with leukemic dissemination.

BL is a mature B-cell lymphoma which resembles highly proliferative B-cells present in the follicular germinal center (GC). The biology of this lymphoma is characterized by translocations involving the *MYC* gene and leading to its overexpression and the typical high proliferation rate. Notably, however, *MYC* gene rearrangements are not unique to this subtype of mature B-cell lymphoma. Clinically, as described above (see section "Epidemiology") there are three recognized variants of BL: endemic, sporadic, and immunodeficiency-associated, which appear to correlate with distinct profiles of clinical presentation, association with EBV, molecular lesions, and cytogenetic abnormalities. Histologically, BL may present as one of three patterns with no prognostic significance (classic, atypical, and plasmacytoid), previously recognized as disease variants and currently merged under the unique designation of BL. Regardless of the histologic variant, BL is characterized by a diffuse growth pattern that typically replaces extensively the normal underlying tissue architecture. Occasionally, BL cells may also be seen "colonizing" preexisting GCs adjacent to the main tumor or present in the lymph nodes, draining an area involved by diffuse BL. Frequent mitotic and apoptotic cells are present and reflect this lymphoma's high proliferative rate and apoptotic index,

TABLE 89.3

CLINICAL AND BIOLOGIC CHARACTERISTICS OF NON-HODGKIN LYMPHOMA IN CHILDREN

Subtype	Proportion of Cases (%)[a]	Phenotype	Primary Site	Translocation	Affected Genes
Burkitt	39	B cell	Abdomen or head and neck	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)	*IGH – MYC* *IGL – MYC* *IGK – MYC*
Lymphoblastic	28	T-cell[b]	Mediastinum or head and neck	t(1;14)(p32;q11) t(11;14)(p13;q11) t(11;14)(p15;q11) t(10;14)(q24;q11) t(7;19)(q35;p13) t(8;14)(q24;q11) t(1;7)(p34;q34)	*TCRαδ – TAL1* *TCRαδ – LMO2* *TCRαδ – LMO1* *TCRαδ – TLX1* *TCRβ – LYL1* *TCRαδ – MYC* *TCRβ – LCK*

[c]Includes DLBCL and its variants, ALCL and some types of peripheral T-cell lymphoma.
[d]Primarily in T-ALCL.

respectively. Tingible body macrophages interspersed among the neoplastic cells impart a characteristic low-power microscopic "starry sky" appearance. The proliferation index, measured by immunohistochemical nuclear expression for Ki-67, typically approaches 100% of the tumor cells and is a requirement for the diagnosis of BL, regardless of the morphologic subtype, as an acceptable surrogate for the demonstration of *MYC* gene rearrangements. In the classic BL variant the neoplastic cells are monomorphous, medium-sized ("small noncleaved") with moderate amounts of basophilic cytoplasm (see Fig. 89.2).[64,65] The cells have round nuclei, clumped or condensed chromatin with clear parachromatin, and one to three nucleoli. When seen in Wright-stained cytologic preparations, BL cells have a characteristically deeply basophilic cytoplasm with prominent clear cytoplasmic vacuoles. In the atypical variant, the neoplastic cells are more pleomorphic, including large cells with centroblastic appearance and often prominent central nucleoli. The plasmacytoid BL cells, which are seen mostly in association with immunodeficiency, are more monomorphous, predominantly large, with eccentric nucleus, prominent nucleolus, and more abundant, IG-positive cytoplasm. BL cells retrieved from malignant pleural effusions often are larger and more pleomorphic than their tissue or blood counterparts.

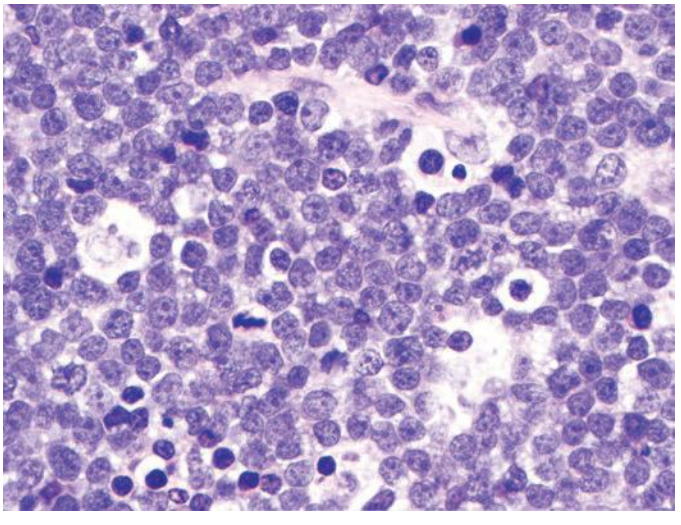

FIGURE 89.2. Burkitt lymphoma. Sheets of medium-sized lymphocytes are present with fine chromatin and multiple nucleoli. In addition, there are scattered large histiocytes containing debris. These histiocytes give the "starry sky" appearance to the histology of BL.

Immunophenotypically, BLs have a mature GC-like profile. They express CD10, CD19, strong uniform CD20, CD22, CD79a, PAX5, BCL-6, and surface IG (IgM, or less commonly IgA or IgG), with IG light chain κ or λ restriction (Table 89.2).[66] They are typically negative for BCL2, CD34, and TDT. The latter two antigens are useful in the differential diagnosis with B-LBL, which is most often positive for these markers. CD21, the receptor for complement fragment Cd3 and the Epstein-Barr virus, is more frequently detected in the endemic than sporadic form.

Cytogenetically, all cases of BL harbor one of three chromosomal translocations which rearrange the *MYC* oncogene locus to regions controlled by regulatory components of the *IGH* or light chain (*IGK* or *IGL*) genes, leading to constitutionally overexpressed *MYC* in the neoplastic B-cells (Table 89.3). These translocations include t(8;14)(q24;q32)/*MYC-IGH* (80% to 90% of the cases), t(2;8)(q11;q32)/*IGL-MYC*, and t(8;22)(q23;q11)/*MYC-IGK*. The translocations associated with BL are relatively easily detected by classical cytogenetic methods and more recently by fluorescent in situ hybridization of interphase nuclei.[67] In addition to these classic translocations, a significant proportion of pediatric BLs also contain other nonspecific but recurrent cytogenetic abnormalities, some of which may correlate with prognosis, at least in cases with high-stage presentation.[68]

Diffuse Large B-cell Lymphoma

Diffuse Large B-Cell Lymphoma (DLBCL) is a mature B-cell neoplasm composed predominantly of large cells (i.e., nuclear size equal to or exceeding that of macrophage nuclei), with a diffuse growth pattern, and with a proliferation index typically less than that required for a diagnosis of BL (typically 90% or less). The neoplastic cells may have a predominantly centroblastic (>80% in children),[69] immunoblastic (<10% in children),[69] or anaplastic appearance, defining three morphologic variants with no known prognostic implications (see Fig. 89.3).[65] Tumors rich in T-lymphocytes and histocytes are defined as a distinct entity in the most recent WHO Classification as T-cell/histocyte-rich large B-cell lymphoma.

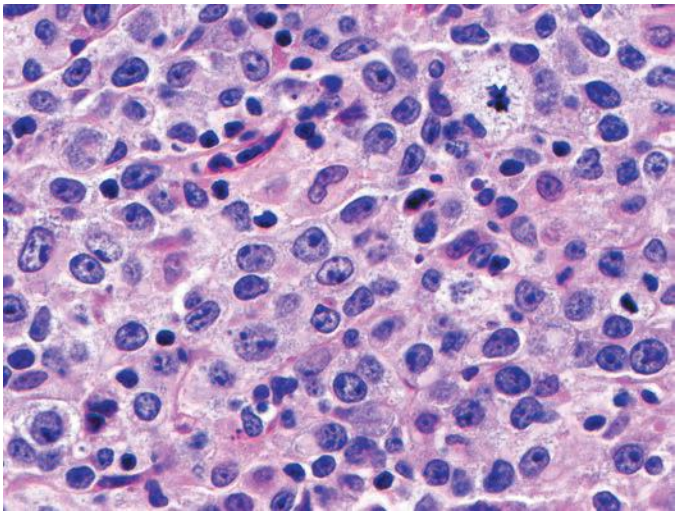

FIGURE 89.3. Diffuse large B cell lymphoma. Sheets of variably sized large cells with prominent nucleoli and chromatin clearing. There is variation in cell size, in contrast to the more uniform cells of BL.

Immunophenotypically, DLBCLs express one or more pan-B–associated markers CD19, CD20, CD22, CD79a, and PAX5. Surface or cytoplasmic IG are expressed by 50% or more cases. Some cases may express CD5, CD10, BCL2, BCL6, IRF4/MUM1, and CD30 (Table 89.3). Gene expression profiling and immunohistochemical studies have defined subgroups with distinct biology in DLBCL. These groups do not currently determine therapy in children. The GC-like group, which is predominant in children[69] is characterized by a $CD10^{+/-}$, $BCL6^{+/-}$, IRF4/MUM1− immunophenotype, while the non-GC subtype is $CD10^{-}$, $BCL6^{+/-}$ and $IRF4/MUM1^{+}$. Rare cases of anaplastic lymphoma kinase (ALK)-expressing DLBCL with plasmablastic features can be found among DLBCL of children.[70–72] These have been included under the designation of ALK-positive large B-cell lymphoma in the WHO Classification 2008.[24]

Cytogenetics of DLBCL often include complex karyotypes with recurrent, but nonspecific abnormalities. While in adults many of the GC-like cases contain the t(14;18) characteristic for follicular lymphoma (FL), this is not the case in pediatrics, perhaps due to the unique biology of FL in this age group (see below).[69] The rare ALK-positive cases may harbor the t(2;5) or t(2;17), resulting in *ALK* gene overexpression.[70–72]

Primary Mediastinal (Thymic) Large B-cell Lymphoma

Primary mediastinal (thymic) large B-cell lymphoma (PMBL) is an uncommon subtype of diffuse large B-cell lymphoma (<10% of large cell lymphomas in children) thought to arise from nonrecirculating thymic medullary B-cells.[65,73–78] The latter feature may explain the biologic behavior of this tumor, which never involves the bone marrow (prerequisite feature for a diagnosis of PMBL and exclusion of DLBCL with secondary mediastinal involvement). Patients present with signs and symptoms of a large mediastinal mass, frequently with extension into adjacent structures including lung, pericardium, chest wall, and superior vena cava. Extrathoracic extension at diagnosis is uncommon but with disease progression can include kidneys, brain, soft tissue, skin, and adrenal glands. In the pediatric age group, the presence of extrathoracic disease at presentation is an adverse prognostic feature.[76]

Histologically, PMBL is characterized by a diffuse growth pattern and is composed of tumor cells that may range from medium-sized to large. They may have a centroblast-like appearance, may show lobated, "flower-like" nuclear outlines, or may have an anaplastic, Reed-Sternberg–like appearance. Often, they have abundant pale cytoplasm, with a "clear cell" appearance. The neoplastic cells are typically surrounded by thin to thick, dense fibrotic bands. Small benign-appearing lymphocytes and eosinophils may be present and add to the difficulty in differentiating PMBL from Hodgkin lymphoma.

Immunophenotypically, PMBL cells express CD45 and B-cell–associated antigens PAX5, CD19, CD20, CD22, and CD79a (Table 89.2), characteristically lack IG, and very often show variable degrees of CD30 expression,[79] as well as CD23 and IRF4/MUM1 positivity. Expression of CD10, BCL-6, and BCL2 is less common. Although not unique to PMBL, the expression of the myelin and lymphocyte protein (MAL) may be useful in differentiating it from other mature B-cell and post-thymic T-cell lymphomas.[80]

Molecular studies uniformly reveal clonal IG gene rearrangements even if IG expression is not demonstrable by immunologic techniques. The lymphoma cells show mutated IG V region genes consistent with post-germinal center B-cells.[81,82] Uncommonly, evidence of clonal EBV genome may be present in the tumor cells. The relatively few cytogenetic studies reported show aneuploid tumor cells, often with gains of chromosome 9p or Xq.[83,84] The tumor cells may overexpress *REL* or *MAL* in a minority of cases.[85] *BCL6*, TP53, CDKN2A alterations and *MYC* rearrangements may be present.[83–87]

Unclassifiable Large B-cell Lymphomas

The most recent WHO Classification has recognized the existence of some borderline B-cell lymphomas, where complete morphologic, immunophenotypic, and genetic characterization does not allow a clear distinction between clinically significant categories of aggressive B-cell NHL or between DLBCL and classical Hodgkin lymphoma. This recognition has led to the definition of two heterogeneous disease categories that are not to be applied for cases where sufficient information is not available for a definitive distinction. These rare cases do occur in the pediatric age group and, at the present time, it appears that they are best managed as aggressive B-cell lymphomas in these patients.

B-cell Lymphoma, Unclassifiable, with Features Intermediate between Diffuse Large B-cell Lymphoma and Burkitt Lymphoma

This is a heterogeneous category of mature B-cell lymphomas, often with morphologic features of both DLBCL and BL, but with intermediate biologic features: cases of DLBCL with a gene expression profile similar to BL, many of which harbor dual translocations involving *MYC* and *BCL2* ("double-hit lymphomas"), correlating with a particularly poor outcome; cases of DLBCL with high proliferation rate and immunophenotype resembling BL, but lacking a detectable *MYC* translocation; or cases with morphology typical for BL, but atypical immunophenotype or genetic features. Some of these cases would have been classified as "Burkitt-like lymphoma" in previous classification systems.

B-cell Lymphoma, Unclassifiable, with Features Intermediate between Diffuse Large B-cell Lymphoma and Classical Hodgkin Lymphoma

This category has been introduced mainly to reflect a distinct group of B-cell lymphomas occurring in the mediastinum and showing features intermediate between PMBL and classical Hodgkin lymphoma ("gray-zone lymphomas").[88] However, lymphomas with similar features have also been described in peripheral lymph nodes. Gene expression profiling studies

have suggested related molecular signatures for PMBL and classical Hodgkin lymphoma,[89–91] offering a possible explanation for these phenotypically intermediate categories, although specific genomic studies of gray-zone lymphomas have not been reported.

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphomas (ALCLs) are mature T lineage lymphomas characterized by anaplastic morphology (large "hallmark" neoplastic cells with abundant cytoplasm, pleomorphic, often horseshoe-shaped nuclei) and strong uniform expression of CD30. The most recent WHO Classification has recognized two distinct biologic entities sharing these features: ALK-positive ALCL and ALK-negative ALCL. The vast majority of pediatric ALCLs are ALK-positive and therefore, the latter disease subtype will be referred to exclusively in the remainder of this chapter. In children, ALCL tends to involve lymph nodes and extranodal sites including skin, soft tissues, lungs, and bones.[92] Approximately 20% to 25% of patients have bone marrow involvement at diagnosis that may not be obvious without ancillary studies.[93] Histologically, ALK expression by these lymphomas has allowed recognition of a wide spectrum of morphologic variants. These range from classical (common) cases, where the anaplastic cells predominate, growing in diffuse sheets (see Fig. 89.4) or within sinusoidal lymph node space; to the small cell variant,[65,94] where the anaplastic cells are a minor component, admixed with predominantly small neoplastic cells; and the lymphohistiocytic variant,[95,96] containing a minority of "hallmark" cells surrounded by a reactive lymphohistiocytic population that forms the bulk of the tumor. The monomorphic variant, more common in children (author's unpublished observation) consists of sheets of monotonous immunoblastic cells with a high mitotic rate and "starry sky" appearance, mimicking BL. Rare cases have a sarcomatoid appearance, consisting of spindled $CD3^+$/ALK^+/$CD30^+$ neoplastic cells. Although none of these variants appears to have prognostic implications, the small cell variant appears to be associated more often with systemic dissemination and leukemic peripheral blood involvement at presentation.[97,103]

Immunophenotypically, ALCLs express one or more T-cell–associated antigens including CD2, CD3, CD4, CD7, CD43, or CD45RO (Table 89.2).[65,104] T-cell antigens CD5 and CD8 are usually negative. Some cases lack demonstrable T-cell antigens but have evidence of *TCR* gene rearrangements.[65] Most ALCLs express cytoplasmic cytotoxic cell–associated proteins TIA-1, granzyme B, or perforin. A membranous and Golgi pattern of CD30 expression is characteristic of the neoplastic cells of ALCL.[105,107] The most intense reactivity to CD30 antibodies is seen in the large cells, whereas the smaller cells are weakly positive or more often negative. Most ALCLs are positive for the EMA (epithelial membrane antigen) with a pattern similar to CD30.[108] Myeloid-associated antigens (CD13, CD15, CD33) are often expressed by neoplastic cells, especially when analyzed by flow cytometry.[109] Expression of myeloid markers CD13 and CD33 appears to differentiate ALK^+ ALCL from ALK− ALCL.[110]

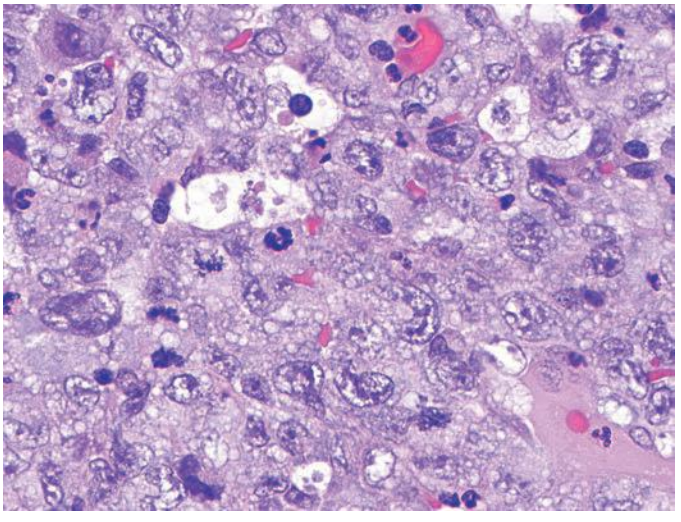

FIGURE 89.4. Anaplastic large cell lymphoma. Heterogeneous population of large lymphocytes is present with clearing of the nuclear chromatin and moderately abundant *pink* cytoplasm. Some cells have *irregular* and *horseshoe*-shaped nuclei ("hallmark" cells).

Cytogenetically, the t(2;5)(p23;q35)/*NPM-ALK* translocation is demonstrable in over 75% of ALK^+ ALCLs (Table 89.3).[111,112] Several other translocations involving the *ALK* gene have been described, including t(1;2)(q25;p23), t(2;3)(p23;q21), inv(2)(p23q35), t(2;22), t(2;17)(p23;q11), and t(2;19)(p23;p13).[97,113–115] All of these translocations lead to cytoplasmic overexpression and activation/phosphorylation of the *ALK* gene product as a result of dimerization of the gene partner-associated proteins. The NPM-ALK fusion is unique in that it is associated with both nuclear and cytoplasmic expression of ALK, due to the unique nuclear localization properties of NPM (nucleophosmin). As a result ALCLs associated with this translocation show nuclear and cytoplasmic ALK expression, while all other tumors show cytoplasmic ALK only, allowing immunohistochemical staining for ALK to predict the underlying genetic lesion in these lymphomas.

Of note, ALK expression is not unique to ALCL, but has also been demonstrated in a large subset of inflammatory myofibroblastic tumors, a predominantly pediatric mesenchymal neoplasm that also harbors translocations involving *ALK*; as well as in other pediatric tumors, where alternative mechanisms of overexpression may be operative.[116–118] Therefore, careful immunophenotypic characterization of ALK^+ neoplasms should be performed to confirm the diagnosis of ALCL.

Uncommon Pediatric Lymphomas

While the lymphoblastic and large cell lymphomas detailed above represent the vast majority of pediatric NHLs, a small but significant proportion of lymphomas occurring in this age group consists of low-grade B-cell lymphomas and some subtypes of peripheral T-cell lymphoma (see Table 89.1). The diagnosis of these rare lymphomas in children is often delayed or initially interpreted as a reactive process or as one of the more common pediatric lymphomas.

Some of these neoplasms (including FL and marginal zone lymphoma [MZL]) appear to constitute distinct clinicopathologic entities in this age group and will be detailed below. Other rare lymphomas of children and adolescents include hepatosplenic T-cell lymphoma, mycosis fungoides,[119–126] panniculitis-like T-cell lymphoma,[127,128,129] HTLV-1–associated leukemia/lymphoma,[130–132] and natural killer (NK) lymphoma.[129,133–135] For the most part, the clinical and biologic features of these lymphomas in children resemble their adult counterparts. A detailed presentation of all of these lymphoma subtypes is beyond the scope of this chapter. Only hepatosplenic lymphoma will be discussed below, with an emphasis on the frequent bone marrow involvement at presentation and the importance in differential diagnosis with the more common pediatric leukemias.

Follicular Lymphoma

Follicular lymphoma (FL) is a neoplasm of follicular germinal center B-cells that retains a follicular or nodular growth pattern. Children may develop FL pathologically and clinically similar to the adult disease, as well as FLs with unique clinicopathologic features, designated by the most recent WHO Classification as pediatric follicular lymphoma (P-FL). P-FL comprises <3% of all pediatric lymphomas,[2,136,139–141] and usually presents with disease localized to lymph nodes of the head and neck area or

testicles.[140,142–145,146] In striking contrast to adults, transformation to higher grade lymphoma is distinctly uncommon in P-FL, and the patients have prolonged remissions and high event-free survival rates, with or without therapy.[138,139,140]

P-FL is characterized by a follicular growth pattern, often as large, irregular GCs with monotonous, predominantly centroblastic cells, similar to the grade 3 FL seen in adults.[181,183,184,186] Neoplastic cells of P-FL express CD10, CD19, CD20, CD22, CD79a, and BCL6; may be weakly positive or negative for surface IG IgM or IgG; and are negative for BCL2.[65,140,141] P-FLs have *BCL6* rearrangements but lack the t(14;18)(q32;q21), *BCL2* rearrangements and P53 overexpression, despite their apparent high histologic grade (Table 89.3).[142–145] This is in contrast to the majority of adult FL, which express BCL-2 and have a t(14;18) that involves rearrangement of *BCL2*.[65] The distinction between classic FL and P-FL is important in the pediatric age group. In two separate studies of pediatric nontesticular FL, BCL2 expression was an important determinant of outcome,[139,140] with patients with $BCL2^+$ lymphomas presenting with advanced disease stage or disease refractory to therapy; whereas children with BCL2 negative tumors (likely mostly P-FL cases) presented with stage I disease, achieved complete remission, and had no relapses.[140]

Marginal Zone B-cell Lymphoma

MZL B-cell lymphoma is rarely diagnosed in the pediatric age group, with only a few reports available to date.[141,147,148] As with adults, MZLs in children and young adults may be nodal or extranodal in their presentation. The extranodal MZLs of mucosa-associated tissue are also referred to as MALT lymphomas. Extranodal sites of presentation include salivary glands, lung, orbit, ocular adnexa, lip, breast, stomach, and sinonasal cavity. Gastric forms are associated with *H. pylori* infection. Nodal MZL is reportedly more frequent in males and presents usually with localized disease. Extranodal MZL also tends to be localized in these young patients and shows a slight male predominance. Most children with MZL do exceptionally well with treatment. Both nodal and extranodal types demonstrate morphologic and immunophenotypic features similar to their adult counterparts. Morphologically, the marginal zone and interfollicular areas of the lymph node are infiltrated by a mixture of small lymphocytes, centrocyte-like cells, and monocytoid B-cells. A small number of immunoblastic cells may be present. Plasma cells and sometimes significant plasma cell differentiation may be present. Additionally, over two-thirds of pediatric nodal MZLs display disruption of residual normal follicles resembling progressive transformation of GCs, a feature that appears to be unique to MZLs in this age group. Immunophenotypically, the neoplastic cells express CD20, CD79a, IgD, and IgM; but not CD5, CD10, CD43, CD103, and cyclin D1.[65] Extranodal MZLs must be distinguished from benign marginal zone hyperplasias of tonsils or appendix with λ IG light chain restriction.[149]

Hepatosplenic T-cell Lymphoma

Hepatosplenic T-cell lymphoma is an aggressive extranodal malignancy of cytotoxic T-cells usually of γδ and less commonly αβ T-cell receptor type.[65,150–155] This rare lymphoma has a peak incidence in adolescents and young adults, with male predominance,[65,151] although a female predisposition is reported for αβ hepatosplenic lymphomas.[153,154] A relatively high percentage of cases follow solid organ transplantation or immunosuppressive therapies for other conditions.[156–159] Patients typically present with enlarged spleens and livers, but no appreciable lymphadenopathy. Isolated thrombocytopenia is a common presentation. Circulating lymphoma cells are commonly present at diagnosis but may be difficult to distinguish from atypical lymphocytes. A more obvious leukemic phase may develop as the disease progresses.[153,154] Cases of αβ hepatosplenic lymphoma are histologically, cytogenetically, and clinically similar to the γδ form.[154]

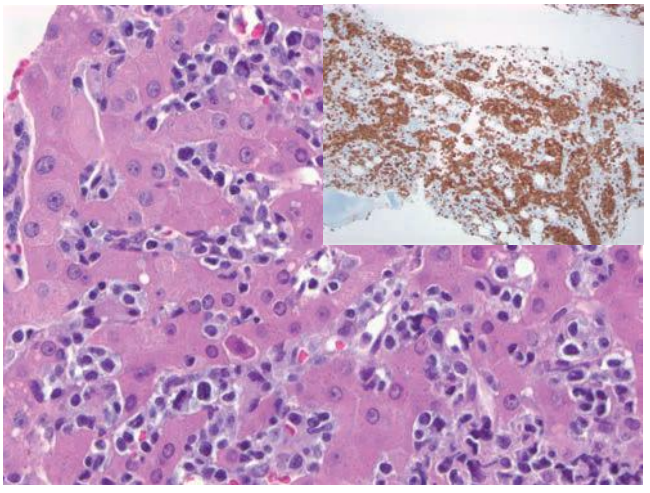

FIGURE 89.5. Hepatosplenic T cell lymphoma. Prominent hepatic sinusoidal infiltration by intermediate to large lymphoid cells with clumped chromatin and occasional nucleoli. Inset: Immunohistochemical staining for CD3 highlights a sinusoidal pattern of bone marrow infiltration.

In liver and spleen samples, the neoplastic cells are medium-sized to large, with scant to moderate amounts of cytoplasm and a predominantly sinusoidal location[154,155] (see Fig. 89.5). Azurophilic cytoplasmic granules have been described in a minority of cases. The nuclei may be round or convoluted with condensed chromatin and inconspicuous nucleoli. With disease progression, a blast cell transformation with large cells having prominent nucleoli may occur.[156,160,161] This is the most frequent lymphoma cell appearance in bone marrow samples from pediatric patients, and therefore it is an important consideration in the differential diagnosis with acute leukemias, especially of myeloid lineage. The bone marrow biopsy samples frequently show a characteristic sinusoidal infiltrate.[154,155,161] Erythrophagocytosis may be evident.[154,155,162,163] The lymphoma cells have a fairly consistent immunophenotypic expression pattern of $CD2^+$, $CD3^+$, $CD4^-$, $CD8^{\pm}$, $CD5^-$, $CD7^+$, $CD16^+$, and $CD56^{\pm}$ (Table 89.2).[65,153,164] The αβ hepatosplenic lymphomas have a similar immunophenotype except for a slightly more frequent expression of CD57.[154] TCR γδ or less commonly TCR αβ proteins can be detected by flow cytometric analyses.[150,155] Cytotoxic granular protein TIA-1 is detected in most cases, whereas granzyme B or perforin are detected in only a minority of cases.[153,154,162,165,166]

Cytogenetically, an isochrome 7q, often with trisomy 8 and other random chromosomal abnormalities, is found in the majority of reported cases.[154,158,160,161,167–170]

CLINICAL FEATURES

The clinical presentation for children with NHL is quite varied (Tables 89.3 and 89.4).[1,2,7] The primary sites of disease, which vary according to histologic subtype, are the primary determinants for the signs and symptoms observed. Children with advanced-stage T-LBL or mediastinal large B-cell lymphoma typically present with a mediastinal mass (Figs. 89.6 and 89.7), whereas children with BL typically present with abdominal disease (usually arising from the terminal ileum and often serving as a trigger point for an intussusception). By way of contrast, children with large cell lymphoma may present with primary involvement of either mediastinum or abdomen.

Those children presenting with an abdominal mass may have associated nausea, vomiting, and abdominal pain. Abdominal distension secondary to obstruction and associated ascites may be present on physical examination. Extension of the mass into the pelvis may result in ureteral compression and hydronephrosis. The presence of an anterior mediastinal mass may result in some

TABLE 89.4

STAGES OF NON-HODGKIN'S LYMPHOMA[a]

Stage I

A single tumor (extranodal) or involvement of a single anatomical area (nodal), with the exclusion of the mediastinum and abdomen.

Stage II

A single tumor (extranodal) with regional node involvement.

Two or more nodal areas on the same side of the diaphragm.

Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm.

A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable.

Stage III

Two single tumors (extranodal) on opposite sides of the diaphragm.

Two or more nodal areas above and below the diaphragm.

Any primary intrathoracic tumor (mediastinal, pleural, or thymic).

Extensive primary intraabdominal disease.

Any paraspinal or epidural tumor, whether or not other sites are involved.

Stage IV

Any of the above findings with initial involvement of the central nervous system, bone marrow, or both.

[a]Based on the classification proposed by Murphy.

degree of respiratory distress, ranging from slight cough to severe respiratory compromise, including arrest.[7] The respiratory status may also be compromised by the presence of a pleural effusion. A mediastinal mass may obstruct venous return to the heart, resulting in a superior vena cava syndrome.[7] This syndrome is characterized by swelling in the neck and shoulder region and prominent venous vasculature, a condition which may predispose the patient to the development of a deep venous thrombosis.

The degree of tumor burden at the time of diagnosis is quite variable. Some children present with isolated lymph node involvement, whereas others may present with more widespread disease (Fig. 89.8). Involvement of the bone marrow may be associated with pancytopenia, pallor, and bruising. Blurred vision, headache, or the presence of a cranial nerve palsy on physical examination may be present when the central nervous system is involved. Skin lesions may be present at the time of diagnosis in approximately 4% of children; however, this is usually associated with the CD30+, ALK+ anaplastic subtype of large cell lymphoma.[171,172] Involvement of bone may be associated with local swelling, pain, or limp. Boys may present with testicular enlargement secondary to tumor infiltration. Involvement of the ovary may be identified on diagnostic imaging studies.

MANAGEMENT

Initial workup and staging: Modern therapy for the NHLs of childhood is determined by both the histologic diagnosis and the disease stage. It is therefore imperative that an expeditious and comprehensive staging workup be performed after the diagnosis is established. This generally includes: computerized tomography of the neck, chest, abdomen, and pelvis; nuclear imaging; bilateral bone marrow aspirates and biopsies for cell count and differential, flow cytometry if the marrow is overtly involved, cytogenetics, and molecular pathology; lumbar puncture for cerebrospinal fluid cytology.[2,7] Over the past [5] years there has been a change in the type of nuclear imaging studies done in the pediatric NHL staging workup. Historically, gallium and bone scans were considered part of the workup; however, positron emission tomography (PET) is becoming a more widely used staging modality for children with NHL.[173] Data on how PET compares to conventional gallium and bone scanning is lacking. Uniform criteria for the interpretation of PET findings in children both at diagnosis and in response evaluation are needed. In some large cooperative groups studies, PET is not used at all. Thus, it is important to know what imaging studies are being done for a staging workup when risk-adapted (e.g., stage-adjusted) protocol results are reported. A complete blood count with differential and chemistry panel including serum lactate dehydrogenase (LDH) should also be obtained. Upon completion of the above workup, patients are designated with a disease stage—usually according to the St. Jude system described by Murphy (Table 89.4).[8] Those with stage I or II are considered to have limited-stage disease, whereas those with stage III or IV are considered to have advanced-stage disease.

Initial management: Upon expeditious completion of the diagnostic and staging workup, appropriate therapeutic options can be implemented. Before chemotherapy is started, however, a number of issues must be considered. Some children are at high risk for tumor lysis syndrome (TLS). This primarily includes children with advanced-stage BL and some children with LBL who have a large tumor burden at diagnosis, which may be reflected by an elevated serum LDH. Some of these children will have metabolic abnormalities with some degree of renal dysfunction at diagnosis, which only worsens once chemotherapy is started (e.g., hyperkalemia, hyperuricemia, hyperphosphatemia, etc.). Therefore, these children should have excellent intravenous access and vigorous hydration before starting chemotherapy. Hyperuricemia has historically been managed using hyperhydration coupled with allopurinol, a xanthine oxidase inhibitor. Uricolytics, such as uricozyme, which cleave uric acid to the more soluble and readily cleared allantoin, have been used for decades. A recombinant form of this drug, rasburicase, has been shown to be very effective and well tolerated with a reduced risk of associated allergic reaction.[174] The advantage of these agents is the precipitous drop in serum uric acid which negates the need for alkalinization, thus facilitating phosphorous excretion. Of note, a study of rasburicase in children at high risk for TLS demonstrated preservation of renal function with no significant associated hyperphosphatemia or hyperkalemia.[174]

Therapy: There have been significant improvements in treatment outcome for children with newly diagnosed NHL over the past 25 years.[1] This has been largely accomplished through incremental refinements in sequential multicenter trials which feature both a stage- and histology- or immunophenotype-directed approach to treatment assignment. Two of the initial successful regimens for children with NHL were the multiagent LSA_2L_2 regimen[175,176,177] designed for children with ALL, and the cyclophosphamide-based COMP regimen.[175] A randomized trial by the Children's Cancer Group (CCG) comparing these two approaches validated a stage- and histology-directed therapeutic approach to pediatric NHL.[175] Specifically, children with limited-stage disease did well regardless of the treatment arm. In contrast, among those with advanced-stage disease, those with BL had a better outcome with COMP and those with LBL had a better outcome with LSA_2L_2; there was no clear therapeutic advantage with either approach for children with advanced-stage large cell lymphoma. Other trials validated and built on these observations.[96,178,215]

Subsequent to the CCG trial comparing LSA_2L_2 and COMP, the dominant theme of most trials for children with limited-stage disease has been the reduction of treatment-related acute and late effects without compromising treatment outcome.[180,182,183,198,201,202] This has been attempted by shortening the duration of therapy, dose reduction of certain agents, and elimination of involved field irradiation. In the first of two sequential trials performed by the Pediatric Oncology Group (POG),[183] it was demonstrated that involved field irradiation could safely be eliminated from a 33-week treatment plan that featured three courses of cyclophosphamide, Adriamycin, vincristine, and prednisone (CHOP), followed by a 24-week maintenance phase of 6-mercaptopurine and low-dose methotrexate. In the subsequent trial it was shown that the 24-week maintenance phase could be safely eliminated for children with Burkitt or large cell lymphoma; however, for children with LBL the result was inferior.[183] Even with the 24-week maintenance phase, one-third of children with LBL experienced a recurrence; however, the majority were successfully salvaged, resulting in a similar overall survival to other histologic subtypes. Other groups have approached limited-stage LBL with a more intensive initial treatment regimen.[197] For example, the French Society of Paediatric Oncology (SFOP) cooperative group trial treats children with LBL with the same regimen used for those with advanced-stage disease.[197] A somewhat intermediate intensity approach is currently being studied by the Children's Oncology Group (COG), in which patients with limited-stage LBL are receiving a regimen modeled after approaches used for low-risk ALL.

Treatment advances for children with advanced-stage disease have primarily focused on improving histology- and immunophenotype-directed treatment strategies (United States and Europe, respectively). Intensification of therapy, addition of new active agents, and refinement in risk-adapted therapy have all been credited with improvement in outcome.

Burkitt lymphoma: For children with advanced-stage BL, initial improvements in treatment outcome beyond that achieved with COMP were attained by the incorporation of high-dose methotrexate and cytarabine (Table 89.5). Two year event-free survival rates of approximately 80% for children with stage III BL were reported with the Total B regimen which featured 1 gram/m2 methotrexate and sequentially escalating doses of continuous infusion cytarabine; for those with bone marrow involvement however, the outcome was inferior (approximately 20%).[181] The POG modified the Total B approach in the PG8617 protocol by incorporating high-dose pulses of cytarabine and intensified intrathecal therapy; this resulted in an improved treatment outcome for children with stage IV disease.[185] The optimal duration of therapy was examined in other trials. For example, the French (SFOP)[186] demonstrated that the duration of therapy could be reduced to 4 months; Schwenn et al.[190] reported an excellent result with a 2-month regimen for those with stage III disease. Further advances in therapy were subsequently achieved by dose intensification of cyclophosphamide, methotrexate, and cytarabine and by the incorporation of new active agents (e.g., etoposide). The German Berlin-Frankfurt-Münster (BFM)[201] and SFOP[180] cooperative groups have reported encouraging results, using risk-directed treatment assignment based on clinical features such as stage, degree of surgical resection, tumor burden, degree of bone marrow involvement, and disease sites. For example, in the SFOP LMB-89 regimen,[180] Group A treatment is restricted to those who completely resected limited-stage disease, whereas Group C, which is the most intensive arm, comprises those who have greater than 70% marrow blasts or central nervous system

TABLE 89.5

TREATMENT OUTCOME FOR ADVANCED-STAGE BURKITT LYMPHOMA

Protocol	Stage	No. Patients	Event-Free Survival Rate	Reference
POG 8617	IV	34	4 y EFS = 79% ± 9%	185
	B-ALL	47	4 y EFS = 65% ± 8%

disease. Group B is intermediate in intensity and is given to those with incompletely resected limited-stage disease, stage III, and those with <70% bone marrow replacement. Approximately 85% of children with advanced-stage B-cell lymphoma are cured with this approach. An international collaborative study (LMB-96) was conducted to determine whether the intensity of LMB-89 therapy could be safely reduced for patients with Group B and C therapy. Among Group B patients it was demonstrated that the avoidance of cyclophosphamide dose escalation in the second course of COPADM and deletion of a maintenance sequence could be safely implemented without compromising the outcome.[216] Among Group C patients however, reduction in therapy was associated with a poorer outcome.[217] The BFM cooperative group has also reported excellent results with a regimen that features high-dose methotrexate (5 g/m^2), ifosfamide, doxorubicin, etoposide, cytarabine, vincristine, and steroids.[201] In their most recent trial, it was demonstrated that a 4-hour infusion of methotrexate resulted in a noninferior outcome compared to the 24-hour infusion; however, this was not found to be true for those with advanced-stage disease.[218] The current BFM study is examining a rituximab window phase to evaluate both activity and toxicity—responses to single agent rituximab were observed in some patients, and the toxicity profile was generally acceptable.[219]

LBL: Strategies to improve the outcome for children with LBL have generally built on the results of the CCG trial, which demonstrated a superior result with an ALL-like treatment approach (i.e., LSA_2L_2). The incorporation of high-dose methotrexate has been featured in a number of successful treatment regimens (Table 89.6).[197,205,206,207] For example, the SFOP modified the LSA_2L_2 regimen by incorporating courses of high-dose methotrexate throughout the maintenance phase of therapy with an excellent treatment result.[197] The BFM cooperative group achieved an outstanding result (i.e., 5-year event-free survival rate of 90%) with an approach which featured a high-dose methotrexate consolidation phase (5 g/m^2 every other week for a total of 4 courses).[205] The improved outcome with higher doses of methotrexate may be the result of higher levels of intracellular methotrexate polyglutamates achieved with dose escalation.[220] The necessity of methotrexate in the treatment regimen has been questioned.[207] In a randomized trial performed by the POG, it did not appear that high-dose methotrexate added to the treatment result for children with LBL in the setting of an anthracycline- and asparaginase-rich backbone[207,221] however; the result for children with T-ALL entered on this trial was inferior in the arm without high-dose methotrexate.[221] The COG recently completed a randomized trial which also examined the need for high-dose methotrexate in children with LBL. In this study, the arm featuring the incorporation of high-dose methotrexate was being compared to an arm which featured the incorporation of extended intrathecal therapy. Preliminary reports suggest no difference in the treatment arms, although the final analysis is pending. Improvements in treatment outcome have also been attributed to other interventions such as the incorporation of a delayed intensification phase[205] (i.e., re-induction phase), L-asparaginase,[212] and new active agents.[191] A randomized trial performed by the POG demonstrated a survival advantage for those patients receiving additional doses of L-asparaginase. L-asparaginase is a featured component of the very successful Dana Farber approach. Anthracyclines are also commonly used in successful NHL treatment regimens. For example, they are a featured component in the POG 9404 regimen.[207,221] The use of epipodophyllotoxins in the treatment of LBL is more controversial. In this regard, etoposide was a featured agent in the successful NHL13 regimen[222]; however, their use in the POG T3 protocol was found to be associated with an increased rate of secondary AML.[212]

It has been difficult to identify clinical features among children with LBL that are reliably predictive of outcome—that is, for whom novel or intensified therapy could be planned. However, the use of flow cytometric technology to measure disease extent at diagnosis (minimal disseminated disease, MDD) has identified higher risk patients. A study by Couston-Smith et al. demonstrated that the detection of MDD in the bone marrow of LBL patients at the time of diagnosis was predictive of outcome.[223] Those with greater than or equal to 1% lymphoblasts in the marrow had a significantly inferior event-free survival compared to those with a lesser amount. Of interest, the level of disease detection in the peripheral blood was comparable to that found in the bone marrow, suggesting that disease response (minimal residual disease, MRD) could be followed with a peripheral blood test instead of bone marrow examination.[223] This data regarding the prognostic significance of MDD at diagnosis is the basis for two ongoing clinical trials for advanced-stage T-cell LBL in the United States.

Large cell lymphoma: Determining the optimal treatment approach for children with advanced-stage large cell lymphoma has been more of a challenge for various reasons. The CCG randomized trial comparing COMP and LSA_2L_2 did not show an advantage to either approach for children with advanced-stage large cell lymphoma.[175] Further complicating the picture is the fact that historically, children with large cell lymphoma in the United States were treated on the basis of the histologic diagnosis (i.e., uniform therapy for all immunophenotypic subtypes), whereas in Europe, children with large cell lymphoma have been treated primarily according to immunophenotype (e.g., T-cell, B-cell, or $CD30^+$ALCL).[96,196,208,224] With histology-directed therapy, the 5-year event-free survivals for children with advanced-stage disease have generally been in the range of 60% to 75%[175,178,179,188,208,210,211] (Table 89.7). These results have largely been achieved using CHOP-based therapy (cyclophosphamide, Adriamycin, vincristine, and prednisone). During the past 15 years, the investigators in the United States have used an immunophenotype-directed approach for children with large cell lymphoma, in part because of the excellent results achieved in Europe using this strategy. For example, in France (SFOP), children with advanced-stage B-cell large cell lymphoma are treated according to a BL regimen (LMB89) with an excellent result (3-year event-free survival >80%). Most groups are now treating BL and B-cell large cell lymphoma similarly. The PMBL, however, have an inferior outcome with an approximate 70% event-free survival reported with modern therapy.[216] Preliminary results from protocols featuring dose-adjusted EPOCH-R in adults with PMBL been encouraging[225–227] and have recently prompted the development of a protocol examining this approach in children.

TABLE 89.7

TREATMENT OUTCOME FOR ADVANCED-STAGE LARGE CELL NON-HODGKIN LYMPHOMA

Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference

APO vs. A-COP+	III & IV III & IV	62 58	3 y EFS = 72% ± 6% 4 y EFS = 62% ± 7%	209

CHOP, cyclophosphamide, Adriamycin, vincristine, and prednisone; EFS, event-free survival.

There are still quite varied approaches used for those children with $CD30^+$ ALCL.[96,211,224] In Europe, an immunophenotype-directed approach has been used. In the German BFM trials, children $CD30^+$ ALCL have been treated with a B-cell approach (BL like) with an outstanding result (3-year event-free survival rate of approximately 80%).[196,224] The United Kingdom Children's Cancer Study Group studied the activity of a B-cell approach (NHL 9002), based on the very successful French LMB-89 B-cell protocol. In this UK study, children with stage II, III, and non-CNS^+ stage IV ALCL treated with the Group B arm of the LMB-89 regimen achieved a 55% 5-year event-free survival rate.[213] It is unclear why this approach appeared to be inferior to the BFM B-cell approach; however, the BFM approach features more frequent use of alkylators. In SFOP trials, children with $CD30^+$ ALCL have been entered on regimens specific for that subtype.[96] The HM 89 and HM 91 both feature an initial treatment phase (one course of COP followed by two courses of COPADM) based on their very successful B-cell protocol, LMB-89. The maintenance phases, however, were different from LMB-89: the HM 89 protocol

featured alternating courses of VEM (etoposide, methotrexate, and cyclophosphamide) and VAD (vincristine, doxorubicin, and decadron), for a total of 8 courses; and the HM 91 regimen featured alternating courses of VEBP (vinblastine, etoposide, bleomycin, and prednisone) and Sequence 1 (vincristine, methotrexate, cyclophosphamide, and doxorubicin) for a total of 8 courses. The 3-year event-free survival for all stages treated with these two regimens was 66% (54% to 76%); however, among stage III and IV patients, the 3-year event-free survival was 55%.

In the United States, a histology-directed approach has historically been used to treat children with large cell lymphoma. The APO regimen is one of the most active regimens, and features an induction phase (doxorubicin, vincristine, prednisone, and intrathecal methotrexate) followed by sequential maintenance phases (doxorubicin, methotrexate, vincristine, prednisone, 6-mercaptopurine, and intrathecal methotrexate).[193,210,211] A POG randomized trial which examined the potential benefit of adding intermediate-dose methotrexate and high-dose cytarabine to the APO regimen found no difference in outcome regardless of immunophenotype.[211] Among the 86 patients with advanced-stage disease, a 4-year event-free survival and overall survival of 71.8% and 88.1%, respectively, were reported.

During the past decade, cooperative group trials in Europe and the United States built on the BFM B-cell and APO strategies, respectively. Both studies are examining the benefit of adding vinblastine, an agent which has activity as a single agent in multiply relapsed ALCL patients.[215] In the ALCL99 trial (BFM-based), the addition of vinblastine to the BFM backbone did not improve long-term event-free survival.[228] Another observation in this trial was that the infusion of methotrexate could be changed from 1 gram/m^2 given over 24 hours with IT MTX to a 3-hour infusion of methotrexate at a dosage of 3 g/m2 (without IT MTX), without compromising outcome.[229] The shorter infusion was also associated with less toxicity. In this trial, various prognostic factors were examined. Interestingly, stage was not associated with prognosis[230]; however, those with a small cell variant or lymphohistiocytic histologic component had a poorer outcome than children who lacked this subtype.[231] Preliminary results from the COG APO trial also indicated that the inclusion of vinblastine did not improve treatment outcome, although the final report is pending.

Relapse: Approximately 20% to 30% of children with NHL will have a treatment failure with frontline therapy as manifested by either recurrent or, less commonly, refractory disease.[1] The prognosis for children with recurrent or refractory NHL has generally been felt to be quite poor. Therefore, most oncologists consider either intensive or novel salvage chemotherapy regimens, followed by an intensification phase including either autologous or allogeneic hematopoietic stem cell transplantation (HSCT) in the majority of cases. However, the role of HSCT in this setting is somewhat controversial.[232]

There are a number of studies which feature HSCT.[201,233–243] For example, some children with BL who had a poor early response to therapy were successfully salvaged with high-dose intensive chemotherapy followed by autologous HSCT in European Cooperative Group trials.[201,236,238,239,241] The Spanish Working Party for Bone Marrow Transplantation reported that 58% of the children who had either refractory/recurrent NHL, or high risk in first CR, were event-free survivors following HSCT.[238] SFOP reported that 8 of 24 children with refractory or recurrent NHL were long-term disease-free survivors using HSCT.[239,243] In a St. Jude single institution review of 20 children with recurrent or refractory NHL, approximately 45% were survivors following HSCT.[243] Published studies featuring HSCT for pediatric NHL are relatively small in number, and vary with respect to the type of HSCT (autologous versus allogeneic), salvage therapy, preparative regimen, and histologic subtype, making direct comparisons difficult.

The availability of novel and targeted therapies has made the histologic subtype of NHL a crucial factor in determining the appropriate initial salvage therapy, and in some cases the type of HSCT (i.e., allogeneic versus autologous) for those children who experience a failure following primary therapy.

(a) Various options can be considered for children with recurrent ALCL. Single agent vinblastine has been shown to be active even in children who have experienced multiple relapses. Of interest, some of these patients have experienced extended event-free survival after completing 1 to 2 years of therapy.[244] Multiagent chemotherapy regimens have also been reported to be active and include the ICE regimen (ifosfamide, carboplatin, and etoposide)[245] and the MIED regimen (methotrexate, ifosfamide, etoposide, and dexamethasone),[246] with long-term event-free survival achieved with subsequent auto-HSCT in patients who are chemosensitive going into HSCT. The BFM reported prognostic factors for children with chemosensitive disease that went on to get an auto-HSCT; those with CD3$^+$ tumors, or "relapse on therapy" had a poorer outcome.[247] The BFM also published very promising results with the use of allo-HSCT for children with high-risk ALCL, suggesting a possible graft-versus-lymphoma effect.[248]

(b) One of the most commonly used regimens for children with recurrent CD20 mature B-cell lymphoma (e.g., BL, DLBCL) is the RICE regimen, which includes rituximab, ifosfamide, carboplatin, and etoposide. A COG study demonstrated activity of this regimen in patients with either BL or DLBCL with subsequent event-free survival following either auto-HSCT or allo-HSCT.[249] A number of studies have suggested that autologous HSCT is beneficial in the management of children with BL who are poor early responders to initial therapy.[201,234,239] It is less clear which approach is optimal for those children with BL who relapse in the bone marrow, although many would favor an allogeneic approach if a suitable donor is available.

(c) Children with recurrent T-cell LBL are generally managed with salvage regimens for recurrent T-ALL; if chemosensitive, they are generally managed with allo-HSCT, as auto-HSCT has not been found to be very effective.[250]

There is a spectrum of preparative regimens which have been studied in children with recurrent or refractory NHL.[201,233–243] Carmustine, etoposide, cytarabine, and melphalan (BEAM); and carmustine, cytarabine, cyclophosphamide, and thioguanine (BACT) are two of the earliest drug combinations used successfully.[234,235,242] SFOP credited their excellent salvage rate in part to the inclusion of high-dose busulfan in the preparative regimen.[239] Gordon et al.[237] reported excellent results for children with recurrent peripheral T-cell lymphoma using a regimen that featured thiotepa. Additional prospective clinical trials which examine HSCT strategies in children with recurrent or refractory NHL are clearly needed; it has been suggested by one group that the potential graft-versus-lymphoma effect of the allogeneic HSCT approach be studied.[241]

LONG-TERM SEQUELAE

Improvements in the cure rate for children with NHL have prompted investigators to more closely examine long-term treatment-related late effects. Areas of concern include second malignancies, second cancers, and fertility. Attempts to reduce these unwanted sequelae include trials which have eliminated or reduced the doses of certain chemotherapeutic agents or involved field irradiation.

In the first of two sequential randomized trials for limited-stage NHL, the POG demonstrated that involved field irradiation could be safely eliminated without compromising the excellent treatment outcome.[183] The elimination of involved field irradiation was also shown to be possible without compromising outcomes in a

St. Jude study of patients with advanced-stage disease.[251] Involved field irradiation of primary tumor masses is not used in most current NHL trials. However, cranial irradiation is considered in the management of children with LBL who present with overt involvement of the central nervous system. Historically, the use of cranial irradiation for CNS prophylaxis in children with LBL has been considered controversial; however, studies by the BFM[252] and St. Jude[222] have demonstrated that prophylactic cranial irradiation can be safely omitted from the treatment plan without compromising outcomes.

Alkylating agents such as cyclophosphamide and ifosfamide cause a dose-related depletion of germinal cells and tend to be more gonadotoxic in males. Studies suggest that fertility is generally maintained at a cumulative cyclophosphamide dose of <4 g/m^2, whereas sterility is likely at doses greater than 7.5 g/m^2.[253] In this regard, various clinical trials have examined the possibility of eliminating or reducing the dose of cyclophosphamide in the treatment of certain NHL subtypes.[209] For example, in the LMB-96 trial for children with high-grade mature B-cell lymphomas, it was demonstrated that escalation of the cyclophosphamide dosage in the second course of COPADM could be avoided in Group B patients without compromising the outcome.[216]

Pediatric NHL trials have also been influenced by the desire to avoid or limit anthracycline-related cardiac toxicity. Although adults have been shown to tolerate cumulative Adriamycin doses of 550 mg/m^2, children treated with lower cumulative doses have been shown to have clinically significant abnormalities in ventricular contractility.[254] Factors which have been shown to be predictive of cardiac dysfunction include higher anthracycline dose intensity, cumulative anthracycline dose, female sex, younger age at time of treatment, combined modality therapy which includes mediastinal irradiation, and time interval since completion of therapy.[255,256] In addition to trials which attempt to reduce the cumulative dose of anthracyclines,[188] the study of cardioprotectants is also indicated.

FUTURE DIRECTIONS

Although significant progress has been made in the treatment of children with NHL, 25% to 30% continue to have refractory or recurrent disease. Treatment-related late effects are of additional concern. Thus, the continued goal and challenge for the pediatric oncologist is to develop more effective treatment approaches which are not associated with significant late effects. This will require further refinement in risk-adapted treatment planning, which will be made possible by the identification of additional prognostic biologic and clinical factors.

Various strategies may contribute to further improvement in treatment outcome, such as the development of new active agents or new schedules for the delivery of current agents. One of the most promising novel approaches is the use of immunotherapeutic agents such as rituximab for patients with CD20$^+$ B-cell lymphomas.[257–259] In adults, the use of Rituxan has been shown to improve outcome for adults with DLBCL and FL. Pediatric trials which include rituximab for children with CD20$^+$ B-cell lymphomas are ongoing. The BFM recently reported on the activity and toxicity profile of rituximab given as window therapy before starting conventional therapy.[219] The COG performed two pilot studies which incorporated rituximab into Groups B and C of LMB-96 based therapy—preliminary results are promising, with final reports pending. Anti-CD30 (SGN30) has been shown to have activity in adults with CD30$^+$ ALCLs.[260] A pediatric trial of SGN30 combined with ICE (ifosfamide, carboplatin, and etoposide) was recently completed, with results forthcoming. An antibody drug conjugate (i.e., SGN35) which links auristatin to anti-CD30 has been shown to be active in CD30$^+$ ALCL and Hodgkin lymphoma occurring in adults.[261–263] Small molecule inhibitors, which have been shown to be active in adults with CML, may have a role in some types of childhood NHL; phase I studies are currently ongoing.[264,265] Crizotinib, a small molecule inhibitor of c-MET/ALK, has been shown to be active against ALCL in adults;[266] pediatric trials are ongoing. Future plans for the use of targeted therapeutic agents, including immunotherapeutic agents and small molecule inhibitors, include their combination with conventional agents in the management of children with newly diagnosed ALCL.

The continued molecular characterization of chromosomal abnormalities associated with pediatric NHL may prove helpful in refining the classification of clinically relevant histologic subtypes,[28,267,270] evaluating response to therapy, and developing novel therapeutic approaches which target the molecular lesion directly.

CHAPTER 90

CHRONIC LYMPHOCYTIC LEUKEMIA

James B. Johnston, Matthew Seftel, Spencer B. Gibson

Chronic lymphocytic leukemia (CLL) is characterized by the accumulation of mature-appearing lymphocytes in the blood, marrow, lymph nodes, and spleen.[1,2,3,4] Small lymphocytic lymphoma (SLL) is the same disease, but primarily there is involvement of lymph nodes and spleen. Both CLL and SLL are antedated by monoclonal B-cell lymphocytosis (MBL) in which small numbers of CLL cells can be detected in the blood of asymptomatic individuals.[1,2,3,4] The CLL cells are monoclonal B lymphocytes that express CD19, CD5, and CD23 with weak or no expression of surface immunoglobulin (Ig), CD20, CD79b, and FMC7.[1,2,3,4] Recent evidence suggests that CLL cells have a similar gene expression profile as memory B-cells, and there is considerable heterogeneity in CLL in terms of cellular morphology, phenotype, biology, molecular genetics, and prognosis.[1,2,3,4,5–7] The incidence of CLL varies throughout the world, being highest in North America and rare in the Far East. In North America, CLL/SLL accounts for one-quarter of all leukemias, with the incidence reported by the Surveillance, Epidemiology and End Results (SEER) Program being 5.13/100,000 for the years 1993 to 2004.[8] A total of 75% of cases were CLL and 25% SLL. However, the incidence is likely much higher, as many patients are diagnosed by flow cytometry and are not included in tumor registries.[9] By combining data from flow cytometry and the cancer registry the incidence of CLL/SLL is 7.99/100,000, with the median age at diagnosis being 71.5 years.[9] The median age at diagnosis is younger for males (70 years) than for females (73 years), with the male:female ratio being 1.3:1[9] (Fig. 90.1). One third of patients are less than 65 years and 10% less than 50 years. Using SEER data, it has been shown that relative survival is poorest for those >80 years, and worse for men.[10] Interestingly, the 10-year relative survival has increased over the last 20 years for all age groups except for those 80 years of age or older at the time of diagnosis (Fig. 90.2).[10] Moreover, relative survival has improved for men, diminishing the difference previously seen between the sexes.

Although the median age at diagnosis for CLL patients in the population is 71.5 years, it is 64 years in CLL clinics and as low as 58 years in specialized clinics.[11,12,13] Thus, it is likely that many older patients are not being referred for assessment and therapy.

PATHOPHYSIOLOGY

Predisposing Factors Including Familial Chronic Lymphocytic Leukemia

Unlike other leukemias, there is no firm evidence linking an occupational exposure with an increased incidence of CLL.[14] However, CLL patients have a higher incidence than normal individuals of having had an infection just prior to the diagnosis, suggesting a role for infection in the etiology of this disease.[15] Moreover, a number of studies have demonstrated that about 20% of CLL patients have very similar (stereotypic) heavy-chain complementarity-determining region 3 (HCDR3) sequences in their B-cell receptors (BCR), and this affects mainly patients with an unmutated IgV_H gene (see section "Cell of Origin").[2,16,17,18,19,20] Moreover, approximately 1% of BCRs from both mutated and unmutated cases are identical.[20] Compared to normal B-cells in the elderly, there is skewing of IgV_H gene usage in CLL and the biologic features of the disease are reflected in the gene used and whether the HCDR3 is stereotypic.[2,16,18,19] These findings suggest that a common antigen or an antigenlike element may be responsible for triggering this malignancy, perhaps an infective organism or an autoantigen.[2,16,18,19] Although patients with CLL have an increased risk of a prior diagnosis of pernicious anemia, they do not have an increased risk of other autoimmune diseases.[4,21] A recent study has shown that the BCRs from CLL cells, and not the BCRs from normal B-cells or other B-cell malignancies, can induce cell-autonomous signaling, which is dependent on the interaction

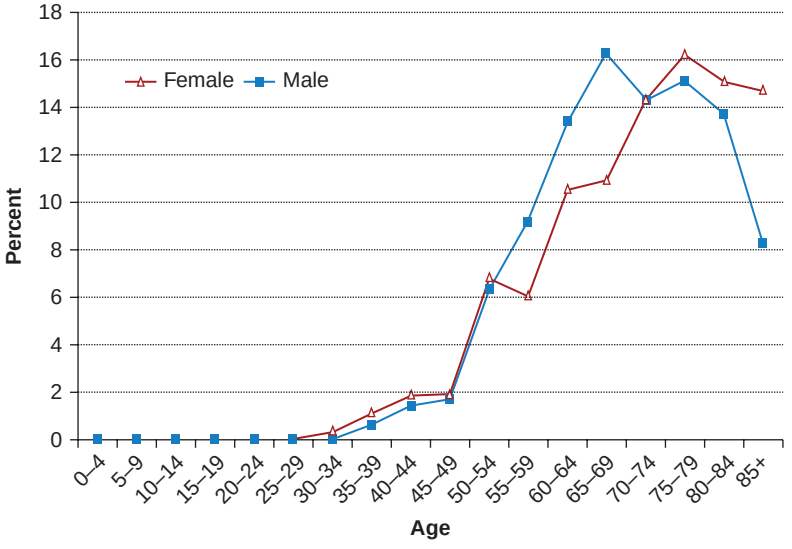

FIGURE 90.1. Age distribution of 351 males and 265 females diagnosed through the provincial cancer registry and a centralized flow cytometry facility in Manitoba over a 5-year period (1998 to 2003). The median age at diagnosis was 70 years for men and 73 years for women ($P = 0.0281$). Overall median age was 71.5 years. From Seftel MD, Demers AA, Banerji V, et al. High incidence of chronic lymphocytic leukemia (CLL) diagnosed by immunophenotyping: a population-based Canadian cohort. Leuk Res 2009;33:1463–1468, with permission.

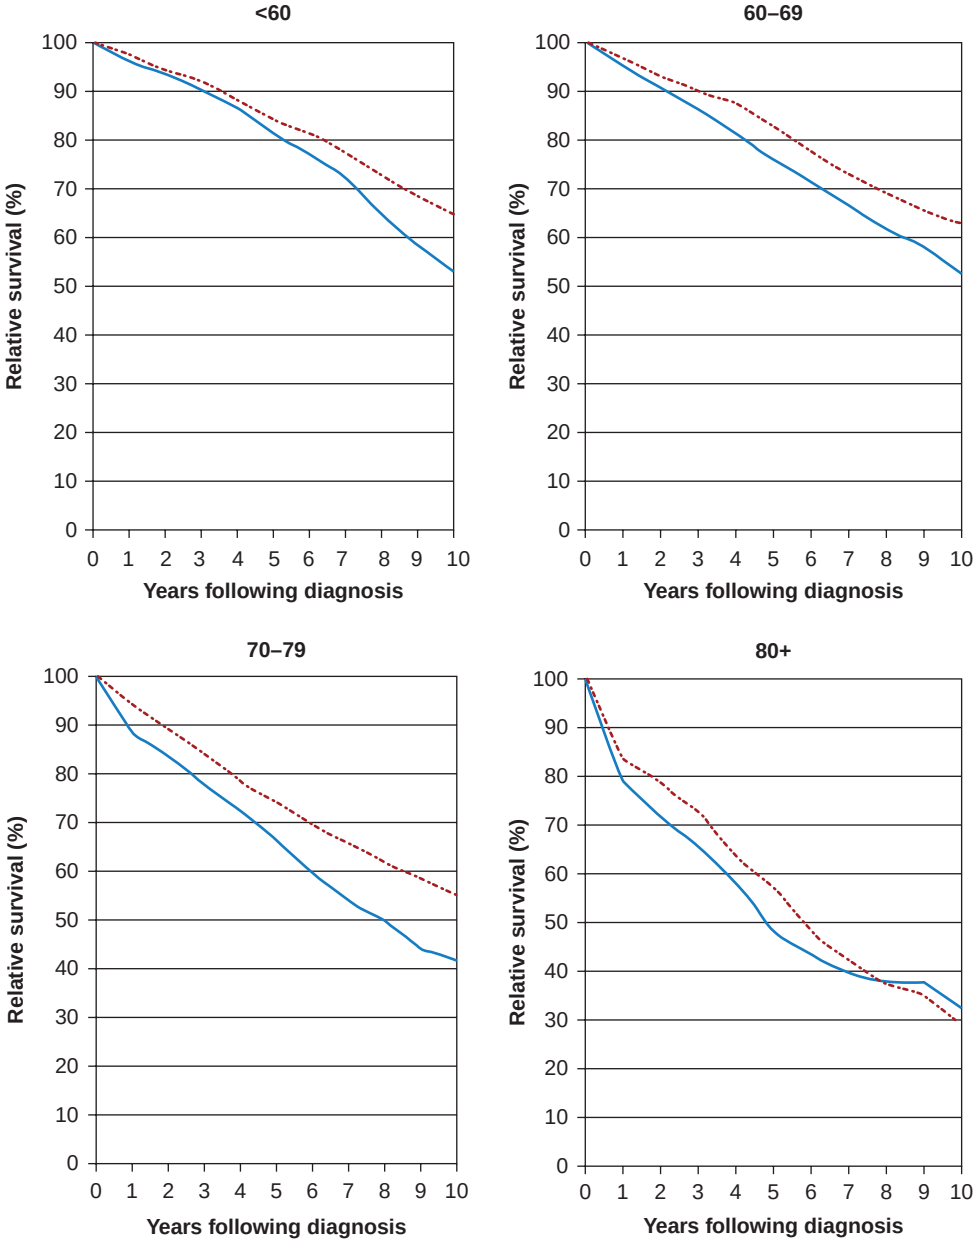

FIGURE 90.2. Ten-year relative survival curves of patients with chronic lymphocytic leukemia (CLL) by major age group. Period estimates for 1980 to 1984 (*solid lines*) and 2000 to 2004 (hatched lines). From, Brenner H, Gondos A, Pulte D. Trends in long-term survival of patients with chronic lymphocytic leukemia from the 1980s to the early 21st century. Blood 2008;111:4916–4921, with permission.

of HCDR3 with internal epitopes on nearby BCRs.[20] As only specific HCDR3 structures may interact with the epitope and induce signaling, this may explain the high incidence of stereotypic HCDR3s. However, no obvious differences in signaling are seen between the BCRs of mutated or unmutated cases or whether the HCDR3 was stereotypic.

A family history of CLL or another lymphoproliferative disorder is a strong risk factor for CLL, and it is estimated that 1 in 10 patients with CLL has a family history of CLL or another lymphoproliferative disorder.[14,22] There is a thirtyfold increase in the risk of CLL in first-degree relatives of patients with CLL,[22–24] and 13% to 18% of first-degree relatives have a peripheral blood $CD5^+$ MBL.[25,26] However, whether individuals with these abnormal cells will eventually develop CLL is presently unknown.[25] Patients with familial CLL are approximately 10 years younger than those with sporadic CLL,[14,23] and anticipation may occur in familial CLL, with affected children being 15 to 20 years younger than their parents at diagnosis.[27–30] However, other authors have not observed anticipation.[14] There is no consistency in the clinical features of affected members with familial CLL and no difference in the clinical features of patients with familial CLL or sporadic CLL.[14,31] As discussed in the section on "Cell of Origin", there are two forms of sporadic CLL; those with somatic hypermutations of the IgV_H gene and those without. At the present time, it is unclear as to whether familial CLL differs from sporadic CLL with regard to the incidence of IgV_H gene mutations.[32,33]

The pattern of inheritance in familial CLL is unknown, but there is no linkage to HLA type.[34] Several recent studies have attempted to identify a susceptibility gene for familial CLL.[35,36] A 3.68 Mb minimal region has been identified at 13q21.33-q22.2, which has been found to be shared in four CLL families, including family members with $CD5^+$ MBL.[37] These findings suggest that candidate genes at this and other sites may be involved in the pathogenesis of inherited CLL.[14] It has been suggested that polymorphisms in the *ataxia telangiectasia mutated* (*ATM*) gene may pre-dispose individuals to develop

CLL, but a recent study has discounted this hypothesis.[37] Patients with familial CLL have also been shown to have elevated plasma levels of B-lymphocyte stimulator (BLγS) and an increased frequency of a C→T polymorphism at –871 in the BLγS promoter.[38] Finally, in one CLL family, a single nucleotide polymorphism (SNP) in the promoter site of the death-associated protein kinase 1 (DAPK1) gene was observed in affected family members.[39] This polymorphism silenced this gene by binding the transcriptional regulator HOXB7.114. These results suggest that multiple abnormalities may be involved in the development of familial CLL.

Cell of Origin

There has been controversy as to the normal counterpart of the CLL cell.[2,19] As the CLL cell is $CD5^+$, it was previously believed that the normal counterpart was the $CD5^+$ B lymphocyte, which is present in the mantle zone of lymph nodes and in small numbers in the peripheral blood.[40] However, the $CD5^+$ B lymphocyte lacks mutations of the IgV_H gene,[41] whereas the CLL cell has undergone mutations in approximately 50% of cases.[2,19] Additional studies suggest that CLL cells with unmutated, as well as mutated, IgV_H have been antigen exposed.[2,19,42] Firstly, surface immunophenotyping shows activation markers to be present in both mutated and unmutated cases.[42] Secondly, there is a skewing toward specific IgV_H gene usage in CLL cells (IgV_{H1-69}, IgV_{H3-23}, IgV_{H3-7}, and IgV_{H4-34}) with some genes, for example, IgV_{H1-69} being more common in unmutated CLL and others, for example, IgV_{H4-34}, IgV_{H3-23}, and IgV_{H3-7} being more common in mutated cases.[16] Thirdly, as discussed previously, 10% to 20% of patients have changes in their BCR, suggestive of antigen exposure.[17,18] Finally, gene expression studies indicate that both mutated and unmutated IgV_H CLL cells are memory B-cells.[6,7] The results of these studies indicate that the CLL cell is antigen-experienced, suggesting that the expressions of CD5 and CD23 on these cells are secondary changes, perhaps representing cell activation or nonspecific changes secondary to the malignancy. Thus, the cell of origin of the CLL cell may be the memory B-cell, regardless of whether there are mutations of the IgV_H gene. This would explain why all CLL cells are $CD27^+$, which is typically a marker of the memory B-cell.[43] Although most normal $CD27^+$ B-cells have IgV_H gene mutations, a small fraction does not.[44] Altered DNA methylation is observed in CLL and the methylation pattern in the unmutated IgV_H form of CLL is similar to a $CD5^+$ naive B-cell form, whereas the mutated form is most similar to a memory B-cell.[45] Significant hypomethylation occurs in the production of the CLL cells, with many similar changes for the both the mutated and unmutated forms which may explain the similar gene expression profiles for both types of CLL. Based on the methylation patterns. a third form of CLL has been proposed, which is antigen-experienced but has lower levels of mutations than the IgV_H mutated form. The influence of DNA methylation on gene expression in CLL and how this can be altered is an area of great interest.[45,46]

A recent study has demonstrated that the hematopoietic stem cell is abnormal in CLL having increased expression of early lymphoid transcription factors, such as IKAROS.[47] When CLL hematopoietic stem cells are transplanted into immunosuppressed mice there is an increased production of polyclonal B-cells including increased numbers of monoclonal or oligoclonal B-cells that are either $CD5^+$ or $CD5^-$, generally have mutated IgV_H and, as in CLL cells, preferentially used VH1, 3, and 4 similar to that seen with MBL (Fig. 90.3). However, the clonal cells have VDJ recombinations that are different from the original patient's cells. These clones do not have the typical genetic changes seen by fluorescence in situ hybridization (FISH) studies in CLL cells. These results indicate that the stem cells from CLL patients have the capacity to generate monoclonal B-cells and the authors speculate that a "second hit" is required for these clones to become CLL cells.

Abnormalities in Apoptosis

Although a defect in apoptosis typifies CLL, with the majority of cells being long-lived, noncycling, and in G_0, there is a small fraction of replicating cells in the lymph nodes and marrow that is responsible for disease progression.[2] Chemotherapeutic agents induce apoptosis, and defects in apoptosis may also be responsible for drug resistance.[48–50] Considerable knowledge has been obtained regarding the apoptotic pathways, and the major steps are shown in Figure 90.4. Apoptosis occurs through the activation of caspases, which are cysteine proteases that cleave other caspases at aspartate acid residues, converting the inactive proforms to active enzymes. The downstream caspases, caspases 3, 6, and 7, cleave specific proteins leading to the typical morphologic changes of apoptosis. Apoptosis can be initiated through 2 main pathways, which interact and subsequently activate the same downstream caspases.

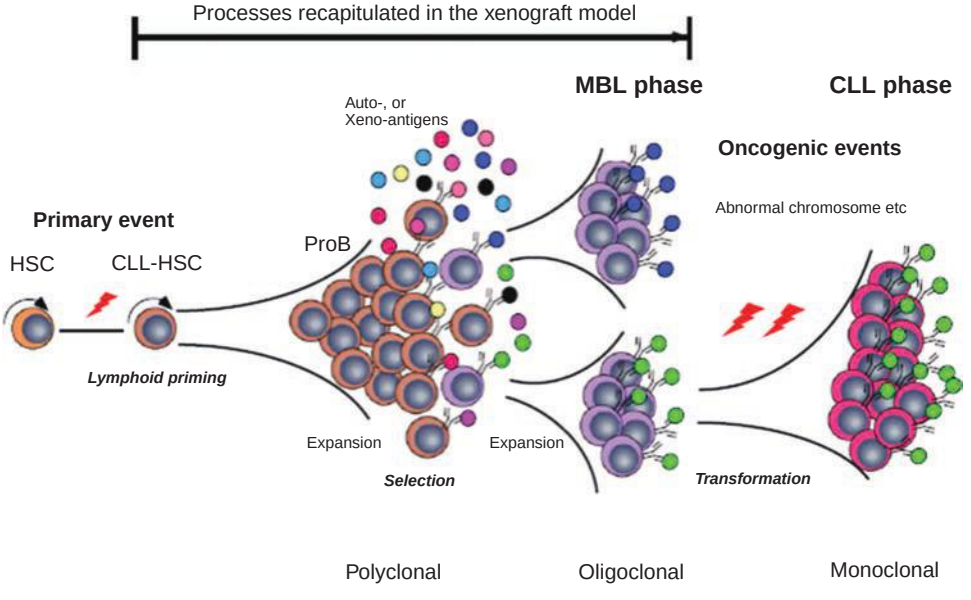

FIGURE 90.3. Schematic presentation of human chronic lymphocytic leukemia (CLL) development based on the xenogeneic transplantation model. CLL human stem cells have accumulated genetic abnormalities that might play a role in amplified B-cell differentiation, and produce a high number of polyclonal B-cells carrying the same genetic aberrations. B-cell clones are selected, and expanded in response to B-cell receptors (BCR) signaling driven presumably by xenoantigens, simulating progression of monoclonal B cell lymphocytosis (MBL). Additional abnormalities such as aberrant karyotypes might play a role in progression from MBL into human CLL. This final step was not recapitulated in the xenograft model. From Kikushige Y, Ishikawa, Miyamato T, et al. Self-renewing hematopoietic stem cell is the primary target in pathogenesis of human chronic lymphocytic leukemia. Cancer Cell 2011;20:246–259, with permission.

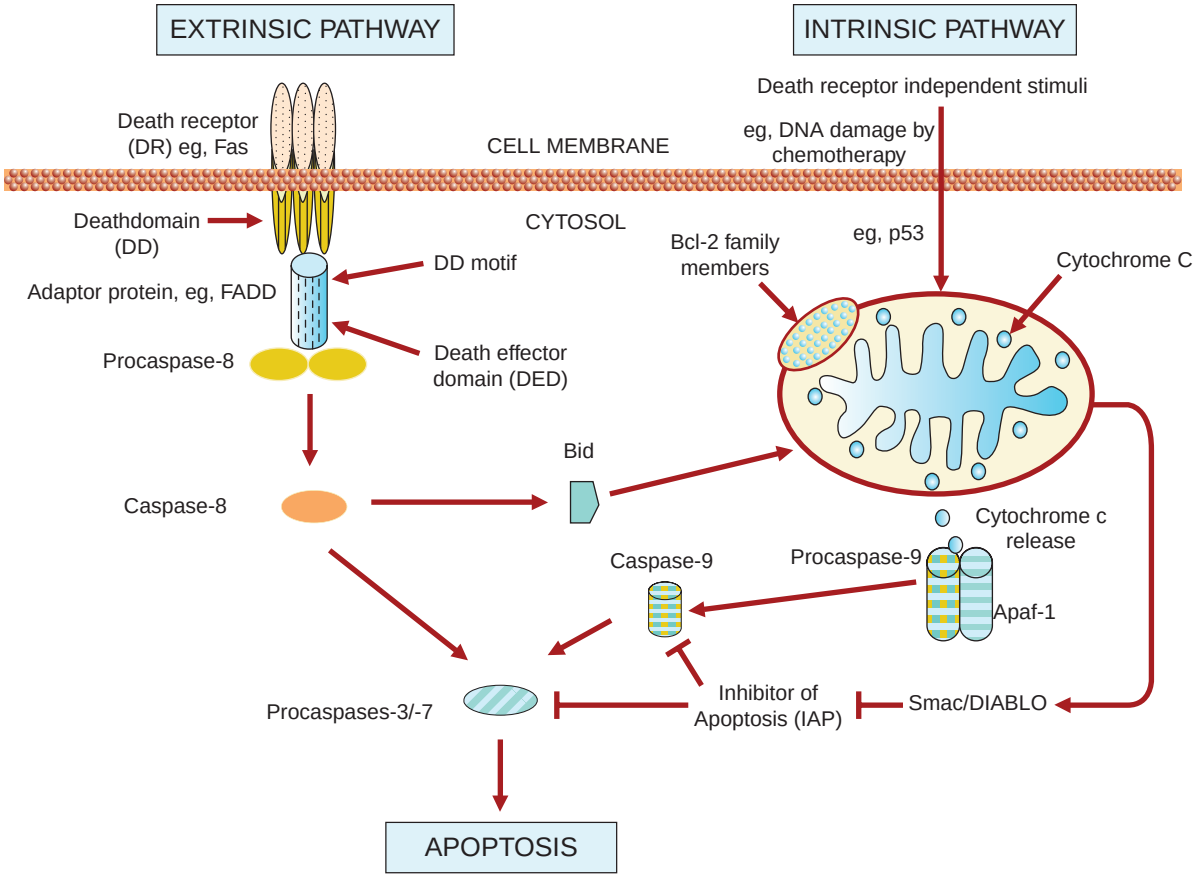

FIGURE 90.4. Apoptotic pathways in chronic lymphocytic leukemia.

Two Major Apoptotic Pathways

The *intrinsic apoptotic pathway* is typically initiated by DNA damage, which causes the up-regulation of TP53, an increase in the BAX:BCL2 ratio, and the release of cytochrome *c* from between the inner and outer mitochondrial membranes into the cytosol. Cytochrome *c* binds to and activates apoptosis-activating factor-1 (APAF1) in the cytosol in a process that requires deoxyadenosine triphosphate (dATP). The *N*-terminal of APAF1 binds to and causes the autoactivation of procaspase 9 and, subsequently, caspase 3.[51] The cytochrome *c*/mitochondrial system is important for the activity of chemotherapy, and a deficiency in APAF1 can cause drug resistance,[52] although whether the variable levels of APAF1 in CLL influence sensitivity to chemotherapy is unknown.[51] As discussed later, the triphosphate derivatives of fludarabine and cladribine can substitute for dATP, and part of their cytotoxic activities is related to the binding of APAF1and direct activation of caspases 9 and 3.[53–55] SMAC/DIABLO is also released from the mitochondria along with cytochrome *c* and induces apoptosis by binding to the inhibitor of apoptosis (IAP) family of proteins, which normally inactivate a number of caspases, including caspase 3.[56]

The *extrinsic apoptotic pathway* also plays a major role in apoptosis. There are presently 6 known death receptors (DRs), and these include the Tumor necrosis factor (TNF) receptor, FAS (APO-1 or CD95) and DR4/DR5 (receptors for TNF-related apoptosis-inducing ligand [TRAIL]). These receptors contain a cytosolic domain called the death domain, which recruits adaptor proteins such as FADD/MORT1 to the receptor complex after binding to ligand. The recruiter adaptor protein has a death domain end and a death effector domain (DED). Once bound to the TNF receptor, the DED binds to caspases 8 and 10, which then become activated by autoactivation.[51] Apoptosis through this pathway is controlled by the presence of the receptor and a variety of inhibitors that can bind to the DED in place of the caspases. One of these inhibitors is FLICE inhibitory protein (FLIP), which is a homologue of procaspase 8 and contains 2 DED domains but lacks proteolytic activity.[57] It been reported that CLL cells have high levels of FLIP expression rendering the cells resistant to DR-induced apoptosis.[58]

There is cross-talk between the intrinsic and extrinsic pathways. Thus, caspase 8 can activate Bid, which causes the release of cytochrome *c* from the mitochondria.[50,59] Alternatively, triggering of the intrinsic pathway in CLL cells by chemotherapy or irradiation can activate caspase 8,[60] possibly by activation of caspase 3.[61]

Apoptosis through the TNF receptors plays an important role in controlling lymphoid cell populations, and defects either in FAS ligand or the receptor result in the autoimmune lymphoproliferative syndrome (ALPS) with lymphadenopathy, splenomegaly, and an increase in the risk of subsequent autoimmune diseases and lymphomas. FAS is normally up-regulated in activated lymphocytes, and CLL cells are not sensitive to FAS ligand, even if FAS (CD95) is increased through the use of *Staphylococcus aureus* protein A from Cowan I plus interleukin (IL)-2, CD40 ligation, or through α- or γ-interferon.[60–63] DR4 and DR5 receptors are present on CLL cells, but the extent of sensitivity of these cells to TRAIL is controversial.[57,64] CLL cells secrete both TRAIL[65] and FAS ligand,[60,65] which may suppress normal T-cells and contribute to the immunosuppression seen with this disease.

Apart from the direct induction of apoptosis through the interaction with TNF ligands, the TNF receptors may play a role in the activity of chemotherapeutic agents. Chemotherapeutic

agents may up-regulate receptors for FAS[66,67] or DR4/DR5,[68,69] which could prime the cells to physiologic levels of FAS ligand or TRAIL. However, although fludarabine and chlorambucil increase FAS messenger RNA levels in CLL cells in vitro, they do not affect the levels of FAS protein.[60] In contrast, irradiation does increase FAS protein levels, but none of these agents sensitizes CLL cells to FAS ligand.[60] Fludarabine and chlorambucil increase the messenger RNA and cell-surface protein expression levels of DR4/DR5 in CLL cells, and this sensitizes the cells to TRAIL.[64]

Modulators of the Apoptotic Pathway in Chronic Lymphocytic Leukemia

The above pathways are modulated by a variety of proteins, which may be altered in CLL. The *BCL2 family* consists of approximately 20 members that can either promote or inhibit apoptosis. These proteins are located in the cell membrane, nuclear membrane, and mitochondrial membrane, and function by binding to other proteins or influencing cell permeability and the release of cytochrome *c* from the mitochondria. Some BCL2 family members (e.g., BAX, BCLXS, BAK, and BAD) promote apoptosis, whereas others (e.g., BCL2, BCL-xL, and MCL-1) inhibit apoptosis.[70–76] In addition, another group (e.g., BAG1) can influence the activities of the other family members. CLL cells have high BCL2, BAX, and BAK levels but have low levels of BCLXL and BAD.[70–76] The BCL2 overexpression is related to hypomethylation of DNA, rather than to a translocation, and may contribute to the longevity of the CLL cell.[70] CLL cells with high BCL2 levels have more prolonged in vitro survival than those with low levels, and decreasing BCL2 expression by antisense oligonucleotides can induce apoptosis.[70] Whether the BAX and BCL2 levels or the BAX:BCL2 ratios are predictive of drug sensitivity in CLL is controversial.[71–76] MCL1 protein levels are variable in CLL, and it has been suggested that patients with high levels are more resistant to chemotherapy.[74] An insertion of either 6 or 18 nucleotides in the promoter of MCL1 is found in CLL cells with a lower incidence in normal B cells.[77] An analysis of matched pairs of normal versus leukemia cell samples indicates that the MCL1 promoter insertions represent somatic alterations and not hereditary polymorphisms. This insertion is associated with higher levels of MCL1 protein and nonresponsiveness to chemotherapy.[77] However, other groups have not confirmed these findings and the importance of an insertion in the MCL1 promoter remains to be determined.[78] In addition, a guanine-to-adenosine substitution at position 125 (G125A) in the BAX promoter has been associated with decreased BAX expression, advanced disease, and drug resistance in CLL.[79]

A number of other proteins play a role in apoptosis, and their expressions can be affected by the genetic changes in CLL, as discussed in the section on "Genomic Abnormalities." The tumor-suppressor gene, *TP53*, is a transcriptional activator and is located on chromosome 17p13.[80,81] TP53 protein is phosphorylated and stabilized after DNA damage, such as that produced by radiation or alkylating agents, through activation of ATM kinase and DNA-dependent kinase.[80] Cell cycle blockage at G_1 or G_2 may occur, allowing the cell to repair the damage before entering the S- or M-phase.[80] However, TP53 may also induce apoptosis, and this occurs preferentially in tumor cells, a feature that may explain the relative tumor specificity of anticancer agents.[81] Mechanisms for TP53-induced apoptosis are through up-regulation in the expressions of the TRAIL DRs, DR4, and DR5, and increased expression of the proapoptotic BCL2 family members, BAX, NOXA, and PUMA.[82] *TP53* mutations are typically associated with deletions of the second allele (deletion 17p13), and mutations or TP53 gene deletions are observed in 10% to 15% of CLL patients (see section "Genomic Abnormalities"); these abnormalities are associated with high lymphocyte counts, drug resistance to anticancer agents in vitro and in vivo, and poor patient survival.[2,72,73,83,84] In a longitudinal study of 181 patients, the percentage of leukemic cells with a *TP53* mutation increased during the course of the disease, indicating that the mutation provides a survival advantage for the tumor cells.[83] The *murine double minute-2* (*MDM2*) gene is located on chromosome 12 and is transactivated by TP53.[80] The MDM2 protein enhances the binding of TP53 to ubiquitin, and TP53 is subsequently degraded.[80] Thus, overexpression of MDM2 in cell lines reduces the capacity of *TP53* to block the cell cycle in G_1 after irradiation and speculatively could also decrease TP53-induced apoptosis and produce drug resistance.[72] However, although the MDM2 protein has been found to be overexpressed in two-thirds of CLL cases, this does not correlate with disease stage, aggressiveness, or drug resistance.[72,85]

The *ATM gene* is located on chromosome 11q22-q23 and is responsible for phosphorylation and activation of p53 after DNA damage.[80,86] Approximately 10% to 20% of CLL patients have a mutation of *ATM*, and about half of these will have a defective response to irradiation, similar to that with a *TP53* mutation, if all alleles are mutated or if one is mutated and the other lost because of a deletion of 11q22-23.[86,87] Approximately one third of patients with a mutated *ATM* have a deletion 11q22-23 and one third of those with a deletion 11q22-23 have a mutation on the other allele.[86,87]

Microenvironment

Overview

The microenvironment in the peripheral blood, spleen, lymph nodes, and marrow plays an important role in the biology of CLL. In the bone marrow and lymph nodes, follicular dendritic, stromal, and/or fibroblast cells interact with CLL cells whereas in the peripheral blood the interaction is with "nurselike" cells and T-cells.[88] Co-culture of CLL cells with "nurselike" or stromal cells decreases spontaneous apoptosis in the leukemia cells, promotes CLL cell proliferation, and confers drug resistance.[89–91] This effect seems to require cell–cell contact and CLL cells interact with the microenvironment through activation of their cell surface receptors. The BCR plays a central role in CLL biology in the microenvironment through maintenance and expansion of the CLL cell clone. BCR signaling is controlled by intracellular tyrosine kinases such as spleen tyrosine kinase (Syk), and Bruton's tyrosine kinase (BTK; Fig. 90.5).[92,93–97] In addition, aberrantly expressed CD40L on CLL cells can interact with CD40 on microvascular endothelial cells which leads to the release of the TNF family members, BAFF (B-cell activating factor of the TNF family), and APRIL (a proliferation-inducing agent).[98] Receptors for BAFF and APRIL (BMCA, TAC1, and BAFF-R) are present on CLL cells and stimulation leads to increased survival and induction of the expression of CD40L on the CLL cells thus further potentiating the cycle. This exemplifies the cross-talk between CLL and stromal cells in the microenvironment. Adhesion molecules are also important for CLL cell survival. β1 and β2 integrins on CLL cells bind to CD54 and CD106 on stromal cells and this promotes cell survival.[99,100] Moreover, neutralizing antibodies against various integrins induces the CLL cells to undergo apoptosis.[101] Caveolin-1 expression by CLL cells in lymph nodes may stimulate CLL proliferation and migration but also mediates immune synapses with autologous T lymphocytes which contributes to immune tolerance.[102] Finally, CD44 on CLL cells is a receptor for hyaluronic acid and collagen, thus helping retain the cells in the microenvironment.[103]

In addition to cell–cell contact, the extracellular milieu contains molecules such as growth factors, proteins, and lipids that contribute to CLL progression.[89] Stromal and CLL cells produce cytokines that may stimulate leukemia cell growth in an autocrine or paracrine fashion while inhibiting survival of normal lymphoid and marrow cells. This latter effect can lead to the

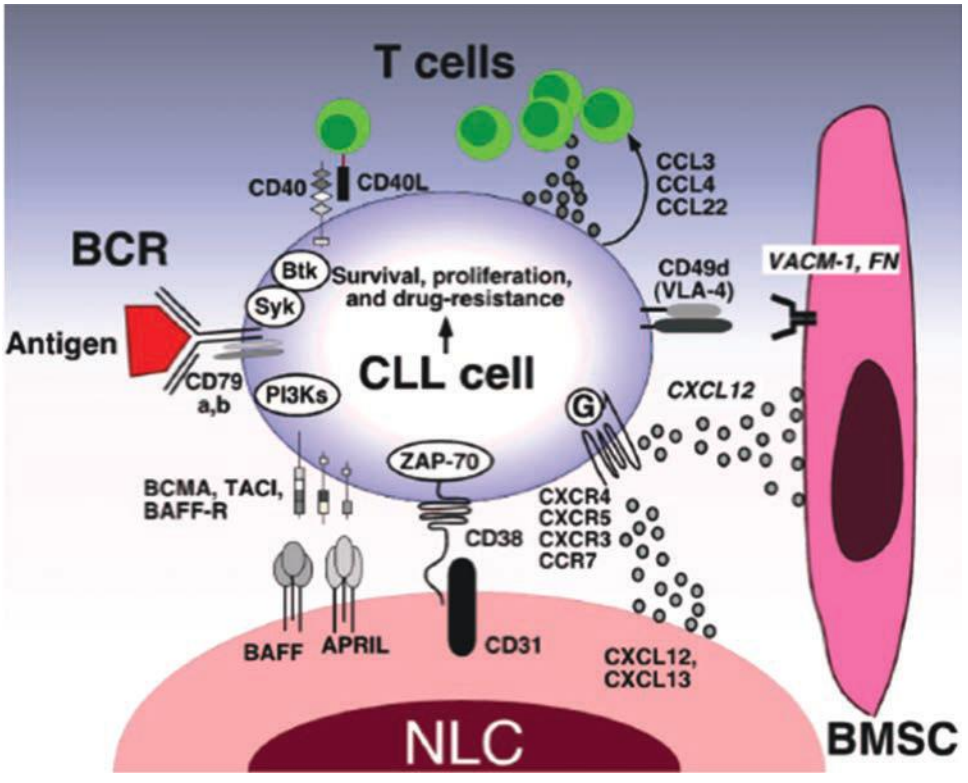

FIGURE 90.5. Molecular interactions in the chronic lymphocytic leukemia (CLL) microenvironment. Molecular interactions between CLL and stromal cells in the BM and/or lymphoid tissue microenvironments that are considered important for CLL-cell survival and proliferation, CLL-cell homing, and tissue retention. Contact between CLL cells and nurselike cells (NLCs) or bone marrow stromal cells (BMSCs) is established and maintained by chemokine receptors and adhesion molecules expressed on CLL cells. NLCs express the chemokines CXCL12 and CXCL13, whereas BMSCs predominantly express CXCL12. The chemokine receptors CXCR3 and CCR7 are additional chemokine receptors on CLL cells that are involved in lymphatic tissue homing. NLCs and BMSCs attract CLL cells via the G-protein–coupled chemokine receptors CXCR4 and CXCR5, which are expressed at high levels on CLL cells. Integrins, particularly VLA-4 integrins (CD49d), expressed on the surface of CLL cells cooperate with chemokine receptors in establishing cell–cell adhesion through respective ligands on the stromal cells (VCAM-1 and fibronectin). NLCs also express the TNF family members BAFF and APRIL, providing survival signals to CLL cells via corresponding receptors (BCMA, TACI, and BAFF-R). CD38 expression allows CLL cells to interact with CD31, the ligand for CD38 that is expressed by stromal and NLCs. Ligation of CD38 activates ZAP-70 and downstream survival pathways. Self- and/or environmental Ags are considered key factors in the activation and expansion of the CLL clone by activation of the BCR and its downstream kinases. Stimulation of the BCR complex (BCR and CD79a,b) induces downstream signaling by recruitment and activation of Syk, Btk, and PI3Ks. Finally, BCR stimulation and co-culture with NLCs also induces CLL cells to secrete chemokines (CCL3, CCL4, and CCL22) for the recruitment of immune cells (T-cells and monocytes) for cognate interactions. $CD40L^+$ ($CD154^+$) T-cells are preferentially found in CLL-proliferation centers, and can interact with CLL cells via CD40. From Burger JA. Nurture versus nature: the microenvironment in chronic lymphocytic leukemia. Hematology (Am Soc Hematol Educ Program) 2011;2011:96–103.

immunosuppression and myelosuppression that typify this disease. In addition, the chemokine receptors CXCR4 and CXCR5 on CLL cells regulate CLL cell trafficking to the stromal cells (which produce the receptor ligands, CXCL12 and CXCL13, respectively) in the microenvironment where the CLL cells produce IL-6 and IL-8, which in turn provide signals for cell survival.[11,104] Upon BCR activation, CLL cells secrete cytokines such as CCL3 that attract additional accessory cells such as T-cells to join the CLL and stromal cells.[105] In addition to signaling, stromal cells also supply essential nutrients to the CLL cells. For example, CLL cells have limited capacity to transport cystine for glutathione synthesis due to low expression of Xc-transporter.[106] In contrast, stromal cells can effectively transport cystine and convert it to cysteine which can then be released into the microenvironment where the CLL cells take up the cysteine for GSH synthesis. CLL cells can also influence stromal cells signaling through microvesicles.[107] Microvesicles are released by CLL cells and can modulate the activity of the bone marrow stromal cells (BMSCs). The microvesicle can activate the AKT/mammalian target of rapamycin (mTOR)/p70S6K/hypoxia-inducible factor-1alpha axis in CLL-BMSCs with production of vascular endothelial growth factor (VEGF), a survival factor for CLL cells.[107,108] They can also transfer various messages to target cells that may be critical to disease progression. In the clinic, molecular targeting of the microenvironment through CXCR4 antagonists or BCR kinase inhibitors disrupts the interactions between CLL cells and the microenvironment.[109,110,111] These chemotherapeutic agents have shown promising pre-clinical activities.

Cellular Features of the Microenvironment

BMSCs and other cells of the lymphatic tissue have intrinsic characteristics to support CLL cell functions.[111,112] Normal hematopoiesis depends upon BMSCs as the BMSCs provide attachment sites and growth signals for the hematopoietic precursors. In CLL the BMSCs create niches where CLL cells are nourished and protected from either spontaneous or chemotherapy-induced apoptosis. The CLL cells bind to BMSCs with high affinity which allows tight adhesion and migration of the CLL cells underneath the BMSCs. Both murine and human BMSCs have similar effects on CLL cell growth and cell survival. BMSC are of mesenchymal origin and are similar to mesenchymal stromal cells in other tissues. Follicular dendritic cells (FDCs) are also found in lymphatic tissue and support CLL cell survival. These FDCs are being used to express CLL specific antigens and are under clinical investigation for the development of vaccines for CLL.[113] The CLL cells also cross-talk with stromal cells through the CXCR4–CXCL12 and the CD40–C40L axis discussed in detail later.

Nurselike cells (NLC) are differentiated monocytes that are large, round, and adherent cells that bind to CLL cells mainly in

the peripheral blood system. However, NLCs can be found in the spleen and secondary lymphoid tissue.[89] There is diverse cross-talk between NLC and CLL cells. NLC express CXCL12, CXCL13, and CD31 plexin B1 BAFF and APRIL and vimentin.[88,112] All these cell-surface markers interact with CLL receptors providing survival and proliferative signals.

T lymphocytes also interact with CLL cells. The number of circulating T-cells in CLL patients is often increased and this might be due to interactions with CLL cells. T-cells can either suppress or stimulate expansion of CLL cells. In the proliferation centers, T-cells co-localize suggesting that T-cells support the CLL proliferation.[112,113] This is supported by evidence that CLL cells fail to proliferate in immunodeficient mice, demonstrating that activated $CD4^+$ T-cells could be important for CLL proliferation.[114]

Survival Factors in the Microenvironment

B-cell receptor (BCR): The BCR is the most studied receptor in mature B-cells due to its important role in recognizing foreign antigens and activating B-cell proliferation and transformation into plasma cells. It has also been implicated in B-cell survival. In CLL cells, the BCR can be activated by binding to antigen-presenting cells, such as FDCs, and this promotes cell survival and protects the cells against drug-induced apoptosis.[88,90] Activation of ZAP-70 through ligation of the BCR may play an important role in promoting cell survival in CLL.[93–96] Overall, the protective effect of BCR activation against apoptosis has been related to increased expression of antiapoptotic BCL2 family members, especially MCL1.[97] Indeed, biopsies of CLL cells in the lymph nodes and bone marrow of CLL patients indicated that BCR activation signatures are found in CLL cells in these microenvironments.[115] Inhibitors of the BCR-activated kinases including SYK, mTOR, phosphoinositide 3′-kinase (PI3K), and BTK, have been found to decrease CLL cell viability through modulation of the microenvironment.[116,117,118,119] BCR pathway inhibitors appear to be highly active in refractory CLL, independent of the presence of poor prognostic markers, such as deletion 17p13.[119] However, the extent of BCR activation in CLL remains controversial inasmuch as CLL cells are less responsive than naive B-cells to BCR activation.

Interleukins: CLL cells have receptors to various ILs and the levels of IL-4 and IL-8 are elevated in the blood of some patients. The addition of IL-4 and IL-8 to CLL cells protects them against spontaneous and drug-induced apoptosis.[120] A number of other IL (e.g., IL-1, IL-2, IL-6, and IL-8) can also prevent CLL cells from undergoing spontaneous apoptosis and these may be derived from the CLL cells (IL-1, -6, and -8), T cells (IL-2 and -4) or stromal cells.[88,121,122] CLL cells differ from normal $CD19^+$ B-cells in producing the lymphoid stem cell growth factor, IL-7, suggesting that this cytokine might also be important in disease pathogenesis.[123] IL-7 does not itself induce proliferation or prevent apoptosis of CLL cells in vitro.[123] However, the prevention of apoptosis of CLL cells by co-culturing with endothelial cells appears to be related to the maintenance of intracellular IL-7 levels, which occurs by signaling through the cell-surface β2-integrin.[123] Both IL-2 and IL-15 stimulate the proliferation of CLL but not normal B-cells.[124] Moreover, IL-2 is sequestered by the CLL cells and by the increased serum levels of the IL-2 receptor (TAC receptor) seen in this disease, preventing its interaction with normal lymphocytes.[125,126] High levels of IL-6 have been shown to be a better prognostic marker than Ig mutation status in older CLL patients indicating the importance of ILs in disease progression.[104] This may also partly explain the immune dysfunction seen in CLL.

Tumor necrosis factor-α (*TNF-α*): CLL cells produce TNF-α in vitro.[127,128], and TNF-α decreases apoptosis in these cells through the induction of BCL2 expression[127,129–131] In addition, TNF-α may induce the proliferation of CLL cells while suppressing the growth of normal lymphocytes and marrow cells.[127,129–131] The serum level of TNF-α is increased in most patients with CLL, and the highest levels are observed in those with advanced disease.[130] An increase in the serum levels of the soluble receptors for TNF-α has also been observed in CLL.[132]

Transforming growth factor-β (*TGF- β*): TGF-β is secreted by CLL and marrow stromal cells.[133,134] TGF-β inhibits DNA synthesis in both CLL and normal B-cells, although the degree of inhibition can be quite low in CLL as a result of the loss of TGF-β receptors.[135,136] In contrast to normal B-cells, CLL cells are consistently resistant to apoptosis induced by TGF-β.[137]

Adhesion molecule receptors: It has long been known that adhesion molecules on the cell surface are important for cell survival. For adherent cells, such as epithelial cells, removal of the cells from their attachments and resuspending the cells in culture results in apoptosis, called anoikis.[99] Binding of adhesion molecules such as integrins can prevent aniokis suggesting that cell–cell contact is important in maintaining cell viability. Although CLL cells can be in suspension they do adhere to other cells in the marrow, lymph nodes, and peripheral blood and adhesion molecules play a role in protecting the leukemia cells against apoptosis.[138] As mentioned previously, β1 and β2 integrins and CD44 are also present on the CLL cell surface.[99,100,103]

BMCA, TAC1, and BAFF-R: CLL cells express BAFF and APRIL along with their corresponding receptors BMCA, TAC1, and BAFF-R.[139] The addition of exogenous BAFF and APRIL to CLL cells prevents spontaneous and drug-induced apoptosis.[141] These molecules are known factors in B-cell survival, differentiation, and apoptosis.[139] Conversely, the addition of a soluble form of the BMCA receptor or neutralizing antibodies against BAFF or APRIL results in increased apoptosis.[140] CLL cells secrete BAFF and APRIL and the plasma levels of APRIL are higher in CLL patients than in normal individuals.[139,140] In addition, antigen-presenting cells, such as dendritic cells, express high levels of BAFF and APRIL.[140] Because CLL cells have receptors for BAFF and APRIL, autocrine and paracrine survival signaling likely occurs in CLL.[139,140] This concept is supported by the fact that the ability of "nurselike" cells to provide survival signals to CLL cells is reduced by the presence of decoy receptors for BAFF and APRIL.[139]

Vascular endothelial growth factor (VEGF) receptor: VEGF is an angiogenic factor that is involved in cell survival for many cancers.[141] In CLL, VEGF protects the leukemic cells from both spontaneous and drug-induced apoptosis whereas apoptosis is increased by adding inhibitors to VEGF receptor kinase.[142,143] CLL cells express VEGF receptors 1 (VEGFR1) and 2 (VEGFR2) and increased protein levels of VEGFR2 are associated with elevated lymphocyte counts and advanced disease.[143,144] Furthermore, CLL cells secrete VEGF and the levels of VEGF are increased in the plasma of CLL patients.[144,145] The mechanism responsible for VEGF production by CLL cells is unclear but activation of CD40 by CD40 ligand (CD40L), which may be produced by CLL and other cells (see below) may be important for this activity.[142]

CD40: CD40 is a glycoprotein of the TNF superfamily that is expressed on B-cell surfaces and is important for B-cell differentiation and function, whereas the CD40 ligand (CD40L) is expressed on activated T-cell surfaces. In addition to T-cells, NLC also express CD40L.[146] CD40L binds to normal B lymphocytes promoting proliferation and cell survival.[147] Similarly, stimulation of CD40 on CLL cells induces proliferation and the release of cytokines[148] and also prevents apoptosis induced by chemotherapy.[149,150] CLL cells may also release CD40L, and the level of ligand is high in the plasma of CLL patients.[151] As CLL cells have both CD40 and CD40L, it has been suggested that the cell may stimulate its own growth and survival, perhaps through up-regulation of the antiapoptotic protein survivin (a member of the IAP family).[147,151,152] In contrast to the CD40 survival function, increased CD40 expression may lead to better recognition by cytotoxic T-cells and increased CLL cell killing.[153] Moreover,

co-stimulation of CD40 and FAS on CLL cells can increase apoptosis.[154] A novel therapeutic approach has thus been recently explored in which CLL cells are induced to secrete CD40L by a viral transfection strategy.[155]

Stromal-derived growth factor-1 (SDF-1) receptor: SDF-1 is a chemokine that is normally secreted by stromal cells. The receptor for SDF-1 is CXCR4, which is expressed on CLL cells and the addition of SDF-1 protects CLL cells from spontaneous and drug-induced apoptosis.[156] Similarly, CLL cell survival is increased when the cells are co-cultured with stomal cells.[157] NLC can also express SDF-1 and the levels of SDF-1 are increased in the plasma, suggesting that this cytokine is probably important for CLL cell survival.[158]

Basic fibroblast growth factor (bFGF) receptor: It has been demonstrated that the bFGF levels in the serum of CLL patients are elevated and that bFGF treatment of CLL cells prevents apoptosis through a decrease in TP53 expression and up-regulation of BCL2 expression.[159]

NOTCH receptors. The Notch family consists of four receptors NOTCH 1 to 4 and five ligands, including Jagged1 and Jagged 2. All NOTCH receptors and ligands are constitutively expressed on CLL cells and on BMSCs.[113] As discussed in detail later, NOTCH 1 gain-of-function mutations are detected in approximately 10% of CLL patients at diagnosis and the incidence increases with disease progression and the development of drug resistance. This is consistent with NOTCH signaling being involved in CLL survival and resistance to apoptosis. The microenvironment may also influence NOTCH signaling in CLL cells through integrins and chemokine receptor activation.[113]

Albumin: Albumin is the major protein in the blood and can decrease both spontaneous apoptosis and apoptosis induced by irradiation or chlorambucil in primary CLL cells in vitro.[160] This effect is related to the uptake of albumin into the CLL cells with activation of AKT protein kinase. In contrast, the protective effect of albumin against chlorambucil is not seen in normal B or T lymphocytes.

Lysophosphatidic acid (LPA): LPA is a soluble phospholipid with a wide range of biologic activities and can protect epithelial and fibroblast cell lines from apoptosis.[161] Similar to albumin, LPA protects CLL cells, but not normal B-cells, from spontaneous and drug-induced apoptosis and this effect is mediated through the AKT kinase.[161] Blockage of the LPA receptor or inactivation of AKT prevents the protective effect of LPA. As albumin allows for the solubilization of lipids in plasma it is possible that the protective effect of albumin is mediated through the carriage of LPA.[161]

Cell Survival Signaling Pathways in Chronic Lymphocytic Leukemia

The microenvironment influences survival responses primarily through receptor activation. This leads to activation of signal transduction pathways that regulate gene expression and BCL2 family member functions. These survival signaling pathways have overlapping functions and cross-talk with each other. The following is a brief description of the survival pathways in CLL.

The transcription factor nuclear factor-κB (NF-κB) plays an important role in suppressing apoptosis by inducing the expression of a variety of antiapoptotic genes.[162,163] NF-κB is inactivated by IκB, which binds NF-κB and prevents its access to the nucleus; activation of NF-κB occurs by the phosphorylation of IκB, which leads to the coupling of IκB with ubiquitin. This complex is degraded by a protease called the proteasome. The levels of NF-κB are high in CLL and are increased further by stimulation with CD40 ligand, which plays an important role in preventing apoptosis and prolonging cell survival in CLL.[164] In addition, inactivation of the proteasome by inhibitors such as lactacystin, MG132, and bortezomib can induce death of CLL cells but not of normal lymphocytes.[165–167] Cell death is mediated through the cytochrome *c*/mitochondrial pathway, and these agents may be useful in drug-resistant disease.[165–167]

The protein kinase AKT is activated through phosphatidylinositol 3′-kinase and can suppress apoptosis by inactivating bad, caspase 9, and other proapoptotic proteins through phosphorylation.[168,169] In addition, AKT can activate NF-κB and regulate the expression of antiapoptotic genes. This pathway is activated by autologous plasma in CLL, which may explain the relative resistance of these cells to spontaneous and drug-induced apoptosis when they are grown in plasma.[169] Overexpression of TCL1 in a transgenic mouse model leads to the expansion of B-cells which have similar characteristics as CLL cells.[170] The B-cells overexpressing TCL1 have increased levels of activated AKT, which may explain the enhanced survival of these cells.[171]

The mitogen-activated protein kinase (MAPK) signaling pathway is also activated in CLL cells. This pathway consists of extracellular regulated kinase (ERK), Jun N-terminal kinase (JNK), and p38 MAPK. BCR activation leads to ERK activation and up-regulation of BCL2 family members.[172] During apoptosis, ERK activation is often suppressed.[173] p38 MAPK activation is elevated in CLL cells and plays a role in CLL survival mediated by human stromal cells.[174] In contrast, JNK activation is associated with increased apoptosis in CLL cells.

The JAK-STAT signaling pathway is an emerging pathway activated in CLL cells contributing to cell survival and drug resistance. In CLL, STAT3 is constitutively phosphorylated on serine 727 and is associated with increased transcriptional activation. STAT3 contributes to increased expression of antiapoptotic proteins such as X-linked apoptosis inhibiting protein (XIAP).[175–177] STAT3 has also been shown to cross-talk with the NF-κB in CLL cells increasing cell survival.[178] The JAK-STAT pathway is activated by growth factors such as VEGF.[179] These factors are found in the microenvironment indicating that the JAK-STAT pathway might be a good target for disrupting the CLL microenvironment.

Abnormalities in Cell Division

Although CLL cells in the peripheral blood are not dividing, the telomeres of these cells are shorter than in normal B-cells, suggesting that the leukemic cells have undergone more frequent cell divisions than normal B-cells.[180] Moreover, the telomeres in CLL cells with unmutated IgV_H genes have shorter telomeres than those cases with mutated IgV_H genes.[180] Using deuterated water (^2H_2O) to label DNA, it has been estimated that 0.11% to 1.76% (median, 0.39%) of the CLL cells in patients are dividing each day, which is the same or greater than that observed in the B-cells from normal individuals.[181] Although CLL cells in the peripheral blood are not dividing, cells in the "proliferation centers" in the lymph nodes or marrow are dividing, where, under the influence of $CD4^+$ cells they express the proliferation markers, survivin and Ki67, and become $CD38^+$.[2,14,182,183] Moreover, greater uptake of ^2H_2O is observed in the $CD38^+$ cell fraction as compared to the CD38– cells confirming their role in cell proliferation.[184] Gene expression profiling has demonstrated that CLL cells in the lymph nodes have increased expression of genes related to BCR activation, as compared to cells from the peripheral blood.[115] These changes include increased expression of phosphorylated Syk and NF-κB and are less marked in marrow than in the lymph nodes. As predicted, the changes are greater in unmutated IgV_H cases than in mutated IgV_H cases and correlate with the rate of cell proliferation, as measured by Ki67.

Passage through the cell cycle is controlled by the interaction of the cyclins and the cyclin-dependent kinases (CDKs); the levels of the CDKs remain constant, whereas the levels of the five different cyclins fluctuate and activate the appropriate CDK, leading the cell through the cycle (Fig. 90.6).[185] In addition, 2 classes of CDK inhibitors, the INK4 proteins and the Cip/Kip proteins, control the

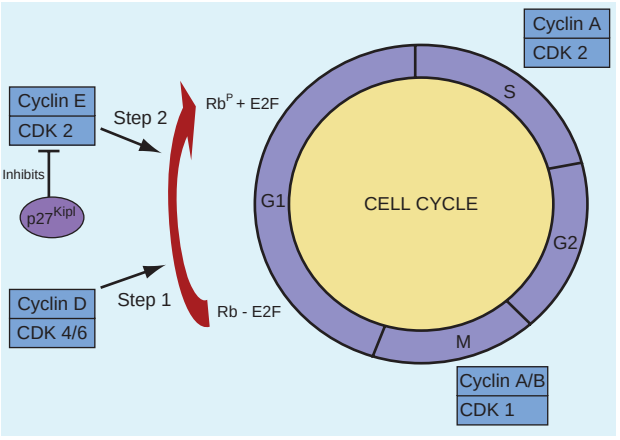

FIGURE 90.6. Control of the cell cycle. Both cyclins D2 and D3 are overexpressed in chronic lymphocytic leukemia cells, but the retinoblastoma (Rb) protein is not phosphorylated, perhaps related to overexpression of $p27^{Kip1}$. CDK, cyclin-dependent kinase.

activity of the CDKs.[186] Normally, when quiescent cells enter the cell cycle, the D cyclins (D1, D2, and D3) in conjunction with CDKs 4 and 6 bring the cell into the S-phase. The D cyclin/CDK4/6 initiates phosphorylation of the retinoblastoma (Rb) protein, which is then further phosphorylated by cyclin E/CDK2. Another function of the D cyclins/CDK4 is the sequestration of the CIP/KIP inhibitors $p27^{Kip1}$ and $p21^{Cip1}$, which normally inhibit the activity of cyclin E/CDK2. Although the majority of the peripheral blood CLL cells are quiescent and in G_0/G_1, the expression of cyclins D1, D2, and D3 are increased in these cells.[187–189] Despite these findings, the Rb protein is not phosphorylated in unstimulated CLL cells[190]; this may be related to overexpression of $p27^{Kip1}$, high levels of which are associated with high lymphocyte counts and poor patient survival.[191] CDK1 (cdc2) is a serine/threonine kinase involved in G2-M phase transition and gene expression studies have shown that this gene is highly expressed in patients with del 11q22-23 cells.[192]

Genomic Abnormalities

Tremendous strides have been made in the analysis of the CLL genome, providing insight into pathogenesis and identifying genes that are important as markers of disease progression and drug resistance. Initial classical cytogenetic studies were carried out in the 1980s, but it was difficult to obtain metaphases in CLL.[84,193] When analysis was possible, clonal chromosomal abnormalities were detected in approximately 50% of cases,[84,193–206] and it is likely that the normal karyotyping in many of the remaining cases was due to analysis of contaminating normal T-cells. Of the 50% of cases with clonal abnormalities, one half had one clonal abnormality, and the remainder had 2 or 3 abnormal clones.[195] However, with the more recent use of the CD40 ligand, or a combination of IL-2 and CpG-oligodeoxynucleotides, to stimulate CLL cells, metaphases are now routinely obtained in over 90% of cases with aberrations detected in greater than 80% of samples.[207–209]

Using FISH and comparative genomic hybridization (CGH) to analyze interphase cells (FISH) or isolated DNA (CGH), abnormalities are detected in over 80% of cases.[84,193] FISH is highly sensitive, but the specific abnormality to be studied needs to be known in advance, and this is therefore not a good technique to screen for new abnormalities. In contrast, CGH has been used to screen for chromosome gain or loss (i.e., aneuploidy, gene amplification, or deletions not detected by conventional cytogenetics).[193] More recently, new assays, including SNP and DNA sequencing have advanced our ability to detect genetic abnormalities.

Analysis by Conventional Cytogenetics

Using conventional cytogenetics, the International Working Party on Chromosomes in CLL reported in 1990 that clonal chromosomal abnormalities were obtained in 311 patients (51%) out of a total of 604 cytogenetically evaluable cases (Table 90.1).[200,201] The most common clonal abnormality was trisomy 12 (36%, or 19% of all evaluable cases), either by itself or in combination with other cytogenetic changes. Other frequently observed alterations included structural abnormalities of chromosome 13 (20%, or 10% of all cases) and of chromosome 14 (16%, or 8% of all cases).[199,200] The 13q abnormalities usually involved a 13q14

[c]In 50% of cases, clonal abnormalities were not obtained. As these studies were not carried out on purified chronic lymphocytic leukemia cells, some of the cases with normal cytogenetics reflect analysis of normal T-cells.

deletion (site of the *RB1* gene) or translocations with a breakpoint at chromosome 13q14. The 14q abnormalities included translocations from a variety of chromosomes, usually involving chromosome 11, suggesting that these patients had actually mantle cell lymphoma. Less than 5% of patients had an 11q22-q23 deletion. The abnormalities of chromosomes 12 and 13 occurred with equal frequency in cases with a single clonal abnormality and in patients having more than one clonal abnormality.[195,199] In contrast, abnormalities of chromosome 14 occurred primarily in patients having more than one clonal abnormality.[195,199] In general, patients with abnormal karyotyping had a worse prognosis than those with normal cytogenetics, and the outlook was poorest for those with multiple clonal abnormalities.[196–202] In addition, the higher the percentage of cells at metaphase with a clonal chromosomal abnormality, the worse the prognosis. Of patients with a single clonal abnormality, those with trisomy 12 had the worst prognosis, and those with $13q^+$ had a similar survival as cases with normal karyotyping.[199,200] It is interesting that trisomy 12 was usually seen in those 15% of cases with CLL variants, either CLL/prolymphocytic leukemia (CLL/PLL) or "atypical" CLL, and this may explain the poor prognosis associated with these morphologic variants.[202–204] When all patients were considered, regardless of the number of clones, those with chromosome 14 abnormalities had the worst prognosis.[199] As most of the chromosome 14 abnormality group had a t(11;14)(q13;q32), in retrospect, they likely had mantle cell lymphoma and not CLL.[3] 11q22-q23 deletions have been detected in 13% of patients by karyotyping, and these patients had disease progression and poor survival.[205]

Nowadays, metaphases may be obtained in over 90% of patients using either CD40 ligand or a combination of IL-2 and CpG-oligodeoxynucleotides with abnormalities being detected in over 80% of patients.[207–209] These studies demonstrate that many more abnormalities can be detected using classical cytogenetics than seen with FISH alone and that both balanced and unbalanced translocations are observed.[207–209] Mayr et al.[208] observed translocations in one third of CLL patients, and half of these were balanced. The presence of these translocations was a poor prognostic feature and was independent of other prognostic factors for overall survival. Moreover, patients with 13q deletions and translocations had a poorer prognosis than patients with 13q deletions without translocations.

Analysis by Fluorescence in Situ Hybridization

A landmark study by Döhner et al.[84] in 2000 demonstrated the importance of FISH in CLL. In 325 patients, 268 (82%) had abnormalities, with deletion 13q14 being most frequent (55%), followed by deletion 11q22-23 (18%), trisomy 12q13 (16%), deletion 17p13 (7%), and deletion 6q21 (7%).[84] There was one abnormality in 175 (65%) patients, 67 (25%) patients had 2 aberrations, and 26 (10%) patients had more than 2 chromosomal changes. A hierarchical model categorized patients into 5 groups with different prognoses (Fig. 90.7). The median survival times for patients with a 17p13 deletion, an 11q22-q23 deletion, trisomy 12q, normal karyotype and a 13q deletion as the sole abnormality were 32, 79, 114, 111, and 133 months, respectively. Patients with 17p13 or 11q22-q23 deletions had the poorest survival, had more marked lymphadenopathy and splenomegaly, and were more likely to be symptomatic with night sweats and weight loss. Very similar results have been obtained in subsequent prospective studies.[210,211] The incidence of these specific abnormalities detected by FISH differed from the incidence with conventional cytogenetics in older studies, but similar incidences are now being observed where metaphases are being induced using CD40 ligand or a combination of IL-2 and CpG-oligodeoxynucleotides[207–209] (Table 90.1). Patients with unmutated IgV_H are more likely to have deletions of 17p13 or

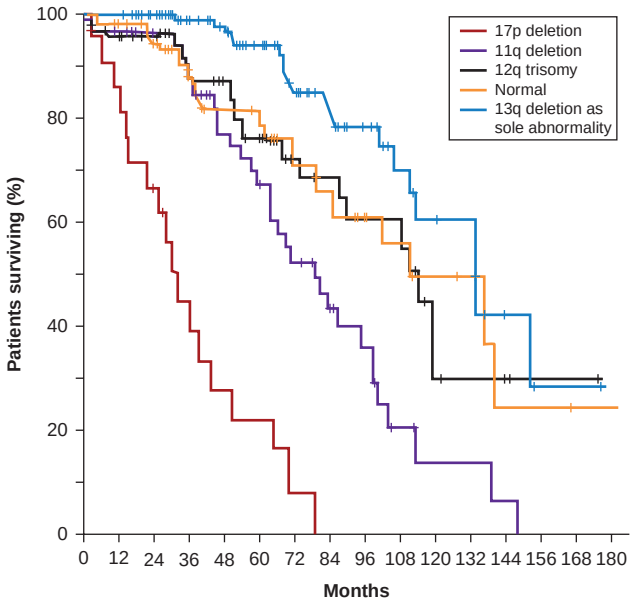

FIGURE 90.7. Survival according to molecular genetic changes in chronic lymphocytic leukemia. From Döhner H, Stilgenbauer S, Benner A, et al. Genomic aberrations and survival in chronic lymphocytic leukemia. N Engl J Med 2000;343:1910–1916, with permission.

11q22-23 whereas patients with mutated IgV_H are more likely to have deletion 13q14.[193] The incidence of trisomy 12 is the same in patients with mutated or unmutated IgV_H.[193]

More recent evidence indicates that the prognosis with a 13q14 deletion depends on the extent of the deletion.[212,213] There are two anatomical landmarks for deletion 13q14: (a) the minimal deleted region (MDR) containing the *deleted in leukemia (DLEU)* 2 gene, microRNA (miR)-15A/16-1 cluster, and the first exon of the *DLEU1* gene; and (b) the *RB1* gene.[212] Of patients with deletion 13q14, 60% had loss of MDR only and 40% also had loss of the *RB1* gene. The prognosis is poorer if >70% nuclei have the deletion or if there is a concomitant loss of *RB1*.[212,213]

It has been recommended that all CLL patients should be routinely examined for an *IGH* translocation.[214,215] Of 1,032 patients at the Mayo Clinic with a presumptive diagnosis of CLL, 76 (7%) were found to have an *IGH* translocation, with 34 involving a translocation with *cyclin D1*, 18 a translocation with *BCL2*, and 6 a translocation with *BCL3*.[214] Upon review, half of the patients with translocations were found to have CLL and half had the leukemic phase of another lymphoid malignancy.

Trisomy 12 frequently occurs in "atypical" CLL or CLL/PLL.[203] However, not all the "atypical" cells in an individual patient contain trisomy 12, indicating that the chromosomal abnormality is not responsible for the atypical morphology.[201,216] In addition, although trisomy 12 connotes aggressive disease, it is unclear whether the proportion of cells with trisomy 12 increases over time.[201,217] Half the patients with CLL/PLL have a *TP53* mutation, suggesting a role for the gene in the pathogenesis of this variant.[218]

Assessment of Genomic Complexity

Recent evidence has suggested that prognosis in CLL is closely linked to the complexity of genetic abnormalities, as well as to the specific defect.[219–220,221,222–224] The majority of patients using either CGH or SNP arrays will have 1 to 3 copy number abnormalities, and these techniques detect abnormalities not seen with FISH and demonstrate that increasing genomic complexity predicts poor prognosis. Moreover, although the presence of 11q21–22 and 17p13 deletions predict the presence of genomic complexity, genomic complexity can be present with

low-risk FISH and is a useful independent prognostic predictor. Kay et al.[219] evaluated genomic complexity using CGH in patients commencing treatment with chemoimmunotherapy. Chromosome deletions were more common than gains and although abnormalties were typically seen in patients with high-risk FISH, complex abnormalities were also seen in patients with 13q deletions. Complex changes were associated with poor response to treatment. Similarly, Ouillette et al.[223] have shown that increasing genomic complexity by SNP is an independent prognostic marker, predicting rapid disease progression, poor response to chemotherapy, and short survival. Genomic complexity has also been shown to correlate with resistance of the CLL cells to undergo apoptosis with radiation in vitro.[222]

Clonal Evolution

Chromosomal abnormalities may be identified in MBL and early CLL, with the likelihood of deletions of 11q22-23 and 17p13 increasing over time and with the development of drug resistance.[2,193] By FISH analysis, one-quarter of patients will have the development of new abnormalities after 5 years, particularly in patients who are ZAP-70 positive, CD38 positive, and those with unmutated IgV_H.[211] Interestingly, patients with unmutated IgV_H have an increased risk of developing deletions of 11q22-q23 or 17p13, whereas those with mutated IgV_H develop deletions of 13q.[211] The risk of developing new genetic abnormalities may be further increased by chemotherapy, as treatment with fludarabine increases the expression of TP53-dependent genes, thus increasing the risk of selecting 17p13 deleted cells.[224] Indeed, 42% of fludarabine-resistant CLL patients have either *TP53* mutations or deletions of 17p13.[225]

Whole Genome and Exome Sequencing

Several recent studies using whole genome and exome sequencing have identified important new mutations in CLL.[226,227,228,229] Nine genes are mutated at increased frequency with 4 being known to be important in CLL, *TP53* (15%), *ATM* (9%), *myeloid differentiation primary response gene 88* (*MYD88*; 10%), and *NOTCH1* (4%). *TP53* and *ATM* have been discussed in detail in other sections. MYD88 is an adaptor molecule of the IL-1 receptor-tolllike receptor signaling pathway and *MYD88* mutations are associated with mutated IgV_H, deletion 13q14, and good prognosis.[226] Stabilizing *NOTCH1* mutations in exon 34 generate a stop codon, producing a shortened and more active isoform of the protein.[227] NOTCH1 is one of 4 NOTCH receptor proteins activated by the Serrate/Jagged or Delta family expressed on neighboring cells and this results in release of the N–IC domain from NOTCH which in turn assembles a transcriptional complex that controls expression of a number of genes.[229] Mutations of *NOTCH1* occur in 8.3% of CLL cases at diagnosis, increase frequency with a Richter syndrome (RS) progression (31%), and drug resistance (20.8%).[227] A number of subsequent studies have demonstrated that NOTCH1 mutations are associated with unmutated *IgVH*, trisomy 12, and correlate with drug resistance, the development of RS, and poor survival.[227,229,230–232,233,234]

Five genes with unestablished roles have also been identified in CLL and these include *splicing factor 3b subunit 1* (*SF3B1*; 15%), *ZMYM3, MAPK1, FBXW7*, and *DDX3X*.[226] SF3B1 is a component of one of the five small nuclear ribonucleoproteins (SnRNP) that form a complex and are involved in splicing messenger RNA. Mutations of *SF3B1* are relatively common in CLL occurring in 15% to 17% of patients and the mutations cause aberrations in splicing activity. Mutations are associated with a deletion of 11q22-23 (36%), are a cause of fludarabine resistance, and are independent prognostic markers for survival.[226,234,235]

Effects of Chromosome Changes on Gene Expression

Deletion 13q13

The most frequent structural abnormality in CLL is a deletion of 13q14 affecting 55% of cases.[84] Of these cases 76% are monoallelic and 24% biallelic, and deletions occur most commonly in patients who have mutated IgV_H disease.[84] The deleted region has been shown to involve the MDR, containing the *DLEU2* gene and microRNA (miR)-15a/16-1.[236] *DLEU2* encodes a noncoding RNA, but its function is unknown, whereas miR-15a/16-1 inhibits proliferation and apoptosis.[236] Using transgenic mice it has been demonstrated that deletion of miR-15a/16-1 alone can lead to MBL and CLL, which is related to increased cell proliferation as a result of the loss of miR-15a/16-1.[237,238] Moreover, as in CLL, many of these cases have a very similar CDR3, suggesting that a common antigen and/or autoantigen causes induction of the monoclonal population. In addition, the disease is more aggressive if there is a concomitant deletion of *DLEU2*, suggesting that this element functions as a tumor-suppressor gene. In the clinical scenario, deletion 13q14 generally encompasses a much larger area than just MDR, with additional loss of a large area called the common deleted region (CDR) which contains *DLEU1, DLEU7*, and *RNASEH2B*.[237,238] Loss of this region, which is telomeric to MDR, results in more aggressive disease than for mice lacking MDR alone. This observation is similar to that in the clinical scenario where loss of *RB1*, which is centromeric to MDR, leads to more aggressive disease.[212,213] Thus, the effect of MDR deletion is potentiated by the loss of adjacent chromosomal material and the prognosis with a deletion 13q14 worsens with the extent of the deletion.

Deletion 11q22-q23

Deletion 11q22-23 occurs in approximately 20% of cases, is seen in younger patients, and is associated with marked lymphadenopathy, rapid disease progression, and poor survival.[84,239–241] The critical region for the deletion is a 3-Mb segment at 11q22.3-q23.1, and candidate genes in this region include radixin (*RDX*), which has homology to the neurofibromatosis-type 2 (*NF2*) tumor-suppressor gene and the *ATM* gene.[240] The ATM protein is a protein kinase activated by DNA double-strand breaks and this leads to phosphorylation and activation of TP53. One third of patients with a deletion 11q22-23 have a mutation on the remaining *ATM* allele and this subgroup has a defective response to DNA damage with radiation or chemotherapy and a poorer overall survival (OS) than the group of patients with a deletion 11q22-23 and wildtype ATM on the other allele.[37,86,87] Thus, the other two-thirds of patients must have an additional defect leading to their poor prognosis. Recently, 36% of patients with deletion 11q22-23 have been shown to have a mutation in *SF3B1*, an abnormality associated with drug resistance and poor survival.[226,235] Although CLL cells with a deletion 11q22-23 do not differ from other CLL cells in growth fraction, NF-κB expression, or response to mitogenic stimuli, they have reduced levels of a number of adhesion proteins, which may explain the marked lymphadenopathy observed in these cases.[240] Complementary DNA microarray analysis has demonstrated that patients with a deletion of 11q22-11q23 have a distinct expression pattern, and overexpress genes involved in cell signaling, cycling, and apoptosis.[192,240,241].

Deletion 17p13

Deletion 17p13 is usually associated with a mutation of *TP53* on the other allele and these patients usually have aggressive and drug-resistant disease with poor survival[72,73,83,84,210] Further details regarding this abnormality are discussed later.

Trisomy 12q13

Trisomy 12 occurs as a result of duplication of one homologue and is seen in 10% to 20% of CLL patients. Trisomy 12 is frequently associated with "atypical" CLL and CLL/PLL. Patient survival is only minimally affected when trisomy 12 is detected by FISH, whereas survival is shortened if trisomy 12 is detected by classical cytogenetics.[84,199,200] 12q13–15 contains the *MDM2* gene, and overexpression of MDM2 could simulate a *TP53* mutation, as MDM2 binds and inactivates TP53.[72,84] However, although MDM2 is overexpressed in two-thirds of patients, the increase does not correlate with disease stage, aggressiveness, or drug resistance.[85]

Translocations of 14q32

Translocation of 14q32 involving *IGH* occurs in 7% of patients with CLL and many of these cases turn out to have a different disorder.[84,193,214] The t(11;14) (q13;q32) occurs typically in mantle cell lymphoma, and the rearrangement on chromosome 11 involves the *BCL1* gene, a G_1 cyclin also called *CCND1* or *cyclin D1*. A t(14;18) (q32;q21) translocation is seen commonly in follicular lymphomas, and this rearrangement juxtaposes the *IGH* locus on chromosome 14 to the 3′ end of *BCL2* on chromosome 18. This rearrangement causes overexpression of BCL2 in the follicular lymphomas with inhibition of apoptosis; although the levels of BCL2 in CLL are equivalent to those in follicular lymphomas, the overexpression in CLL is related to *BCL2* gene hypomethylation.[70,71] The t(14;19) (q32;q13.1) is a rare event and involves the juxtapositioning of *BCL3* on chromosome 19 with the *Ig* gene on chromosome 14. The candidate oncogene *BCL3* is a member of the IκB family, and patients with this translocation have atypical morphology and progressive disease.[242]

CLINICAL FINDINGS

Most CLL patients in the general population are elderly (median age 71.5 years). As a result of referral bias the median age of patients seen in the specialist clinic is 64 years, with 20% to 25% of patients being <55 years old.[11,12,243,244] However, the presenting features are similar regardless of age.[243,244] Nowadays, 70% to 80% of patients are diagnosed incidentally when they have a routine blood count and will have early-stage (Rai 0 or I) disease.[245] Alternatively, lymphadenopathy, splenomegaly, or both may be detected during a regular physical examination. When symptomatic, the most frequent complaint is fatigue or a vague sense of being unwell. Less frequently, enlarged nodes or the development of an infection is the initial complaint, and the most frequent infections are bacterial pneumonias. Fever and weight loss are uncommon at presentation but may occur with advanced and drug-resistant disease.

Most symptomatic patients have enlarged lymph nodes, as well as splenomegaly. Enlargement of the cervical and supraclavicular nodes occurs more frequently than axillary or inguinal lymphadenopathy. The lymph nodes are usually discrete, freely movable, and nontender. Painful enlarged nodes usually indicate superimposed bacterial or viral infection. There is usually only mild to moderate enlargement of the spleen, and splenic infarction is uncommon. Less common manifestations are enlargement of the tonsils, abdominal masses due to mesenteric or retroperitoneal lymphadenopathy, and skin infiltration. Skin lesions in CLL may be caused by squamous and basal cell carcinomas which are thought to be related to immunosuppression (see section "Second Malignancies").[246] Other common cutaneous manifestations include shingles and recalcitrant warts. Direct involvement of the skin by CLL typically affects the face and the features can be quite variable, from macules or papules, which may be vascular or to more extensive involvement that may simulate rhinophyma.[247] Patients can also present with symptomatic anemia, which may be related to marrow replacement or, more rarely, to autoimmune hemolysis or aplasia. Alternatively, patients may have bruising or bleeding, most commonly related to thrombocytopenia and rarely to acquired von Willebrand disease, or factor VIII inhibitors. Rarely, patients may present with a paraneoplastic syndrome, such as nephrotic syndrome, paraneoplastic pemphigus, or angioedema (see section "Autoimmune Manifestations").

Peripheral Blood

The median lymphocyte count at diagnosis is 20 to 30 × 10^9/L, and in most patients, there is a continuous increase in the lymphocyte count over time.[13,243,244] In half the patients, it takes more than 12 months for the lymphocyte count to double; cyclic fluctuations of up to 50 × 10^9/L can occur in the lymphocyte counts of untreated patients, and in others, the count may remain stable for years.[244] The CLL cells are small to medium-sized lymphocytes with clumped chromatin, inconspicuous nucleoli, and a small ring of cytoplasm. Cytoplasmic inclusions occasionally may be observed in CLL cells and may be crystalline, globular, tubular, or rod-shaped.[248] Smudge cells (basket cells or shadow cells of Gumprecht) are commonly seen in the peripheral blood smear in CLL, but not in other lymphoid disorders, and are caused by a decrease in the cellular content of vimentin, a cytoskeletal protein required for maintaining cell structure.[249,250] The number of smudge cells can vary from 1% to 75% (median 28%) and appears to be remarkably consistent in individual patients.[250] One study suggests that patients with ≥30% smudge cells are more likely to have mutated IgV_H and have a better prognosis than those with <30% smudge cells.[250] There can be variations in cell morphology, with some cells being PL, whereas others are larger with abundant cytoplasm, and some are plasmoid or cleaved.[204,251] The French/American/British classification system divides patients into 3 groups depending on the percentage of abnormal cells.[251] In *classical CLL*, >90% of cells are small, and when 11% to 54% of the cells are PL, it is termed *CLL/PLL*. When >15% of the lymphocytes are plasmoid or cleaved and <10% are PL, it is termed *atypical CLL*.[203,204,251] Approximately 80% of patients have classical CLL, and 20% have CLL/PLL or atypical CLL. If ≥55% of the cells are PL, the patient has PLL.

Bone Marrow and Lymph Nodes

Marrow infiltration in CLL may be interstitial, nodular, mixed (nodular and interstitial), or diffuse, with mixed being the most common and nodular the least common.[3,252] Diffuse involvement, in which there is effacement of the fat spaces by tumor, carries the worst prognosis.[3,252] The marrow involvement is random and contrasts with follicular lymphomas, in which paratrabecular involvement is the rule. In contrast to marrow, involvement of the lymph node is diffuse. Proliferation centers with PL and paraimmunoblasts are typically seen in both marrow and lymph nodes.

Immunophenotyping

CLL can usually be readily differentiated from other disorders by immunophenotyping[1–3,253,254,255] (Table 90.2). The leukemic cells have the B-cell markers CD19, CD20 (low), CD43, and CD79b (low) and must be $CD5^+$. In addition, the cells show clonal light chain restriction, weak expression of sIgM and sIgD, and are $CD23^+$ and $CD10^-$. The cells are also $CD27^+$,[43] consistent with being memory B-cells.[5] Alternatively, the presence of CD27, CD5, and CD23 could reflect the activated nature of the CLL cell.[42] Matutes et al.[254,256] recommend 5 markers to differentiate CLL from other B-cell malignancies (Table 90.3). Typical CLL should be surface Ig (weak), $CD5^+$, $CD23^+$, CD79b or CD22 (weak), and $FMC7^-$.

One of the typical features of the CLL cell is the overexpression of membrane CD23, which is related to deregulation of NOTCH2 signaling and may play a role in the decreasing apoptosis.[257,258] The presence of CD23 is useful to differentiate CLL from mantle cell lymphoma, which is also $CD5^+$.[257] Cell surface CD23 undergoes spontaneous proteolysis, producing elevated serum levels of CD23, the level of which is a marker of disease stage and progression.[257]

The BCR complex is required for the proliferation of B-cells after immune stimulation and is a complex formed by sIg and Igα/Igβ (CD79a/CD79b). CLL cells lack CD79b, which is related to overexpression of an alternatively spliced form of the gene.[259] The FMC7 antibody identifies an epitope of CD20 and usually strongly stains hairy cell leukemia and PLL; however, only 16% of CLL cases stain positively, presumably because CD20 is only weakly expressed in typical stable CLL.[253,260] In general, those patients who are $FMC7^+$ have high levels of surface IgM, low expression of CD23, and poor prognosis.[253] Although the myelomonocytic antigens (CD11b, CD13) may be expressed in multiple myeloma, acute lymphoblastic leukemia, and in the CD5− chronic lymphoid leukemias, they are not expressed in CLL.[261]

TABLE 90.3

SCORING SYSTEM FOR DIAGNOSIS OF CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Marker	Marker Intensity	Score	Marker Intensity	Score
Surface Ig	Weak	1	Strong	0
CD5	+	1	−	0
CD23	+	1	−	0
CD22/CD79b	Weak	1	Strong	0
FMC7	−	1	+	0

+, present; −, absent.
Note: Diagnosis of chronic lymphocytic leukemia requires a score of 4 or 5.

The CD5 antigen is most commonly associated with mature T-cells and is expressed weakly on thymocytes.[2,262] However, normal B-cells carrying the CD5 marker are located in the mantle zone of the lymph node, and small numbers of these cells are also present in the peripheral blood.[262] The CD5 molecule has been cloned and appears to be involved in the activation of T lymphocytes. The function of CD5 on the B-cell remains unknown, but its induction has been shown to be inhibited by the T-cell–derived cytokine IL-4. $CD5^+$ B-cells can be stimulated to secrete anti-DNA antibodies and rheumatoid factors in vitro, and increased numbers are found in the peripheral blood of patients with rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome.[262] It has been suggested that the normal counterpart of the CLL cell is the $CD5^+$ B-cell,[19] although detailed immunophenotyping demonstrated significant differences between the two groups.[263] Thus, the $CD5^+$ B-cell appears to be a resting antigen-naive cell, whereas the CLL cell is activated and antigen-experienced. Moreover, the specific activation marker expression pattern varies between cells that have IgV_H gene mutations and those that do not, with the unmutated group resembling B-cells at an earlier state of activation.[41] Older studies suggested that about 5% of cases of CLL could be $CD5^-$ and were more likely to be $FMC7^+$, $CD23^-$, $CD11b^+$, and $CD13^+$ and have a poor prognosis.[261] However, these $CD5^-$ cases should be reclassified, as $CD5^+$ is essential for the diagnosis of CLL.[1,3]

Surrogate Markers for IgV_H Mutational Status

Both CD38 and ZAP-70 have been evaluated as surrogate markers for IgV_H mutational status, as these can be measured readily by flow cytometry. To define the stage of maturation of the CLL cell, Damle et al.[42] measured CD38 levels in CLL. Approximately 50% of patients had >30% $CD38^+$ cells, and these patients had unmutated IgV_H and had a worse prognosis than those with <30% $CD38^+$ cells. However, not all have found such a correlation.[2] CD38 acts as a receptor and enzyme and can produce cell replication and survival with a variety of signals.[264] Activation of $CD38^+$ cells, but not $CD38^-$ cells, through sIgM induces apoptosis and through IgD prolongs cell survival and induces differentiation.[264] In addition, recent evidence suggests that the replicating cells in CLL are the $CD38^+$ cells and the number of $CD38^+$ cells is higher

in lymph nodes, likely reflecting the higher rate of cell proliferation at that site.[115,265] Although CD38 can be measured easily by flow cytometry there is disagreement about the number of cells that are required to define positivity, with values ranging from 5% to 30%.[266,267,268] Moreover, the number of CD38 positive cells can vary over time.[266,267,268]

ZAP-70 is a member of the Syk-ZAP-70 protein kinase family and is expressed in T and natural killer (NK) cells and is important in T-cell signaling.[269,270] However, recent evidence suggests that normal B-cells may also express ZAP-70, particularly when activated.[269,270] Gene expression studies in CLL have also demonstrated that cells with unmutated IgV_H have an increased expression of ZAP-70 whereas those with mutations have low levels.[7] Subsequent studies have shown a 70% to 90% correlation between ZAP-70 expression and IgV_H mutational status, regardless of whether ZAP-70 was measured by flow cytometry (≥20% cells positive), Western blot analysis, or immunohistochemistry.[271–274] Kröber et al.[275] have shown that discordant cases may have poor prognostic features including deletions of 17p13 or 11q22-q23, or IgV_H3–21 expression. ZAP-70 positivity also correlates moderately with CD38 positivity and the presence of poor-risk cytogenetics, that is, deletion 11q22-q23, deletion 17p13, and trisomy 12.[275,276] The poor prognosis associated with ZAP-70 positivity has been related to the magnified signaling by the BCR in ZAP-70–positive CLL cells.[277] A major difficulty presently in the routine use of ZAP-70 is the variability in the assay as a result of the sensitivity of different antibodies and the use of different internal controls.[266,267,268] Moreover, although initial studies suggested that ZAP-70 differed from CD38 in remaining stable during the disease course, more recent evidence indicates that ZAP-70 may also change over time.[267,268]

Immunoglobulin Production in Chronic Lymphocytic Leukemia

Apart from having either κ or λ light chains on the cell-surface membrane, clonality is confirmed by the presence of unique idiotypic specificities of the Igs produced by CLL cells[278] and by *IG* gene rearrangements.[2,18] CLL cells have low to undetectable amounts of monoclonal polyreactive IgM autoantibodies, frequently of the rheumatoid factor type, on their surface.[262,263] Thus, the same monoclonal autoantibody produced by a leukemia cell may react with a variety of antigens (e.g., IgG, cardiolipin, histones, or single- or double-stranded DNA).[262] Surface and cytoplasmic Igs contain either κ or λ light chains but never both. Most cells display a single heavy chain class, usually μ, although some display μ and δ. Less commonly, γ, α, or no heavy chain determinant is found. Although the CLL cell is believed to be frozen at a particular stage in maturation, up to 50% of CLL patients have IgM^+ leukemia cells that are able to undergo isotype switching to IgA (usually) or to IgG.[279,280] Rearrangements of the *IGH* and *IGL* genes are seen in CLL and these remain constant over time.[2] Interestingly, the T-cell receptor β gene can be aberrantly re-arranged in 6% of CLL cases and this is associated with chromosome 6q deletions.[281,282]

CLL cells may secrete idiotypic IgM and in most cases can be induced by mitogens to secrete IgM that can react to a variety of autoantigens.[283,284] Using a sensitive immunoblotting technique, monoclonal proteins can be detected in the serum of virtually all patients although the light chain of the protein is only the same as that on the CLL in half the cases.[285] These findings indicate that the monoclonal protein in many cases is not derived from the tumor cells. Serum electrophoresis detects a monoclonal protein in approximately 5% of CLL cases and an abnormal serum-free light chain ratio is observed in one third of patients.[286,287] The presence of an abnormal ratio correlates with advanced disease, markers of aggressive disease, and poor prognosis.[287]

Functional Immune Abnormalities

Patients with CLL are immunosuppressed, as a result of hypogammaglobulinemia, alterations in T-cell function and to abnormalties in complement activation and neutrophil/monocyte function.[288,289] Moreover, the immunosuppression is potentiated by chemotherapy or immunotherapy. As a result, about 50% of patients have recurrent infections, with sepsis being an important cause of death. Apart from typical bacterial infections, CLL patients are also susceptible to opportunistic infections, particularly if they have received nucleoside analogues, steroids, or monoclonal antibodies. The nucleoside analogues are highly toxic to T lymphocytes, whereas monoclonal antibodies may be cytotoxic to B-cells (e.g., rituximab) or to both B- and T-cells (alemtuzumab).

The CLL cell has no useful immune function and shows poor stimulatory activity in mixed lymphocyte culture[290] and in response to B-cell mitogens, such as pokeweed mitogen, lipopolysaccharide, and the Epstein–Barr virus.[291,292] However, phorbol esters, *Staphylococcus aureus* protein A from Cowan I, anti-μ antibodies, anti-CD40, and loxoribine have been shown to be potent mitogens.[293,294] Moreover, these cells are poor antigen-presenting cells and, as discussed below, can interfere with normal B- and T-cell function.[295]

The risk of infection is closely related to the extent of hypogammaglobulinemia in CLL, and the severity increases with the duration and stage of disease.[288,289,296] The Ig levels are all decreased, and within the IgG class, reduced levels of IgG2 and IgG4 correlate best with the risk of infection; however, the decline in IgA levels is the most important predictor of infection.[296,297] Interestingly, the correlation between Ig levels and infection rate is not absolute, and some patients with normal Ig will have repeated infections whereas others with hypogammaglobulinemia will remain infection-free.[288] Patients with CLL have reduced primary and secondary responses to immunization.[289] Although patients with higher levels of gammaglobulin usually show better responses than those with low levels, the responses of both groups are abnormal. The pathogenesis of the hypogammaglobulinemia is poorly understood. However, impaired B-cell function and regulatory abnormalities of T-cells (including the reversal of normal helper/suppressor cell ratios) probably play a role. In addition, CLL-derived NK-cells have been shown to suppress Ig secretion by normal B-cells in vitro.[298]

The absolute number of T-cells may be increased in untreated CLL, and there are marked abnormalities in the surface markers, including inversion of the T-helper to -suppressor cell ratio, suggesting perturbations in T-cell function.[290,299] In addition, the increase in the number of T-suppressor cells may correlate with the degree of hypogammaglobulinemia.[300] The T-cells usually respond normally to mitogens, such as phytohemagglutinin, in vitro and produce IL-2 and γ-interferon.[301] However, there is decreased T-helper function with reduced reactivity to allogeneic and autologous B-cells.[302,303] Spontaneous and antibody-dependent cytotoxicities are reduced, suggesting an abnormality in the large granular lymphocyte population, including NK-cells.[304]

The cause of these abnormalities is unclear, but the increase in T-cells has been ascribed to stimulation by CLL cells or chronic infection, such as cytomegalovirus (CMV).[289,305,306] Alternatively, the B-, T-, and NK-cell functions may be suppressed by means of immunosuppressive factors produced by CLL B-cells.[307,308] The gene expression profile of $CD4^+$ and $CD8^+$ cells are different in CLL patients as compared to normal individuals.[307] However, the abnormal expression could be induced in $CD4^+$ and CD8+ cells from normal individuals by co-culturing them with CLL cells.[307] Similar studies showed that CLL cells could affect the ability of normal T-cells to form normal immunologic synapses.[308] One potential candidate that could be causing these changes is TGF-β, which is secreted by CLL cells and marrow stromal cells in CLL, and has been shown to be a potent inhibitor of normal B- and

T-cells.[133–137] In addition, CLL cells express both CD40 and the CD40L (CD154), and these cells decrease CD154 expression by normal T-cells with resultant effects on normal B-cell differentiation and isotype switching.[309]

The levels of different complement components are decreased in CLL, particularly in patients with advanced disease.[310] As well, multiple defects in neutrophil and monocyte function have been described in CLL, and these are associated with an increased risk of infection.[288,311]

Autoimmune Manifestations

Despite being immune deficient, CLL patients have an increased incidence of autoimmune cytopenias secondary to autoantibody formation.[312,313,314–316,317,318] The immune cytopenias may be present before or at the time of diagnosis in one third and during the course of disease in two-thirds.[315] CLL is the most common cause of autoimmune hemolytic anemia (AIHA), causing 14% of cases, followed by systemic lupus erythematosus.[312] Moreover, patients with AIHA have an increased incidence of MBL and subsequently developing CLL, but this is not true for patients with immune thrombocytopenia (ITP).[314,316] Overall, 4% to 10% of CLL patients develop AIHA, and this is usually associated with a warm-type antibody against the Rhesus system and a positive direct antiglobulin test (DAT).[312–314,315] Another 7% to 14% of cases may have a positive DAT without evidence of hemolysis. The incidence of this disorder is increased with male sex, older age, high lymphocyte count, advanced disease, and the presence of biologic markers of poor prognosis, such as high β2-microglobulin, high ZAP-70, and unmutated IgV_H.[314,315,317] The diagnosis of AIHA may be difficult in CLL, as multiple factors may produce anemia, a positive DAT can exist without hemolysis, and other diagnostic parameters may be influenced by the disease.[314,315,317] Zent et al.[317] have thus developed diagnostic criteria for the diagnosis of AIHA in CLL and include (a) hemoglobin <100 g/L; (b) ≥1 marker of hemolysis, i.e., reticulocytosis, increased indirect bilirubin without liver disease, increased lactate dehydrogenase (LDH) without another cause or increased marrow erythropoiesis; (c) positive DAT/cold agglutinins or ≥2 markers of hemolysis, without evidence of hypersplenism or bleeding. When fludarabine was introduced, AIHA was seen relatively frequently leading investigators to believe that this was a unique complication of the drug. However, in the LRF CLL4 trial the incidence of AIHA was similar in previously untreated patients who received chlorambucil (12%) as compared to fludarabine (11%), and the incidence was lowest in patients treated with a combination of fludarabine plus cyclophosphamide (5%) indicating that cyclophosphamide has a protective effect.[318] The likelihood of developing AIHA was greater if the patient had a positive direct DAT before treatment, had advanced disease, or had a high β2-microglobulin test.[318] The incidence of a positive DAT before treatment was 14% and approximately one third of patients receiving chlorambucil or fludarabine with a positive DAT developed AIHA. Conversely, the chance that a patient who was DAT-negative would develop AIHA was 7%. Thus, the high incidence of AIHA observed when fludarabine was first used was because patients receiving this drug usually had advanced and previously treated disease. The protective effect of cyclophosphamide has been confirmed in a subsequent study where the incidence of AIHA was 1%.[319] Although the addition of rituximab to chemotherapy would be expected to reduce the incidence of AIHA further, it is reported to occur in <1% to 6.5% of patients receiving FCR.[210,319] The impact of the development of immune cytopenias on survival has been recently evaluated in 2 studies, which have demonstrated that the prognosis of these patients is no worse than those without cytopenias.[315,317]

ITP occurs in <1% to 2% of patients, and the diagnosis is based on an increase in platelet size in the peripheral blood and an increase in megakaryocytes in the marrow, although the latter is often difficult to ascertain as the marrow usually is heavily infiltrated with CLL cells. ITP may be predicted if there is an isolated fall in platelets without splenomegaly as anemia usually precedes thrombocytopenia when cytopenia is caused by marrow replacement. Autoimmune neutropenia occurs rarely in CLL but should be considered if patients remain neutropenic following chemotherapy with recovery in the other blood counts. A bone marrow analysis will be required under these circumstances to assess marrow reserve. Red cell aplasia is also rare and is suspected when a patient develops isolated anemia with reticulocytopenia and none of the usual signs of hemolysis. A marrow shows a reduction in red cell precursors.

Several pieces of evidence indicate that the antibodies causing these cytopenias are produced by normal B-cells and not CLL cells. First, the antibodies are polyclonal and are usually IgG. Second, the autoimmune disorders may occur while the patient's disease is responding to therapy.[312–314,315] It has been suggested that CLL cells act as antigen-presenting cells for normal $CD5^+$ or $CD5^-$ antibody-producing B-cells and that antibody production is increased after inhibition of T-cells, either with advancement of disease or because of therapy.[312,313] Antigen presentation may occur in the spleen which is the major site of removal of senescent red cells and may be potentiated by T-cells through CD40L-CD40.[313,320] There is an association between AIHA in CLL and the expression by the leukemia cells of certain IgVH genes, for example, V1 family gene DP51p1.[320] How this may influence the normal B-cell population to produce red cell antibodies is unknown. In contrast, pure red cell aplasia is caused by a T-cell mechanism rather than the formation of autoantibodies, and these patients respond well to cyclosporine, a drug that affects T-cell function.[313,314,321]

The above abnormalities are caused by normal B- or T-cells, however, antibodies produced by CLL cells can cause cold agglutinin disease, peripheral neuropathy, and paraneoplastic pemphigus.[313] Normal $CD5^+$ B-cells can produce autoantibodies to IgG and single- and double-stranded DNA, as well as other autoantigens, and the number of these cells is increased in autoimmune disorders.[262] CLL cells can be induced to secrete IgM molecules that react with a comparable spectrum of antigens.[264,283,318] Alternatively, IgM^+ CLL cells can undergo isotype class-switching to IgG^+ cells.[278,279]

In contrast, a number of other conditions may be caused by antibodies produced directly by the CLL cells.[313] Thus, the IgM antibody-producing cold agglutinin disease in CLL is produced by the CLL cells against the red cell I antigen and the CLL cells are typically IgV_{H4-21}.[322] Antibody produced by the CLL cells against myelin-associated glycoprotein (MAG) may also cause a polyneuropathy.[313] Paraneoplastic pemphigus causes painful mouth ulcers, conjunctivitis, and pruritic blistering skin lesions.[323] This disorder is diagnosed by distinct histologic changes in the skin and the presence of autoantibodies in the blood directed against cutaneous epitopes.[323,324] Acquired angioedema is associated with recurrent abdominal pain and is caused by consumption of the inhibitor of the first component of complement by tumor.[313] Glomerulonephritis, frequently with nephrotic syndrome, may occur secondary to deposition of intact monoclonal antibody or light chains in the kidney and remits with treatment of the CLL.[313,325] As opposed to the immune cytopenias, all of the above occur with CLL disease progression and resolve with treatment of the leukemia.

DIAGNOSIS

The International Workshop of Chronic Lymphocytic Leukemia (iwCLL) in 2008 changed the diagnosis of CLL to require a peripheral blood B-cell count of $\geq 5 \times 10^9$/L and the presence of monoclonal (kappa or lambda) B-cells which have the

TABLE 90.4

CHRONIC LYMPHOCYTIC LEUKEMIA AND VARIANTS

typical immunophenotype of CLL cells ($CD19^+$, $CD5^+$, $CD23^+$, and decreased expression of surface Ig, CD20, and CD79b).[1] Using these markers a diagnostic scoring system for CLL has been developed and CLL may be considered "atypical" if there are variations in these markers (Table 90.3). The CLL cells are mature-appearing lymphocytes admixed with larger or atypical cells, PL, and cleaved cells. Having more than 55% PL is consistent with PLL. Individuals with a peripheral blood B-cell count of $<5 \times 10^9$/L and CLL cells in the blood have either SLL or MBL. These two disorders can be distinguished as MBL lacks lymphadenopathy or splenomegaly (by physical examination or CT scans;[1] Table 90.4).

DIFFERENTIAL DIAGNOSIS

In most patients, the diagnosis of CLL is easily made after a careful review of the peripheral smear and immunophenotyping, although other conditions must be considered (Table 90.5). On occasion, immunohistochemistry or gene rearrangement studies are required to exclude other diagnoses.

Benign Causes

T-cell–Associated Causes

Chronic infections, such as tuberculosis or syphilis, may produce a lymphocytosis. A transient lymphocytosis may also be seen in viral illnesses, such as pertussis, CMV, or infectious mononucleosis. However, these are usually found in children or young adults and should be easily distinguished from CLL by the clinical features and the morphologic appearance of the cells.

B-cell–Associated Causes

Persistent polyclonal B-cell lymphocytosis is a rare and benign condition seen typically in middle-aged female smokers with a familial tendency.[326–328] The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in Igs and a strong association with HLA-DR7, and an isochromosome $3q^+$ (i3)(q10) is observed in some cases.[326,327] These cells show IgV_H gene mutations and immunophenotypically are marginal zone lymphocytes.[328] Delage et al.[327] have demonstrated multiple *BCL2/IGH* gene rearrangements in this disease and described a family in which there was a high incidence of the gene rearrangements in first-degree relatives in association with a paternal HLA haplotype. These findings suggest that persistent polyclonal B-cell lymphocytosis can be a familial disorder and that the *BCL2/IGHgene* rearrangements may represent the first abnormality before B-cell expansion.[327]

Tropical splenomegaly syndrome or hyperreactive malarial splenomegaly occurs in countries with endemic malaria and may mimic CLL.[329,330] This disease is believed to be a disordered response to malarial antigens leading to overproduction of B-cells and is characterized by massive splenomegaly, an increase in IgM, and, in 10% of cases, an increase in the peripheral lymphocyte count. The disorder responds to antimalarial therapy, and this can be used to differentiate hyperreactive malarial splenomegaly from CLL.

Malignant Causes

Malignant disorders that may be confused with CLL are summarized here for comparative purposes and as an aid in differential diagnosis (Table 90.5). Before flow cytometry became routine, many patients were diagnosed as having CLL but in fact had other disorders[331] (Table 90.2). The most common malignancies to be confused with CLL are PLL and the leukemic phase of non-Hodgkin lymphomas. Morphologically, these disorders may appear similar to CLL.

B-cell–Associated Causes

Monoclonal B-cell lymphocytosis

In MBL there is a persistent increase in the number of monoclonal B-cells in the peripheral blood but the B-cell count remains $<5 \times 10^9$/L; there are three common variants, CLL-like MBL ($CD5^+$, CD20 dim), atypical MBL ($CD5^+$, "bright CD20," and CD5- MBL (Fig. 90.8).[1,332,333] MBLs are found in 3.5% of adults older than 40 years of age with normal blood counts with the incidence increasing with age.[334,335] The incidence of MBL is even higher (13.5%) among healthy members of CLL families[25,26,336] and in otherwise healthy people with a lymphocyte count $>4 \times 10^9$/L. A more recent study using 8-color flow cytometry detected MBL in up to 12% of healthy individuals with normal blood counts, suggesting

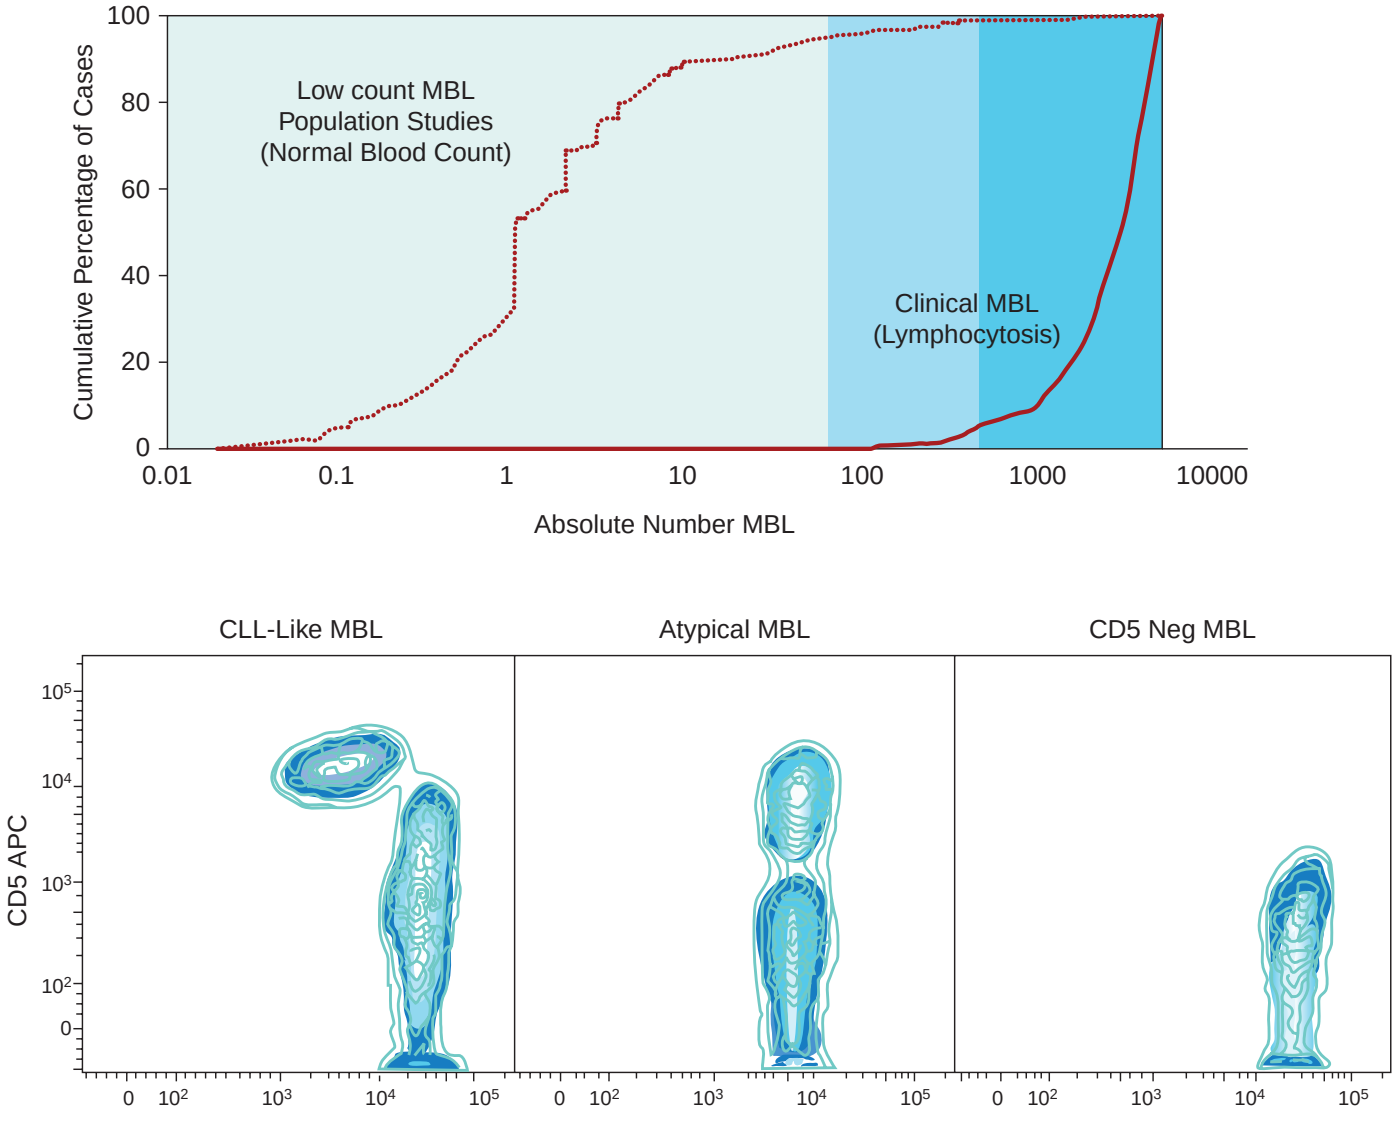

FIGURE 90.8. Role of absolute B-cell count in monoclonal B cell lymphocytosis (MBL) and immunophenotype patterns. The *top panel* shows the absolute number of B-cells as a cumulative function of the number of cases dividing low-count MBL (normal white blood cell count, absolute lymphocyte count) from clinical MBL (with lymphocytosis). The *bottom panel* from left to right shows the three major immunophenotypic patterns seen in MBL. From Marti GE. MBL: mostly benign lymphocytes, but… Blood 2011;118:6480–6481.

that the incidence of the abnormality may be even higher depending on the sensitivity of the assay.[337] Rather than having a continuous distribution of B-cell numbers in MBL there appears to be a bimodal distribution with a lower peak of 0.0001 to 0.010 $\times$ 10^9 clonal B-cells/L (detected when screening the healthy individuals, "population MBL") and a second peak of 0.05 to 0.5 $\times$ 10^9 clonal cells/L (detected when testing individuals for a slightly elevated lymphocyte count, "clinical MBL").[338] Although the risk of patients with "population MBL" progressing to CLL is exceedingly low, these patients may harbor CLL-like genetic abnormalities, such as deletion 13q14, trisomy 12, or deletion 17p13, and have IgV_H gene mutations.[339,340] Moreover, there are multiple T-cell clones in half the cases, suggesting that the whole immune system is affected, perhaps related to chronic immune stimulation.[340] Support for this concept has been the observation that multiple B-cell clones may also be observed in these individuals.[334,337] The difference between "clinical MBL" and low-count Rai stage 0 CLL appears quite arbitrary and 40% of patients diagnosed with CLL using the older criteria for CLL (lymphocyte count >5 $\times$ 10^9/L) are now considered to have MBL.[341] Recent evidence indicates that the survival of CD38− "Clinical MBL" (79% patients, <30% cells positive) is no different from age- and sex-matched controls whereas the survival of CD38$^+$ "Clinical MBL" (21% patients, ≥30% cells positive) and Rai stage 0 patients is reduced.[342] Rawstron et al.[336] have estimated that approximately 1% of the "Clinical MBL" cases will progress to CLL and require treatment each year.

An ethical issue over MBL has been the possibility of unintentional transmission of this syndrome by blood transfusion or hematopoietic cell transplantation (HCT).[337,343] This issue is discussed further in the section on HCT for CLL.

B-cell Prolymphocytic Leukemia

B-cell PLL is characterized by larger, less mature-appearing cells than are seen in CLL, and the nucleus has condensed chromatin and prominent central nucleoli.[344,345] Patients with CLL/PLL have 11% to 54% PL, but in PLL ≥55% of the cells are PL.[251] PLL appearing de novo is an aggressive disease, and patients frequently are symptomatic with fever, weight

loss, or abdominal discomfort and are found to have massive splenomegaly, minimal lymphadenopathy, and resistance to therapy.[344,345] Leukocyte counts in excess of 150 × 10^9/L, consisting almost entirely of PL, are common, as are anemia and thrombocytopenia. The cells invariably have intense staining for surface membrane Ig, FMC7, CD20, and CD79b, whereas this may or may not occur with CLL/PLL.[251] One third of cases have a deletion of 11q23, one half a deletion of 13q14, and one half a mutation of *TP53*.[346,347] Although occasional patients may initially have stable disease, progression is the rule, and the median survival is 65 months.[345]

Leukemic Phase of Non-Hodgkin Lymphoma

The leukemic phase of non-Hodgkin lymphoma used to be referred to as *lymphosarcoma cell leukemia* and includes the leukemic phase of mantle cell lymphoma, follicular lymphoma, splenic lymphoma with villous lymphocytes (splenic marginal zone lymphoma), other marginal zone lymphomas, and, rarely, large-cell lymphomas. The lymphocytes in mantle cell lymphoma are larger than those seen in CLL and have more cytoplasm; in contrast to CLL and the other disorders, there is variation in cell morphology, with some cells looking like classical CLL cells, others having irregular nuclei, and some looking like PL.[348,349] Two-thirds of patients have marrow involvement and one third have leukemic presentation.[348] Patients with a leukemic picture have aggressive disease. The cells strongly express surface Ig and are $CD19^+$, $CD20^+$, $CD5^+$, $CD23^-$, $CD10^-$, and $FMC7^+$.[350] These cells have the t(11;14)(q13;q32) and, by immunohistochemistry, stain strongly for cyclin D1. As the breakpoint for t(11;14)(q13;q32) covers a large area, polymerase chain reaction (PCR) using only one set of primers misses many cases, and Southern blot analysis or FISH may be required.[350,351] The leukemic phase of follicular lymphomas may be confused with CLL; usually, the cells are small, the nuclear chromatin is smooth and not clumped, there is almost no cytoplasm, and the nucleus is indented.[352] Occasionally, large cells are seen, and, when possible, a lymph node biopsy should be carried out to type the follicular lymphoma. The cells are identified by immunophenotyping and are $CD19^+$, $CD20^+$, $FMC7^+$, $CD23^-$, $CD5^-$, and $CD10^+$. The diagnosis can be confirmed by demonstrating a t(14;18)(q32;q21). Approximately 10% of peripheral B-cell lymphocytosis is caused by splenic marginal zone lymphoma; these cells have characteristic filamentous projections and, frequently, a nucleolus.[331,353] The cells are usually SIg^+ (strong), $CD19^+$, $CD20^+$, $CD23^-$, $CD5^-$, $CD79b^+$, and $FMC7^+$. The other forms of marginal zone lymphomas (mucosa-associated lymphoid tissue and monocytoid B-cell lymphomas) and lymphoplasmacytic lymphomas may also rarely involve the marrow and peripheral blood.[3]

Hairy Cell Leukemia

In hairy cell leukemia (Chapter 91) the cells are of moderate size with eccentric oval nuclei and variable prominent nucleoli. The cells differ from CLL cells in being tartrate-resistant acid-phosphatase positive ($TRAP^+$) and CD5–, $CD11c^+$, $CD25^+$, $CD103^+$. and $CD123^+$.[354] In contrast to classical hairy cell leukemia, in which the lymphocyte count is usually low, the variant form of hairy cell leukemia has a higher lymphocyte count, but the cells have prominent nucleoli, are TRAP–, and are CD25– and CD123–.[355]

T-cell–Associated Causes

The chronic T-cell disorders are much less common than the B-cell disorders but can be classified into 4 groups.[251]

T-cell Prolymphocytic Leukemia

Formerly called T-cell CLL, T-cell PLL cells have a prominent nucleolus and the nucleus may be either round to oval in half the cases or irregular, often with convolutions.[347] Splenomegaly is typically present, with, lymphadenopathy in half the cases and skin involvement (nodules or a maculopapular rash) in 20%. Periorbital edema may also occur. Cells are $CD3^+$, $CD4^+$, $CD7^+$, and $CD8^-$, but in one-quarter of patients, the cells are both $CD4^+$ and $CD8^+$ or, more rarely, $CD4^-$ and $CD8^+$.[347] Most patients (81%) achieve a complete remission (CR) with intravenous alemtuzumab with a median survival of 2 years.[347]

Adult T-cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma is most common in Asia and has a variety of clinical presentations.[356,357] Patients may present acutely with lymphadenopathy or hepatosplenomegaly, although skin involvement, lytic bone lesions, hypercalcemia, and involvement of other organs have been described. Alternatively, there may be a chronic form of the disease with peripheral lymphocytosis and skin involvement, which may either resolve entirely or develop into the acute form of the disease.[357] A prognostic classification has been developed based on the proliferative capacity of the peripheral blood leukemic cells.[358] The cells are usually $CD4^+$ and are infected with human T-cell leukemia/lymphoma virus-1.

Sézary Syndrome

Sézary syndrome is the leukemic form of mycosis fungoides, and affected patients have diffuse skin involvement plus lymphadenopathy and splenomegaly, although peripheral lymphocytosis can occur in isolation.[359] The cells are typically large with cerebriform nuclei, coarse chromatin, and inconspicuous nucleoli, and are usually $CD4^+$.[359] The diagnosis of Sézary's syndrome requires a peripheral blood Sézary cell count of >1 × 10^9/L or that >20% of the lymphocytes be identified as Sézary cells.[359]

Large Granular Lymphocytic Leukemia

Large granular lymphocytic (LGL) leukemia is characterized by moderate lymphocytosis (1 to 49 × 10^9/L) and the presence of cells that are bigger than CLL cells with abundant cytoplasm containing azurophilic granules.[360–362] However, there is considerable variation, even within the same patient. In some cases, the lymphocytes may appear normal, and the granules may be coarse, fine, or absent.[360] Large granular lymphocytes may be NK-cells that mediate nonmajor histocompatibility complex-restricted cytotoxicity or $CD3^+$ T-cells that mediate nonmajor histocompatibility complex-restricted cytotoxicity.[360] T-LGL leukemia is the most common form, making up 85% of cases, and is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis (25%), but this is a distinct entity from Felty syndrome.[360] It has been suggested that the neutropenia is related to the expression of FAS ligand by LGL cells.[363] The usual immunophenotyping of T-LGL leukemia is $CD3^+$, $CD4^-$, $CD8^+$, $CD16^+$, $CD56^-$, $CD57^+$, and $TCR\alpha\beta+$; T-cell receptor gene rearrangement studies confirm T-cell monoclonicity. If therapy is required, responses may be observed with cyclosporin or methotrexate.[364,365] NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia.[361] However, chronic NK-cell leukemia can occur, with a clinical course similar to that of T-LGL leukemia.[362] These cells are usually $CD3^-$, $CD4^-$, $CD8^-$, $CD16^+$, $CD56^+$, and $CD57^-$.[360]

INVESTIGATIONS AND STAGING

Investigations

A complete blood count, review of the peripheral smear, and immunophenotyping are required for diagnosis and prognosis in CLL. Recommended investigations have been published by the IWCLL and the European Medical Society of Oncology (EMSO).[1,5]

These investigations depend on whether a patient is being seen in general practice or within the context of a clinical trial.

Standard Tests for General Practice

Physical Assessment

This includes measuring the bidimensional size of the largest nodes in the cervival, supraclavicular, axillary, inguinal, and femoral regions with measurement of the spleen and liver. The performance status should also be documented.

Laboratory Measurements

Complete blood count with white cell differential (including the percentage of PL) and reticulocyte count. DAT, routine plasma biochemistry [including renal/liver function tests, and LDH], serum protein electrophoresis and/or immunoelectrophoresis, and Ig levels.

Screening for hepatitis B and C, cytomegalovirus (CMV), and human immunodeficiency virus (HIV) should be carried out before treatment. Therapy for patients who are HIV-positive will need to be individualized depending on their condition and medications. Patients who have antibody to CMV will require monitoring and treatment if there is viral reactivation with alemtuzumab or allogeneic HCT.[366] Patients who have hepatitis B antigenemia will require therapy with suppressive therapy (such as lamivudine) during chemotherapy in order to prevent viral reactivation.[1,5]

A number of prognostic markers may help in determining the rate of disease progression and overall prognosis in newly diagnosed patients and is discussed in detail below. FISH is recommended prior to therapy as the presence of certain abnormalities (deletion 17p13 or 11q22-23) can influence treatment.

Radiology

A baseline chest x-ray is useful to determine any pre-existing lung disease.

Additional Tests for Clinical Trials and Specific Clinical Situations

Laboratory Measurements

A marrow aspirate/biopsy may be useful: (a) to assess normal marrow reserve and to establish the cause of anemia and thrombocytopenia for patients with Rai stage III or IV disease; (b) to assess the cause of persistent cytopenias following chemotherapy, and (c) to assess cellularity and the extent/pattern of marrow infiltration, which is of prognostic value.[252]

Radiology

A meta-analysis has recently demonstrated that CT scans are not of value for routine management.[367] Findings of the baseline CTs were not prognostically important and disease progression could be detected by clinical examination and blood counts. The presence of persistent radiologic disease following therapy predicted a shorter progression-free survival (PFS) and OS for patients treated with chemotherapy but was not of value when rituximab was added to chemotherapy, as in the German CLL8 study,[210] where FC (fludarabine/cyclophosphamide) was compared with FCR (fludarabine/cyclophosphamide/rituximab). Thus, the use of prognostic markers and the detection of minimal residual disease (MRD) following therapy are of greater value in CLL than CT scans. However, CT scan may be used: (a) in clinical trials; (b) to confirm a remission prior to hematopoietic cell transplant, where tumor burden is prognostically important, and (c) to assess tumor burden prior to treatment with alemtuzumab. Patients with lymph nodes >5 cm respond poorly to alemtuzumab and require alternate therapy.[367] PET scans are not useful for staging in CLL, as 18F-FDG uptake in CLL is low. However, they are useful to identify a suitable node for biopsy when determining whether new lymphadenopathy is related to disease progression, transformation, or a second malignancy.

Staging

Two staging systems are in general use, and are based on physical examination and results of a routine blood count.[368,369] The Rai staging system is generally used in North America, and the original system divided patients into 5 groups on the basis of lymphocytosis alone (peripheral blood lymphocyte count $\geq 15 \times 10^9$/L and ≥40% lymphocytes in the marrow), clinically apparent lymphadenopathy or splenomegaly, and the presence of anemia (hemoglobin <110 g/L) or thrombocytopenia (platelets $<100 \times 10^9$/L; Table 90.6).[368] A simplified 3-stage version of this scheme is now generally accepted (Table 90.6).[1] The Binet staging system is most frequently used in Europe,[369] and staging is based on the number of involved areas, the level of hemoglobin, and the platelet count (Table 90.7). The diagnosis of CLL required a peripheral blood lymphocyte count of $\geq 4 \times 10^9$/L with ≥40% lymphocytes in the marrow. The 5 areas of involvement were 3 lymph node areas (cervical, axillary, and inguinal, whether unilateral or bilateral), the spleen, and the liver.

Several points should be emphasized about these staging systems:

(a) The staging is based on clinical examination and not on CT scans.

(b) The cause of cytopenia was not defined in the original descriptions of Rai stages III/IV or Binet stage C disease. A recent detailed study from the Mayo Clinic demonstrated that one-quarter of all CLL patients develop cytopenia, with 54% being due to marrow replacement by tumor, 18% due to immune cytopenias, and 28% due to other causes, for example, chemotherapy or uremia.[317] Recent studies have shown that the survival of patients with immune cytopenias is much better than those due to marrow replacement by tumor and likely not different to those without cytopenias.[315,317] It has thus been suggested that patients should be subclassified according to the cause of their cytopenia.

TABLE 90.6

RAI CLASSIFICATION SYSTEM FOR CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Stage	Modified Stage	Description	Median Survival (y)
0	Low-risk	Lymphocytosis[a]	>10
I	Intermediate-risk	Lymphocytosis + lymphadenopathy	7–9
II	Intermediate- risk	Lymphocytosis + splenomegaly ± lymphadenopathy	7–9
III	High-risk	Lymphocytosis + anemia[a] ± lymphadenopathy or splenomegaly	1.5–5
IV	High-risk	Lymphocytosis + thrombocytopenia[a] ± anemia, splenomegaly or lymphadenopathy	1.5–5

[a]Lymphocytosis, originally lymphocytes $>15 \times 10^9$/L for >4 weeks; anemia, hemoglobin <110 g/L; and thrombocytopenia, platelets $<100 \times 10^9$/L.

TABLE 90.7

BINET CLASSIFICATION FOR CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Stage	Blood Counts	Involved Areas[a]	Median Survival (y)
A	Hb >100 g/L and platelets >100 × 10^9/L	<3	>10
B	Hb >100 g/L and platelets >100 × 10^9/L	≥3	7
C	Hb <100 g/L, or platelets <100 × 10^9/L, or both	Any number	2–5

Hb, hemoglobin.
[a]The five areas of involvement include head and neck, axillae, groins, palpable spleen, and clinically enlarged liver.
Data from Binet JL, Auquier A, Dighiero G, et al. A new prognostic classification of chronic lymphocytic leukemia derived from a multivariate survival analysis. Cancer 1981;48:198–206, and Shanafelt TD. Predicting clinical outcome in CLL: how and why. Hematology (Am Soc Hematol Educ Program) 2009:421–429.

(c) The diagnosis of CLL in the original studies was not based on immunophenotyping, whereas nowadays the diagnosis of CLL depends on a peripheral blood B-cell count of ≥5 × 10^9/L. Thus, a number of patients in the original studies likely had non-Hodgkin lymphomas with leukemic involvement. This might partly explain the poorer prognosis for patients with advanced stages, as compared with more recent observations. However, the relative survival of patients with confirmed CLL and stages Binet B/C disease has increased over the past 20 to 30 years, suggesting that the improved survival nowadays is related to improved therapy or supportive care.[370]

PROGNOSIS

CLL is a very heterogeneous disease, both in presentation and disease progression. The Rai or Binet clinical staging systems are simple and reliable prognostic measures. However, the prognostic value of these systems has been somewhat tempered, as there is variation in survival within each stage and the majority of patients are in Rai stage 0/I at diagnosis.[245] Thus, 30% to 50% of patients with early-stage disease will require therapy in 1 to 4 years and have a median survival of 7 to 8 years whereas occasional patients may have a spontaneous remission.[245,371] This uncertainty about the future creates great anxiety for the patient and has led to tremendous efforts to develop reliable prognostic markers[267,268,372] (Table 90.8). Stratification of patients into different risk groups will allow for a more rational approach to treatment options and will identify specific patient groups to be studied in clinical trials. Several general points about prognostic markers should be made. First, these markers have generally been evaluated in patients less than 65 years of age and their value in older patients is less certain.[11,12] Thus, although *IgV*$_H$ status and FISH results are useful predictors of survival for younger patients they are less useful in those ≥75 years.[11,12] Second, the markers have been studied at the time of diagnosis and their utility throughout the disease course is less clear. The exception here is for FISH, which is usually carried out prior to treatments; new genetic abnormalities can develop during the disease course and the results of FISH are important for prognosis and influencing treatment decisions. Finally, a prognostic marker may be able to predict one aspect of the disease course, for example, time to first treatment, but may not be able to predict PFS or OS.

Some prognostic markers, such as clinical staging, lymphocyte morphology and doubling time, CD38, serum LDH, β_2-microglobulin levels, and FISH are routinely available, but others are either experimental or only available at specialized centers. In the following section we review the most commonly used and new potentially important prognostic markers. Further details on other markers can be obtained in recent reviews.[267,268]

Rai and Binet Staging

The median survival of patients in the Rai staging *low-risk* group (~55% to 60%) who have an isolated lymphocytosis, is more than 10 years.[267,370,373–375] Patients in the *intermediate-risk* group (~35% to 40%) have lymphadenopathy, splenomegaly, or both, and have a median survival of 7 to 9 years. Patients in the *high-risk* group (~5% to 10%) have anemia, thrombocytopenia, or both and a median survival of 1.5 to 5 years. Survival in the high-risk group depends on the cause of the cytopenia, being poorest

TABLE 90.8

PROGNOSTIC MARKERS IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Prognostic Marker	Better Prognosis	Worse Prognosis
Sex	Female	Male
Age	<70 y	>70 y
Plasma vitamin D level	High	Low
Rai stage	0, I, and II	III and IV
Lymphocyte count	<12 × 10^9/L	≥12 × 10^9/L
Lymphocyte doubling time	>12 mo	< 12 mo
Number of "smudge cells"	≥30%	<30%
β2-microglobulin level	Low	High
Flow cytometry: B-cell count	<11 × 10^9/L	≥11 × 10^9/L
CD38[a]	<20% cells positive	≥20% cells positive
ZAP-70	<20% cells positive	≥20% cells positive
FISH	Deletion 13	Deletion 11q22-23 or 17p13
IgV$_H$ mutation status	Mutated	Unmutated

[a]The precise number of cells required for CD38 positivity varies according to the study.

in those with marrow failure due to CLL infiltration, whereas those with immune cytopenias have a good prognosis.[315,317] The median survival of patients with Binet stage A is >10 years, stage B is 7 years, and stage C is 2 to 5 years.[375] Although both staging systems provide useful prognostic information, they do not correlate well with each other. Thus, there are more patients with Binet stage A as there are in the Rai low-risk groups, whereas the opposite is true for Binet stage B and Rai intermediate-risk groups.[375]

Age and Sex

Approximately 25% of CLL patients in the clinic are ≤55 years, and the clinical features, prognostic markers, and staging at presentation are generally similar to older patients.[12,243,244] Survival of both groups of patients is the same, although the proportion of deaths that can be directly attributed to CLL is greater for the younger age group.[244] These results indicate that a subgroup of younger patients has aggressive disease and the risk of a Richter's transformation is fivefold higher in the younger age group.[244] The male-to-female ratio for CLL is 1.3:1, and women are more likely to have early-stage disease. Regardless of stage and age, women have a better prognosis than men.[376,377] The mechanism(s) responsible for the improved survival in women is (are) unknown but has been related to an increased incidence of IgV_H mutated disease with good prognostic genetic markers in women.[377] In addition, hormonal differences may be important as clinical responses have been observed in CLL when patients with co-existing prostate cancer were treated with estrogens.[377]

Lymphocyte Characteristics

Morphology

Approximately 20% of patients have atypical CLL or CLL/PLL, and these patients have a more advanced stage, a higher proliferative index, and a poorer prognosis.[203,204,217,254] These patients are also more likely to have trisomy 12 or deletion of 17p13 (*TP53* mutation), to be $CD38^+$, and to have unmutated IgV_H.[204,217,284] However, in a multivariate analysis, aberrant cell morphology was found to be an independent prognostic marker.[378] Patients with ≥30% smudge cells have a better prognosis than those with <30% smudge cells.[250]

Number

Survival decreases with increasing B-cell or lymphocyte count at the time of diagnosis,[341,379] A B-cell count of $>11 \times 10^9$/L predicts a shorter treatment-free survival and OS independent of CD38, ZAP-70, and IgV_H mutational status.[379]

Doubling Time

The lymphocyte doubling time (LDT) is a useful measure of disease aggressiveness. Indolent CLL is associated with a slow LDT, whereas patients with a LDT of <12 months have a significantly worse survival rate.[380,381] A recent study from Britain has demonstrated in 1,154 patients with Binet stage A disease that patients with a LDT of <12 months required treatment in 2.5 years and had a median survival of 12.6 years whereas those with a LDT of ≥12 months required treatment in 18.6 years and had a median survival of 20.3 years.[381]

Immunophenotyping

Variations in immunophenotyping, such as an increase in surface Igs, $FMC7^+$, or increased intensity of CD20, may be associated with atypical morphology, trisomy 12, and poor prognosis.[204,253,254,382]

A number of studies have demonstrated the importance of $CD38^+$ as a prognostic marker and this can be measured in either peripheral blood or marrow.[266,363,381,383–385] However, there is still controversy as to the number of cells required to denote positivity.[247,248] Initial studies suggest a correlation between the presence of an IgV_H gene mutation and $CD38^-$ (<30% $CD38^+$ cells), however, this has not been confirmed by others.[266,267] In all of these studies, $CD38^+$ has been associated with shorter survival and correlates with increasing Rai stage, intrathoracic and abdominal lymphadenopathy, short doubling time, increased β_2-microglobulin levels, and atypical morphology.[383–385] Moreover, the CD38 status is useful to predict which patients within a particular clinical stage will progress.[381,384,385] When followed over time, $CD38^-$ patients may become $CD38^+$, and this is associated with deletion of 17p13 (*TP53* mutation) and disease progression.[374]

ZAP-70 is also a useful prognostic marker although further studies are required to standardize the assay and it is still unclear whether equivalent results are obtained on analyzing the marrow or peripheral blood.[266] There is a 70% to 90% correlation between ZAP-70 expression and absence of IgV_H mutations, regardless of whether ZAP-70 is measured by flow cytometry (>20% cells positive), Western blot analysis, or immunohistochemistry.[271–275] ZAP-70 positivity correlates moderately with CD38 positivity and the presence of poor-risk cytogenetics, that is, deletion 11q22-q23, deletion 17p13, and trisomy 12.[275] Kröber et al.[275] have also demonstrated that discordant cases may have poor prognostic features including deletions of 17p13 or 11q22-q23, or IgV_H3–21 expression. Thus, some patients with a mutated IgV_H3–21 gene express high levels of ZAP-70 and do poorly.[271,275] Alternatively, low ZAP-70 expression in some patients with unmutated IgV_H can correlate with the presence of deletions of 17p13 or 11q22-23.[275] ZAP-70 positivity may be a stronger predictor for time to treatment (TTT), PFS, or OS than an unmutated IgV_H.[273,276] A comparison of the prognostic markers by the CLL Research Consortium has demonstrated that ZAP-70 is the most important marker for TTT.[386] Thus, ZAP-70 positive patients had a median time from diagnosis to treatment of 2.6 years versus 8.4 years for ZAP-70 negative patients. The CD38 status did not add additional prognostic information but for ZAP-70 negative patients unmutated IgV_H patients had a median survival of 6.3 years versus 10 years for mutated IgV_H patients (Fig. 90.9). It is unclear why ZAP-70 positive CLL patients have a poor prognosis, although it has been related to the magnified signaling by the Ig cell receptor in ZAP-70 positive CLL cells.[386]

Alterations in T-cells are also prognostically important in CLL and a low CD4/CD8 ratio with a decreased number of NK-cells is observed in advanced disease with hypogammaglobulinemia.[387]

Molecular Genetics

FISH Studies

FISH has become a standard technique in CLL and patients with a deletion of 17p13 have a median survival of 2 to 3 years, compared with 6 to 7 years for those with a deletion of 11q22-23, 9 years for those with a trisomy 12 or normal FISH, and 11 years for those with a deletion of 13q14 alone.[84] The identification of deletions of 17p13 or 11q22-23 is particularly important as their presence can alter therapy and prognosis.[2,84,210,267,388,389]

The significance of a deletion 17p13 depends on when it is detected.[390,391] Thus, 4% to 5 % of patients at diagnosis have a deletion of 17p13 and although half of these patients require treatment in 3 years one third will have stable disease.[390] In contrast, at the time of first treatment, 10% patients have deletion 17p13 and these patients are resistant to chemotherapy with only one third surviving 3 years.[210] By the time patients are fludarabine-resistant, 33% will have a deletion of 17p13 and these patients have a very poor prognosis.[225] Most patients with deletion 17p13 have a *TP53* mutation on the other allele, however, patients may have a *TP53* mutation without a deletion of 17p13.[392,393] Thus,

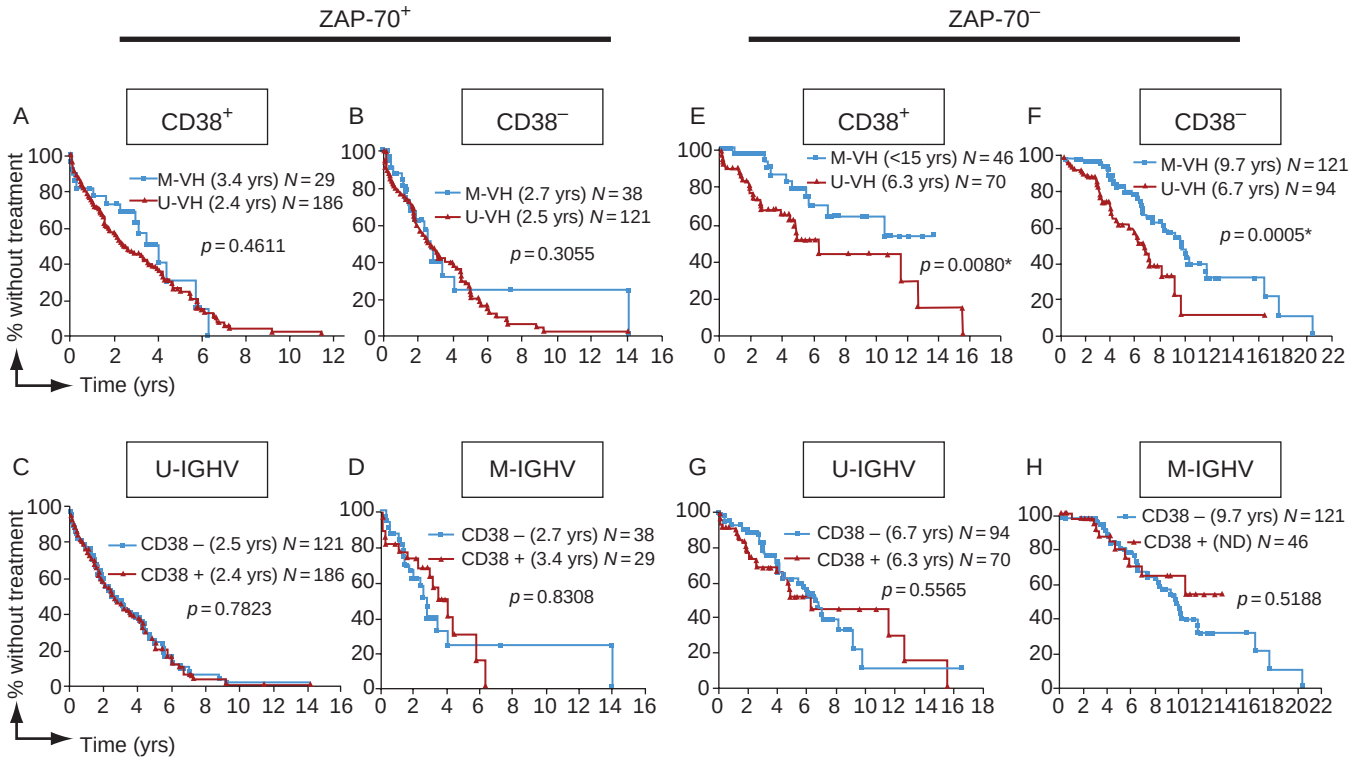

FIGURE 90.9. Relationship between ZAP-70 and CD38 or IGHV mutation status in defining the time from diagnosis to initial therapy. Kaplan–Meier curves depict the proportion of untreated CLL patients in the validation cohort ($N = 705$) from diagnosis to initial therapy. Panels A through D depict the time from diagnosis to initial treatment of patients who have CLL cells that express ZAP-70 (ZAP-70$^+$), whereas panels E through H show the time from diagnosis to first treatment of patients with CLL cells that were ZAP-70 negative (ZAP-70$^-$). Panels A and E or B and F show how IGHV mutation status can segregate cases that are CD38$^+$ or CD38$^-$, respectively. Panels C and G or D and H show how CD38 can segregate cases that use U-IGHV or M-IGHV, respectively. The *P*-values were determined using the log-rank test. The symbols represent the time at which patients were censored. From, Rassenti LZ, Jain S, Keating MJ, et al. Relative value of ZAP-70, CD38 and Ig mutation status in predicting aggressive disease in chronic lymphocytic leukemia. Blood 2008;112:1923–1930, with permission.

fludarabine-resistant patients may have deletion 17p13 alone (~10%), deletion 17p13 with a *TP53* mutation (~25%), or a *TP53* mutation alone (~10%).[225,392,393] Prognosis is equally poor in all groups leading to the suggestion that patients may require *TP53* sequencing in addition to FISH studies.[394,395] The type of *TP53* mutation is also important with mutations in the DNA binding domain portending a particularly poor prognosis.[394,395]

Patients with deletions of 11q22-23 typically are middle-aged men with bulky lymphadenopathy, and prognosis can be significantly improved with immunochemotherapy.[210,389] The addition of rituximab to fludarabine/cyclophosphamide (FCR) can improve the CR rate from 15% to 51% ($p < 0.0001$) and the OS at 3 years from 83% to 94% ($p = 0.036$).[210]

Patients with trisomy 12 may have atypical morphology but the incidence does not correlate with stage and these patients respond well to chemotherapy.[2,210]

Mutations of the Immunoglobulin Gene and IgV_H3–21 Usage

Approximately 50% of patients with CLL have mutations of the IgV_H gene, and these patients generally have stable disease and normal cell morphology.[2,6,7,267,268] In contrast, patients without IgV_H mutations are more likely to have atypical morphology, deletion of 11q22-23 and/or 17p13, and *NOTCH1* mutations.[2,233] As a result, these patients generally have advanced disease, drug resistance, an increased risk of developing RS, and poor survival. Indeed, a recent large British study demonstrated that for Binet stage A patients the IgV_H mutational status was the most important prognostic indicator in a multivariate analysis.[381] The median TTT for patients with mutated IgV_H had not been reached and the median survival was 23.3 years, compared to a median TTT of 4.6 years and OSof 12.5 years in patients with unmutated IgV_H. The use of IgV_H3-21 has been associated with a poor prognosis, regardless of mutation status, perhaps related to overexpression of genes involved in transcription and cell cycle control.[396]

Telomere Length and Telomerase Activity

In CLL, the telomeres are generally shorter than in normal B-cells and are shortest in IgV_H unmutated cells.[180,397,398,399,400] In response, telomerase may be increased, with activity being inversely related to telomere shortening. These abnormalities have been observed in patients with early-stage CLL with telomere shortening continuing to occur over time and being associated with telomere fusions and abnormal genetics, particularly deletions of 17p13 and 11q22-23.[2,398,399,400] Not surprisingly, increased telomerase and short telomeres have been associated with poor survival.[398]

NOTCH and SF1B3 Mutations

NOTCH1 and *SF1B3* mutations have recently been identified as common and important prognostic markers in CLL and were discussed earlier.[226,227,228,229,230,231,232,233,234,235] Mutations in exon 34 of *NOTCH1* is present in 4% to 10% of patients (usually unmutated IgV_H), but the incidence increases in patients with trisomy 12 (41.9%),[232] those with drug-resistant disease (20%),[227,233] and in those with Richter's syndrome (one third).[227,234] The *NOTCH1* mutations decrease the rate of NOTCH1 protein clearance and thus increase the protein level and NOTCH1 activity.[208] This results in increased NF-κB activity with cellular proliferation and increased cellular inhibitor of apoptosis protein 2 (c-IAP2) and X-linked inhibitor of apoptosis protein (XIAP) with

decreased apoptosis.[230] Interestingly, disruption of TP53 function is only observed in 10% of cases with a *NOTCH1* mutation and thus *NOTCH1* mutations are associated with non-*TP53*-mutated drug resistance.[233] Mutations of *SF3B1* occur in 15% to 17% of CLL patients and cause aberrations in splicing of a variety of mRNAs.[226,229,234,235] Mutations generally occur in patients with unmutated IgV_H, are associated with a deletion of 11q22-23 (36%), are a cause of fludarabine resistance, and are independent prognostic markers for survival.[226,234,235]

MicroRNA Expression

Low levels of MiR-181b at diagnosis have been shown to predict disease progression, and the level of the MiR decreases over time in patients with progressive disease.[401] Both BCL2 and MCL1 are targets for MiR-181b and the levels of these antiapoptotic proteins increase as the level of MiR-181b falls.[401]

Marrow Histology

Nodular and interstitial growth patterns in the marrow are associated with similar marrow tumor burdens and median survival times of 90 and 46 months, respectively, whereas diffuse infiltration or a "packed marrow" is associated with a greater marrow tumor burden and a median survival time of only 28 months.[1,252] Fibrosis of the marrow also indicates an aggressive clinical course.[402] Although the extent of lymphocyte involvement in the marrow is of prognostic importance, the marrow biopsy is preferable as it provides a more reproducible measure of lymphocyte infiltrate and can demonstrate the pattern of marrow involvement.[403] However, it should be noted that other investigators have not found that the pattern of marrow involvement adds any additional prognostic information over clinical staging.[404]

The pattern of marrow involvement after chemotherapy is also prognostically important. Patients with persistent lymphoid nodules in the marrow after chemotherapy [nodular partial remission (nPR)] have persistent leukemia and have a shorter time to relapse compared to those in CR.[405] However, the extent of involvement does not correlate with the rapidity of disease recurrence.[406]

Fludarabine resistance

One of the most important prognostic factors is fludarabine resistance. Patients who do not respond to fludarabine or relapse within 6 months of treatment have a median survival of 9 to 10 months with standard chemotherapy.[407,408]

Plasma Markers

Plasma LDH levels are a measure of cell turnover and increased levels are associated with the presence of other poor prognostic markers, such as high CD38 or ZAP-70, or the presence of deletion 17p13.[268] Moreover, a sudden increase in LDH may indicate disease progression or the development of a RS.

Plasma β_2-microglobulin is derived from the cell membrane of nucleated cells and is noncovalently linked to the α-chain of the class I major histocompatibility complex.[268] Increased levels of β_2-microglobulin have been shown to be a marker of poor prognosis predicting TTT, duration of response, and OS.[11,210,409–411] It has been assumed that β_2-microglobulin levels reflect tumor burden, however, β_2-microglobulin levels remain a useful prognostic indicator in patients with similar low-bulk Binet stage A disease.[409,410] Moreover, the levels have been found to correlate very closely with the plasma levels of the inflammatory cytokines (IL-6, IL-8, and TNF-α), indicating that it reflects the cytokine milieu.[11] β-microglobulin is cleared by the kidneys and it has been suggested that its prognostic value can be increased by correcting for renal function.[411]

The plasma levels of the inflammatory cytokines may be increased in CLL and are important prognostic markers for survival, particularly in the elderly.[11,130,412–415] It is likely that many cell types secrete the cytokines which may act by increasing CLL cell adhesion in the microenvironment.[11] The chemokine, CCL3, has also been recently shown to have prognostic value in CLL.[105] CCL3 is secreted by CLL cells with BCR stimulation in the microenvironment and elevated plasma levels predict a short TTT.[105] Finally, Yan et al.[416] have measured 23 cytokines by a multiplex assay in 84 patients and were able to identify 3 groups that showed clustering of different cytokines. Patients could be stratified into these groups to predict TTT and OS.

Two groups have recently demonstrated the importance of plasma vitamin D levels in CLL.[417,418] In one study from the Mayo Clinic, one third of patients had vitamin D deficiency.[417] The plasma level did not correlate with the season, and there was no correlation between age, sex, stage, lymphocyte count, nor other prognostic markers. However, patients with low levels had a shorter TTT and reduced OS. A subsequent study from Italy in untreated Binet stage A patients confirmed these results.[418] In both studies, TTT appeared inversely related to the vitamin D level. As the vitamin D receptor is highly expressed on CLL cells it has been suggested that vitamin D has a direct cytotoxic effect on CLL cells.[417,418]

Prognostic Index

Despite the ever-increasing number of prognostic markers there is conflicting evidence as to the value of these markers and whether combining markers will improve prognosis. Wierda et al.[13] at the MD Anderson have developed a predictive model using generally available measurements. The value of this index in early-stage patients has been validated at the Mayo Clinic and in a large Swiss–Italian multicenter study.[373,374] Six factors were originally identified for the index (age, sex, Rai stage, lymphocyte counts, number of lymph node regions involved, and β2-microglobulin level) with each factor being scored to generate a prognostic index.[13] However, the subsequent studies did not find lymphocyte count to be of prognostic value, and the European study has simplified the index to include age, sex, Binet stage (which includes number of lymph node sites), and β2-microglobulin.[374] The MD Anderson have also subsequently developed a prognostic index incorporating clinical finding with IgV_H mutational status and the presence of deletions of 17p13 and 11q22-23.[419]

TREATMENT

Therapy for CLL has undergone dramatic changes over the past 25 years. Previously, chlorambucil, or sometimes cyclophosphamide, was the agent of choice. Treatments were given intermittently to control blood counts, organomegaly, or symptoms. However, rigorous trials were never carried out to determine the optimum treatment dose or schedule for these agents. In the 1980s the nucleoside analogues were shown to have activity in CLL and the evaluation of these agents in clinical trials required increased precision in the diagnosis of CLL, standard indications for treatment, and definitions of response, including MRD. There was subsequently a re-evaluation of the role of chlorambucil in CLL and the development of combination therapies in CLL, using primarily alkylating agents and nucleoside analogues. Since that time there has been the development of monoclonal antibodies and exciting new agents which inhibit the BCR pathway. In the following sections we review each of these areas and provide a summary of the standard of care for CLL.

Indications for Treatment

The majority of patients with CLL present with Rai stages 0/I disease. They do not require treatment but do need careful monitoring for evidence of disease progression. Premature treatment

may actually cause harm and initial studies with chlorambucil in patients with Rai 0 or Binet A disease showed a delay in disease progression but no improvement in survival and an increase in the incidence of epithelial tumors and acute leukemia.[420] The indications for treatment are based on the following clinical findings.[1]

(a) Rai stage 0–II disease in patients who are symptomatic (weight loss of >10% body weight in previous 6 months, extreme fatigue, night sweats or fevers of >100.5°F or 38°C for >2 weeks without evidence of infection), or have progressive anemia/thrombocytopenia or lymphocytosis (>50% increase over 2 months or doubling time <6 months)
(b) Rai stages III/IV to improve the hemoglobin level and/or platelet counts, although asymptomatic patients can be monitored and treatment initiated when there is clear evidence of disease progression
(c) Bulky or progressive lymphadenopathy (masses >10 cm in diameter) or splenomegaly (>6 cm below left costal margin)
(d) AIHA/ ITP.

Response Criteria and Minimal Residual Disease

To facilitate comparisons of results obtained in clinical trials, the IWCLL[1] has established criteria for clinical responses in CLL, and the details of these definitions are outlined in Table 90.9. The presence of organomegaly in clinical practice is based on clinical examination but CT scans are required for clinical trials. In the original NCI-WG definitions patients were considered to be in CR even if there were lymphoid nodules in the marrow, as these can occur normally. However, it was subsequently demonstrated that patients in CR achieved a shorter remission if there were nodules in the marrow, indicating that some of these nodules are malignant.[405] Thus, patients with residual lymphoid nodules in the marrow are classified as having a *nPR*.

As therapy for CLL has become more effective, there has been interest in the prognostic value of MRD following treatment and in determining whether therapy should be aimed at eliminating MRD.[421–423,424] The optimum specific antibody combinations for detecting MRD were defined in 2007 as CD5/CD19 with CD20/CD38, CD81/CD22, and CD79b/CD43.[423] Concordance between peripheral blood and marrow MRD was ~90% when assessed >3 months after treatment, and was poorer if testing was done <3 months after treatment, particularly if alemtuzumab was used. The detection sensitivity with flow cytometry was one CLL cell in 10,000 leukocytes and flow cytometry detection rates showed concordance with a real-time quantitative allele-specific oligonucleotide (R-ASO) Ig heavy chain gene (IgH) PCR assay, although the PCR assay was more sensitive. This flow cytometry assay was used to assess MRD following FCR or FC in the German CLL8 trial.[424] MRD levels were lower in patients treated with FCR and for both treatment arms the reduction in MRD following therapy correlated with improvements in PFS and OS.[406] This randomized study confirmed the prognostic importance of MRD measurements and the long-term benefit of achieving MRD negativity with therapy.

Chemotherapy

Alkylating Agents

In the past, the standard treatment for CLL was the alkylating agent, chlorambucil, but nowadays this drug is generally only used in older and frail patients. The precise mechanism of action is unclear but it likely produces its antitumor effect by binding covalently with DNA, RNA, and cellular proteins.[425,426] Chlorambucil has been used in CLL for 60 years but the optimum treatment schedule and duration of therapy are still unclear. Traditionally, chlorambucil was administered continuously in a daily dosage of 0.1 mg/kg or intermittently as 0.4 mg/kg every 2 weeks, and these treatment schedules had equivalent efficacy, although the intermittent route produces less myelosuppression.[427,428] More recent studies have used chlorambucil administered in boluses, every 2 to 4 weeks (Table 90.10). Overall, the response rate with these regimens is 31% to 90%, with 4% to 60% of patients achieving a CR.[429,430,431,432,433,434,435] The response rates have depended on dose intensity and criteria for remission. Although very high

TABLE 90.9

CRITERIA FOR RESPONSE IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Parameter[a]	Complete Response (CR)[b]	Partial Response (PR)[c]	Progressive Disease (PD)[d]	Stable Disease (SD)[e]
Symptoms	None	Any	Any	Not CR, PR or PD
Lymph nodes	<1.5 cm	Decrease ≥50%	New node or ≥50% increase	
Hepatomegaly/splenomegaly	None	Decrease ≥50%	Detected enlargement or ≥50% increase	
Lymphocytes	$<4 \times 10^9$/L	Decrease ≥50% from baseline	Increase ≥50% over baseline	
Hemoglobin	>110 g/L	>110 g/L or ≥50% increase from baseline	Development of a cytopenia secondary to progressive CLL	
Neutrophils	$>1.5 \times 10^9$/L	$>1.5 \times 10^9$/L and/or		
Platelets	$>100 \times 10^9$/L	$>100 \times 10^9$/L or >50% increase		
Marrow	Normocellular <30% lymphocytes, no nodules	No marrow requirements for a PR		

[a]In clinical trials CT scans of abdomen, pelvis, and thorax are desirable. Response should be by CT scan if abnormal before therapy.
[b]Features should be maintained at least 2 months after completion of chemotherapy. If marrow hypocellular, repeat after 4 weeks or until peripheral blood counts have recovered (should be <6 months after chemotherapy). If nodules are present in marrow, do immunohistochemistry to confirm that they are monoclonal B-cells. If CLL nodules present, then is a "nodular PR". If patient fulfills criteria for a CR but counts remain low as a result of chemotherapy, it is denoted CRi (CR with incomplete marrow recovery).
[c]For PR, require =50% decrease in lymphocytes, nodes, and liver/spleen with a recovery in one of the blood counts, as indicated, for >2 months.
[d]If transformed to a more aggressive histology, such as Richter's syndrome.

TABLE 90.10

RESPONSE RATES IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) TO DIFFERENT CHLORAMBUCIL REGIMENS

Author	Chlorambucil Schedule	Total chlorambucil per month (mg)[a]	CR (%)	PR (%)	PFS (Months)
Rai (2000)[429]	40 mg/m^2 every 28 days (6–12 mo)	68	4	33	14
Hillmen (2007)[430]	40 mg/m^2 every 28 days (6–12 mo)	68	2	53	11.7
Eichorst (2009)[431]	0.4–0.8 (median 0.5) mg/kg days 1 and 15 (12 mo)	70	0	51	18
Knauf (2009)[432]	0.8 mg/kg days 1 and 15 (6 mo)	112	2	29	8
Catovsky (2007)[433]	10 mg/m^2, days 1–7, every 28 days (6–12 mo)	119	7	65	23
Robak (2000)[434]	12 mg/m^2/day every 28 days	571	12	45	
Jaksic (1997)[435]	15 mg/day continuously	420	60	30	

[a]Assuming a patient weighing 70 kg and SA 1.7 m^2.

response rates have been reported by Jaksic et al.[435] lower doses of chlorambucil are generally used. Cyclophosphamide differs little, if at all, from chlorambucil in its effectiveness in CLL.[436] Cyclophosphamide may be given orally using 2 to 3 mg/kg/day or 20 mg/kg once every 2 to 3 weeks and it causes less myelosuppression than chlorambucil.

To improve response rates, alkylating agents have been combined with steroids or other agents. Monthly chlorambucil with prednisone increased the response rate (47%) and survival compared to daily chlorambucil plus prednisone (response rate, 37%) or prednisone alone (response rate, 11%).[427] In a second study, the frequency of response and the number of patients alive at 2 years were higher when chlorambucil (6 mg/day) was combined with prednisone (30 mg/day) for 6 weeks than when chlorambucil was used alone; however, no difference in survival was demonstrated between the 2 groups.[437] Steroids cause a re-distribution of the CLL cells and there is usually an increase in the peripheral lymphocyte count with the initiation of steroids. In practice, prednisone is frequently combined with chlorambucil or used prior to chlorambucil to produce a rapid decrease in lymph node/spleen size and reduce pancytopenia related to marrow packing.[433] However, corticosteroids should be used sparingly as they do not increase survival and may produce significant side effects.

Nonrandomized studies initially reported excellent responses using intermittent cyclophosphamide, vincristine, and prednisone (COP) in patients with advanced CLL,[438,439] with approximately 44% of patients achieving a CR.[438] However, a subsequent randomized study comparing COP to chlorambucil showed no difference in survival or disease progression at 9[440] or 53[441] months. When COP was compared with chlorambucil and prednisone in untreated patients, the response and survival rates were identical.[442] In a similar study, a significantly higher response rate was observed using COP (59%) compared to chlorambucil and prednisone (31%), but the CR and OS rates were similar for both groups.[443]

The addition of low doses of doxorubicin to COP (CHOP) or CAP (cyclophosphamide, doxorubicin, and prednisone) or the use of multiple agents has been examined. The French Cooperative Group on CLL compared COP to CHOP in previously untreated patients with Binet stage C disease.[444] The 3-year survival rates were 28% with COP and 71% with CHOP, and the median survival times were 22 and 62 months, respectively.[445] However, these results are controversial, as no survival advantage has been observed when CHOP is compared with standard chlorambucil and prednisone.[446,447] Indeed, higher doses of chlorambucil (15 mg/day continuously) produced a statistically higher response rate than CHOP (89.5% vs. 75.0%) and an improved survival (median, 68 months vs. 47 months).[435]

Other combination regimens have been studied. In advanced or refractory disease the M2 program, consisting of cyclophosphamide, bischloroethylnitrosourea, melphalan, and prednisone, produced a CR rate of 17% and a PR rate of 44%.[448] In addition, the median survivals were not significantly different from those achieved with less aggressive regimens. A CR rate of 30% was achieved in untreated patients.[448] A combination protocol including prednisone, vincristine, cytosine arabinoside, cyclophosphamide, and doxorubicin (POACH) achieved response and survival rates not significantly different from those reported for chlorambucil and prednisone, with complete and overall response rates of 21% and 56%, respectively, for previously untreated patients and 6% and 21%, respectively, for previously treated patients.[449] VAD (vincristine, doxorubicin, and dexamethasone) has been examined in relapsed or refractory CLL.[450] No CRs were observed, and although 21% had a PR, 33% had progressive disease.

To determine whether aggressive multiagent therapy is better than standard chlorambucil (with or without prednisone) in CLL, a meta-analysis of 10 randomized studies involving 2,035 patients, mostly with Binet stage B and C disease, was carried out comparing chlorambucil with COP, CHOP, and chlorambucil/epirubicin.[451] This analysis did not reveal an improvement in survival by using an anthracycline-containing regimen compared to standard chlorambucil, demonstrating that more aggressive treatment approaches were not required to make an impact on survival.

Bendamustine has demonstrated high activity in CLL.[432,452] The drug was developed as an alkylating agent and has three components: (a) a 2-chloroethylamine alkylating group that is seen with the other nitrogen mustards; (b) a butyric side chain that is also contained in chlorambucil, and (c) a benzimidazole ring which is believed to contribute to the unique action of this agent.[452–454] Bendamustine produces more extensive DNA cross-linking and breaks than other alkylators, activates a base-excision DNA repair pathway rather than O^6-alkylguanine-DNA alkyltransferase repair used by chlorambucil and cyclophosphamide, is active against cell lines that are resistant to the nitrogen mustards, and may act through the induction of apoptosis and mitotic catastrophe.[452–454] Bendamustine has been compared to chlorambucil in the first-line treatment of CLL (Table 90.11).[432,455] Bendamustine produced a higher CR rate, a threefold increase in PFS and time to next treatment (31.7 vs. 10.1 months) but no difference in survival. The quality of life was similar with both drugs and, not surprisingly, patients who were sensitive to either drug had an improved survival. However, adverse events were twofold

more common with bendamustine and included skin rashes, marrow suppression, and nausea/vomiting.[432] As discussed later, bendamustine is now more typically administered with rituximab.

Nucleoside Analogues

The nucleoside analogues have demonstrated significant activity in the low-grade lymphoproliferative disorders.[456] Pentostatin (2′-deoxycoformycin;dCF) is an inhibitor of adenosine deaminase, which is responsible for the deamination of deoxyadenosine and adenosine to deoxyinosine and inosine, respectively. After therapy with pentostatin, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyadenosine diphosphate, and dATP, and this occurs preferentially in lymphocytes.[457] The intracerebral accumulation of deoxyadenosine and adenosine likely causes nausea and vomiting, a major toxicity with this agent.[458] Cladribine (2-chlorodeoxyadenosine; CdA) and F-ara-A are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-adenosine monophosphate (fludarabine); fludarabine is rapidly dephosphorylated in the plasma to F-ara-A.[459,460] Like deoxyadenosine, cladribine and F-ara-A are taken up into lymphocytes by a nucleoside transport system and accumulate in lymphocytes as their phosphorylated derivatives. A correlation has been found between the protein levels of the hNT2 transport protein and in vitro cytotoxicity.[461,462] The triphosphate derivatives of deoxyadenosine, cladribine, and F-ara-A can kill lymphocytes in three ways.[52,463] First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome *c* from the mitochondria; the released cytochrome *c* interacts with Apaf-1 and dATP causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of the triphosphates can enhance the effects of endogenous dATP on the apotosome, inducing apoptosis. Finally, cladribine differs from the other two drugs in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to CdATP, which is directly toxic to the mitochondria.

Pentostatin produces CR and PR rates of 16% to 25% in previously treated patients, with an additional 20% to 30% of patients exhibiting other forms of clinical improvement.[464,465] The standard dose is 4 mg/m^2 intravenously (IV) every other week.[456,465] Toxicities include infection, myelosuppression, nausea/vomiting, and pruritus.

Fludarabine has greater activity in CLL and is equally efficacious when administered orally or IV, although a higher dose is required when given orally.[466] Using 25 to 30 mg/m^2 IV daily for 5 days, repeated monthly, the overall response rate is approximately 45% in previously treated patients, with the CR rate being 3% to 20%.[467–469] In untreated patients, the response rate is approximately 70%, with the CR rate being 20% to 40%.[429,469–471] The main toxicities with fludarabine are myelosuppression and infections, particularly when patients have been previously treated with alkylating agents. Nausea, vomiting, and neuropathy rarely occur. In an attempt to reduce toxicity, fludarabine has been administered as 30 mg/m^2 IV daily for 3 days, repeated every 4 weeks.[472] Compared to the standard 5-day treatment schedule, the response rate was lower at 46% (CR, 10%), but there was a significant reduction in the infection rate and no difference in survival. The addition of prednisone does not improve the response rate over fludarabine used alone and significantly increases the risk of unusual infections (e.g., *Pneumocystis jirovecii* pneumonia and *Listeria monocytogenes* sepsis).[473] Five major phase III studies have determined whether initial treatment with fludarabine could produce an increased remission rate compared with standard chemotherapy and whether this would translate into improved survival.[429,431,433,434,469,470] A summary of the results of these studies is in Table 90.11.

- In the European Cooperative Group study fludarabine was compared with CAP (cyclophosphamide, Adriamycin, prednisone).[469] The responses with fludarabine were similar to those

[c]Alive at 24 mo.

for CAP, but the duration of responses was significantly longer with fludarabine with a tendency toward a longer survival.

- In a French Cooperative Group study patients were randomized to CHOP, CAP, or fludarabine.[470] The response rates were similar for CHOP and fludarabine, and both were better than CAP. However, time to relapse and survival rates were similar regardless of treatment.
- Three groups have compared fludarabine and chlorambucil, and although the doses of fludarabine were similar in all, the dose of chlorambucil was lowest in the North American Inter-Group CLB-9011 study (Table 90.11).[429] In this study, there was a higher response rate, longer duration of response, and improved PFS in patients treated with fludarabine but no difference in OS. However, a follow-up analysis at 10 years showed a survival advantage for fludarabine.[474] In the LRF CLL4 study from the United Kingdom, the response rates were higher for fludarabine than for chlorambucil, but there was no difference in PFS or OS.[433] In the German CLL5 trial only patients >65 years were studied, and fludarabine produced a higher response rate compared to chlorambucil.[431] Again, there was no difference in PFS or OS.

In CLL, cladribine has been less extensively evaluated than fludarabine but the former probably has equivalent antitumor activity.[434,456,475–480] The drug is given in monthly cycles, in doses of 0.1 mg cladribine/kg/day by continuous infusion × 7 days,[477] or 0.12 to 0.14 mg/kg/day over 2 hours × 5 days,[475,478] or 10 mg/m^2/day orally × 5 days.[482] The results of studies with cladribine have varied greatly,[434,475,476,478] with response rates in previously treated patients varying from 48% to 72% and CR rates varying from 4% to 39%.[456,475] In previously untreated patients, approximately 80% of patients respond, and the CR rate varies from 10% to 45%.[434,456,475,479] In a multicenter study with patients randomized to receive initially either cladribine or chlorambucil, and resistant patients being switched to the other drug, cladribine produced a higher remission rate and more prolonged remissions than chlorambucil (Table 90.11).[434] However, as with the randomized studies comparing fludarabine with alkylating agents, survival was similar whether the initial treatment was with cladribine or chlorambucil. The variation in the response rates to cladribine in previously treated patients may be related to the extent of prior therapy. In vitro studies have shown that cladribine is more myelosuppressive than fludarabine,[459] and in the clinical setting, repeated treatments with cladribine can produce prolonged thrombocytopenia.[434,475–480] As is fludarabine, cladribine is very immunosuppressive, and infections are the major toxicity, particularly when cladribine is given in conjunction with prednisone.[289,434,479]

Neither cladribine nor fludarabine causes the accumulation of adenosine, which likely explains the lack of nausea/vomiting observed with these agents when compared to pentostatin. However, all of these nucleoside analogues can produce neurotoxicity, and peripheral neuropathy is now being documented as a potential devastating toxicity.[481] The nucleoside analogues are all highly immunosuppressive, being both myelosuppressive and producing a marked fall in the CD4$^+$ cell count, which may persist for years.[456] Although initial studies demonstrated that the nucleoside analogues could trigger AIHAs, the frequency of this complication is no greater with the analogues than with other agents.[433,434] Graft-versus-host disease has been observed in patients being treated with nucleoside analogues who receive blood transfusions, and it has been recommended that these patients receive only irradiated blood products.[482] Reports have also indicated a higher incidence of acute myeloid leukemia (AML)/myelodysplasia in patients receiving nucleoside analogues,[483,484] and this risk may be further increased in patients receiving a combination of chlorambucil and fludarabine.[484] Recent studies have demonstrated that fludarabine can be toxic to the lung, in addition to pre-disposing these patients to pneumonia.[485] Once infections have been ruled out, the pulmonary toxicity syndrome often responds to steroids.[485]

An in vitro study has demonstrated cross-resistance between fludarabine and cladribine in the leukemic cells of 90% of patients,[459] and clinical studies have confirmed that patients resistant to fludarabine are unlikely to respond to cladribine, and vice versa.[479,486] In a clinical trial of 28 patients who were resistant to fludarabine, only 1 patient had a PR with cladribine.[486] Thus, patients who are resistant to one of the nucleoside analogues should not be treated with another, particularly as such therapy increases the risk of infections secondary to myelosuppression and immunosuppression.

Combinations of Nucleoside Analogues with Alkylating Agents

To improve antitumor activity the nucleoside analogues have been combined with other agents. Combined therapy with steroids does not improve the antitumor effect and markedly increases the risk of infection.[473,478] In vitro studies have demonstrated that the nucleoside analogues can inhibit DNA repair, which explains the synergistic antitumor activity seen between these agents and irradiation or alkylating agents.[487–489] Moreover, this effect is seen preferentially in CLL cells compared to normal marrow cells.[488] Synergy has also been observed between fludarabine and cyclophosphamide in phase II clinical studies.[490–492] O'Brien et al.[490] combined fludarabine 30 mg/m^2 IV daily × 3 with cyclophosphamide 300, 350, or 500 mg/m^2 IV daily × 3 and demonstrated a 38% response rate in patients who were resistant to fludarabine alone. In previously untreated patients, more than 80% responded with a 35% CR. Moreover, the duration of response was longer than for fludarabine alone. Similar findings have been observed in 3 large randomized clinical trials[433,493,494] (Table 90.12). The efficacy and toxicity of cladribine with cyclophosphamide is similar

TABLE 90.12

PHASE III STUDIES COMPARING FLUDARABINE AND FLUDARABINE/CYCLOPHOSPHAMIDE (FC) IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

Reference	Treatment	Patient Number	CR (%)	PR (%)	PFS[a]	Survival
German CLL Study Group (2006)[493]	Fludarabine	164	7	76	Median, 20 mo	3 y, 80.7%
	FC	164	24	70	Median, 48 mo	3 y, 80.3%

	FC	141	23.4	50.4	Median, 31.6 mo	2 y, 79%

[a]PFS, progression-free survival.

to that of FC in previously untreated patients.[495] Pentostatin has also been combined with cyclophosphamide in one study.[496] In 23 previously treated patients treated with pentostatin 4 mg/m^2 IV and cyclophosphamide 600 to 900 mg/m^2 IV repeated every 3 weeks × 6, 17 patients responded with 4 CRs and 13 PRs. It is important to note that10 of 13 fludarabine-resistant patients responded with one CR. A concern with combining the nucleoside analogues with alkylating agents is an increased risk of myeloid leukemias, as may be the case when fludarabine and chlorambucil are combined.[484]

A recent systematic review has summarized all these studies.[497] In brief, the addition of cyclophosphamide to a nucleoside analogue increases the response rates and PFS over single agents but this does not translate into improved survival, likely as a result of effective second-line therapies.

Steroids

As steroids kill CLL cells with a *TP53* mutation,[68] they can be useful for palliation in patients resistant to alkylating agents and nucleoside analogues.[498] However, as discussed later, nowadays they are usually combined with a monoclonal antibody. High-dose steroids, such as methylprednisolone at 1 gm/m^2/day × 5 days, repeated monthly, can be helpful in advanced-stage patients, who are drug resistant and have bulky disease, marrow failure, or both.[498] In 25 patients treated with methylprednisolone, with or without chemotherapy, the overall response rate was 77% with the median duration of response being 12 months (range, 7–23+). Of the 10 patients with p53 mutations, 5 responded to this therapy. The management of CLL patients maintained on steroids is discussed in the section "Systemic Complications Requiring Therapy."

Monoclonal Antibodies

Anti-CD20

The cell-surface antigen CD20, plays an important role in the activation, proliferation, and differentiation of B-cells and antibodies to CD20 have transformed the therapy of the B-cell lymphoproliferative disorders.[499,500] The chimeric monoclonal antibody, rituximab, contains a human IgG1 Ig constant region and a murine variable region directed against CD20.[499,500] This agent was licensed for use in relapsed indolent lymphoma in 1997 by the US Food and Drug Administration (FDA) and since that time many variants of this antibody have been developed, with ofatumumab and GA101 being most studied in the clinic. Rituximab has shown significant activity against low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity by complement-dependent cytotoxicity (CDC), antibody-dependent cell-mediated cytotoxicity (ADCC), or by the direct induction of apoptosis. An intact FcγR is required for ADCC and it has been suggested that polymorphisms in FcγRIIIa (CD16) may influence the response to rituximab.[499] A variety of new anti-CD20 antibodies has been developed to enhance antitumor activity that are humanized, unlike rituximab which is chimeric. The anti-CD20 monoclonal antibodies are classified as type I or type II based on their ability to redistribute CD20 into lipid rafts that can influence antibody activity.[499] Type I antibodies, exemplified by rituximab and ofatumumab, redistribute CD20 into lipid rafts and potently activate complement. In contrast type II antibodies, as exemplified by tositumomab and GA101, induce programmed cell death that is independent of caspase activation and DNA breaks, and is not affected by BCL2.[501,502,503] The ability to induce programmed cell death correlates with the induction of intercellular homotypic adhesion which alters the actin cytoskeleton causing permeabilization of the lysosome and the release of cathepsin B into the cytoplasm.[501,502,503] Recent studies suggest that this leads to increased free radical formation from NADPH oxidases, which results in loss of plasma cell membrane and cell death.[503] In animal models, the type II antibodies are more effective in clearing CD20 positive lymphocytes from blood and lymphoid organs.[504]

Using the standard rituximab regimen that is effective in follicular lymphomas (375 mg/m^2 IV weekly × 4), initial studies showed that rituximab had little activity in CLL (13% response rate), compared to a 50% response rate in the follicular lymphomas.[505] This decreased activity was attributed to the low levels of CD20 on CLL cells and the high plasma CD20 levels observed in CLL; the high plasma CD20 levels are believed to divert rituximab from the cellular target and to reduce the half-life of the antibody.[506] The plasma CD20 is believed to be derived from cell breakdown, and the level correlates with disease stage but not the lymphocyte count.[506] However, 2 studies have shown that rituximab can rapidly, albeit transiently, reduce the peripheral lymphocyte counts of CLL patients.[507,508] The treatment had little effect on lymphadenopathy and did not normalize blood counts, and this discrepancy has been related to the fact that the CLL CD20 levels are lower in the nodes and marrow than in the peripheral blood.[509] In an attempt to increase the effectiveness of rituximab in CLL, the dose of rituximab has been escalated, using either a weekly or thrice weekly schedule, and response rates of 36% to 45% have been achieved without a significantly higher toxicity than is observed with the standard schedule.[510,511] Of special interest is the observation that "shaving" or removal of CD20 and rituximab from the CLL surface by monocytes and macrophages results in the appearance of CLL cells in the circulation that have neither CD20 nor rituximab on their surface.[512] This occurs primarily with high doses of rituximab, raising the question as to whether rituximab would be best administered using lower doses applied more frequently.[513]

Rituximab can cause reactions (e.g., fevers/rigors, dyspnea, hypotension, and nausea/vomiting) as a result of the release of inflammatory cytokines (e.g., IL-6, IL-8, TNF-α, and γ-interferon) and this complication primarily occurs in patients with lymphocyte counts of greater than 50 × 10^9/L.[507,508,510,511] The reactions usually occur with the first treatment, and the likelihood of a reaction decreases with each subsequent treatment. Pretreatment with steroids and "stepped-up dosing" decreases the severity or likelihood of a reaction.[508] More recently, the development of immune neutropenia has been observed after rituximab and usually resolves spontaneously in 1 to 3 weeks or in 3 to 5 days with G-CSF.[514]

Rituximab has been administered with high-dose methylprednisolone for patients with high-risk disease including those with deletions of 17p13 and 11q22-23.[515,516] Approximately two-thirds of patients will respond with a median PFS of 1 year, and main side effects include hyperglycemia and fluid retention.

Ofatumumab is a fully human type I monoclonal antibody directed against a different epitope on CD20 that results in tighter binding and increased complement activation.[499,517] The pivotal study by Wierda et al.[518] showed a response rate of 58% in patients who were resistant to fludarabine and alemtuzumab (FA) and 47% in patients who were resistant to fludarabine with bulky (>5 cm) lymphadenopathy (BF). The median PFS and OS were 5.7 and 13.7 months for the FA group and 5.9 and 15.4 months for the BF group. The treatment schedule was with 8 weekly treatments followed by 4 monthly treatments. The first infusion was with 300 mg followed by 2,000 mg for all other infusions. Treatment was well tolerated and the FDA subsequently licensed ofatumumab for patients resistant to FA. A subsequent analysis indicated that rituximab-resistant patients had a similar response to ofatumumab as patients who were rituximab-naive.[519] Ofatumumab has been administered with high-dose steroids with two-thirds of patients with fludarabine resistance and bulky lymphadenopathy responding.[520] This included patients with deletions of 17p13, where the response to ofatumumab alone is 14%.[518]

GA101 (obinutuzumab) is a humanized type II antibody with a novel mechanism of action and is presently being evaluated against rituximab in a number of clinical trials for CLL.[499]

Anti-CD52

The monoclonal antibody, alemtuzumab (Campath-1H), is a humanized IgG1 antibody against CD52, with the antigen-binding site being of rodent origin; targets are B and T lymphocytes, NK-cells, monocytes and eosinophils with sparing of normal hematopoietic stem cells.[521,522] As with rituximab, alemtuzumab can kill tumor cells by CDC, ADCC, or the direct induction of apoptosis and has become an important agent for the treatment of fludarabine-resistant patients with deletions of 17p13 or 11q22-23.[521,522] In the pivotal CAM 211 multicenter study on 93 patients with fludarabine-resistant disease, patients were treated for 12 weeks with alemtuzumab.[523] The CR rate was 2%, PR rate 31%, and 54% of patients had stabilization of their disease. Many patients with symptoms such as night sweats, fatigue, or weight loss had resolution of their symptoms. The median time to response was 1.5 months and median time to progression was 4.7 months for all patients and 9.5 months for responders. Median survival for all patients was 16 months and 32 months for responders. As an historical comparison, the median survival of fludarabine-resistant CLL patients is 10 months.[523] Alemtuzumab was particularly efficacious at clearing the peripheral blood (first) and marrow/spleen (later) of CLL cells, but was less active against lymphadenopathy. Lymphadenopathy resolved in two-thirds of patients but no patient with nodes >5cm had complete resolution of lymphadenopathy. Unfortunately, patients had infusion-related toxicities (i.e., nausea/vomiting, fevers, rigors, and rash) with the initiation of treatment and there was an increased incidence of infections. Patients were maintained on prophylactic trimethoprim/sulphamethoxazole and famciclovir until 2 months after treatment was completed. Infections occurred in 55% of patients and CMV reactivation was the most common opportunistic infection. Because of the high risk of infections with alemtuzumab, especially in heavily pretreated patients, care must be used in patients who had previous infections or a poor performance status. To reduce the risk of CMV valganciclovir 450 mg twice a day has been recommended although 900 mg 3 times a week may also be effective and produce less myelosuppression.[524,525] Guidelines are available for the use of alemtuzumab, particularly with regard to prophylactic antibiotics and CMV monitoring.[366,522]

Alemtuzumab appears to have equivalent clinical activity when administered subcutaneously (sc), even though it takes longer to achieve a steady plasma concentration of antibody.[526,527] Thus, Stilgenbauer et al.[526] were able to reproduce the results of the CAM 211 study using sc alemtuzumab. Of patients receiving sc alemtuzumab, 90% have local injection-site reactions, with erythema/edema, pruritus, and pain at the site of injection. However, the reactions disappear with continued treatments, usually within 2 weeks. During the initial 2 weeks, the local reactions can be controlled by ice-packing the injection site before the injection and for about 1 hour after the injection. Alemtuzumab has also been evaluated as front-line therapy in 2 studies.[430,528] Of 41 previously untreated CLL patients receiving sc alemtuzumab, 38 received more than 1 week of therapy, and in this group, the CR rate was 19% and the PR rate 68%.[528] Consistent with these findings, the CR and PR rates with alemtuzumab in the CAM 307 study were 22% and 61%, respectively.[430] Following alemtuzumab therapy in previously untreated patients, the lymphocyte subtypes gradually recover, but remain at <25% baseline for >9 months following therapy.[528] Despite this, infections were not a problem.

Because of its unique properties, there has been interest in evaluating alemtuzumab for the treatment of patients with resistant disease.[225,529] Of 36 fludarabine-resistant patients treated with alemtuzumab, 15 (42%) had *TP53* mutations and/or deletions and 6 of the 15 (40%) responded to alemtuzumab.[225] The median duration of response was 8 months (range, 3 to17 months). When used as initial therapy in previously untreated patients, the response rates for 7 patients with a deletion of 17p13 was 64%.[430] Alemtuzumab has also been administered following standard chemotherapy for the purpose of consolidation.[530–532] In these studies the dose and duration of alemtuzumab ranged from 10 to 30 mg 3 times a week for 4 to 12 weeks. The CR and MRD-negative responses can be increased with this therapy and this is associated with a longer PFS. However, these positive effects are counterbalanced by an increased risk of infections and the development of Epstein–Barr positive large-cell lymphomas.[530–532] Until further studies direct otherwise, the use of alemtuzumab in front-line therapy or for the purpose of consolidation should be confined to clinical trials.

Alemtuzumab has been combined with high-dose steroids in 17 untreated and 22 previously treated patients with a deletion of 17p13.[533] The overall response rate and CR rate were 85% and 36%, respectively, with a median OSof 23.5 months demonstrating the effectiveness of the regimen in this high-risk group of patients. Side effects included hypokalemia, hyperglycemia, and infections. Two-thirds of patients needed granulocyte colony-stimulating factor for neutropenia, half needed (val)ganciclovir for CMV reactivation. Although grade 3 to 4 infection occurred in half the patients, this was age-related and only occurred in 29% of patients less than 60 years of age. Alemtuzumab has also been combined with rituximab in patients with molecular markers indicative of aggressive disease.[534] Patients received alemtuzumab 30 mg subcutaneously 3 times a week for 4 weeks with rituximab 375 mg/m^2 weekly for 4 treatments. Of 30 patients, 90% responded with 37% CRs, and the median duration of response of responders was 14.4 months. Neutropenia was common and CMV reactivation occurred in 10%.

Anti-CD23

The anti-CD23 antibody, lumiliximab, has limited activity alone but results of a phase I/II study suggests that the addition of lumiliximab with FCR may increase the response rate without additional toxicity.[535]

Chemoimmunotherapy

Combinations with anti-CD20 Antibodies

Combinations with Rituximab

Synergy has been demonstrated between rituximab and chemotherapy in vitro, although the mechanisms underlying this phenomenon are unclear.[536–538] Synergy may be related to effects of rituximab on the levels of antiapoptotic proteins, as rituximab reduces the cellular levels of BCL2 through inhibition of IL10 in lymphoma cell lines in vitro,[537] and the levels of *MCL1* and XIAP are decreased in the CLL cells of patients undergoing treatment with the antibody.[539] Alternatively, fludarabine may down-regulate the expressions of CD46 and CD55 on the CLL cells, proteins that antagonize the effects of activated complement.[538]

Fludarabine has been combined with rituximab (FR) in the clinic.[540–542,543] In one study, 31 previously treated or untreated CLL patients received 4 monthly cycles of fludarabine (25 mg/m^2 IV daily × 5 days) combined with 4 monthly treatments with rituximab (375 mg/m^2 IV), the first 2 rituximab treatments given with the last 2 cycles of fludarabine.[540] The CR rate was 33%, the PR rate was 55%, and treatment was well tolerated. Byrd et al.[541] compared concurrent versus sequential treatment with fludarabine and rituximab in untreated CLL patients (CALGB 9712). There were 51 patients who received 6 cycles of fludarabine followed by 4 weekly treatments with rituximab (sequential

regimen), and 53 patients who received 6 cycles of concurrent fludarabine and rituximab followed by consolidation with 4 weekly treatments with rituximab. In the concurrent regimen, there were 47% CRs and 43% PRs, whereas the sequential regimen appeared less effective with 28% CR and 49% PR. Treatment was generally well tolerated; infusion-related toxicity, myelosuppression, and infections were the major toxicities. A follow-up analysis showed that both groups had a similar outcome with the combined median PFS being 42 months and the median OS being 85 months.[543] A retrospective comparision has been made to patients treated with fludarabine alone (CALGB 9011).[542] The CR and PR rates in the CALGB 9011 study were 20% and 43%, respectively, and the CR and PR rates in the CALGB 9712 study (all patients) were 38% and 46%, respectively. The 2-year PFS and OS for patients receiving fludarabine were 45% and 81%, respectively, and for patients receiving fludarabine with rituximab were significantly better at 67% and 93%, suggesting that the addition of rituximab in first-line therapy prolongs survival.

The MD Anderson Cancer Center developed the combined fludarabine with cyclophosphamide and rituximab (FCR) regimen using fludarabine 25 mg/m^2 and cyclophosphamide 250 mg/m^2 administered IV on days 1, 2, and 3 with rituximab 375 mg/m^2 IV on day 1 with the first course and then 500 mg/m^2 IV for courses 2 to 6. The treatments were given every 28 days for 6 cycles for the treatment of both untreated and previously treated patients (Table 90.13).[544,545,546] In 224 previously untreated patients the CR, nPR, and PR rates were 72%, 10%, and 13%, respectively.[545] A retrospective comparison among fludarabine, FC, and FCR also suggested that FCR increased OS, with OS at 6 years being 54%, 59%, and 77% for patients treated with fludarabine, fludarabine and cyclophosphamide/mitoxantrone, or FCR.[545] The subsequent CLL8 prospective randomized phase 3 study from the German CLL Study Group confirmed these findings. FCR has subsequently become a standard first-line therapy for selected patients (Table 90.13). Previously untreated patients were randomized to FCR or FC using the MD Anderson treatment regimens. As FCR is an aggressive treatment regimen, patients were required to have an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 1, a cumulative illness rating scale (CIRS) of 6 or less, and a creatinine clearance of ≥70 ml/min. Prophylaxis with antivirals was not given and prophylaxis against *Pneumocystis jirovecii* only recommended for severe leukopenia lasting >7 days. Approximately one-quarter of patients in both the FC and FCR groups were unable to tolerate the full 6 cycles of therapy and drug dosages had to be reduced by >10% in 47% of patients on FCR and 27% of patients on FC. The CR and PR for FCR were 44% and 46% and for FC were 22% and 58% (p = <0.0001). The median PFS was 51.8 months with FCR and 32.8 months with FC (p < 0.001) whereas OS at 3 years was 87% with FCR and 83% with FC (p = 0.01) (Figs. 90.10 and 90.11). Although an improvement in CR rate was seen for all Binet stages with FCR, only Binet stage B showed an improvement in PFS and OS with chemoimmunotherapy. The response of patients with a deletion of 17p13 was equally poor for patients treated with FCR or FC, and although PFS was increased with FCR (11.3 vs. 6.5 months, p = 0.019) there was no improvement with survival. However, supporting a previous observation,[388] FCR overcame the poor prognosis associated with FC in patients with a deletion 11q22-23, with an improved CR rate (51% vs. 15%, p = <0.0001)), prolonged PFS at 3 years (64% vs. 32%, p = <0.0001), and increased OS at 3 years (94% vs. 83%). FCR caused more neutropenia than FC, and neutropenia and infections occurred more commonly in those >65 years. Deaths related to both regimens only occurred in 2% to 3% of patients, and it should be emphasized that these patients were carefully chosen according to performance status, comorbidities, and renal function. In addition, the median age of patients was only 61 years.

The MD Anderson studies have demonstrated that about 20% of patients can have cytopenias lasting longer than 3 months following FCR and that 28% of patients whose blood counts have recovered following treatment can have a late cytopenia that usually occurs in the first year of remission.[545] The incidence of immune cytopenias was reported to be 6.5% in the MD Anderson series with AIHA typically occurring between cycles 3 and 6 and most patients responding to standard therapies.[319] In contrast, in the CLL8 study, only 1% of patients developed immune cytopenias. In addition, the risk of serious or opportunistic infections at the MD Anderson was 10% and 4% in the first and second

[a]A, alemtuzumab; C, cyclophosphamide; F, fludarabine; FluCam, fludarabine/alemtuzumab; P, pentostatin; R, rituximab.
[b]Median PFS was 32.8 mo with FC and 51.8 mo with FCR (p < 0.001). Overall survival at 37.7 months was 84.1% with FCR and 79.0% with FC (p = 0.01). Patients with Binet stage B disease primarily benefited from the addition of rituximab.
[c]nPR and PR were combined.
[d]High-risk patients with a β2-microglobulin of ≥4 mg/L and aged <70 years.
[e]Dose of pentostatin, 2 mg/m^2.
[f]Dose of pentostatin, 4 mg/m^2.

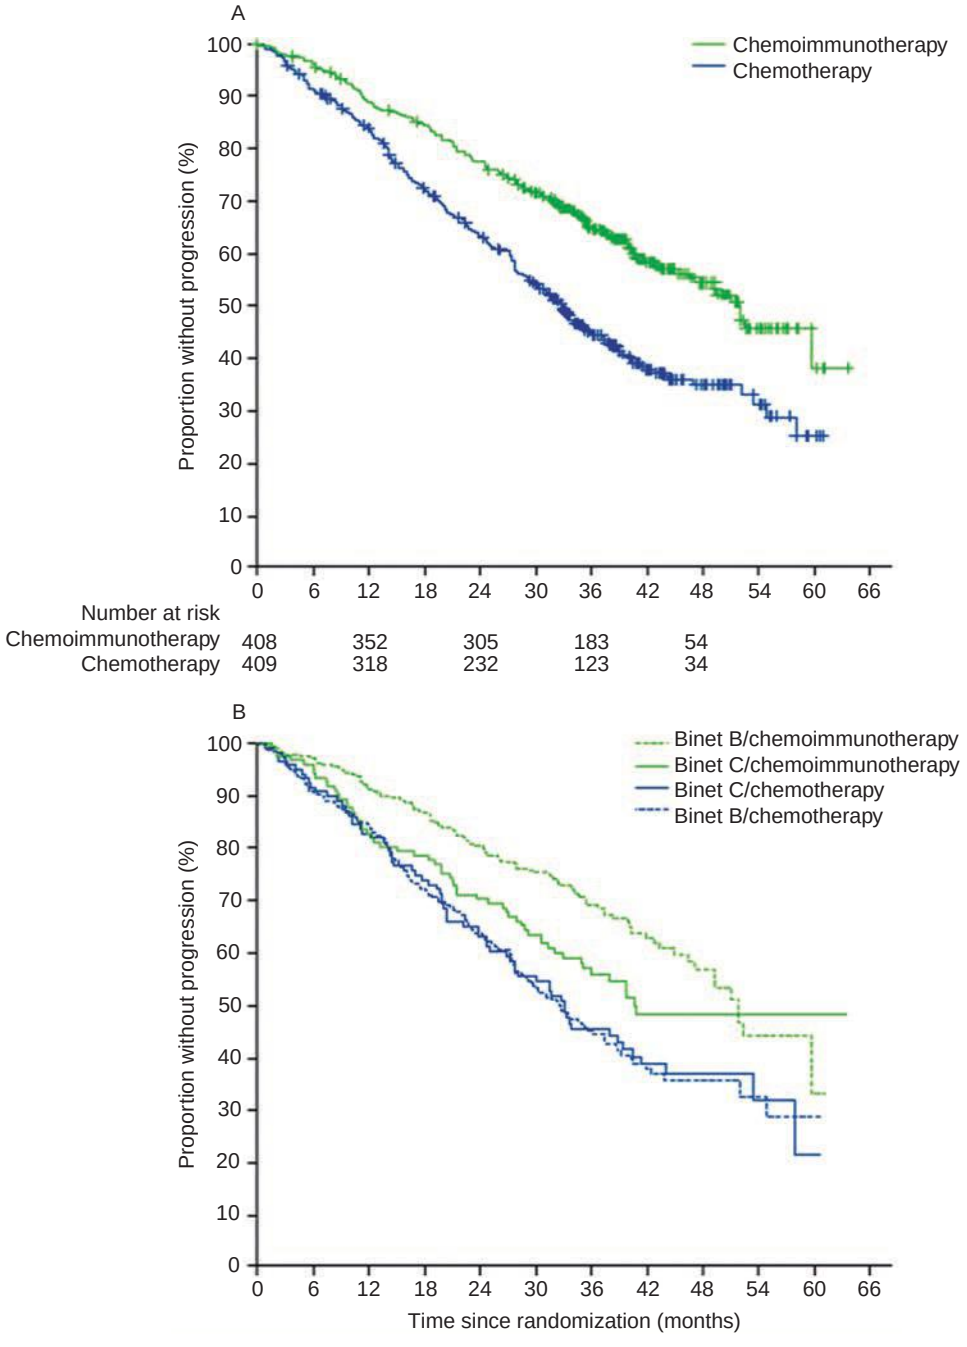

FIGURE 90.10. Progression-free survival in all patients and in patients with Binet stage B and C chronic lymphocytic leukemia. From Hallek M, Fischer K, Fingerle-Rowson G, et al. Addition of rituximab to fludarabine and cyclophosphamide in patients with chronic lymphocytic leukemia: a randomised, open-label, phase 3 trial. Lancet 2010;376:1164–1174.

years of remission, respectively, with a relatively high incidence of shingles at these times. In addition, 4.5% of patients developed AML or myelodysplasia, with the median onset from the initiation of chemotherapy being 35 months (median, 3 to 118 months).[547] Thus, although FCR is a highly effective therapy, there are significant toxicities and care must be taken in deciding which patients require, and/or can tolerate, this treatment. Patients with deletion 11q22-23 should receive FCR, if possible, Results of the CALGB 10404 study, comparing the front-line activities of FR and FCR in CLL, should help clinicians individualize treatment.[543]

To enhance activity, mitoxantrone has been added to the FCR regimen (R-FCM).[548] In patients less than 70 years old, the response rate was 93% with 82% CR (46% MRD negative) with marrow suppression being the primary toxicity. Again, patients with high tumor burden, deletion 17p13, and high β2-microglobulin levels did poorly. These patients received maintainance rituximab which will make it difficult to compare the effects on PFS and OS with the FCR studies where maintainance rituximab was not given.

Variations in FCR have been developed to reduce the significant myelosuppression of FCR. In one regimen, patients received 6 cycles of reduced doses of fludarabine and cyclophosphamide with increased doses of rituximab followed by maintenance rituximab every 3 months until relapse.[549] This regimen decreased myelosuppression without compromising the response rate, but effects on survival are not yet known. Pentostatin has been substituted for fludarabine, as it is less myelotoxic.[550,551] Using pentostatin 2 mg/m^2 IV, cyclophosphamide 600 mg/m^2 IV, and rituximab 375 mg/m^2 IV, repeated every 3 weeks for 6 cycles the CR, nPR, and PR rates were 41%, 22%, and 28%, respectively, in 64 previously untreated patients.[550] In contrast to FCR, patients >70 years of age appeared to do particularly well with

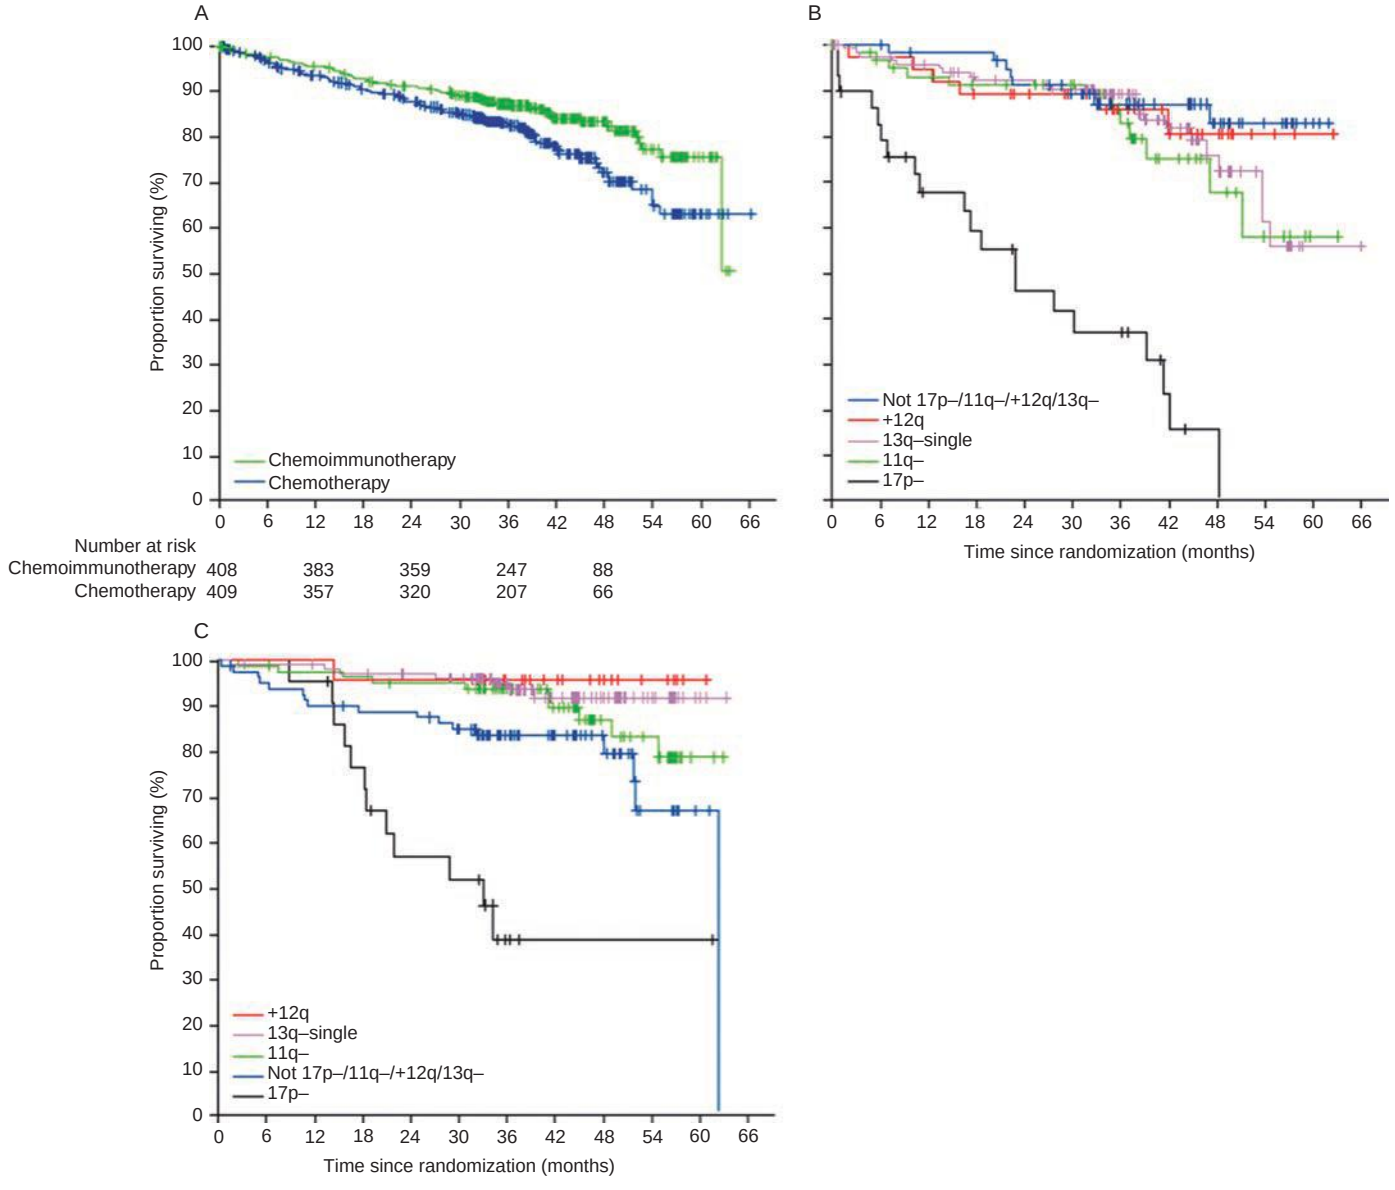

FIGURE 90.11. Overall survival in all patients (A), and in genetic subgroups of chemotherapy (B) and chemoimmunotherapy groups (C). Chemoimmunotherapy = fludarabine, cyclophosphamide, and rituximab. Chemotherapy = fludarabine and cyclophosphamide. From Hallek M, Fischer K, Fingerle-Rowson G, et al. Addition of rituximab to fludarabine and cyclophosphamide in patients with chronic lymphocytic leukemia: a randomised, open-label, phase 3 trial. Lancet 2010;376:1164–1174.

this regimen having similar response rates and toxicities as seen with younger patients. The regimen appeared to be less myelotoxic than FCR and although patients with 11q22-23 deletions did as well as patients without high-risk cytogenetics, patients with deletions of 17p13 did not respond to PCR. Pentostatin and rituximab have been evaluated in 33 patients using a higher dose of pentostatin (4 mg/m^2) than for PCR.[551] The CR was 27%, nPR 15%, and PR 33%, confirming the importance of additional cyclophosphamide to enhance response rate.

Bendamustine has been combined with rituximab (BR) for 117 previously untreated CLL patients.[552] The CR was 23% and PR 65% with a median estimated event-free survival of 34 months. Marrow toxicity occurred in half the patients and although neutropenia appeared to be less than in the CLL8 study, there was a higher incidence of anemia and thrombocytopenia. Whether BR is better than FCR is being evaluated in the phase III German CLL10 study. Bendamustine/rituximab has also been evaluated in 78 previously treated CLL patients, of whom 22 were fludarabine-resistant and 14 had a deletion of 17p13.[553] The CR, nPR, and PR rates were 9%, 3%, and 47%, respectively, and the median event-free survival was 14.7 months.

Combinations with Ofatumumab

Ofatumumab has been combined with fludarabine and cyclophosphamide (O-FC) for previously untreated CLL patients and has comparable activity to FCR.[554]

Combinations with anti-CD52 Antibody

Alemtuzumab may reverse drug resistance, as 1 CR and 4 PR were obtained in 6 fludarabine- and alemtuzumab-resistant CLL patients treated with a combination of FA.[555] Sayala et al.[556] administered alemtuzumab 30 mg sc 3 times a week with oral fludarabine 40 mg/m^2 for 3 consecutive days every 4 weeks to 17 fludarabine-resistant CLL patients who were not responding (NR) or had only a PR to alemtuzumab alone. Three patients responded

(2 NR to a PR and 1 PR to a CR). Elter et al.[557] administered FluCam (fludarabine 30 mg/m^2 IV with alemtuzumab 30 mg IV for 3 consecutive days every 4 weeks for 6 cycles) to 36 heavily pretreated patients. The CR and PR rates were 30% and 53% with the median time to progression being 13 months with an OS of 36 months. Of 9 fludarabine-refractory patients, 6 responded to FluCam. This combination was well tolerated and there were few infections. A subsequent study in previously treated patients who were sensitive to fludarabine or alemtuzumab (response to either agent had lasted >12 months) demonstrated improved survival when patients were treated with FluCam as compared to fludarabine.[558] The CR and PR rates were 13% and 69% for FluCam and 4% and 71% for fludarabine, respectively. The PFS was significantly longer for FluCam (23.7 months vs. 16.5 months, P = 0.0003) and although the median OS was not reached for FluCam it was 52.9 months for fludarabine (P = 0.021). However, it is unclear how many of these patients had been treated with rituximab-containing regimens, and so the clinical applicability of the study is unclear. A small study using FluCam in elderly patients (median age 66 years) with deletions of 17p13 or p53 mutations showed that 6 of 7 patients achieved a CR and one a PR, with excellent tolerability.[559] The likelihood of response diminished and the incidence of complications increased when previously treated patients received FluCam.

A clinical trial with alemtuzumab in combination with fludarabine and cyclophosphamide (FCCam) for relapsed or refractory CLL was discontinued because of myelotoxicity, infections, and a treatment-related mortality (TRM) of 9%.[560] The response rate also did not appear to be as high as FluCam or FCR.[560] In addition, a prospective phase III trial comparing FCR with FCCam in previously untreated patients showed that FCCam produced a lower response rate and was more toxic than FCR.[561]

The MD Anderson has combined FCR with alemtuzumab (CFAR) both in previously untreated and treated patients.[562,563] In untreated patients <70 years and with a β2-microglobulin ≥4 mg/dl, the CR, nPR, and PR rates were 70%, 3%, and 18%, respectively, with a median PFS of 38 months.[562] These results did not appear to be significantly better than expected with FCR. For heavily pretreated patients, the CR, nPR, and PR rates were 29%, 4%, and 33%, respectively, but the estimated PFS of 10.6 months and OS of 16.7 months was similar to that observed with FCR.[563] Moreover, the infection rate was higher with CFAR. Thus, the addition of alemtuzumab to FCR appears to increase toxicity without significant benefit.

New Agents

A number of new agents are under development but only those agents already available for clinical use or hold promise are discussed (Fig. 90.12).[564]

CDK Inhibitors

Flavopiridol is one of a number of CDK inhibitors and is active in CLL, producing responses in 50% of resistant patients, including those with loss of TP53 function.[565] Indeed, the drug is so effective that the major side effect is tumor lysis. The mechanism of action of flavopiridol, and probably other CDK inhibitors, is likely through the inhibition of CDKs, the inhibition of transcription with a reduction in mcl-1 and XIAP, and the induction of endoplasmic reticulum stress.[566]

Inhibition of BCL2

A number of drugs have been developed to inhibit BCL2, which is increased in CLL. ABT-263 (Navitoclax) is a potent inhibitor of BCL2, BCL$_X$L, and BCLW and potently induces cell death in CLL cells in vitro. In initial studies in heavily pretreated patients, one third of patients achieved a PR.[564]

Immune Modulation

Lenalidomide has multiple mechanisms of action in CLL affecting angiogenesis, cytokine levels, and the microenvironment. In refractory CLL, lenalidomide can produce responses in up to one third of patients with major toxicities including marrow suppression and tumor flare, which can be controlled with prednisone.[567] Because of the risk of tumor lysis syndrome, it has been suggested to start lenalidomide using 2.5 mg/day with monthly escalations up to 20 mg/day.[568,569] The median dose achieved varies between 5 and 15 mg/day, depending on the extent of prior treatment and patient age.[567–569,570] The dose-limiting toxicity is marrow suppression although most patients have side effects with higher drug doses, including fatigue, bowel disturbance, and skin rash.[567–569,570] In previously untreated patients, approximately two-thirds of patients respond with up to 15% CRs.[569,570] In a study on patients >65 years, response depended on the drug dose with the median achieved being 5 mg/day.[570] A total of 10% achieved a CR, 5% CR with residual cytopenias, 7% nodular PR, and 43% PR. Interestingly, serum Ig increased with lenalidomide and there was a fall in CCL3 and CCL4. However, the drug needs to be given continuously and patients with deletion 17p13 respond less well than other patients.[570]

Effectors of the Microenvironment

With the understanding of the importance of the BCR pathway for cell survival and proliferation in CLL, a number of drugs have been developed to inhibit different stages in the pathway and have recently been reviewed.[110,111] These include a SYK kinase inhibitor (fostamatinib); a Lyn/BTK inhibitor (dasatinib); and perhaps the two most exciting drugs, the PI3-kinase delta inhibitor, GS-1101 (formerly CAL-101) and the BTK inhibitor ibrutinib (PCI-32765).[571,572] In early studies these agents have demonstrated remarkable activity with little toxicity and there are a large number of ongoing studies evaluating these novel agents, either alone or in combination with standard therapies.

Treatment of Resistant Disease

The majority of CLL patients will initially respond to therapy resistance, however, they will eventually develop resistance, and these patients become progressively more difficult to treat.[564,573] The definition of drug resistance is a lack of response to treatment or relapse within 6 months and is based on the original definition by Keating et al.[407] where the median survival of patients who were fludarabine-resistant was 10 months. However, nowadays, most patients will be treated initially with chemoimmunotherapy and may relapse 2 to 3 years later with refractory disease, where the time of relapse has just been postponed because of the more effective initial treatment. Thus, as opposed to "fludarabine-refractory" CLL, it is preferable to describe resistance as "refractory" CLL.[573] As discussed in the section, "Molecular Genetics," approximately 45% of patients who are fludarabine-resistant have either deletions of 17p13 or p53 mutations, with the site of mutation influencing drug resistance.[392,393,394,395] Of the remaining 55% of cases approximately 20% will have a deletion of 11q22-23. Mutations of *NOTCH1*, *SF3B1*, and *BIRC3* have also been associated with refractory disease.[226,227,228,229,230,231,233,392]

Thus, it has been suggested that CLL patients can be divided into three groups: (a) "highest-risk" where patients are unlikely to respond to chemotherapy, and these patients include those with a *TP53* mutation/17p13 deletion, are resistant to fludarabine, or relapse within 2 years of FCR (approximately 20% (b)); (b) "high-risk" where patients are likely to relapse early after chemotherapy, and these include patients with a high β2-microglobulin, deletion of 11q22-23 or unmutated IgV_H; and (c) "low-risk" where patients are untreated and have no *TP53* mutations/deletions, no deletions

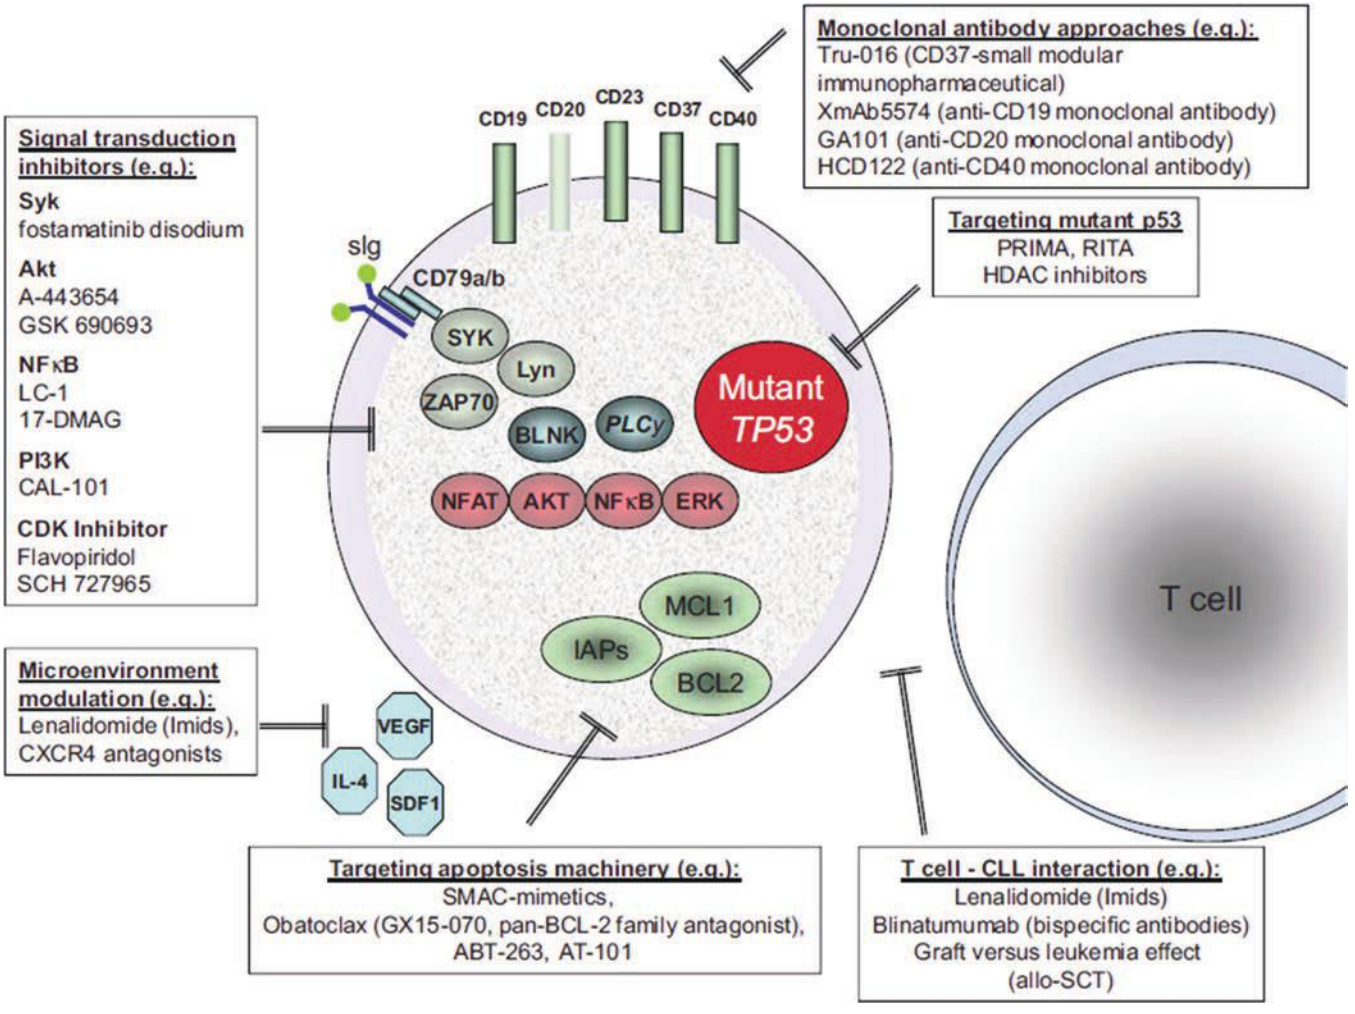

FIGURE 90.12. Selection of targets and novel agents in early clinical trials of CLL. There are multiple "biologic" therapeutic approaches in current clinical development in CLL. Signal transduction inhibition will often target the B-cell receptor cascade, which has been shown to be critical to CLL cell survival. A number of surface molecules of CLL cells can be targeted by antibodies. Different members of the apoptosis machinery are targets currently explored in clinical trials. Microenvironmental stimulation and T-cell interaction are of critical importance for CLL cell survival, and are being increasingly utilized for treatment strategies. There is ongoing interest in using mutant p53 as a "druggable" target, and a number of agents have been identified that may preferentially target mutant p53.34. Improving efficacy in CLL with p53 pathway defects is likely to offer the greatest overall benefit. From Stilgenbauer S, and Zenz T. Understanding and managing ultra high-risk chronic lymphocytic leukemia. Hematology (Am Soc Hematol Educ Program) 2010;2010:481–488, with permission.

of 11q22-23, mutated IgV_H, and low β2-microglobulin.[573] Patients in the highest-risk group should be considered for investigational agents, alemtuzumab, and allogeneic HCT. Patients in the high-risk group should receive FCR and an investigational agent to try to maintain the remission. Low-risk patients should be treated with FCR or an alternative regimen.[573,574]

Hematopoietic Stem Cell Transplantation

Because CLL is not curable with standard therapy, HCT is worthy of consideration, particularly in younger patients who are more able to withstand this potentially arduous therapy. In addition, recent advances in the identification of clinical or biologic risk factors indicative of aggressive disease (i.e., fludarabine resistance, or deletions of 17p13) have permitted the recognition of patients who have a very poor prognosis with standard therapy and may benefit from HCT. As genomic abnormalities are known to develop over time in CLL, it is reasonable to consider early transplantation in these patients, before the development of drug resistance and even more aggressive disease. Detailed reviews have recently been published on the subject.[575,576,577]

Autologous Transplantation and Cellular Therapy

The dose intensity of the preparative regimen is of critical importance for autologous HCT (autoHCT), as the intent of such myeloablative chemotherapy and/or radiotherapy is to eradicate residual CLL. This is followed by the reinfusion of autologous hematopoietic progenitor cells that are hopefully free of residual CLL cells. Until recently, autoHCT had been an attractive option in CLL, as the TRM of this procedure is relatively low and durable remissions were achievable.[578,579] However, subsequent randomized controlled trials demonstrated that autoHCT, when used as consolidation after first-line therapy, offers no survival advantage over observation[580] or standard dose chemotherapy.[581] In addition, the German CLL study group compared the results of their single arm trial of autoHCT as first-line therapy for CLL to the outcomes in a similar cohort of CLL patients who received first-line FCR. Survival was no better in the autoHCT cohort.[582] An additional concern with autoHCT is that of treatment-related myelodysplasia/acute myeloid leukemia (MDS/AML). The incidence of AML/MDS for CLL patients 5 years post-autoHCT is as high as 12.4%.[583] Taken together, before autoHCT can be revisited as a therapeutic tool in CLL, new approaches are needed to

improve methods of in vivo or ex vivo purging of CLL cells in the harvested autologous cells, the choice of conditioning regimens, post-autoHCT maintenance therapy, or the induction of an autologous graft-versus-CLL effect.

Chimeric Antigen Receptor Modified T-cells

The induction of autologous T-cells that are reactive against CLL cells represents a highly promising form of cellular therapy. This concept has led to early-phase clinical trials using chimeric antigen receptor modified T-cells (CARTs). Autologous T-cells are genetically modified to express chimeric antigen receptors, with T-cell specificity against the CD19 bearing B-cells found in CLL and other lymphoid malignancies.[584,585] These CLL-specific T-cells are then re-infused into recipients. Preliminary clinical results suggest that such therapy has the ability to achieve rapid and profound responses in heavily treated, chemorefractory CLL patients. However, despite their exciting potential, further data will be required before such strategies can be adopted into widespread clinical practice.

Allogeneic Transplantation

Whereas autoHCT primarily depends on dose intensity to eradicate CLL, allogeneic HCT (alloHCT) offers the added advantage of adoptive cellular immunotherapy. This probably explains the higher efficacy of this treatment, albeit at the cost of increased therapy-related toxicity. The difference in response between autoHCT and alloHCT is most likely due to the graft-versus-leukemia (GVL) effect. Specifically, CLL cells disappear with the onset of graft-versus-host disease, relapse risk increases with the use of T-cell–depleted grafts, and there are reports of favorable responses to donor lymphocyte infusions.[586–588,589]

In myeloablative alloHCT, the proposed benefit in preventing CLL relapse has been offset by relatively high treatment-related toxicities, with cumulative nonrelapse mortality approaching 50%.[590,591] However, the GVL effect associated with alloHCT has raised considerable interest in nonmyeloablative (NMA) or reduced-intensity conditioning (RIC) alloHCT. The principle of this approach is that the nonhematopoietic toxicity, profound pancytopenia, and opportunistic infections associated with intense myeloablative preparative regimens are avoided, and the beneficial GVL effect is retained. A pivotal European registry-based study demonstrated that in 73 heavily pretreated patients receiving NMA alloHCT, the cumulative TRM was relatively low at 19%. With a median follow-up of 22 months, the cumulative event-free and OS was 58% and 70%, respectively. In this study, only 1 patient relapsed after the 2-year post-transplant mark,[575,591] A retrospective comparison of these 73 NMA cases with 82 matched myeloablative HCT patients from the EBMT registry showed a significant reduction in TRM but an increased relapse incidence in the NMA population.[591] There was no significant difference between the 2 alloHCT modalities in terms of event-free and overall survival. Although NMA/RIC and conventional myeloablative alloHCT approaches have yet to be prospectively compared, the NMA/RIC strategy is probably at least as effective as the latter, and, in addition, allows the expansion of transplant eligibility criteria to older or more medically fragile or complex recipients. Current internationally accepted guidelines recommend NMA/RIC regimens for all CLL allograft recipients.[575] A summary of recently updated studies in NMA/RIC alloHCT for CLL is provided in Table 90.14.

The best preparative regimen for use in NMA/RIC alloHCT is unknown. Several regimens have gained popularity, almost all of which include fludarabine in combination with alkylating agents (such as cyclophosphamide, melphalan, or busulphan), with or without anti-T–cell antibody therapy to augment recipient immune suppression. In the absence of controlled studies, preparative regimen choice should be individualized depending on patient (e.g., age, extent of CLL control pre-transplant, comorbidities) and donor variables (e.g., degree of HLA match), as well as familiarity of the transplant team with a specific regimen. The use of a partially matched donor generally requires the use of a regimen with heightened immune suppression, such as the addition of antithymocyte globulin.[592,593] The inclusion of alemtuzumab in the preparative regimen is more contentious, as its administration is thought to be associated with higher rates of post-transplant CLL relapse and poorer survival.[592,594] The reason for this is possibly related to the potent ability of alemtuzumab to reduce graft-versus-host disease, with a corresponding reduction in the graft-versus-tumor effect. The dose of alemtuzumab may be important in this regard, as lower doses may provide sufficient GVHD prophylaxis without excess risks of relapse or infection.[595]

Traditionally, related donors have been the preferred source of donor cells for alloHCT. However, one concern in CLL is the high incidence of familial CLL.[335] In addition, MBL is prevalent not only in relatives of CLL patients, but at substantial levels in the healthy adult population; estimates of MBL range from 0.14% to >20%, depending on the population studied.[596] It is presently unknown what proportion of these patients will develop clinically relevant CLL. However, MBL is transferrable from donors to allogeneic transplant recipients.[597] Consequently, it has been proposed that related donors be routinely screened for MBL and excluded from donation if found to have this syndrome.[598] In the current era of high-resolution typing of unrelated donors, the prospect of more widespread use of unrelated donors is feasible, especially if histocompatible-related donors are unavailable or medically ineligible. The use of well-matched (at least 7/8 HLA allele compatibility) unrelated donor results in outcomes at least as favorable as those of related donor transplants[593,599] To date, no published randomized studies have compared alloHCT to nontransplant-based therapy for CLL. However, there are data to suggest that alloHCT may overcome the poor prognostic impact of fludarabine-refractory CLL.[592] In addition, alloHCT may result in durable disease control and quite possibly cure in CLL patients with adverse cytogenetic markers (including 17p13 mutations).[594] A case control study that compared RIC/NMA allografting with nontransplant controls that were matched for age and disease stage suggested that allografting may be superior to a nontransplant approach.[600] Moreover, a decision analysis using a Markov model concluded that alloHCT remains the preferred approach for patients with relapsed or refractory CLL, even when accounting for the significant upfront costs and toxicity of the HCT.[601]

Although there is increasing confidence in alloHCT for high-risk or relapsed CLL, controlled trials are required to address issues such as optimal patient selection, preparative and GVHD regimens, and, most important, whether this procedure is truly superior to modern nontransplant approaches. We recommend that CLL patients who are candidates for HCT be managed within the context of a clinical trial.

Radiotherapy

Radiation is rarely used for CLL nowadays, but for many decades irradiation of the spleen was the primary treatment for this disease;[602–608] irradiation of the mediastinum,[609,610] extracorporeal irradiation of the blood,[611,612] TBI,[613–617] and hemibody irradiation[618] may also reduce the peripheral blood lymphocyte counts and the size of lymph nodes, spleen, and liver.

Splenic irradiation has produced survival rates comparable to those achieved with chlorambucil or COP in Rai stage III and IV patients.[615] However, in general, splenic irradiation is reserved to treat patients with large painful spleens or those with cytopenias related to splenomegaly who are not medically fit for splenectomy. Although almost all patients experience a reduction in spleen size and relief from pain with irradiation, the effects on hemoglobin and platelets are more variable.[604,606] It is likely that differences in therapeutic effect are related to the extent of prior treatments, as untreated patients respond much better to irradiation than those who have previously undergone therapy.[602] High doses of splenic irradiation may cause neutropenia and thrombocytopenia, and it is thus recommended to initially use small fraction sizes (e.g., 0.25 to 0.50 Gy on alternate days, or 3 times per week).[602,603] The dose of irradiation is gradually increased according to response and toxicity, and the usual maximum cumulative dose is 5 to 10 Gy.

TBI has been given alone[613–615] or in combination with chemotherapy.[616,617] Patients treated with TBI plus cyclophosphamide and prednisone had higher response rates than those treated with TBI alone.[616] Intermittent low doses of irradiation may also be effective.[612,614,615] In one study, 48 patients with progressive disease received 5 to 10 rad TBI 3 to 5 times per week for a total of 100 to 400 rad.[614] A total of 88% of the patients responded, with one third achieving a CR, although mild anemia and thrombocytopenia persisted in some individuals. The regimen was generally well tolerated, although significant myelosuppression occurred, and rest periods of weeks to months were intermittently required to allow marrow recovery. The Ig levels returned to normal in most of the patients who achieved a CR.

Splenic irradiation can produce systemic effects with a decrease in lymphadenopathy and a reduction in lymphocyte count and can induce CRs.[602,608] The mechanism(s) underlying these phenomena is unclear, and many factors may be involved.[602] CLL cells are highly sensitive to ionizing radiation in vitro, and a correlation has been observed between the radiosensitivity of CLL cells in vitro and the patients' clinical response to radiation therapy.[619] However, irradiation may also produce its effects through the inhibition of CD8+ T-cells and the induction of cytokine release from CLL cells.[602,620] Finally, radiation of the spleen can produce a "radiotherapeutic splenectomy," thus decreasing "pooling" and improving normal blood counts.

Splenectomy

Splenectomy is primarily carried out in CLL for the treatment of AIHA or ITP but may also be useful for patients with massive painful splenomegaly or in whom the leukemia is predominantly confined to the spleen.[621–625] In addition, splenectomy may be considered when cytopenias are believed to be due to hypersplenism and have not responded to chemotherapy.[621–624] Neal et al.[624] noted an improvement in the hemoglobin and platelet counts in two-thirds of patients with advanced-stage CLL who underwent splenectomy, and the improvement was maintained during the 1-year follow-up. In this study, neither the spleen size nor the degree of marrow involvement was predictive of response, although others have observed a correlation between spleen size and the improvement in blood counts after splenectomy.[621] Approximately 50% of patients have post-operative infections, and half of these require antibiotics.[621] Moreover, the perioperative mortality from sepsis is 5% to 10%, but this is primarily in patients with advanced disease and poor performance status.[621] Thus, in selected patients with good performance status, splenectomy may increase the blood counts sufficiently to permit aggressive chemotherapy. In addition, more individuals may now be candidates for this procedure as laparoscopic splenectomies become routine.[625] Patients should be immunized with pneumococcal, meningococcal, and hemophilus influenza vaccines about a month before splenectomy, although there will be variability among patients as to how well they can produce an antibody response.[288]

SYSTEMIC COMPLICATIONS REQUIRING THERAPY

Infection

Patients with CLL have an increased risk of infection, which is partly related to the effects of the disease and partly to the effects of chemotherapy. Although a number of immune abnormalities occur in CLL, the incidence of infection is most closely related to hypogammaglobulinemia which increases with disease stage and duration.[288,289,626,627] The risk of infections, particularly opportunistic ones, is increased by steroids, nucleoside analogues, and monoclonal antibodies. Patients treated with alkylating agents are primarily affected by bacterial infections, whereas those on fludarabine-based treatments can get other opportunistic infections, such as *Pneumocystis jirovecii*, CMV, herpes simplex, and varicella zoster. The addition of steroids markedly increases the risk of infections with fludarabine and should be avoided.

Patients with hypogammaglobulinemia and recurrent bacterial infections may be treated with intravenous Ig. High-dose Ig, 400 mg/kg IV every 3 weeks, reduces the incidence of bacterial infections by 50%, particularly those caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*, but the total number of severe bacterial infections and nonbacterial infections is not reduced, and this treatment does not prolong survival.[628] A subsequent study using this regimen showed that the reduction in infections did not improve the patients' quality of life or survival and that the treatment was not cost effective, because of the high doses of Ig infused.[629] Lower doses of gammaglobulin may be as effective, for example, 250 mg/kg every 4 weeks or 10 g every 3 weeks.[630,631] Molica et al.[632] randomized CLL patients with an IgG of less than 6 g/L and a serious infection in the previous 6 months to 300 mg/kg gammaglobulin every 4 weeks or to observation. Patients receiving gammaglobulin had a reduced number of infections, but the effectiveness did not correlate with restoration of the IgG levels. Thus, it is recommended that selected patients with hypogammaglobulinemia and frequent bacterial infections may receive prophylactic Ig.[289,633]

Granulocyte-macrophage colony-stimulating factor can increase the neutrophil count and function in CLL, although whether this reduces the incidence of infections remains unclear.[634,635] However, the use of granulocyte colony-stimulating factor after fludarabine has been shown to reduce the risk of neutropenia and the incidence of pneumonia.[636] In general, older patients with more advanced disease have greater risk of infection than younger patients, particularly if they have had prior therapy. Prophylactic antibiotics may be of benefit, particularly when patients are receiving nucleoside analogues, monoclonal antibodies, and steroids, and frequently, antibiotics are incorporated into the newer and more immunosuppressive regimens. Thus, patients may be maintained on trimethoprim-sulfamethoxazole (cotrimoxazole) to prevent *Pneumocystis jirovecii* pneumonia, acyclovir to prevent herpes viruses, valganciclovir to prevent both CMV, and fluconazole to prevent fungal infections. However, the use of these antibiotics varies widely and whether all patients should receive prophylactic antibiotics or only older patients or those with a history of shingles is still unclear.[289,633]

In general, vaccines are less effective in CLL because of impairment in the immune system.[288,633] However, it is still recommended to immunize these patients for pneumococcus and influenza, the latter annually. These patients should not receive live vaccines, and these include, typhoid, yellow fever, measles, mumps, rubella, BCG, and herpes zoster.[288,633]

Autoimmune Complications

As discussed previously, immune cytopenias are the commonest autoimmune complications occurring in 4.3% to 9.7% of patients with AIHA in about 7% of patients and <1% to 2% having ITP, red cell aplasia, or immune neutropenia.[312,313,314,633] The disorders are caused by the immune dysregulation in CLL, may be triggered by chemotherapy, and are treated with immunosuppressives. In contrast, other autoimmune disorders in CLL are caused by antibodies produced by the CLL cells, for example, cold agglutinin disease, and these will respond to treatment of the CLL. It is thus important to be constantly aware of the potential development of these disorders and to treat them appropriately.

The immune cytopenias are treated initially with steroids, using prednisone 1 mg/kg/day, and 75% of patients respond to this therapy.[312,633] A response may be seen within days, although it may take several weeks in some patients. Patients with AIHA should also be maintained on folic acid, 5 mg/day, and after the hemoglobin and reticulocyte counts have normalized (usually in 1 to 2 weeks), the prednisone can be tapered slowly over a period of 2 to 3 months. These patients should be watched for all the usual complications of prednisone, such as gastric irritation, diabetes mellitus, an increased risk of opportunistic infections, and osteoporosis. Thus, these patients may need to be maintained on an H_2-blocker or proton pump inhibitor, may require oral hypoglycemics/insulin, and should be maintained on prophylaxis against *Pneumocystis jirovecii* [e.g., trimethoprim-sulfamethoxazole (one double-strength tablet orally twice a day on Saturdays and Sundays, or one double-strength tablet 3 times a week)] if they are on steroids for longer than a few weeks.[637] They are also at risk of other infections, such as oral candidiasis or herpetic infections and may require therapy or prophylactic antibiotics such as valacyclovir. Many of these patients are elderly, and the prolonged course of prednisone increases the risk of osteoporosis and vertebral collapse. Thus, patients should be maintained on bisphosphonates. The authors prefer an intravenous formulation to reduce the risk of the gastric irritation that may result from corticosteroids (e.g., pamidronate 30 mg IV every 3 months).[638] It is important that patients with AIHA and dangerously low hemoglobins are transfused, because, despite theoretical concerns, these patients rarely have severe transfusion reactions.[639] In addition, any infection should be treated promptly, as sepsis can inhibit the compensatory reticulocytosis and worsen the anemia.

If a more rapid response if required, or if the patient does not respond to prednisone within 7 to 10 days, 1 gram of methylprednisolone IV or intravenous Ig (0.4 g/kg/day × 5 days or 1 g/kg/day × 2 days) should be added.[314] This can produce a rapid response, but the response is transient, and re-treatments are generally required every 3 to 4 weeks.[314,640] There is no standard therapy for patients who do not respond to this therapy or who cannot be weaned off prednisone without a relapse. Cyclosporin is a reasonable option and produces a major response in two-thirds of CLL patients with ITP or anemia and is highly effective in red cell aplasia.[314,641,642,643] In one study using cyclosporin 300 mg/day, the median time to initial response was 3 weeks (range, 1 to 13 weeks), and the median time to best response was 10.5 weeks (range, 1 to 48 weeks).[643] The median duration of response was 10 months (1+ to 39+ months), and some patients who had fludarabine-associated cytopenias were re-treated effectively with fludarabine. Immune cytopenias also may be treated with other immunosuppressive drugs, such as 6-mercaptopurine or cyclophosphamide, although no controlled trials related to their use have been published.[314] Rituximab is also useful for the immune cytopenias, either alone[644–647] or in combination with a cyclophosphamide-containing regimen when treatment of the underlying leukemia is also required.[648,649,650] The response rate of 48 steroid-resistant CLL patients with immune cytopenias (AIHA 26, ITP 9, Evan syndrome 8, and red cell aplasia 5) receiving RCD (rituximab, cyclophosphamide, and dexamethasone) was 90% with the median duration of response being 24 months.[649] There were 40% of these patients who had progressive disease at the time of treatment and all patients who relapsed with immune cytopenias had progression of their CLL. Further studies to prolong the duration of remission of the immune cytopenias will require better control of the underlying CLL. Good responses in small numbers of patients with CLL and AIHA have also been reported with alemtuzumab.[651]

Splenectomy may also be a useful treatment for patients with AIHA, and the number of patients eligible for this procedure is increasing with the use of laparoscopic splenectomy.[625] Splenic irradiation may be carried out in those who are not surgical candidates, but it may take up to 2 months to see a response; the responses last for approximately 1 year.[312,604]

The thrombopoietin analogues, rombiplastin, and eltrombopag, have also been shown to be effective in small numbers of CLL patients with refractory thrombocytopenia, although the drugs need to be given indefinitely.[314,652]

TRANSFORMATION OF CHRONIC LYMPHOCYTIC LEUKEMIA

Based on cytogenetic and molecular studies, it has been demonstrated that multiple clones may occur in CLL and that clonal evolution is a frequent occurrence.[208,217–219] The transformation of CLL to a high-grade non-Hodgkin lymphoma was originally described by Maurice Richter in 1928 (RS) and over time a Richter's transformation became synonymous with the development of diffuse large B-cell lymphoma, Hodgkin lymphoma, PLL, or acute leukemia in CLL.[653] However, nowadays, RS or Richter's transformation is taken to reflect the development of diffuse large B-cell lymphoma in a patient with CLL or SLL.[3,654,655] The likelihood of a second lymphoid malignancy is three- to fivefold higher in CLL than in the general population, is significantly increased by prior treatment with a purine nucleoside analogue, and almost half of these second malignancies are RS.[656]

In 75% of cases of RS the transformation is clonally related to the CLL and in 25% of cases is unrelated.[234] By multivariate analysis the 4 most important factors predictive for a transformation are mutated *NOTCH1*, IgV_{H4-39} usage, trisomy 12/deletion 11q22-23/*TP53* disruption, and CD38 positivity (≥30%).[234] The risk of developing a clonally related RS is markedly increased if the patient has IgV_{H4-39} in addition to a *NOTCH1* mutation (75% risk at 5 years) and least if the patient has neither (0% at 5 years).[234] Of these lymphomas, 40% have a *NOTCH1* mutation suggesting enrichment of CLL cells harboring the mutation over time.[227] In contrast, patients who develop a clonally unrelated transformation generally have IgV_H mutated CLL.[656]

In contrast, *NOTCH1* mutations are not involved in clonally unrelated RS.[234] As discussed later, the clonally unrelated cases of RS in CLL behave as does de novo diffuse large B-cell lymphoma and may occur as a result of immunodeficiency or to an inherent predisposition to these malignancies.[657] Finally, Epstein–Barr associated diffuse large B-cell lymphoma may develop in CLL following therapy with FA, and these tumors may resolve spontaneously.[532] Whether they are clonally related to the underlying CLL is not known.

RS occurs in 5% of patients with the median time to onset being 4 years, although patients can present with concomitant CLL and RS.[654,655,658,659] The incidence of RS may actually be as high as 16.2% at 10 years, as many cases are probably misdiagnosed as having CLL progression.[660] Patients with clonally related RS have a very poor prognosis and typically present with rapidly increasing lymphadenopathy or splenomegaly, fever, or weight loss, high LDH, and frequent extranodal involvement of kidneys, lungs, and the gastrointestinal tract. Preferably, the diagnosis should be made on a lymph node biopsy but in sick patients a needle aspirate of a node with cytology demonstrating large cells is sufficient.[655] PET/CT scanning with ^{18}F-FDG is a highly sensitive technique to detect a Richter's transformation and is useful in helping to decide which node to biopsy.[661] However, hypermetabolism may also be seen with other transformations, with a coexisting solid tumor or infection, or with accelerated-phase CLL. The lymph node with accelerated-phase CLL shows increased numbers of proliferation centers, increased Ki67-positive CLL cells or PL, and no evidence of large-cell transformation.

Of 148 patients with RS at the MD Anderson, 135 received therapy using a variety of treatment regimens including R-CHOP (rituximab-cyclophosphamide, doxorubicin, vincristine, and prednisone).[658] The addition of rituximab appeared to increase the response rate and for all patients the OR was 39% with 12% CR. For 7 patients in remission who underwent an allogeneic SCT the 3-year survival was 75%. Thus, although the OS was poor some patients did well and a RS prognostic score was thus developed based on performance status, LDH, platelet count, tumor size, and the number of prior treatments.[658] However, the varying prognosis with RS likely depends on whether the tumors are clonally related or unrelated to the underlying CLL.[659] Where the RS was clonally unrelated, the median survival was 62.5 months, no different from de novo diffuse large B-cell lymphoma, versus 14.2 months for clonally related RS. Patients with disruption of *TP53*, either through deletion or mutation, had a median survival of 9.4 months versus 47.1 months for patients with no disruption.

Occasionally, Hodgkin lymphoma develops in CLL, and is about 10% as common as RS.[662] As in RS, the Hodgkin's transformation occurs about 4 years after CLL is diagnosed with the mean age at diagnosis being 65.7 years versus a median age of 61 years for RS.[662] Histologically, there are 2 types of transformation. The type 1 transformation is characterized by scattered Reed–Sternberg cells in a field of typical CLL cells and the type 2 transformation shows Reed–Sternberg cells in a field of inflammatory cells, separate from the CLL cells.[663] Most patients have advanced Rai stage disease at transformation and 70% of cases are mixed cellular or nodular sclerosing Hodgkin lymphoma.[662] As with RS, patients present with fever, lymphadenopathy, and weight loss.[662] One-quarter of patients achieve a CR with chemotherapy and one-quarter a PR, with a mean survival of 1.7 years (range, 0 to 14 years).[662] Patients who had previously received fludarabine for their CLL had a much poorer survival than patients who had not required treatment of their CLL. The cell of origin for the Reed–Sternberg cell in these patients has been debated, with some studies showing a clonal relationship to the underlying CLL cell, whereas others do not. However, whether the variation in response of these patients to chemotherapy is related to their clonal relationship to the underlying CLL is not yet known. In contrast to RS, Epstein–Barr viral infection is frequently seen in this transformation, but the exact role of the infection in this transformation is not yet known.

Prolymphocytic transformation of CLL occurs slowly over several years with the gradual accumulation of increasing numbers of prolymphocytes [PLL/CLL] until there are ≥55% prolymphocytes (PL).[254] In general, this type of transformation occurs more frequently in patients with unmutated IgV_H and trisomy 12.[254] The underlying genetic cause for the transformation is presently unknown, but *MYC* rearrangements have been described.[664] Although most cases of PL in CLL represent a transformation of the CLL clone, cases of separate CLL and PL clones in the same patient have been described.[665]

Multiple myeloma may also develop in patients with CLL.[666,667] Some studies have suggested that the two diseases develop separately, whereas in others, multiple myeloma develops from the CLL clone. Acute leukemia occurs in less than 1% of CLL patients, and this contrasts with the almost invariable progression of patients with chronic myeloid leukemia to acute leukemia.[668] Hairy cell leukemia is also more common in CLL.[657] Of 31 cases of acute leukemia developing in patients with pre-existing CLL, 10 were lymphoblastic, 7 myeloblastic, and 1 plasmacytic; in 13 cases, the cell type was not identified.[668] Both acute B- and T-cell lymphoblastic leukemias have been described in CLL,[669–672] and although this usually occurs after many years, the concomitant presentation of CLL and acute lymphoblastic leukemia also has been reported.[669] In B-ALL, evidence of clonal evolution has been documented in some cases, whereas in T-cell cases, a common lymphoid progenitor precursor has been postulated as the source of both malignancies.[669–672]

SECOND MALIGNANCIES

Second malignancies are commonly found in the lymphoid malignancies, but are particularly common in CLL because of the significant immunosuppression seen in this disease.[673,674] Compared to the general population and patients with follicular lymphoma, the incidence of second malignancies is increased twofold, with

the most common malignancies being squamus and basal cell carcinomas of the skin.[674,675,676,677,678] Melanomas are also common, followed by cancers of the gastrointestinal tract, lung, breast, and prostate.[674,675,676,677,678] Clinical features associated with an increased incidence of second malignancies include older age, male sex, a β2-microglobulin >3 mg/dl, an increased LDH, and an elevated creatinine.[675] In addition, these malignancies can be more aggressive than in patients without CLL, and an increased mortality is observed with skin cancers, melanomas, Merkel cell tumors, and lung cancer.[674,678,679–681] The risk of developing AML or myelodysplasia with alkylating agents or nucleosides alone appears to be low, although the risk may increase if both are given together and the risk of developing AML/myelodysplasia with front-line FCR chemotherapy is 4.5% which occurs approximately 3 years following initiation of therapy.[484,547] This appears directly related to the potent myelosuppression seen with this regimen. Finally, patients with CLL may develop myeloproliferative disorders.[682]

Chronic myeloid leukemia, myelofibrosis, and essential thrombocythemia may also rarely occur in CLL. As second malignancies are a common cause of death in CLL, patients should be monitored for the development of new malignancies which should be promptly treated when identified.

SUMMARY OF THERAPY

The indications for treatment and the type of treatment will vary according to the patient's age and condition. If the patient is not participating in a clinical trial, the following are general guidelines.[1]

1. Patients with Rai stages 0–II usually do not require therapy unless there is evidence of significant disease progression or symptoms, for example, weight loss, night sweats, or fatigue.
2. Patients with Rai stages III/IV disease frequently require treatment but this may be deferred until the patient is symptomatic or if there is disease progression.
3. Other indications for treatment include AIHA/ ITP and massive uncomfortable lymphadenopathy or splenomegaly.
4. Patients with Rai stage III or IV disease may require a bone marrow aspirate and biopsy prior to chemotherapy to ensure that the anemia and/or thrombocytopenia are related to marrow infiltration.
5. Prior to therapy, patients should have FISH analysis, a Coomb's test, and be screened for common viral pathogens, including hepatitis B and C, and CMV.
6. Most treatment regimens include rituximab, and the standard initial therapy for patients with adequate performance status, comorbidity score, and renal status is FCR, particularly if the patient has a deletion 11q22-23. Other common regimens include FR and PCR, or chlorambucil with or without rituximab for the elderly and frail. Bendamustine with or without rituximab is also highly effective and is presently being compared with FCR in the German CLL10 study.
7. Approximately half the patients who become refractory to the above regimens have a deletion 17p13 and treatment options for resistant patients include alemtuzumab alone, or high-dose steroids in combination with rituximab or alemtuzumab. Ofatumumab is used for patients who are refractory to alemtuzumab or with lymph nodes >5 cm, but is not very effective for patients with loss of p53 function.
8. Prophylaxis against *Pneumocystic jirovecii* and herpes infections should be given to patients receiving nucleoside analogues, steroids, or alemtuzumab and continued for 6 months following therapy. The authors use trimethoprim-sulfamethoxazole (co-trimoxazole) 1 double strength twice a day on Saturdays and Sundays with valacyclovir 500 mg/day (or an equivalent). For patients allergic to trimethoprim-sulfamethoxazole, dapsone 100 mg 3 times a week or pentamidine by aerosol once a month may be used.
9. Steroids should primarily be reserved to treat immune cytopenias and should be avoided, if possible, when patients are receiving chemotherapy. There is no evidence that steroids increase the response rate obtained with alkylating agents or nucleoside analogues alone, and they increase the risk of infection. However, if used judiciously, prednisone may be combined with chlorambucil to enhance marrow clearing of tumor and to reduce organomegaly.
10. Patients with immune cytopenias or red cell aplasia should initially be treated with prednisone 1 mg/kg/day orally, but may also benefit from gammaglobulin, cyclosporine, cyclophosphamide, or rituximab. Patients who are going to receive a prolonged course of prednisone should be maintained on pamidronate 30 mg IV every 3 months, or an equivalent, to prevent osteoporosis and prophylactic antibiotics for *Pneumocystic jirovecii* and herpes infections.
11. Radiotherapy is reserved for local lesions that are particularly bulky and troublesome and is used only when chemotherapy is not required for control of more disseminated disease. The lowest dose of radiotherapy capable of shrinking the tumor mass should be used. Splenic irradiation may be helpful in patients who require a splenectomy but who are not surgical candidates. Radiotherapy is most useful in patients who have had little prior therapy.
12. Splenectomy may be useful in patients with painful splenomegaly or who have cytopenias that are unresponsive to other therapies. Minimally invasive surgical techniques should be considered.
13. Prophylactic gammaglobulin is useful in reducing the frequency of infections in patients with hypogammaglobulinemia and frequent bacterial infections. G-CSF and erythropoietin may be useful to maintain neutrophil counts and hemoglobin.
14. Although not standard therapy, alloSCT may be considered for younger patients (<65 years) who have developed refractory disease.
15. Most patients in CLL clinics will die from disease progression or transformation, infections, and second malignancies (skin, melanomas, and solid tumors). Thus, patients need to be monitored for these complications with each visit and second malignancies promptly treated.

CHAPTER 91

HAIRY CELL LEUKEMIA

James B. Johnston, Michael R. Grever

Hairy cell leukemia (HCL), or leukemic reticuloendotheliosis, is a chronic B-cell disorder that was initially described by Bouroncle et al. in 1958.[1] The disease is characterized by the presence of typical hairy cells in the peripheral blood and marrow, pancytopenia, and a variable degree of splenomegaly.[1,2–3,5,6] The disease has always aroused interest, initially over the unique morphologic and clinical features of this disorder. The tumor cells are B-cells that typically express CD11c, CD25, CD103, and CD123, are usually IgVH-mutated and are unique memory B-cells in expressing multiple immunoglobulin (Ig) isotypes. More recently, it has been demonstrated that most hairy cells contain a mutated active form of the *BRAF* gene (V600E) which may be used as a diagnostic tool and a potential target for therapy. Most cases of HCL are very sensitive to interferon (IFN)-α and the nucleoside analogs pentostatin (2′-deoxycoformycin, dCF) and cladribine (2-chlorodeoxyadenosine CdA).[5,6] Less responsive patients generally respond to monoclonal antibodies, such as rituximab (against CD20) or to immunotoxin-labeled antibodies to CD22 or CD25. Prior to the development of these treatments the median survival for HCL patients was 4 years whereas now the survival of these patients is no different from an age- and sex-matched control population.

INCIDENCE AND ETIOLOGY

HCL is a rare disorder, accounting for 2% of all leukemias, and occurs more frequently in men, with an incidence in the United States of 2.9 per million per year for men and 0.6 per million per year for women.[5,7] The etiology of HCL is unknown. Several case-controlled studies have identified possible relationships to radiation exposure,[7,8] exposure to benzene,[9] to farm animals, and to commercial herbicides and pesticides.[9,10] A familial predisposition is suggested by reports of the disorder in 15 families where HCL occurred among first-degree relatives. In these families, disease is usually associated with the following haplotypes; A2, B7, and Bw4/6; A1/3 and B7/8; A2, B51, and DR52/53.[11]

PATHOGENESIS

Immunologic,[12,13,14] molecular genetic,[15–21] chromosomal,[22,23] and gene expression[24] studies have demonstrated that the hairy cell is of B-cell origin. Although some T-cell features have been reported,[25,26–30] including two cases in which the retrovirus human T-cell leukemia virus type II was isolated,[31,32] no instances of T-cell receptor gene rearrangements have been found. Fluctuations in the expression of T- and B-cell markers have been demonstrated both in vivo and under various in vitro culture conditions.[33–36] In most instances, the alteration noted was between a surface-immunoglobulin–positive (SIg^+) $CD2^-$phenotype and a SIg^-CD2^+ phenotype. Other B-cell antigens, however, such as CD20, were retained, even with the loss of SIg and the appearance of CD2.[35]

The cell of origin of the hairy cell has been a subject of much debate and has been discussed in several recent reviews.[37–39] Gene expression profiling has demonstrated that the hairy cell is most similar to a memory B-cell, although it differs in that the hairy cell has increased expression of adhesion and chemokine receptor genes.[24] The profile is extremely homogeneous, quite different from other lymphoid malignancies, and the abnormal expression of specific genes explains the properties of this disease which include unique cell structure, marrow fibrosis, marrow suppression, and the tendency of tumor cells to home to spleen and marrow, rather than to lymph nodes. As hairy cells do not express CD27, which is normally expressed on memory B-cells, it has been suggested that the normal counterpart is a memory cell which lacks CD27 but has somatic mutations of the the IgVH genes.[40] However, the profile also demonstrated expression of many genes associated with macrophages suggesting that these cells are unique in having phagocytic properties.[24] Consistent with being a memory B-cell, the majority of cases with HCL show mutations of the variable chain of the Ig gene, demonstrating that the hairy cell has passed through the germinal center (Fig. 91.1).[15–21,41] However, 10% to 20% of cases have unmutated IgVH and in general these patients have very poor prognosis and are resistant to chemotherapy.[17,18] The IgVH gene usage is shown in Figure 91.2 and demonstrates that in classical HCL IgVH 3–23 (17%), 3–30 (8%), and 4–34 (7%) are most commonly used. IgVH 1–69, 3–11, 3–48, and 4–39 are each used in 5% of cases The major difference between the HCL variant and classical HCL, is the usage of IgVH V4–34, which is present in 54% of variant cases but only 17% of classical cases.[20] The majority (94%) of IgVH4–34 cases are unmutated. As expected, the IgVH is more likely to be unmutated in the HCL variant (54%) as compared to classical HCL (17%). It is interesting that, as discussed later, patients with unmutated IgVH or those that use IgVH4–34 have more aggressive and drug-resistant disease.[17,18] The patterns of IgVH gene family usage and the incidence of IgVH mutations is different in HCL and chronic lymphocytic leukemia (CLL).[20] In CLL, the most commonly used IgVH genes are IgVH1–69, 3–21, 3–30, 4–34, and 1–02 and whereas most IgVH 1–69 cases are unmutated, most IgVH4–34 cases are mutated.[42] Overall, approximately 60% of CLL cases have mutated IgVH and 40% are unmutated.

Hairy cells are unique in expressing multiple Ig isotypes that are related to RNA splicing. Thus, individual hairy cells may express IgG alone or in combination with IgM and/or IgD and/or IgA.[15,16,41] Similarly, IgVH mutational analysis has demonstrated intraclonal variation in gene expression, both in the IgVH unmutated and mutated varieties. These studies have suggested that the hairy cell is in maturation arrest before deletional recombination within the heavy chain locus.

Cytogenetics

Cytogenetic studies have been difficult to carry out in HCL, because the number of circulating hairy cells is small, and attempts at marrow aspiration are usually unsuccessful. In addition, until recently it has been difficult to induce hairy cells to proliferate and to obtain hairy cells in metaphase. In early reports, the abnormalities observed in HCL tended to be nonclonal.[43,44] However, more recently, 15 of 19 patients were found to have an abnormal karyotype, and a $14q^+$marker involving the breakpoint q32 at the Ig heavy chain locus was the most frequent clonal abnormality.[22] Abnormalities involving the short arm of chromosome 12 have been observed in four patients.[13] Haglund et al.[45] observed deletions and inversions in 67% of patients. Clonal abnormalities of chromosome 5 were found in 40% of cases (most commonly trisomy 5, pericentric inversions, and interstitial deletions involving 5q13). The frequency with which these abnormalities occur is unique and is not found in other B-cell malignancies. Abnormalities in 5q13 thus occur in one third of patients, and subsequent studies have identified three expressed sequences as candidates for a putative tumor-suppressor gene at 5q13.3.[46] Cytogenetic analysis has been carried out using monoclonal antibodies to CD40, because this

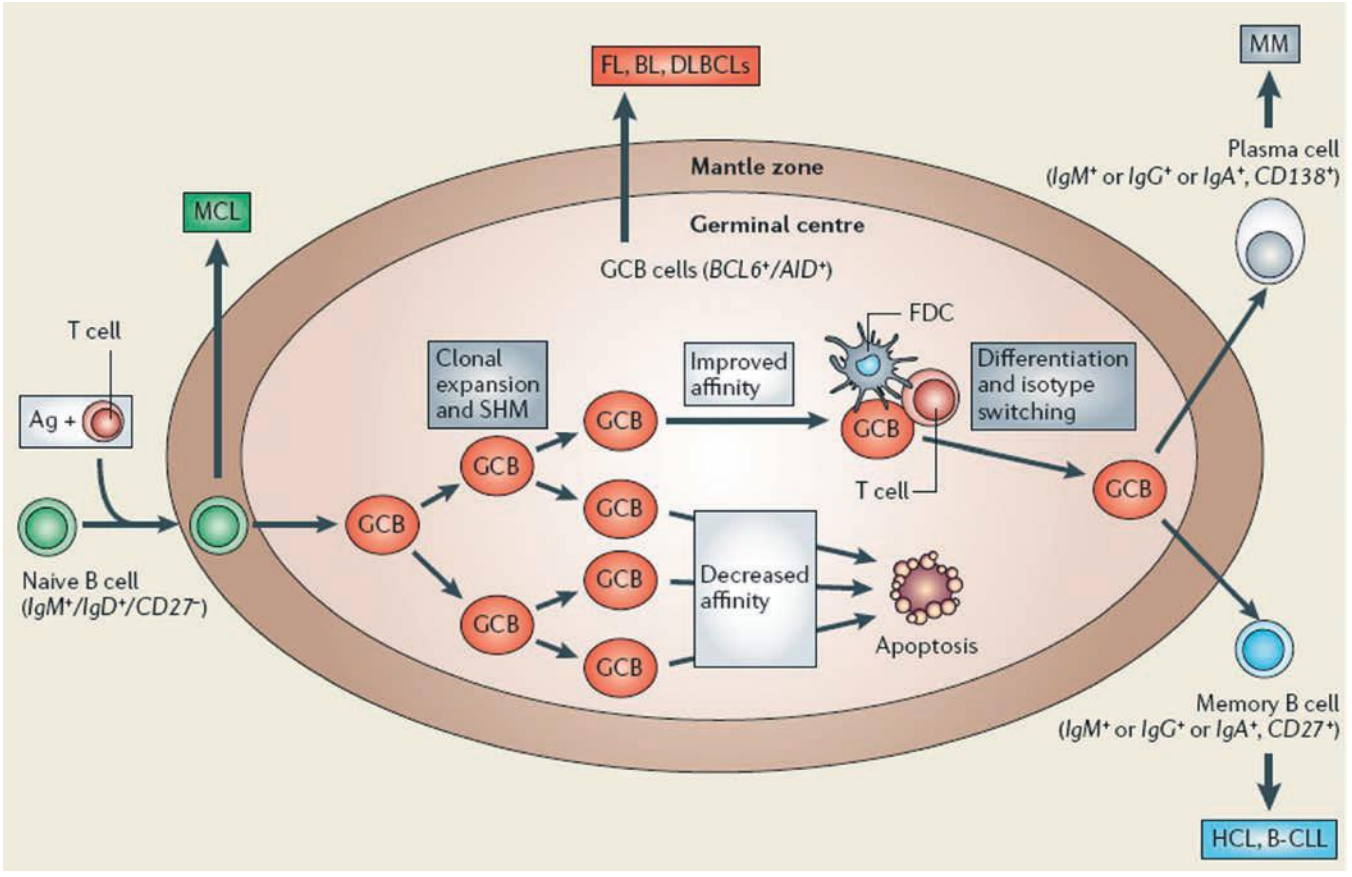

FIGURE 91.1. The germinal center (GC) reaction is a key event in adaptive immunity to T-cell–dependent antigens. In lymph nodes and the spleen, antigen (Ag)-activated naive B-cells (immunoglobulin [Ig] M^+/IgD^+) are driven into primary follicles where, aided by T-cells, they undergo clonal expansion, form the GC, and displace nonproliferating naive B-cells to the periphery or mantle zone (shown in diagram). Within the GC, somatic hypermutation (SHM) mutates the Ig variable region of proliferating B-cells to increase their affinity for the stimulating Ag. Although most GC B-cells (GCB) acquire unfavorable mutations and die by apoptosis, a few improve their Ig affinity and are selected for further differentiation through interactions with T-cells and follicular dendritic cells (FDC). A proportion of these selected B-cells then undergo switch recombination of the Ig constant region, which changes the isotype and, consequently, the antibody-effector function. B-cells of the GC express BCL6, which is required for GC formation, and activation-induced cytidine deaminase (AID) which is essential for SHM and switch recombination. Finally, selected B-cells differentiate into memory B-cells ($CD27^+$) or antibody-secreting plasma cells ($CD138^+$). Follicular lymphoma (FL), Burkitt lymphoma (BL), and some diffuse large B-cell lymphomas (DLBCLs) are thought to derive from B-cells of the GC, mantle cell lymphoma (MCL) mainly from mantle-zone naive B-cells, B-cell chronic lymphocytic leukemia (B-CLL) and hairy-cell leukemia (HCL) from memory B-cells, and multiple myeloma (MM) from plasma cells. The majority of cases of CLL and HCL have undergone SHM, but a proportion have not and these cases have more aggressive disease. (From Tiacci E, Liso A, Piris M, and Falini B. Evolving concepts in the pathogenesis of hairy-cell leukaemia. Nature Rev 2006;6:437–448, with permission).

appears to be the most effective way of inducing hairy cell proliferation.[47] This technique allowed cytogenetic analysis in 42 of 43 cases and demonstrated that clonal abnormalities were present in 19% of cases and involved numeric or structural abnormalities in chromosomes 5, 7, and 14. In contrast, abnormalities of chromosome 5 were not observed in the HCL variant, and translocations more frequently involved either chromosome 2 or 14.[48]

High-density genomewide DNA profiling in HCL showed that, in contrast with CLL, HCL has a remarkably stable genome.[49,50] Using a high-density single nucleotide polymorphism array, it has been shown that only 25% of patients had gross copy number abnormalities.[49] Alterations in the genes for *FGF12* and *FGF* receptor were observed, and increased expression of these genes is typically observed in HCL, which is responsible for the marrow fibrosis seen in this disease.[49] Although a high incidence of *TP53 mutations* was initially reported in HCL, subsequent studies have suggested that this is uncommon and occurs primarily in patients with unmutated IgVH.[17,51,52]

Oncogenes and Signal Transduction

To date, there has been little information regarding the role of oncogenes in HCL. It has been shown that *CSF1R*, which encodes the receptor for macrophage colony-stimulating factor and is normally expressed in macrophages/monocytes, is highly expressed in hairy cells.[53] The addition of macrophage colony-stimulating factor to hairy cells causes enhanced mobility of the cells, the extent of which depends on the underlying stratum, and this effect is mediated through alterations in the integrin $\alpha_v\beta_4$.[54] More recently, it has been demonstrated that, compared with normal lymphocytes, hairy cells have markedly increased levels and activities of the protein tyrosine kinase $pp60^{c\text{-}src}$, which is the product of the proto-oncogene *CSK*.[55] This increase was not observed in CLL cells and was unrelated to the amplification or structural rearrangements of the gene.[55] Cyclin D1 messenger RNA and protein levels are increased in HCL, but the increase is less than is seen in mantle cell lymphoma and is not related to $t^{11,14}$ (q13;q32), which is typically observed in mantle cell lymphoma.[56,57] Finally, because of the high frequency of abnormalities of chromosome 5 in classic HCL, it has been suggested that a transforming oncogene might be located at 5q13.3.[46]

Gene expression profiling identifies a unique homogeneous signature for HCL distinct from other B-cell malignancies. In HCL samples, decreased expression was noted for *CXCR5*, *TNFRAF5*, *CD40*, *CD27*, and *CCR7*, whereas increased expression was noted for *GAS7*, *FGFR1*, *FGF2*, *FLT3*, *TIMP1*, *TIMP4*, *RECK*, *ANXA1*,

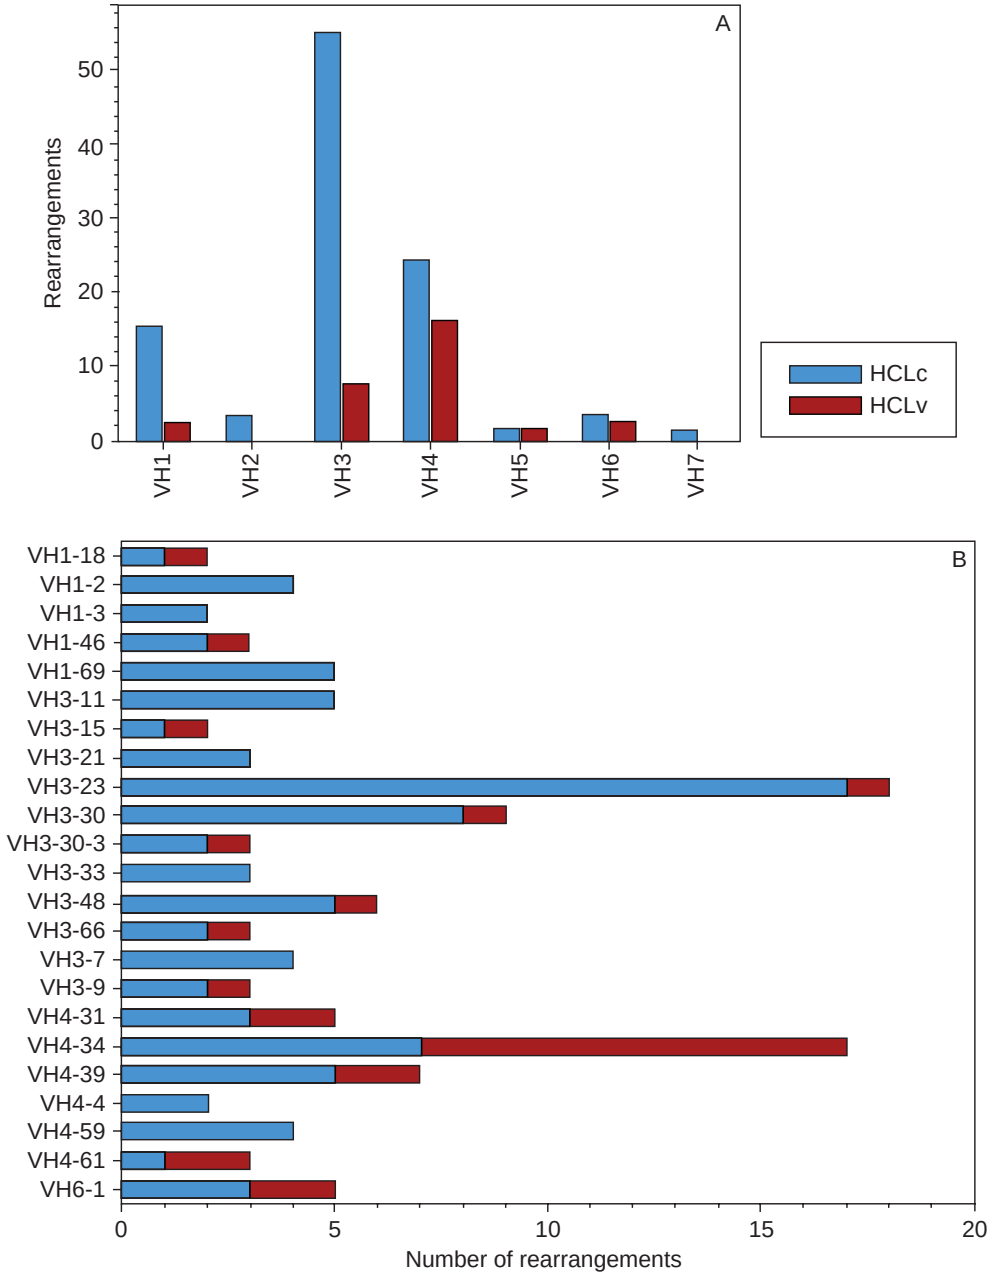

FIGURE 91.2. Immunoglobulin (Ig) VH family and gene usage in hairy-cell leukemia (HCL). Evidence of canonical somatic hypermutation in hairy cell leukemia. Blood 2011;117:4844–4851, with permission.)

Syndecan3, *Cyclin D1*, *IGFBP*, and *NUDT6*.[24] The proposed effects of these changes on the pathophysiology of HCL are outlined in Table 91.1. More recently, a heterozygous mutation of GTG to GAG at codon 600 of the *BRAF* gene has been observed in typical HCL producing a V600E variant protein, in which glutamate substitutes for valine at position 600.[58–62] BRAF is a serine–threonine kinase and the variant protein (V600E) demonstrates increased activity resulting in enhanced phosphorylation and activation of mitogen-activated protein-ERK kinase (MEK) and extracellular signal-regulated kinase (ERK), which increase cell survival and proliferation by increasing the expression cyclin D1 and decreasing p27.[58] The functionality of the variant protein was demonstrated in primary hairy cells by showing the presence of phosphorylated MEK and ERK in these cells, and demonstrating that the phosphorylation was decreased using the BRAF inhibitor, PLX-4720.[58] Initial studies suggested that all patients with classical HCL contained a V600E; however, a more recent study demonstrated that 82% of patients with classical HCL express BRAF, whereas the V4–34 subtype and HCL variant do not express BRAF.[21] Thus, BRAF inhibitors may not be useful in the treatment of the aggressive V4–34 HCL subtype of the HCL variant.

It has also been demonstrated that the activities of MEK and ERK are increased in HCL through the epsilon form of protein kinase C (PKCε), which in turn is activated by tyrosine nitration (Fig. 91.3).[63] Tyrosine nitration is produced by the high levels of reactive oxygen species (ROS) and nitric oxide (NO) in hairy cells.[63] In addition, apart from its role in cell survival, activated PKCε is also involved in causing the unusual hairy cell structure by increasing the Rho guanosine triphosphatases (GTPases), Rac1 and Cdc42.[63] The Rho GTPases are members of the Ras family of GTP-binding proteins and can either be active (GTP-bound) or inactive (GDP-bound).[63] The GTPases are important for actin structure within the cell and controlling cell shape. It has been shown that three groups of Rh0 GTPases, RhoA, Rac1, and Cdc42, are overexpressed in HCL and are responsible for the filamentous projections and growth of these cells.[64]

TABLE 91.1

MECHANISMS FOR HAIRY CELL LEUKEMIA FEATURES

Hairy Cell Feature	Mechanism
Hairy cell projections	Alteration of actin structure through up-regulation of the Rho GTPase Rac 1.
Prolonged survival of hairy cells	Autocrine stimulation by TNF-α, increased cellular levels of bcl-2.
Ability of hairy cell to phagocytose and expression of macrophage markers, for example, CD11c	Up-regulation of annexin1 mediates phagocytic function and c-Maf transcription factor for macrophage differentiation.
Marrow fibrosis and monocytopenia	Up-regulation of FGF2 which activates FGFR1 on the hairy cell producing fibronectin and TGFβ, which causes the adjacent fibroblasts to secrete collagen. TNF-α and TGF-β cause marrow suppression and monocytopenia.
Infiltration of red pulp of spleen by hairy cells with the formation of "pseudosinuses"	Up-regulation of TIMP1, TIMP4, RECK inhibitors of matrix metalloproteinases.
Lack of lymph node involvement by hairy cells	Hairy cells lack L-selectin which is required for binding to venule endothelium and chemokine receptor 7 (CCR7) which is required for transendothelial migration.

GTPases, guanosine triphosphatases; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor.
Swerdlow SH, Campo E, Harris NL, et al. WHO classification of tumours of haematopoietic and lymphoid tissues, vol. 2, 4th ed. WHO 2008; Basso K, Liso A, Tiacci E, et al. Gene expression profiling of hairy cell leukemia reveals a phenotype related to memory B cells with altered expression of chemokine and adhesion receptors. FIGURE 91.3. Proposed pathways of constitutive signaling in hairy cells (HCs). This figure shows the schematic representation of the possible associations into two parallel pathways of active signaling components detected in HCs. Protein kinase C (PKCε) plays a central role, controlling the activation of p60src, Rac1, and extracellular signal-regulated kinase (ERK). PKCε is itself activated through nitration of tyrosine residues by reactive oxygen species (ROS) and nitric oxide (NO) which are increased in HCs. (From Slupsky JR, Kamiguti AS, Harris RJ, et al. Central role of protein kinase Cε in constitute activation of ERK1/2 and Rac 1 in malignant cells in hairy cell leukemia. Am J Path 2007;170:745–754, with permission.) MEK, mitogen-activated protein-ERK kinase; MT, mitochondrial; NOX5, NADPH oxidase 5; iNOS, inducible nitric-oxide synthetase.

Cytokines

There has been great interest in the role of cytokines in the pathogenesis of HCL.[37–39] Identified factors that may be involved include interleukin-2 (IL-2), tumor necrosis factor (TNF)-α, IL-4, IL-6, B-cell growth factor, IFN-α, transforming growth factor-β (TGF-β), and basic fibroblast growth factor (bFGF, FGF2).[65] Some of these factors may be produced by the hairy cells themselves or by normal T-cells.[65,66] T-cell clones have been shown to produce cytokines that stimulate the growth of hairy cells, but not normal B-cells; this effect is prevented by the addition of IFN-α.[66]

A feature of classical HCL is the reactivity of the hairy cells with anti-Tac (CD25), which detects the α-chain of the IL-2 receptor.[67–70] Increased serum levels of IL-2 receptor have been found in untreated HCL patients, and there is evidence that the leukemic cells release the receptor.[70] The serum levels of IL-2 receptor correlate with the extent of disease and decrease after effective therapy with IFN-α.[71,72,73] Paradoxically, even though the IL-2 receptor is present on hairy cells, these cells do not respond to stimulation by IL-2, and IL-2 probably does not play a major role in the pathogenesis of HCL.[65]

It has been demonstrated that TNF-α, but not TNF-β, stimulates the growth of hairy cells, whereas in CLL, both forms of TNF stimulate leukemic cell growth (Fig. 91.4).[74,75] Hairy cells can also produce TNF-α,[76,77] and the serum level of TNF-α is increased in HCL, the level correlating with tumor burden.[77] The TNF-α receptor can also be detected in the serum of these patients, and the level of this receptor also decreases after treatment with IFN-α.[78,79] These findings suggest that TNF-α production by the hairy cells may play an important role in the pathogenesis of HCL by stimulating further growth of hairy cells and producing pancytopenia through the inhibition of normal marrow function.[74,76,77]

Hairy cells secrete low levels of IL-6, and the serum level of this cytokine is increased in HCL.[65,80] The production of IL-6 messenger RNA and IL-6 secretion is markedly increased by incubating HCL cells with TNF.[80] IL-6 antisense oligonucleotide can inhibit the effect of TNF on IL-6 secretion and DNA synthesis, suggesting that IL-6 mediates the activity of TNF in HCL.[80]

Hairy cells also produce bFGF and TGF-β and express the bFGF receptor.[81,82] Adhesion of the hairy cells to hyaluronan via CD44 induces the secretion of bFGF, but not TGF-β.[81] The secreted bFGF then feeds back on the hairy cell to secrete fibronectin, which is a major component of the marrow fibrosis in this disease. As the spleen does not have hyaluronic acid, this explains the lack of bFGF and fibrosis in this organ despite abundant hairy cells.[81] TGF-β has been shown to be present in increased

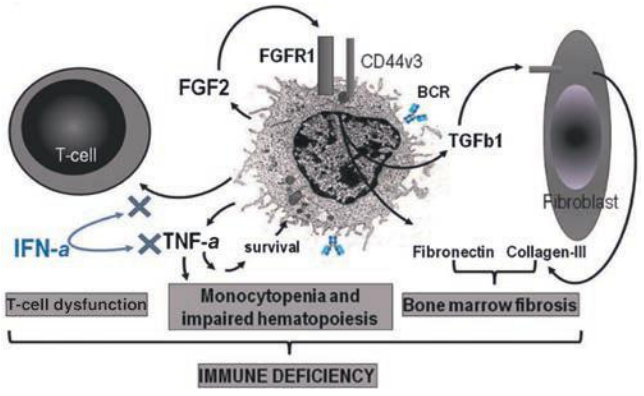

FIGURE 91.4. Immune suppression in hairy-cell leukemia (HCL). Immune suppression is a result of T-cell dysfunction and impaired hematopoiesis with pancytopenia, bone marrow fibrosis, and hypersplenism. T-cell activation, decreased numbers of memory T-cells, restricted T-cell repertoire, and opportunistic infections are the result of inappropriate activation and suppression of T-cell responses directly by cytokines produced by the neoplastic B-cells. Cytopenia with severe monocytopenia is caused by the secretion of tumor necrosis factor (TNF)-α by the hairy cells. TNF-α also has autocrine prosurvival effects on the tumor clone. Treatment of HCL with IFN-α is able to restore the abnormal T-cell repertoire and hematopoiesis by inhibiting cytokine (including TNF-α) mediated effects on the T-cells and tumor cell. Fibrosis is caused by production of fibroblast growth factor-2 (FGF-2) and overexpression of its receptor FGFR1. The FGF2-FGFR1 interaction increases with CD44v3 co-receptor and syndecan family members. FGFR1 signals secretion of autocrine fibronectin and of transforming growth factor-β (TGFβ) by hairy cells. TGFβ stimulates adjacent fibroblasts to produce fibronectin and collagen type III. (From Forconi F. Hairy cell leukaemia: biological and clinical overview from immunogenetic insights. Haematol Oncol 2011;29:55–66, with permission.)

quantities in the plasma and marrow of patients with HCL, and this also contributes to the marrow fibrosis by inducing the production of collagen and reticulin by adjacent fibroblasts.[82]

CLINICAL FINDINGS

The median age in HCL is between 50 and 55 years (range, 22 to 85 years), with the male-to-female ratio being 4:1.[1,2–4,5,6,83] Classically, these patients present with weakness and fatigue, and the symptoms can usually be related to pancytopenia and splenomegaly (Table 91.2).[1,2–4,5,6,83] Ninety percent of patients have a palpable spleen, which may be massive, and one third of patients have hepatomegaly.[1,2–4,5,6,83] Peripheral lymphadenopathy is uncommon,[5] but with computed tomography scanning, significant abdominal lymphadenopathy may be observed.[84,85]The degree of abdominal lymphadenopathy correlates with the duration and extent of disease. The incidence at presentation is 17%, but increases to 56% at relapse after chemotherapy.[84] Less frequently, mediastinal node enlargement may also be observed.[86] Compared to 30 years ago, patients are now being diagnosed earlier and have less marked splenomegaly and anemia at presentation.[6]

Most patients have pancytopenia, the etiology of which is multifactorial but is primarily related to marrow failure and splenomegaly. Marrow failure is related to replacement of marrow by hairy cells and the associated reticulin fibrosis, and to the inhibition of myelopoiesis by cytokines, such as TNF-α, released by the hairy cells.[37–39] Splenomegaly in HCL may produce pancytopenia by three mechanisms. First, the major factor responsible for the cytopenias is pooling (sequestration, margination) of normal peripheral blood cells in the enlarged spleen.[87–92] As much as 90% of the peripheral platelet mass,[88] 30% of the red cell mass,[91] and 65% of the granulocytes[89] may pool in a massively enlarged spleen. In HCL, apparently because of the formation of blood-filled pseudosinuses by the hairy cells, a greater proportion of the peripheral red cell volume (as much as 48%) may be pooled in a massively enlarged spleen.[91] A second mechanism responsible for cytopenias with splenomegaly is the increased destruction of cells in the spleen. Finally, an expanded plasma volume contributes to the appearance of cytopenia with splenomegaly; this is particularly true for the observed anemia.[87,90]

TABLE 91.2

HAIRY CELL LEUKEMIA: CLINICAL MANIFESTATIONS

Manifestation	Incidence (%)
Weakness, easy fatigue	80
Fever, sweats, weight loss, anorexia	20–35
Infection	20–30
Easy bruising, bleeding	20–30
Left upper quadrant abdominal discomfort	25
Autoimmune disorders	15–30
Splenomegaly	80–90
Hepatomegaly	30–40
Ecchymoses, petechiae	20–30

Infections

Prior to the development of effective treatments for HCL, infections were a major problem and the leading cause of death.[83,93–95,96] Nowadays, approximately one third of patients will develop an infection during the course of their disease and two thirds of these will be serious.[96] Fever is rarely a manifestation of the underlying HCL; when present, it should prompt a careful search for an infectious process. Approximately 30% of patients present with infection, and 70% have either documented or suspected infections during the course of the disease.[93] Pyogenic infections account for ~50% of infectious episodes; Gram-negative and Gram-positive bacteria are identified with approximately equal frequency.[83,93] However, nonpyogenic infections occur in >30% of patients,[83,93] and infections can occur with unusual organisms such as atypical mycobacteria, including *Mycobacterium kansasii*, which is a unique feature of HCL, in comparison to other lymphoproliferative disorders.[83,94,97] Other organisms include *Toxoplasma gondii*, *Legionella*, *Listeria monocytogenes*, and *Pneumocystis jirovecii*, as well as various fungi and viruses.[83,98–100]

The high infection rate can be ascribed primarily to neutropenia, although several other immune defects have been described. Monocytopenia is often a prominent feature,[101,102] and functional abnormalities of monocytes and granulocytes may occur.[99,101,103–105] The defects in monocyte production and function may account for the unusual susceptibility of these patients to atypical mycobacterial and fungal infections.[95,96] The T-cells are also highly abnormal in HCL, demonstrating an inversion in the CD4:CD8 ratio, and they have a poor antigen response which is likely related to absence of CD28.[106,107] Moreover, there is clonogenic expansion of $CD8^+$ cytotoxic lymphocytes but the target for these cells has not yet been identified.[108] These abnormalities can resolve with IFN-α therapy, although it may take up to 2 years to see this effect.[109] A depressed helper to suppressor T-cell ratio associated with a decrease in the number of T-helper cells and an increase in the number of T-suppressor cells also has been demonstrated.[109] As expected, lymphocyte functional studies reveal impaired delayed-type hypersensitivity to recall antigens, as well as near-absent antibody-dependent cellular cytotoxicity.[106] In contrast to CLL, the serum Ig levels are normal.[110]

Autoimmune Disorders

Clinical manifestations secondary to various autoimmune disorders are being recognized with increasing frequency in patients

with HCL.[83,111,112,113–115] In one series of patients, these complications were second only to infection as a cause of morbidity.[83,112] The onset may occur any time during the course of the disease and is not related to the tumor burden. Most frequently, patients present with arthritis, arthralgias, palpable purpura, or nodular skin lesions resulting from cutaneous vasculitis, and low-grade fever.[83,112,114] Occasionally, patients may have involvement of the lung, liver, intestine, and kidney, with a clinical picture that resembles polyarteritis nodosa.[83,112,113,115] These patients often have fever, malaise, and weight loss, and a co-existent infection must be ruled out.[83,112] If skin lesions are present, the diagnosis can be confirmed by biopsy, which usually shows changes compatible with a diagnosis of polyarteritis nodosum or leukocytoclastic vasculitis; occasionally, a vasculitis related to the invasion of the vessel wall by hairy cells occurs; this may appear very similar to polyarteritis nodosa with the presence of aneurysms.[114] In some organs, such as the lung, a granulomatous vasculitis may be found.[112] Angiography may reveal peripheral aneurysms.[112] Antinuclear antibodies, rheumatoid factor, immune complexes, and hepatitis B antigen are variably positive.[111] Cryoglobulinemia has been detected in some patients.[116,117] It has been postulated that the increased incidence of vasculitis in HCL may be related to infections with hepatitis B and other viruses, cross-reactivity of antibodies against hairy cells with epitopes on endothelial cells, and decreased clearance of immune complexes by the impaired immune system.[114]

These autoimmune manifestations may be self-limited, but if therapy is required, a short course of corticosteroids is usually effective.[114] Remissions have also been observed after splenectomy, IFN-α, and pentostatin therapy.[112,114,115]

Unusual Manifestations

Lytic Bone Lesions

Although the immunophenotypic profile of hairy cells closely resembles that of B-cells at a developmental stage just before terminal differentiation to plasma cells, lytic bone lesions are distinctly unusual (Table 91.3).[118–121] In some patients with osteolytic lesions, HCL and multiple myeloma were thought to coexist.[122,123] However, several patients with classic HCL and without any evidence of plasma cell proliferation have been reported to develop osteolytic lesions.[119–121] These lesions have a predilection for the proximal femur and usually are associated with extensive bone marrow infiltration by hairy cells.[120,121] The lesions, as with those seen in association with multiple myeloma, respond well to radiotherapy. The administration of corticosteroids can produce prompt relief of bone pain.[118]

Skin Involvement

Cutaneous lesions referable to thrombocytopenia (ecchymoses, petechiae), infection, or vasculitis are common during the course of HCL, but lesions caused by infiltration of the skin by hairy cells are unusual.[124,125] In a retrospective review of 600 cases, skin lesions thought to be due to infiltration by hairy cells were reported in 8.0% of cases, but histopathologic verification was present in only 1.3%.[124] Infiltrative lesions usually are widely disseminated and consist of erythematous maculopapules. Biopsy shows the infiltrates to be perivascular, involving the dermis but not the epidermis.[126]

Splenic Rupture

Surprisingly, even with massive splenomegaly, spontaneous splenic rupture is rare in HCL, occurring in ~2% of cases.[1,127]

Other Organ Dysfunction

Although hairy cell infiltration of multiple organs and tissues is a frequent finding at autopsy, clinically significant organ dysfunction is unusual.[128] Infiltration of connective tissue and fat surrounding organs is common.[128] Central nervous system involvement is unusual, and only a rare case of meningeal involvement has been documented.[128,129] Infection is by far the most frequent cause for neurologic complications.[129] Pleural effusions, ascites, protein-losing enteropathy, and spinal cord compression may occur rarely in HCL and result from tissue infiltration by hairy cells.[118]

LABORATORY FINDINGS

The relative incidence of the most characteristic laboratory findings is listed in Table 91.4. In a series of 725 cases studied by the Italian Cooperative Group, 80% of patients had pancytopenia at presentation, with one third of all patients having a hemoglobin level <8.5 g/dl, neutrophils $<0.5 \times 10^9$/L, and platelets $<50 \times 10^9$/L.[6] A careful inspection of the peripheral blood smear demonstrates the presence of typical hairy cells in >85% of patients,[1,6] and in 13% of cases, there are $>5 \times 10^9$/L hairy cells.[6] In Bouroncle's series of 82 patients, hairy cells accounted for ≥10% of the leukocytes in 80% of patients and ≥50% in 43% of patients.[2] The total leukocyte count was elevated in 20%, but in only 4% did the count exceed 50×10^9/l.[2] Monocytopenia also typically occurs in active HCL.[101,102]

Abnormal liver function studies, usually with an isolated elevation of the serum alkaline phosphatase level, are obtained in 10% to 19% of individuals with HCL.[4] The leukocyte alkaline phosphatase scores are high in most cases. The Ig levels are normal in HCL and monoclonal gammopathy is rare, occurring in 1% to 3% of patients.[3,4] It has been difficult to prove that the hairy cells are secreting the paraprotein[130]; in other cases, the M band was thought to be related to a co-existing myeloma.[120,122,123]

Hairy Cells

The characteristic morphologic appearance of hairy cells on a Wright-stained peripheral blood smear is the single most important diagnostic finding (Fig. 91.5).[12] Other B-cell disorders that may have hairy projections on the cells include B-cell prolymphocytic leukemia, atypical HCL, and splenic lymphoma with villous lymphocytes (SLVL), although careful analysis and flow cytometry can differentiate these disorders.[131] Typical hairy cells are mononuclear with relatively abundant cytoplasm and a cell diameter in the range of 10 to 25 μm. The cytoplasm is pale blue-gray and agranular with a variable number of elongated (hairy) projections. The mechanism for the hairy cell villi has been related to up-regulation of the expression of the Rho GTPases in the hairy cells.[64] The nuclei are round, oval, reniform, or dumbbell-shaped with a nuclear chromatin pattern that is homogeneous and less clumped and lighter staining than that of normal mature lymphocytes and those seen in classic CLL and prolymphocytic leukemia.[6,25,131] A prominent nucleolus is rarely seen. On both transmission and scanning electron microscopy, the cytoplasmic projections appear as elongated slender microvilli or broad-based ruffles or pseudopods (Fig. 91.6).[132] Other ultrastructural features include numerous mitochondria, polyribosomes, strands of rough endoplasmic reticulum, intermediate filaments, and some lysosomal granules.[25] In 50% of cases, cytoplasmic inclusions known as *ribosome–lamellar complexes* are found.[6,133] These complexes appear as rod-shaped structures under light microscopic analysis.[133] Although seen most frequently in individuals with HCL, they are not pathognomonic, having been reported in association with other chronic B-cell lymphoproliferative disorders, acute monocytic leukemia, and even nonhematologic neoplasms.[134] The characteristic filamentous projections can be seen readily in living hairy cells; using supravital dyes and phase-contrast microscopy, one can observe the cytoplasmic projections protruding and then retracting constantly.[6]

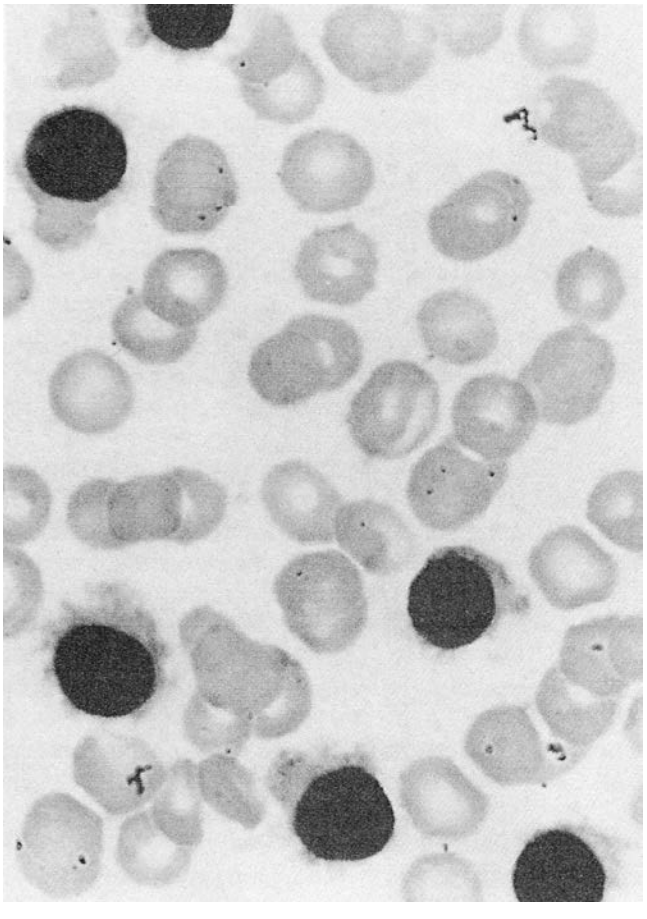

FIGURE 91.5. Hairy cells from a peripheral blood smear (light microscopy). Cells have abundant agranular cytoplasm with multiple cytoplasmic projections. Nucleus is round, oval, or reniform with light-staining homogeneous nuclear chromatin (Wright stain, × 1,500).

A useful diagnostic test for HCL is the presence of acid phosphatase isoenzyme 5 in the cytoplasm of hairy cells, but this can also be positive in other disorders.[6,135–139] Cytochemical staining procedures demonstrate that this isoenzyme, unlike other acid phosphatase isoenzymes, is not inhibited by tartrate.[135–139] The enzyme concentrates primarily in the Golgi area and nuclear membrane.[135] Even though a positive tartrate-resistant acid phosphatase (TRAP) stain is not pathognomonic for the diagnosis of HCL, it has stood the test of time as an important tool in the differential diagnosis of this disease.[137] The test is positive in more than 95% of cases.[4] In one report,[137] the TRAP stain was positive in 76%, intermediate in 21%, and negative in only 3% of 29 patients with HCL. In contrast, in 37 patients with CLL and other lymphoproliferative disorders, the test was positive in only 3%, intermediate in 32%, and negative in 65%.[137] The TRAP stain can now be carried out on paraffin-embedded tissue using 9C5, a monoclonal antibody to TRAP.[138,139] The majority of cases of HCL are detected using this antibody, although only 50% of the cells stain positively.[139]

Gene expression profiling has identified *ANXA1* as one of the most up-regulated genes in HCL.[24] *ANXA1* codes for annexin1, and is not expressed in normal B-cells. By using an immunocytochemical assay staining for the presence of annexin A1 on either paraffin-fixed bone marrow specimens or acetone-fixed cytospins of peripheral blood, 100% sensitivity and specificity has been shown in differentiating HCL from other B-cell malignancies, including variant HCL.[140] This is now considered one of the best tests.

More recently it has been shown that the majority of patients with classical HCL have GTG to GAG mutations at codon 600 of the *BRAF* gene, the (V600E) allowing glutamic acid to be substituted for valine at position 600 of the BRAF protein.[58–62] A recent study by Kreitman et al[21] has demonstrated that all classical HCL cases have the mutation apart from the aggressive and drug-resistant IgVH4–34 subtypes and the HCL variant. Several recent reports have described highly sensitive polymerase chain reaction (PCR) assays to detect the V600E mutation, which should be useful in the diagnosis of HCL and monitoring for minimal residual disease (MRD) following therapy.[60–62]

Immunophenotyping has proved very useful in assisting in the diagnosis of HCL and in differentiating it from variants and other B-cell malignancies.[1,131,141,142,143] Using flow cytometry, very small numbers of abnormal cells can be detected and the diagnosis of HCL can be made on the peripheral blood of the majority of patients. The hairy cells are monoclonal and, in contrast with most other lymphoid malignancies, cases with κ or λ expression are equally represented or there is a predominance of cases with κ expression.[142] Table 91.5 shows the immunophenotype of typical HCL in comparison to other chronic B-cell disorders with which it can be confused. In HCL, the leukemia cells have SIg ($IgM^{+/-}$, IgG, IgD, or IgA) and B-cell–associated antigens (CD19, CD20, and CD22); typically, the cells are positive for CD25, the IL-2 receptor. CD11c (leu-M5), which reacts with the α subunit of p150/95, a member of the lymphocyte function-associated antigen subfamily of integrin molecules, is present on virtually all hairy cells, but it is also present on monocytes and neutrophils and on the cells of other lymphoid malignancies.[6,141] Several antibodies have been raised against hairy cells, although none is entirely specific for this leukemia. B-ly-7 reacts with a 144-kd antigen (mucosal lymphocyte antigen; CD103) on hairy cells and on a small number of normal lymphocytes, which have been postulated to be the normal hairy cell counterpart.[142] Like

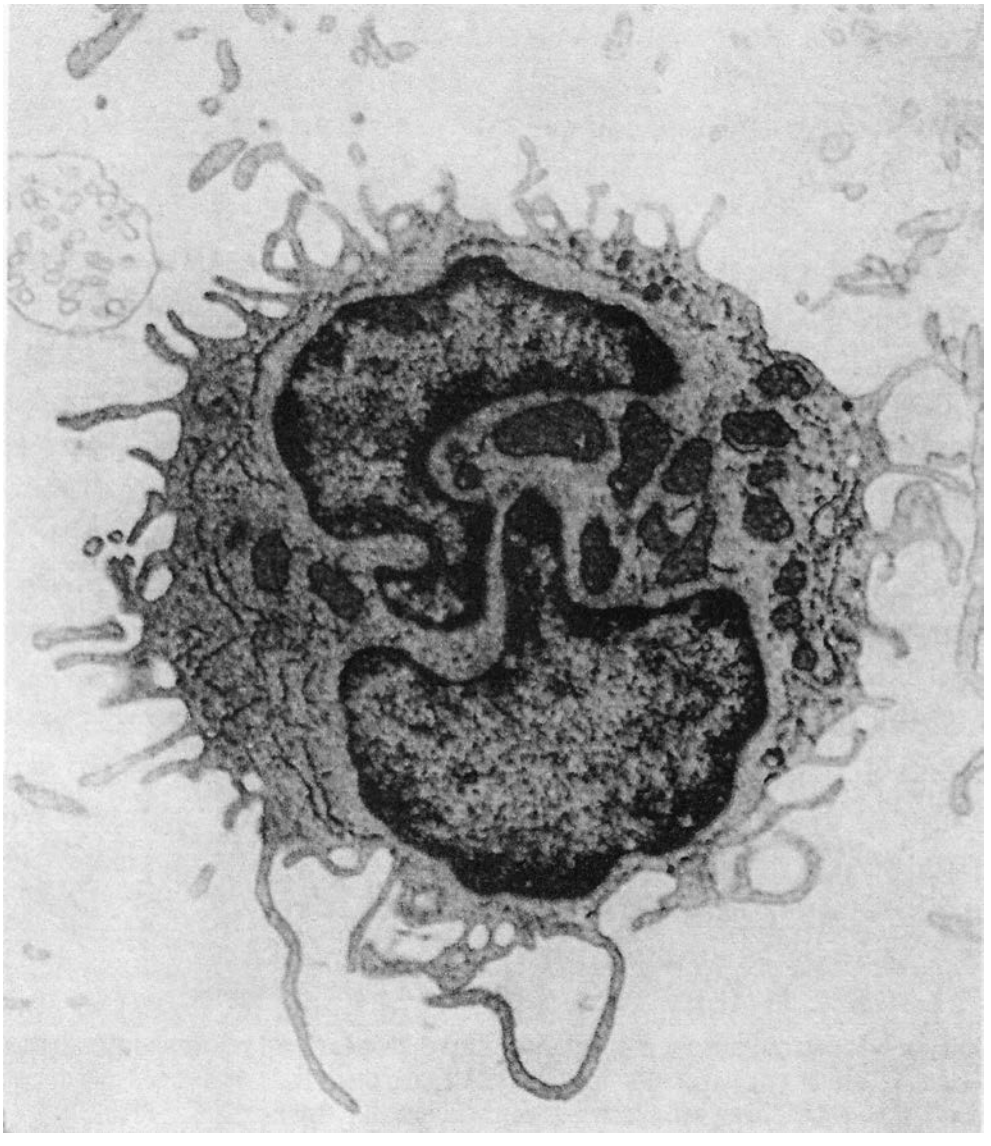

FIGURE 91.6. Hairy cells from the peripheral blood (transmission electron microscopy). The characteristic and delicate cytoplasmic projections are striking. Nucleus is irregular in shape with marginated chromatin (× 11,000).

B-ly 7, the antibodies HML-1, Ber-ACT8, and LF61 can also recognize CD103. Two further antibodies, RAB-I and anti-HC2, are also relatively specific for hairy cells.[6] CD123 (α chain of the IL-3 receptor) is present in 95% of cases with classical HCL and is only rarely detected in other chronic lymphoid malignancies.[142,143,144] Hairy cells are also typically strongly FMC7 positive (an epitope of CD20), negative for CD79b (an epitope of B-cell receptor β chain), and CD27, CD10, and CD38 are rarely positive.[142] In summary, the diagnostic immunophenotypic features for HCL are monoclonal B-cells that are positive for CD11c, CD25, CD103, and CD123.[142]

These antibodies are primarily used on viable or frozen cells, but antibodies have also been developed that can recognize formalin-resistant hairy cell antigens. One of these is DBA.44, which is directed against CD72, strongly stains hairy cells fixed in formalin or Bouin solution, and has good sensitivity.[143,145] However, DBA.44 is not entirely specific for hairy cells and also stains mantle zone lymphocytes and a variety of low- and high-grade B-cell lymphomas. The specificity and sensitivity for the diagnosis of HCL by immunohistochemistry can be increased when DBA.44 staining is used in conjunction with the 9C5 antibody to detect TRAP and an anti-CD20 antibody to detect B-cells.[139,143]

Bone Marrow

More than 99% of patients have marrow infiltration by biopsy, although the occasional patient can have isolated involvement of the spleen.[3] The pattern of bone marrow involvement on biopsy specimens is near to pathognomonic for HCL (Fig. 91.7).[146,147,148] Classically, the infiltration is diffuse and has a "honeycomb" appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm. The individual cells have been described as resembling a fried egg. This pattern of infiltration is quite different from that seen in other chronic lymphoproliferative disorders, such as CLL and lymphoplasmacytic lymphoma, where the lymphocyte nuclei closely approximate each other.[146,147,148] In prolymphocytic leukemia, monocytoid B-cell lymphoma, marginal zone lymphoma, and large granular lymphocytic (LGL) leukemia, in which the malignant lymphocytes are about the size of hairy cells with a low nuclear-to-cytoplasmic ratio, the infiltrates are similar to those seen in HCL. Bone marrow involvement in systemic mast cell disease and even in some nonhematologic neoplasms, such as mesenchymal chondrosarcoma, also may mimic HCL.[149] The hairy cells may be more easily identified using immunohistochemistry with antibodies to CD20 (L26) or DBA.44.

TABLE 91.5

HAIRY CELL LEUKEMIA (HCL): IMMUNOPHENOTYPIC PROFILE AND DIAGNOSTIC MARKERS

Marker	HCL	HCL-Variant	B-PLL	SMZL/SLVL

Br J Haematol 2011;156:186–195.

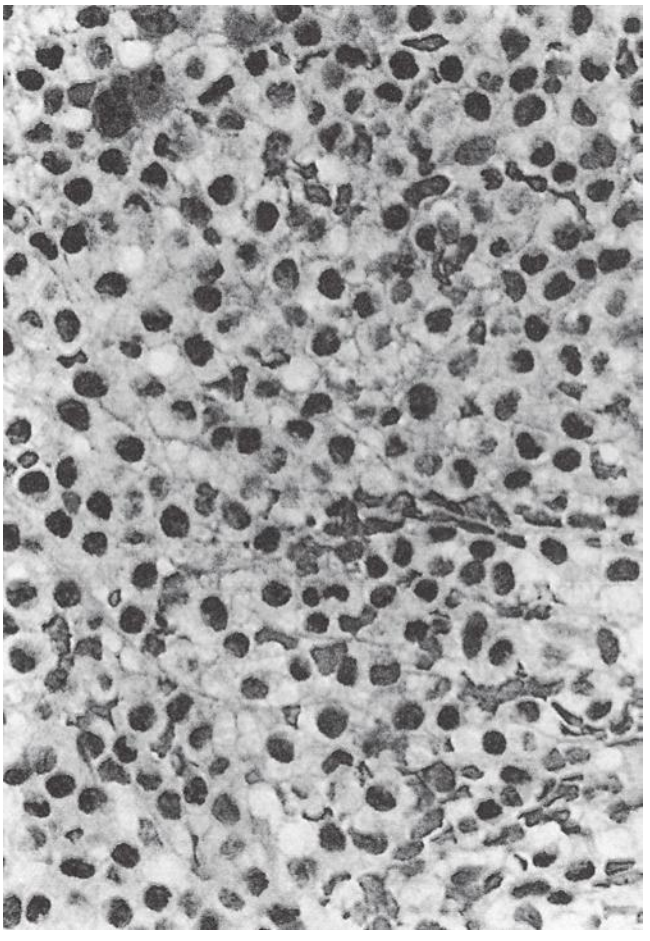

FIGURE 91.7. Bone marrow biopsy (plastic embedded) in hairy cell leukemia. Pattern of the infiltration gives a "honeycomb" appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm. Nuclei are bland and round, oval, or indented (hematoxylin and eosin, × 600).

Silver staining demonstrates diffuse reticulin fibrosis, without a collagenous component; this likely explains the usual difficulty in obtaining a marrow by aspirate ("dry tap"). Recently, it has been demonstrated that this feature is related to the ability of hairy cells to synthesize fibronectin.[150] In addition, hairy cells contain the fibronectin receptor, very late antigen-5, and are able to assemble the fibronectin molecule into multimers.[150] In some patients, the bone marrow is not diffusely involved by hairy cells; instead, focal (patchy) or interstitial infiltrates are seen.[146,147,148] The focal areas may be well-circumscribed nodules or they may have irregular borders. Extravasation of red cells into areas of involvement is often present.[147] Islands of normal hematopoiesis, particularly erythroid islands, are common. Increased numbers of plasma cells, lymphocytes, and mast cells may also be seen.

The overall marrow cellularity is increased in 55% of patients and normal in 38% of patients.[6] However, in 7% of cases, the cellularity is decreased; this can lead to the erroneous diagnosis of aplastic anemia or hypoplastic myelofibrosis.[149,151,152] Patients with hypocellular marrows frequently do not have splenomegaly.

Spleen and Liver

The spleen is almost always involved in HCL, and the pattern of hairy cell involvement, as with that in the bone marrow, is nearly pathognomonic for HCL.[124,153,154] The infiltrates are confined to the red pulp, and, unlike other lymphoproliferative disorders, the white pulp is not expanded and is actually atrophic. Although a variable degree of red pulp involvement is seen in association with all leukemias, it is not a feature of most lymphomas until a leukemic transformation occurs. Blood-filled pseudosinuses lined by hairy cells are a characteristic feature, and, despite monocytopenia, the number of histiocytes is increased in the red pulp. Infiltration of the liver occurs in both portal areas and sinuses.[131] Pseudosinuses, some resembling hemangiomas, may be present.[131]

DIAGNOSIS

The diagnosis of HCL usually is not difficult.[12–4,5,6] Most patients have splenomegaly in the absence of peripheral lymphadenopathy, and a variable degree of pancytopenia with severe monocytopenia. Typical hairy cells are evident in the peripheral blood on a routine smear or on a buffy coat in more than 90% of cases, and the suspected hairy cells should be TRAP positive and be monoclonal B-cells that are $CD11c^+$, $CD103^+$, and $CD25^+$. The marrow aspirate is "dry," and the bone biopsy should reveal the classic pattern of infiltration that may be diffuse, focal, or interstitial with increased reticulin and the cells staining positively for annexin A1. When hairy cells cannot be demonstrated in the peripheral blood, the bone marrow findings are critical for diagnosis. In addition to the typical bone marrow findings, immunophenotypic analysis may be helpful in identifying the leukemic cells (Table 91.5). Rarely, the diagnosis is confirmed only after splenectomy.

DIFFERENTIAL DIAGNOSIS

Disorders to be considered in the differential diagnosis of HCL include lymphoid malignancies that present with splenomegaly in the absence of lymphadenopathy and are listed in Table 91.6.[12,131,146] They can usually be easily separated by their clinical features, morphology, and immunophenotype (Table 91.5). The disorders most likely to be confused with hairy cell leukemia are the hairy cell variant, B-cell prolymphocytic leukemia, and splenic marginal zone lymphoma (SML)/SLVL.[146]

The *HCL variant* makes up 10% to 20% of all HCL cases and was originally described as having morphologic features intermediate between hairy cells and prolymphocytes and nowadays is classified by the World Health Organization (WHO) as being a separate disease from classical HCL.[12,155,156] However, there are other presentations of the HCL variant, including hybrid forms of HCL and prolymphocytic leukemia or CLL, a blastic form of HCL, and an HCL multilobular form.[155,156,157–161] These patients have many of the clinical and laboratory features of typical HCL. The HCL variant differs from typical HCL in a number of ways[155,156]:

(a) Patients are older with a median age at diagnosis of 71 years.
(b) The peripheral leukocyte count is higher (often $>50 \times 10^9$/L).
(c) The hairy cells have a higher nuclear-to-cytoplasmic ratio with more condensed nuclear chromatin and more prominent nucleoli than in classic HCL.
(d) The cells are TRAP-, CD25-, and CD123-, are usually IgVH unmutated, frequently use the IgVH4–34 gene, and do not have the *BRAF* (V600E) mutation.
(e) The monocyte count is normal.
(f) The marrow can usually be aspirated and there is an interstitial pattern of infiltration in the marrow with variable fibrosis.
(g) The clinical course is aggressive with a poor response to therapy and the median survival is 9 years.

B-cell prolymphocytic leukemia may have a presentation very similar to that of HCL, with splenomegaly and minimal or no peripheral lymphadenopathy.[162] Prolymphocytic leukemia can usually be distinguished from HCL in that the nuclear chromatin is more clumped than in hairy cells, the level of peripheral lymphocytosis is high, the TRAP stain is negative or only weakly positive, and expansion of the white pulp in the spleen is evident. Cells can be differentiated from hairy cells by tissue markers.[142]

In *SLVL,* previously known as *malignant lymphoma simulating leukemic reticuloendotheliosis*[163] and now considered to be one of the SMZLs,[12] the white cell count is usually higher than in HCL, being 3 to 38×10^9/L.[163,164] Typically, these patients have prominent splenomegaly and no lymphadenopathy. The leukemia cell is smaller and frequently contains a nucleolus, and the villi are shorter, fewer, and more uneven than in a typical hairy cell and are frequently concentrated at one end of the cell. A small monoclonal band is found in the serum or urine in two thirds of patients and patients may develop a Coombs-positive autoimmune hemolytic anemia.[164] Marrow involvement is patchier without the "fried-egg" pattern or reticulin fibrosis; in the spleen, the white pulp is expanded, and there is a variable degree of red pulp expansion without pseudosinus formation.[163,164] Immunophenotyping can also assist in differentiating these cells from hairy cells.[13] Although these cells have many markers similar to those of hairy cells, only 25% of cases are $CD25^+$, and these do not have the other classic markers for HCL (strong staining for CD11c, CD103, and CD123). In *marginal zone B-cell lymphoma*, the pattern of bone marrow infiltration also tends to be patchy or focal without reticulin fibrosis, but in the spleen, the infiltration is predominantly in the red pulp, such as occurs in HCL.[124] In *nodal marginal zone lymphoma* (*monocytoid B-cell lymphoma)*, the infiltrates resemble those of HCL, but the clinical presentation is different.[12,13] These patients usually have peripheral lymphadenopathy without splenomegaly and a high incidence of extranodal involvement. Bone marrow involvement is less frequent and usually is paratrabecular; peripheral blood involvement is rare. In lymph nodes, the infiltration is interfollicular and sinusoidal, often with preservation of some lymph follicles, a finding similar to that seen in hairy cell involvement of lymph nodes.

Patients with *CLL/small lymphocytic lymphoma (SLL)*, *lymphoplasmacytic lymphoma*, *primary splenic CLL*, and *mantle cell lymphoma* can have the same clinical presentation as HCL, but the laboratory features are quite different.[12,131] The cytologic appearance of the malignant cells on Wright stain and the appearance and distribution of the infiltrates in the bone marrow, spleen, and lymph nodes distinguish these disorders from HCL. In CLL/SLL, the lymphocytes are small with scant cytoplasm and clumped nuclear chromatin. The bone marrow usually is diffusely involved in CLL, but a focal interstitial pattern may be evident early in the course of the disease. In SLL, the bone marrow may not be involved early in the course, and the pattern initially is more focal. Involved lymph nodes in SLL and CLL show diffuse infiltration with small mature lymphocytes that completely efface the nodal architecture. The spleen shows not only white pulp expansion, but also a variable degree of red pulp expansion. The malignant lymphocytes in CLL/SLL are $CD5^+$ in contrast to hairy cells, which are $CD5^-$. In the lymphoplasmacytic disorders, particularly Waldenström macroglobulinemia, splenomegaly, peripheral lymphadenopathy, and a variable degree of pancytopenia are a more common presentation. As with hairy cells, these malignant B-cells are $CD5^-$, but they are $CD103^-$ and usually $CD11c^-$ and $CD25^-$. In addition, the cytologic appearance (plasmacytoid lymphocytes) and the frequent presence of a serum IgM monoclonal spike distinguish them from HCL. Although mantle cell lymphoma is usually associated with generalized lymphadenopathy, splenomegaly may be a prominent feature. Again, this lymphoma can be differentiated from HCL by the cytologic appearance of the cells, immunophenotyping, and the pattern and nature of the infiltration in lymph nodes, spleen, and bone marrow. The malignant cells are small, mature lymphocytes with scant cytoplasm, a round or cleft nucleus, and clumped nuclear chromatin. The bone marrow may demonstrate diffuse or patchy involvement. Lymph nodes are diffusely infiltrated and often show expansion of the mantle zone with residual isolated benign-looking germinal centers. A similar pattern is seen in the expanded white pulp in the spleen with a variable degree of red pulp expansion.

Various *myeloproliferative disorders* present with splenomegaly without peripheral lymphadenopathy, but the diagnosis is established easily by bone marrow biopsy and the findings on a peripheral blood smear.

TABLE 91.6

HAIRY CELL LEUKEMIA: DIFFERENTIAL DIAGNOSIS

Splenic marginal zone lymphomas/splenic lymphoma with villous lymphocytes
Hairy cell variant
B-cell prolymphocytic leukemia
Chronic lymphocytic leukemia/small lymphocytic lymphoma
Lymphoplasmacytoid lymphoma, including Waldenström macroglobulinemia
Mantle cell lymphoma
Myeloproliferative disorders
Malignant histiocytosis
Primary lymphoma of spleen
Monocytoid B-cell lymphoma
Large granular lymphocytic leukemia
Systemic mast cell disease

Malignant histiocytosis occasionally is associated with splenomegaly as the predominant manifestation.[165] The characteristic cytologic and cytochemical features of the malignant histiocytes and the subsequent course of the disease make the process of differential diagnosis easy.

Rarely, a diagnosis cannot be made for a patient with symptomatic splenomegaly short of splenectomy; these patients may have primary lymphoma of the spleen[166] or, less commonly, primary splenic HCL.[167]

LGL leukemia frequently presents with splenomegaly without peripheral lymphadenopathy.[168] The disease is characterized by the presence of cells that are bigger than CLL cells and have abundant cytoplasm containing azurophilic granules. LGLs may be $CD3^-$ NK-cells that mediate nonmajor histocompatibility complex-restricted cytotoxicity, or they are $CD3^+$ cells, that may be in vivo activated cytotoxic T-lymphocytes that mediate nonmajor histocompatibility complex-restricted cytotoxicity.[168] T-LGL leukemia is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis, but is a distinct entity from Felty syndrome.[168] The usual immunophenotype of T-LGL leukemia is $CD3^+$, $CD4^-$, $CD8^+$, $CD16^+$, $CD56^-$, $CD57^+$, and $TCR\alpha\beta^+$. NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia. However, chronic NK-LGL leukemia can occur with clinical features similar to those of T-LGL leukemia.[168] These cells are usually $CD3^-$, $CD4^-$, $CD8^-$, $CD16^+$, $CD56^+$, and $CD57^-$.

Systemic *mast cell disease,* in which splenomegaly may be a prominent feature, rarely presents a problem in differential diagnosis, except for the appearance of the mast cell infiltrates in tissue sections that can closely mimic HCL.[169]

More recently, a condition called *hairy B-cell lymphoproliferative disorder* (HBLD) has been described in five patients from Japan.[170,171] All patients were middle-aged women who presented with clinical and laboratory features consistent with the HCL variant and had a polyclonal increase in IgG. However, the hairy cells were polyclonal. This condition is thus similar to persistent polyclonal B-cell lymphocytosis, a rare and benign condition seen typically in middle-aged female smokers with a familial tendency.[172–174] The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in IgM and a strong association with HLA-DR7.[172] However, HBLD differs from persistent polyclonal B-cell lymphocytosis in that the patients in HBLD are not smokers, there is a polyclonal increase in IgG in HBLD as opposed to the polyclonal increase in IgM seen with persistent polyclonal B-cell lymphocytosis, the cells in HBLD are not binucleated, are $CD11c^+$, and there is no association with HLA-DR7 in HBLD. The disorder needs to be differentiated from the HCL-Japanese variant (HCL-JV) which is similar to the HCL variant in having splenomegaly, a high peripheral leukocyte count with hairy cells, and does not have the diagnostic markers of classical HCL (Table 91.5).[156] However, in contrast with the HCL variant, the clinical course of HCL-JV is indolent and similar to classical HCL.

TREATMENT

Although splenectomy used to be the standard treatment for HCL, therapy for this disease over the past quarter of a century has usually involved IFN-α, the nucleoside analogs, and rituximab.[136,175,176] Splenectomy and IFN-α may still be used for HCL under specific circumstances, but the standard therapy consists of the nucleoside analogs pentostatin or cladribine, which produce complete and durable remissions in the majority of patients. More recently, it has been demonstrated that the monoclonal antibody rituximab, which is directed against CD20, and the immunotoxins LMB-2 and BL22, which are directed against CD25 and CD22, respectively, have significant activity against nucleoside-resistant HCL. As discussed, there has also been recent interest in combining the nucleoside analogs with rituximab. Defining the optimal strategy for this combination with respect to schedule of drug administration and numbers of doses of the monoclonal antibody will require additional investigation.

Splenectomy

Until the mid-1980s, the standard therapy for HCL was splenectomy.[5,177,178,179,180] The variable degree of pancytopenia in all patients during the course of their disease is partly related to splenomegaly.[80,81–83] An enlarged spleen may be responsible for the development of peripheral cytopenias by one or more of three mechanisms: increased sequestration or pooling, increased rate of peripheral destruction, or dilution of the cellular elements in the peripheral blood by an expanded plasma volume.[80,81–83] Other clinical manifestations, such as hypermetabolism, weight loss, early satiety, and left upper quadrant abdominal discomfort, are also caused by splenomegaly. Occasionally, patients may achieve a complete remission (CR) with splenectomy, and these patients may have a pure "splenic" form of HCL.[2] Approximately two thirds of patients have a hematologic response to splenectomy; the procedure may also alleviate early satiety, weight loss, and abdominal discomfort.[5] However, it is unclear whether this procedure prolongs survival, because all the studies are retrospective, and, because of the obvious clinical benefit of splenectomy, randomized prospective trials have not been carried out.[5] Early studies, with small numbers of patients, demonstrated no overall improvement in survival for patients after splenectomy.[177,178] However, in a large, multicenter retrospective analysis of 391 patients, a highly significant survival advantage ($P < 0.0001$) was demonstrated for those patients who underwent splenectomy.[179] In the multicenter analysis, CR, defined as a postsplenectomy hemoglobin >11 g/dl, neutrophils $>1 \times 10^9$/L, and platelets $>100 \times 10^9$/L, was achieved in 40% of patients.[179] An increase was noted in the hemoglobin in 92%, neutrophils in 84%, and platelets in 92% of patients.[179] Jansen et al.[179] also reported that patients with larger spleens responded better than those with smaller spleens, but this has been disputed.[180] The duration of response after splenectomy is variable, but some patients remain asymptomatic for years. Approximately one third, however, achieve only a minimal response or relapse within a few months. In an analysis of prognostic variables after splenectomy in 194 patients, the most important were bone marrow cellularity and the platelet count.[181] *Failure-free survival*, defined as time from splenectomy to death or the need for more therapy, was significantly worse if the postoperative bone marrow cellularity was ≥85% or the platelet count was $<60 \times 10^9$/L, or both.[181]

Although splenectomy is now rarely required in HCL, it may be of value for patients with splenic rupture, patients with the pure "splenic" form of the disease, and patients with splenomegaly and profound thrombocytopenia, having megakaryocytes in the marrow.[5]

Interferon-α

IFN-α, both the natural form and the two recombinant forms (IFN-α2a and IFN-α2b), is effective in the treatment of HCL,[182–188,189,190,191] and a recent study has provided insight into the mechanism for this activity.[192] IFN-α has been shown to induce apoptosis in nonadherent hairy cells; this is related to an increase in the production of TNF by the hairy cells associated with sensitization of the hairy cells to TNF-α.[192] The sensitization is due to a decrease in the levels of inhibitors of apoptosis (IAPs) by IFN-α. It is interesting that IFN-α does not induce apoptosis in hairy cells adhering to vitronectin or fibronectin, because IFN-α does not affect the IAPs in adherent cells. The receptors for TNF-α are not changed by IFN-α. These results may explain why IFN-α can clear

hairy cells rapidly from the bloodstream, but not from the tissues, in which the leukemic cells presumably are adherent.

A CR was defined as normalization of the peripheral blood counts (hemoglobin >120 g/L, platelets >100 × 10^9/L, and neutrophils >1.5 ×10^9/L) for at least 1 month with no morphologic evidence of hairy cells in the marrow or peripheral blood and resolution of organomegaly. A partial remission (PR) was defined as the normalization of peripheral blood counts and the persistence of >5% hairy cells in the marrow; however, treatment must have produced a >50% fall in the hairy cell infiltration in marrow. The aggregate results show that the overall response rate with IFN-α is ~80%, with 13% having a CR and 69% having a PR.[189–191] Responding patients have a reduced incidence of infections, even if they remain neutropenic.[187] The responses occur rapidly, regardless of whether the patients have previously had a splenectomy, with hairy cells disappearing from the peripheral blood within the first week; the platelet counts return to normal within 2 months, the hemoglobin level within 4 months, and the neutrophil counts within 4 to 6 months.[182,187] The percentage of hairy cells in the bone marrow decreases, but they rarely disappear completely, and the reticulin fibrosis persists.[193,194] Patients with $CD5^+$ hairy cells[195] and HCL-variant patients[149] respond poorly to IFN-α.

The optimal dose schedule for IFN-α- in HCL has yet to be established. In most series, the dose is 2 to 4 × 10^6 U/m^2 subcutaneously (SC) three to seven times weekly for 12 months. Higher doses do not appear to increase the response rate and are associated with more toxicity.[186,196] In addition, extending the treatment beyond 12 months does not improve the response rate, and the development of a chronic fatigue syndrome is more prevalent and severe.[197] Doses 1 log lower (2 × 10^5 U/m^2 three times weekly) show activity, but the response is inferior to that achieved with higher IFN-α doses.[198] However, the relapse rate is high (33% to 77%) after the discontinuation of IFN-α, usually 6 to 31 months after cessation of therapy.[188,199] It has been demonstrated that maintenance low-dose IFN-α (1 × 10^6 U, three times/week, or 3 × 10^6 U, once per week) can prolong remissions with minimal toxicity.[191,200,201] In one study, patients received either no maintenance therapy or 1 × 10^6 U IFN-α three times/week; 37 of the 56 patients who did not receive maintenance therapy relapsed at a median time of 19 months, whereas none of the 28 patients receiving maintenance therapy relapsed, with the median follow-up time being 30 months.[200] When patients relapse after IFN-α therapy, a further remission can generally be obtained with IFN-α[200,201] or the nucleoside analogs.[136,175,176] In addition, patients who relapse after therapy with the nucleoside analogs may respond to IFN-α, confirming the lack of cross-reactivity between these agents.[202]

Neutralizing anti-IFN antibodies appear to develop in one third of patients treated with IFN-α2a,[203] but this does not occur with IFN-α2b.[204] The clinical significance of these neutralizing antibodies and their role in the induction of resistance to therapy are controversial. In 51 patients with HCL treated with INF-α2a, 31 (61%) developed antibodies after a median of 6 months of therapy, and in 16 of these, the antibodies neutralized the antiviral activity of recombinant INF-α2a in vitro but had no effect on natural IFN-α.[203] It is interesting that six of the patients with antibodies were clinically resistant to IFN-α, whereas none of the patients without antibodies were resistant. However, in a follow-up study, no further patients were noted to have developed antibodies, and antibodies to IFN could no longer be detected in patients who previously had antibodies, although they continued to receive IFN-α.[205]

Virtually all patients experience toxicity with IFN-α therapy, and the frequency and severity are dose- and age-related. Flu-like symptoms occur in most patients with the initiation of treatment; these symptoms can usually be controlled with acetaminophen or by reducing the IFN-α dosage, and symptoms usually resolve within 2 to 4 weeks. Less common symptoms include: nausea and vomiting; diarrhea; central nervous system manifestations, such as somnolence and confusion; cardiovascular disorders, including hypotension and tachycardia; and skin changes, such as rash and pruritus.[196] With high doses, leukopenia, thrombocytopenia, and anemia may occur, but this is rare with the doses of IFN-α used for HCL. A worsening of pre-existing autoimmune disorders, or the emergence of new autoimmune problems, has also been reported with IFN-α therapy; this appears to be related to the development of multiple autoantibodies.[206] In most reports, patients developed thyroiditis, autoimmune thrombocytopenia, or anemia.[207,208] Kampmeier et al.[209] reported an increased incidence of second malignancies in HCL patients treated with IFN. Of 69 patients treated with IFN-α2b for 12 to 18 months, 13 (19%) developed second malignancies; this incidence was substantially higher than predicted. Six of the tumors were hematologic, and seven were adenocarcinomas. The tumors developed 17 to 105 months after the initiation of IFN-α. However, these results have not been confirmed, and no increase in the incidence of second malignancies was observed in 200 HCL patients in another study, of whom 147 had been treated with IFN-α.[210]

Nucleoside Analogs

The nucleoside analogs pentostatin (pentostatin; Nipent, SuperGen, San Ramon, CA), cladribine (cladribine; Leustatin, Ortho Biotech, Raritan, NJ), and fludarabine (F-ara-A AMP; Fludara, Berlex Laboratories, Richmond, CA) have significant activity in the low-grade lymphoid malignancies (Fig. 91.8).[136,175,176] Both pentostatin and cladribine have now replaced IFN-α as first-line therapy for HCL, and fludarabine is now one of the standard treatments for CLL.

After therapy with pentostatin, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyadenosine diphosphate, and deoxyadenosine triphosphate (dATP); this occurs preferentially in lymphocytes.[211] The intracerebral accumulation of deoxyadenosine and adenosine likely causes the nausea and vomiting that are a major toxicity of this agent.[212] Cladribine and F-ara-A are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-AMP (fludarabine), which is rapidly dephosphorylated in the plasma to F-ara-A.[213,214] As with deoxyadenosine, cladribine and F-ara-A accumulate in lymphocytes as their phosphorylated derivatives and their mechanisms of action have been recently reviewed.[215–217] These agents can kill lymphocytes in three ways (Figs 91.9 and 91.10).[215–217] First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome *c* from the mitochondria; the released cytochrome *c* interacts with Apaf-1 and dATP, causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of triphosphates can enhance the effects of endogenous dATP on the apoptosome, inducing apoptosis. Finally, cladribine differs from deoxyadenosine and F-ara-A in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to cdATP, which is directly toxic to the mitochondria.

Pentostatin is highly effective in HCL and produces a much higher rate of durable CR than is observed with IFN-α (Table 91.7).[189] Pentostatin has been administered in a variety of different doses and schedules for HCL, but regardless of the mode of administration, it produces responses in most patients. Of 960 patients in nine studies, the CR rate ranged from 44% to 89% (median, 76%), and the PR rate varied from 0% to 52% (median, 16%).[189,216,217,218–223,224,225] Patients who relapse after splenectomy or who are resistant to IFN-α also respond to pentostatin, with a median CR rate of 42% and a PR rate of 45%.[225,226,227] In two large studies, the response rates to pentostatin were

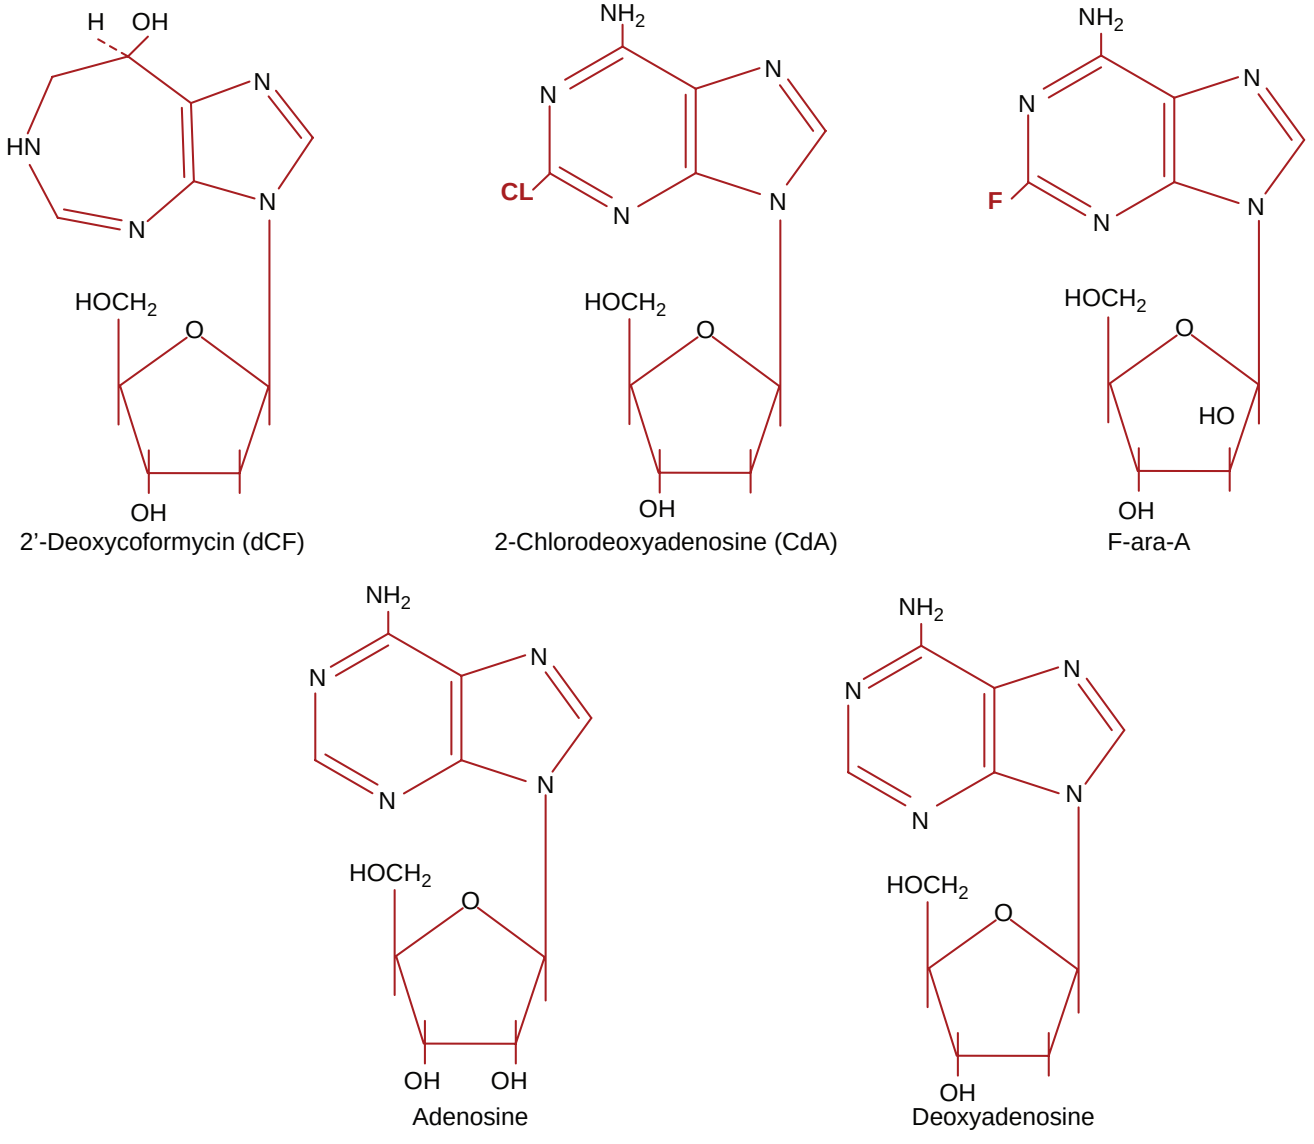

FIGURE 91.8. Structures of nucleoside analogs.

similar in untreated patients and in patients previously treated with IFN-α.[189,224] Moreover, these studies identified young age, initial high hemoglobin, high white cell count, and little or no splenomegaly as favorable prognostic features.[189,224] The most commonly used treatment regimen is pentostatin 4 mg/m^2 intravenously (IV) every second week; the average number of treatments to CR is 8 (range, 4 to 15).[189,220] The peripheral blood lymphocyte count falls rapidly after the initiation of treatment, with the hairy cell count decreasing by 50% to 95% in the first week.[228] Concomitantly, there is a rapid increase in platelets followed by recovery of neutrophils and hemoglobin; the median time to documented peripheral and marrow CR is 4 months.[228] In contrast to IFN-α, there is resolution of the marrow fibrosis after therapy with pentostatin.[228,229] Using immunophenotyping of peripheral blood or bone marrow, immunohistochemistry of the bone biopsy, or gene rearrangement studies, one can detect MRD in HCL patients who are in morphologic CR after pentostatin, suggesting that pentostatin cannot entirely eliminate the hairy cell population.[229,230] In addition, relapses are observed after discontinuation of treatment without evidence of a plateau, although the duration of remissions is considerably longer than for IFN-α.[189,221,231,232,233]

Several studies have evaluated the long-term outcome of patients treated with pentostatin[223,225,232–236] (Table 91.8). The longest follow-up is of 188 patients followed for a median of 14 years with the relapse rates at 5, 10, and 15 years being 24%, 42%, and 47%, respectively.[233] The likelihood of relapse depended on response and pre-treatment parameters with the longest remission being in those who achieved a CR and had a pre-treatment hemoglobin of >100 g/L and platelets >100 $\times$ 10^9/L, and the worst prognosis was in those who achieved a PR and were anemic and/or thrombocytopenic pre-treatment (Fig. 91.11).[233,234] For patients who remain in CR at 5 years the likelihood of remaining in CR by 15 years is 75%. For patients requiring another treatment, the likelihood of achieving a CR decreased but for those who did achieve a CR the prognosis was similar as for those with a first-time CR.[233,234]

In the Phase III intergroup study, patients were randomized to receive pentostatin, 4 mg/m^2 IV every 2 weeks, or IFN-α, 3 $\times$ 10^6 U SC three times per week.[189,236] Patients not responding to one treatment were switched to the other agent. There were 241 patients who received pentostatin and were followed for a median of 9.3 years; 154 received pentostatin as initial therapy, and 87 received pentostatin after failure with IFN-α. For all

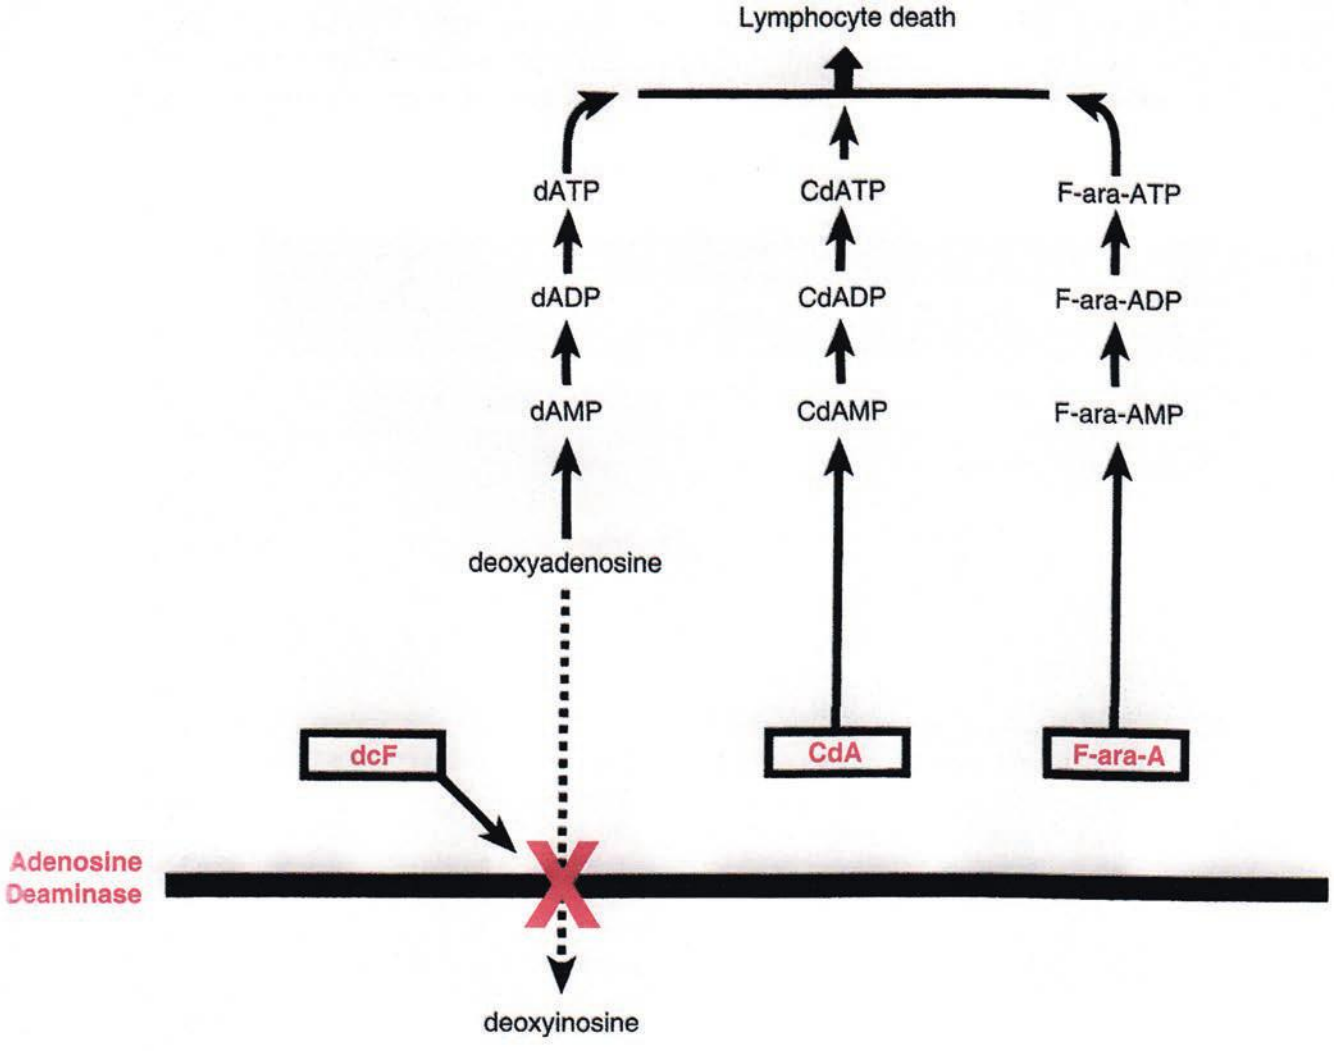

FIGURE 91.9. Metabolism of the nucleoside analogs. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; CdA, 2-chlorodeoxyadenosine; d, deoxy; dCF, 2′-deoxycoformycin.

patients, the estimated 5- and 10-year survivals were 90% and 81%, similar to those predicted for the general population. The survival was similar whether patients were treated initially with pentostatin or were crossed over to pentostatin after treatment with IFN-α (Fig.91.12A). Patients younger than 55 years of age did significantly better than patients 55 years of age or older, and the 10-year survivals for the two groups were 93% and 68%, respectively (Fig. 91.12B). Similarly, in a large multicenter retrospective study from France, the estimated survivals at 5 and 10 years in 230 evaluable patients treated with pentostatin were both 89%.[224] In that study, a hemoglobin level <100 g/L, a white cell count $<2 \times 10^9$/L, and lymphadenopathy were associated with decreased survival.

Pentostatin is generally well tolerated, although nausea and vomiting and lethargy can occur.[189,216,217,,218–223,224,225] Drug-induced neutropenia with fever commonly occurs with initiation of treatment and deaths from infection have occurred. However, for patients receiving 4 mg/m^2 pentostatin every 2 weeks, infections can be avoided by delaying the treatments if the white blood count is $<1.5 \times 10^9$/L.[220] Pentostatin decreases the number of T-cells to a greater extent than that of B-cells, and CD4$^+$ cells are affected to a greater extent than CD8$^+$cells or NK-cells, whereas Ig levels are not affected.[229,237–239] The CD4$^+$ and CD8$^+$ cell counts fall to $<0.2 \times 10^9$/L during therapy;[229,237,238] after discontinuation of pentostatin, the CD4$^+$ counts gradually recover and normalize in 3.0 to 49.5 months (median, 14.5 months).[229] The CD8$^+$ and B-cells recover at the same rate.[229,237,238] Associated with the decrease in T-cells during therapy is an increase in the incidence of herpetic infections, which are easily treated with acyclovir, and there is a gradual decrease in the incidence after discontinuation of therapy.[229,237,238] However, there is no increase in more unusual opportunistic infections, either during therapy or during long-term follow-up, and there is no evidence of a significant increase in second malignancies.[233,236] Although neurotoxicity is a problem with high doses of pentostatin,[240] this is not observed with the doses used for HCL.

Cladribine appears to have activity equivalent to that of pentostatin in HCL, and has the advantage of rarely causing nausea and vomiting although it appears to be more myelosuppressive.[233,234,241–248,249,250,251–253] In initial studies, cladribine was administered as 0.1 mg/kg/day by continuous infusion for 7 days, because in vitro studies indicated that a prolonged exposure to cladribine was required for cytotoxic effect.[246] Response rates varied, with the CR ranging from 50% to 91% (median, 80%) and PR from 0% to 37% (median, 16%).[241–247,248,249,250,251–253]

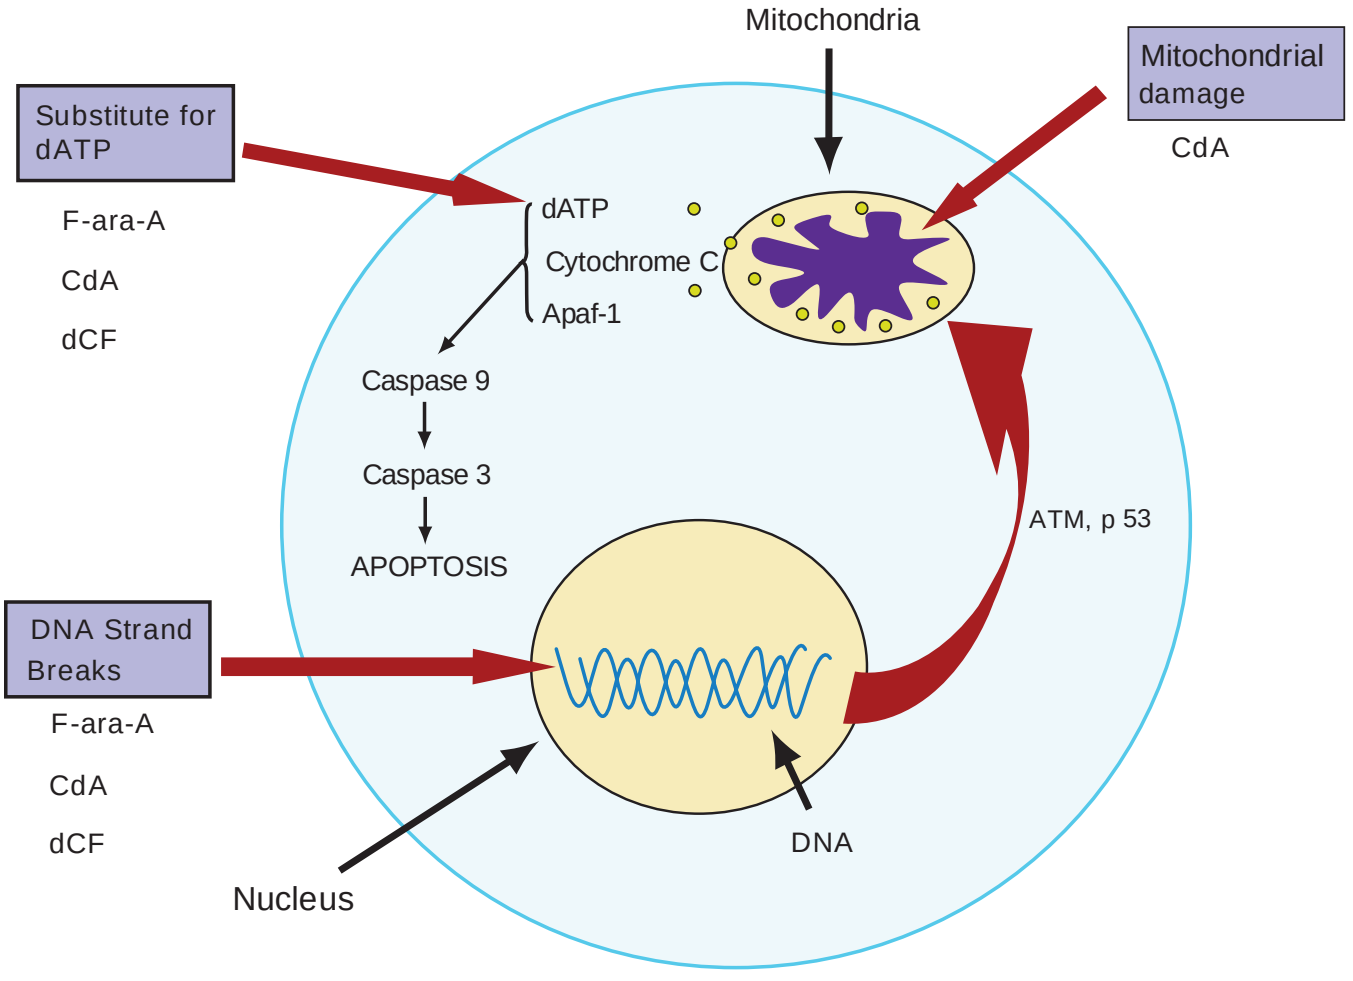

FIGURE 91.10. Mechanism of action of the nucleoside analogs. CdA, 2-chlorodeoxyadenosine; dATP, deoxyadenosine triphosphate; dCF, 2′-deoxycoformycin. (Modified from Genini D, Adachi S, Chao Q, et al. Deoxyadenosine analogs induce programmed cell death in chronic lymphocytic leukemia cells by damaging the DNA and by directly affecting the mitochondria. Blood 2000;96:3537–3543, with permission.)

As with pentostatin, there was a rapid recovery in blood counts, with the platelet count increasing almost immediately, followed by an increase in neutrophils and hemoglobin. Some patients achieved a CR with normal blood counts, whereas the marrows remained hypocellular.[254] Technetium 99 m sulfur colloid scans have demonstrated increased uptake in the distal appendicular skeleton in some of these patients, suggesting abnormal areas of hematopoiesis.[254] Although hairy cells may not be seen in the marrow 3 to 4 months after cladribine treatment, the leukemic cells can still be detected by immunostaining, using the monoclonal antibody, DBA.44,[255] or by using the (PCR) with clonospecific probes for *IGH* genes.[256] When marrows were intermittently examined by DBA.44 for 25 months after treatment with cladribine, there was no increase in the number of hairy cells in the marrow in most cases, suggesting stabilization of residual disease.[255] However, others have suggested that the presence of residual disease is predictive of relapse.[257] Because cladribine has not been compared with pentostatin in a randomized study, it is unknown whether one of these agents is superior in terms of toxicities and long-term outcomes (Table 91.8). However, in patients achieving a CR morphologically, Tallman et al.[257] demonstrated with immunohistochemical stains that there is evidence of residual disease comparable to that observed after pentostatin. Moreover, Else et al.[233] have recently carried out a retrospective analysis of patients treated either with pentostatin or cladribine at the Royal Marsden Hospital. The overall response rates and survivals were the same for both drugs. In a large, long-term study from the Scripps Clinic, 91% of patients achieved a CR with cladribine, and these 349 patients were followed for a median of 52 months (range, 1 to 134 months).[248] Of these patients, 24% relapsed at a median time of 30 months (range, 7 to 85 months). The overall survival at 48 months was 96%. The same group has evaluated 207 patients followed for at least 7 years,[249] and 37% relapsed with patients achieving a CR relapsing later (median 44 months [8 to 118 months]) than those who achieved PR (median 31 months [10 to 108]). Of 60 patients who received a second cycle of cladribine, 75% achieved a CR and 17% a PR. It is interesting that19 of 358 patients treated at Scripps have remained in long-term remission after a single cycle of cladribine. The median time from cladribine was 16 years and 9 had no evidence of MRD, 7 had MRD, and 3 had morphologic evidence of HCL.[253]

A number of patients who were resistant to pentostatin have obtained remissions with cladribine, suggesting a possible lack of cross-resistance between these agents.[224,258] This may be related to the additional action of cladribine on the mitochondria of the leukemia cells.[215,216] Likewise, some patients who have not achieved a CR with cladribine have also achieved durable remissions with pentostatin. Therefore, the overall response rates and relapse rates are comparable with either purine analog.

Cladribine can be toxic and was implicated as the cause of deaths in the National Cancer Institute group C Phase II study in

TABLE 91.7

RESPONSE RATES WITH DIFFERENT AGENTS AND TREATMENT SCHEDULES FOR HAIRY CELL LEUKEMIA

Agent	Author[Ref] (Year)	Dose and Schedule	Number of Patients	CR (%)	PR (%)
Interferon-α

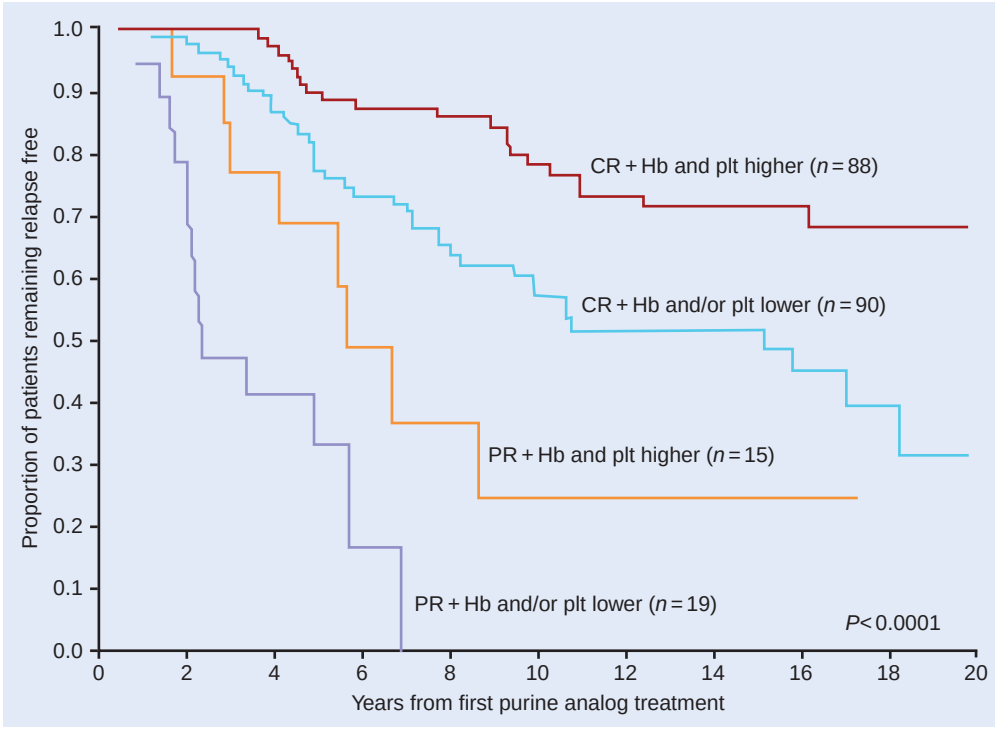

FIGURE 91.11. Relapse-free survival after first-line purine analog therapy. Patients were separated by pre-treatment blood counts and response to therapy. Relapse-free survival was longest in complete responders (CR) with hemoglobin (Hb) >100 g/L and platelet count >100 × 10^9/L (CR + Hb and Plt higher) and shortest in partial responders with hemoglobin <10 g/dl and/or platelet count <100 × 10^9/L (PR + Hb and/or Plt lower). (From Else M, Dearden CE, Mastutes E, et al. Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. Br J Haematol 2009;145:733–740, with permission.)

1.1% of 979 patients.[247] The major cladribine toxicity is marrow suppression; one third to one half of patients developed severe neutropenia with infections and often required prolonged blood support after therapy. This problem is not prevented by prophylactic antibiotics, and, although an infectious cause for the fever is not found in most cases, affected patients may require hospitalization for septic workup and antibiotics. The likelihood of this complication occurring increases with the severity of initial marrow involvement, and it has been suggested that these patients should initially be treated with IFN-α.[259] Alternatively, to reduce the risk of infections, granulocyte colony-stimulating factor has been administered using 5 μg/kg/day SC on days −3, −2, and −1 before a standard 7-day course of cladribine, and then after cladribine until the neutrophil count was >2 × 10^9/L for

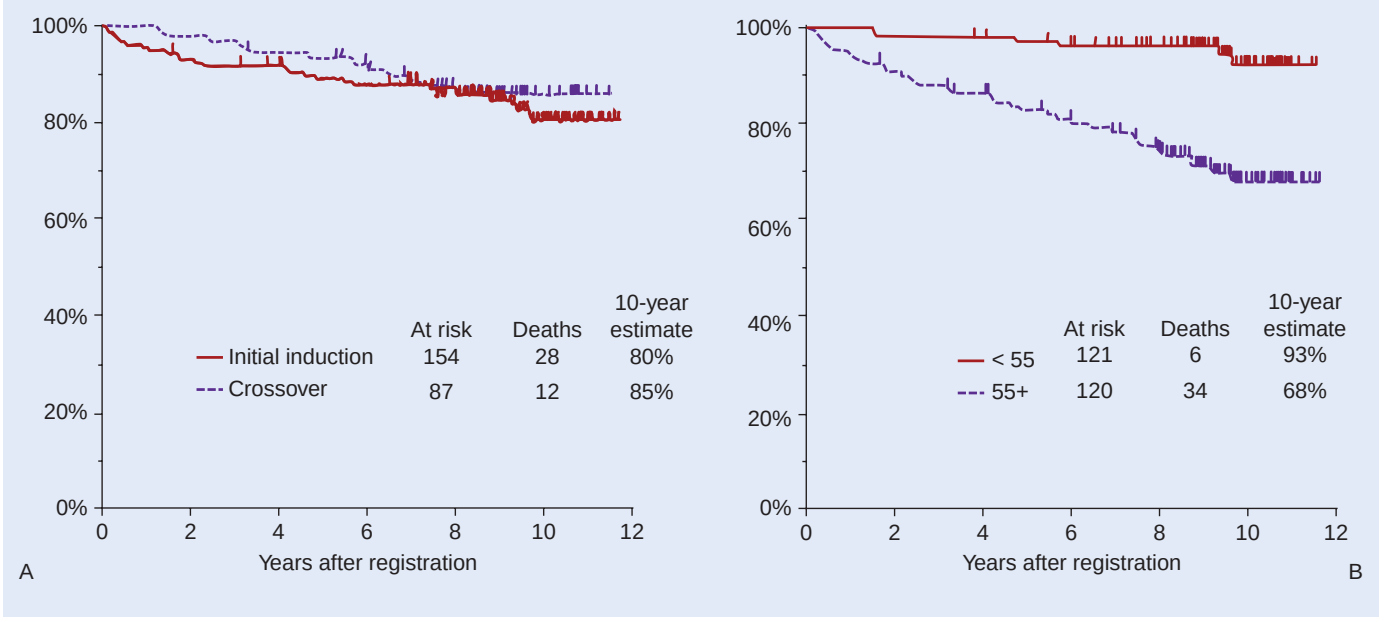

FIGURE 91.12. Long-term responses to treatment with the nucleoside analogs. A: Survival of patients treated initially with pentostatin or after crossover from interferon-α. Survival is similar in both groups ($p = 0.59$). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for 2′-deoxycoformycin (dCF) therapy, by phase of treatment. **B:** Overall survival by age of patients treated with dCF. Survival is significantly better for patients younger than 55 years of age ($p < 0.0001$). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for dCF therapy, by age at start of initial therapy. (From Flinn IW, Kopecky KJ, Foucar MK, et al. Long-term follow-up of remission duration, mortality, and second malignancies in hairy cell leukemia patients treated with pentostatin. Blood 2000;96:2981–2986, with permission.)

2 consecutive days.[260] Although granulocyte colony-stimulating factor increased the neutrophil count before therapy and reduced the severity of neutropenia after cladribine, there was no decrease in the number of febrile episodes and the number of hospitalizations for antibiotics. An identical phenomenon is observed after treatment of HCL with pentostatin,[218,231] and it has been suggested that the fever is related to tumor lysis and the release of cytokines by the tumor.[244] It is important to realize that patients with active infection were not eligible to participate in the initial cladribine trials. Thus, a patient with hairy cell leukemia who requires therapy, but has an active infection, presents a challenging dilemma. In general, it is important to try to treat any infection before administering a purine analog and if there is urgency in treating the leukemia initial therapy with IFN should be considered. Alternatively, pentostatin has been administered to patients with infection when therapy was essential and the incidence of febrile neutropenia may be less following pentostatin than seen with cladribine. The intermittent schedule of drug administration following pentostatin affords an opportunity to titrate the drug administration depending upon the neutrophil count. It is clear that the optimal management of patients with hairy cell leukemia with a concommitant active infection requires further investigation.

Cladribine also produces a profound fall in the $CD4^+$ and $CD8^+$ cell counts, and although $CD8^+$ cell counts may recover within 3 months, the $CD4^+$ count may take longer than 3 years to normalize.[261,262] Despite this, there have, to date, been no long-term problems with opportunistic infections after therapy with cladribine.[239,244] However, infections, sometimes opportunistic, do occur in some of these patients, and deaths have been reported.[243,263] More recently, Epstein-Barr virus, associated diffuse large B-cell non-Hodgkin's lymphoma, have been described in two patients shortly after completion of cladribine therapy.[264,265] Significant neurotoxicity has also been observed with cladribine and may involve the legs or arms.[247] Transfusion-associated graft-versus-host disease has been observed with multiple cycles of cladribine or fludarabine in low-grade lymphomas and CLL,[266,267] but, to the authors' knowledge, this has not yet been observed in HCL.

There has been interest in investigating different modes of cladribine administration to simplify the treatment and minimize toxicity. Liliemark et al.[268] demonstrated an identical "area under the curve" for drug concentration versus time using the same cladribine concentration given by continuous infusion, as a 2-hour infusion, or given orally using twice the IV dose. Similar responses have been obtained with cladribine in HCL using 0.1 mg/kg IV over 2 hours daily $\times$ 5[269] or 0.1 mg/kg SC daily $\times$ 7[270,271] and when the drug was administered as 0.1 mg/kg/day by continuous infusion $\times$ 7. Weekly cladribine (e.g., 0.14 to 0.15 mg/kg/week IV $\times$ 5 to 6 weeks) appears to be as effective as the other schedules.[272,273–276] However, although this regimen was initially felt to be associated with less marrow suppression and to be safer than conventional regimens, recent randomized studies demonstrated that the weekly regimen produced an equivalent incidence of infections and septic deaths as a standard regimen using 0.12 mg/kg over 2 hours daily $\times$ 5.[275,276]

Fludarabine has not yet been evaluated extensively in HCL. However, complete and partial responses have been observed in the few patients treated thus far.[277,278]

Monoclonal Antibodies

Monoclonal antibody therapy is an attractive option for HCL, because many patients have significant neutropenia at the time of diagnosis and the monoclonal antibodies should theoretically not worsen this problem. The chimeric monoclonal antibody rituximab (Rituxan; Genentech, Inc., South San Francisco, and IDEC Pharmaceuticals, San Diego, CA) contains a human IgG1 Ig constant region and a murine variable region directed against the cell-surface CD20, an antigen that plays an important role in the activation, proliferation, and differentiation of B-cells.[279] This agent has shown significant activity against the low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity by complement-dependent cytotoxicity, antibody-dependent cell-mediated cytotoxicity, or the direct induction of apoptosis.[279–281] Using rituximab, 375 mg/m^2 IV once per week for 4 weeks, response rates of 25% to 75% were observed with a variable number of CRs.[283,284,285,286,287] This variation may be related to the extent of prior treatment as the poorest responses were observed in heavily pre-treated patients.[284] A more prolonged duration of therapy may improve efficacy, and Nieva et al.[284] have observed a response rate of 80% with 53% CRs in 15 patients with relapsed or refractory HCL using 8 weekly treatments with rituximab. Kreitman and Pastan[288,289,290] have developed two immunotoxins directed against CD25 and CD22, which contain the modified light chains of the antibodies bound to a truncated form of the Pseudomonas exotoxin. The immunotoxin can kill the targeted cells through a variety of ways and the immune mechanisms utilized by rituximab are not required. BL22 is directed against CD22 and has undergone Phase I and II clinical trials, demonstrating a response rate of up to 72% with a CR rate of 47% in cladribine relapsed/resistant HCL patients.[290] Some of these responses can last many years. Patients with small spleens were more likely to respond with not statistically significant relationship between prior response to cladribine and response to BL22. One unusual toxicity with this regimen is a reversible form of the hemolytic uremic syndrome, which occurs in about 10% of patients and appears unrelated to depletion of plasma ADADTS13.[288,289,290] LMB-2 is a similar structured immunotoxin directed against CD25 which has also demonstrated activity in HCL.[288]

Repeated Treatments or Drug Combinations

As patients who achieve a CR appear to have a much longer remission than those who achieve a PR, attempts have been made to convert PR to a CR. The group at the Royal Marsden Hospital have demonstrated in 8 patients who achieved a PR with cladribine that a second course of treatment at 4 to 7 months led to a CR in 6 patients and the relapse-free survival was the same whether one or two cycles of therapy was required to achieve the CR.[233,234] An alternate approach has been to administer rituximab following chemotherapy to consolidate the remission. Thus, rituximab given 3 to 6 months following cladribine can increase the number of CRs without additional toxicity.[286] More recently, 36 patients (5 with HCLv) have been treated with a standard dose of cladribine followed 1 month later by rituximab 375 mg/m^2 IV weekly for 8 weeks.[287] All patients achieved a CR with 79% having a marrow clear of MRD; with a median follow-up time of 25 months (1 to 63 months), only 1 patient with HCLv has relapsed. Rituximab has also been co-administered with the nucleoside analogs with tolerable toxicity and high response rates.[288,291,292]

Other Treatments

Because HCL is now so easily and effectively treated with the nucleoside analogs, IFN-α, or the monoclonal antibodies, other treatments have become redundant. However, for completeness and interest, they are reviewed briefly. Chlorambucil was previously used when the disease progressed after splenectomy.[293,294] Although some patients improved, the course in others was often worse, with more myelosuppression. The best results were reported by Golomb et al.,[294] who administered chlorambucil, 4 mg orally/day for at least 6 months, to 24 post-splenectomy patients with progressive disease. A reduction in the number of circulating hairy cells and an increase in one or

more of the normal peripheral blood cellular elements occurred in most patients. Six deaths occurred, and time to response was 6 months or longer. Other chemotherapeutic agents, either alone or in combination, have demonstrated some benefit, but the toxic effects were often severe.[295,296] These agents included doxorubicin;[297] rubidazone;[298] combinations of rubidazone, cytarabine, and cyclophosphamide; or cytarabine and cyclophosphamide.[299] PRs also have been reported with androgens,[300,301] as well as with a combination of lithium carbonate and immunotherapy with Calmette-Guérin bacillus.[302] A transient increase in neutrophils can be obtained with granulocyte colony-stimulating factor and may be a useful adjunct to more definitive therapy.[260,303] Steroids are ineffective and increase the risk of infection.[4]

Bone Marrow Transplantation

One case of successful bone marrow transplantation from an identical twin has been reported.[304]

Leukapheresis

Clinical and hematologic improvements, lasting as long as 26 months, have been reported by using leukapheresis to reduce the number of hairy cells in the peripheral blood.[305,306] However, others have found the responses less predictable and more transient.[307]

Radiation Therapy

Low-dose radiotherapy to the spleen can produce transient clinical and hematologic improvements, but the response is slow and unpredictable.[308] However, radiation therapy can be effective for the treatment of massive retroperitoneal lymphadenopathy and lytic bone lesions.[309]

Treatment of Hairy Cell Leukemia Variant

In contrast to classical HCL, the HCL variant is notoriously difficult to treat. Splenectomy has been reported to produce partial responses in approximately half the patients with improvements in the blood counts.[155,156,157] Although response to the nucleoside analogs is generally poor, it is reasonable to treat these patients with a rituximab–nucleoside analog combination or to refer the patient for a clinical trial with a novel agent.[143,156,287–288,289,290,291,292]

SUMMARY

1. Asymptomatic patients with HCL may not require treatment; however, it is generally recommended to start therapy, when the hemoglobin is <120 g/L, platelets <100 × 10^9/L or neutrophils <1 × 10^9/L or if there is evidence of disease progression.[143,175] Patients with active HCL are at risk of infection related to neutropenia, monocytopenia, and lymphocyte dysfunction, and this will resolve after a remission is obtained. Persistent lymphopenia and lymphocyte dysfunction may persist for many months following the use of a purine nucleoside analog. Concommitant use of rituximab may further deplete the lymphocytes. Although the value of prophylactic antibiotics in otherwise healthy patients is unclear, patients with prior infections may require prophylaxis for herpetic infections and *Pneumocystis jirovecii* until the lymphocytes are ≥1 × 10^9/L.[143,176] In addition, it has been recommended by the British Guidelines that HCL patients who have been treated with a nucleoside analog should receive irradiated blood products for the rest of their lives, to prevent graft-versus-host disease.[143]
2. Our recommended approach to therapy is detailed in Figure 91.13. The standard therapy for HCL is with one of the nucleoside analogs, pentostatin or cladribine, which appear to have equal efficacy and produce CRs in the majority of patients. The survival of HCL patients nowadays is no different from age- and sex-matched controls. Cladribine appears to have similar efficacy as pentostatin and appears to have equal efficacy whether administered as 0.1 mg/kg/day × 7, by continuous infusion, or as 0.14 mg/kg/day × 5, as a 2-hour infusion or SC, or on a weekly schedule. Pentostatin is generally administered on a biweekly (4 mg/m^2 IV) basis. Because of the effectiveness of pentostatin and cladribine in HCL and the rarity of this disease, it is unlikely that there will be any prospective studies to compare the efficacy of these two agents and the different treatment regimens.

The major toxicity with the nucleoside analogs is myelosuppression and the risk of infections with initiation of treatment. As a result the authors prefer using pentostatin every other week or weekly cladribine with a blood count just prior to each treatment. For safety, the biweekly or weekly treatments are delayed until the neutrophil count is back to baseline or better. Both pentostatin and cladribine are excreted by the kidneys and the creatinine should be measured before each treatment and therapy only continued as long as renal function is not impaired. It has been suggested that 1.5 l of IV fluid be given with each pentostatin treatment.

Myelosuppression is most common in patients with severe marrow impairment; in such cases, it might be preferable to use IFN-α 3 × 10^6 units SC three times a week initially to obtain marrow clearing before treatment with a nucleoside analog. A morphologic CR can be obtained in ~75% of patients and a PR in 15% of cases, although residual hairy cells can invariably be detected by immunostaining, even with a morphologic CR. Remissions are prolonged, and most relapsing patients respond to a second cycle of therapy. It is unclear whether survival is longer for patients who achieve a CR or a PR. However, for patients who remain in CR for 5 years, the likelihood remaining in CR by 15 years is 75%.[233] Response to cladribine and pentostatin is poorer for patients with the HCL variant and for those with bulky abdominal lymphadenopathy.[310] Prognosis for patients treated with pentostatin is worse for those older than 50 to 55 years of age and those with a hemoglobin level <100 g/L and white cell counts <2 × 10^9/L.[224,233,236]

Patients should have a marrow test 6 months after starting cladribine or pentostatin and if there is residual disease, additional therapy with or without rituximab should be considered. The goal should be to strive for a CR, but to avoid excessive immunosuppressive and marrow toxicities remembering that long-term consequences (e.g., myelodysplasia or opportunistic infections) may result from excessive treatment.

3. IFN-α (3 × 10^6 U SC three times/week for 12 months) produces a lower response rate than the nucleoside analogs (8% CR and 74% PR), and relapses occur after discontinuation of the drug. However, IFN-α may be useful initially in patients with an active infection or severe neutropenia.
4. Initial studies with the monoclonal antibodies against CD20, CD22, and CD25 suggest that these agents may be useful for the treatment of patients refractory to the nucleoside analogs, for patients with poor marrow reserve, and for patients with the HCL variant. Preliminary studies have also shown that concomitant or sequential therapy using rituximab with a nucleoside analog is highly effective therapy, and probably should be considered as initial therapy for the HCL variant.
5. Two thirds of patients benefit from splenectomy, but a CR is rare. Splenectomy is required for patients who have a splenic

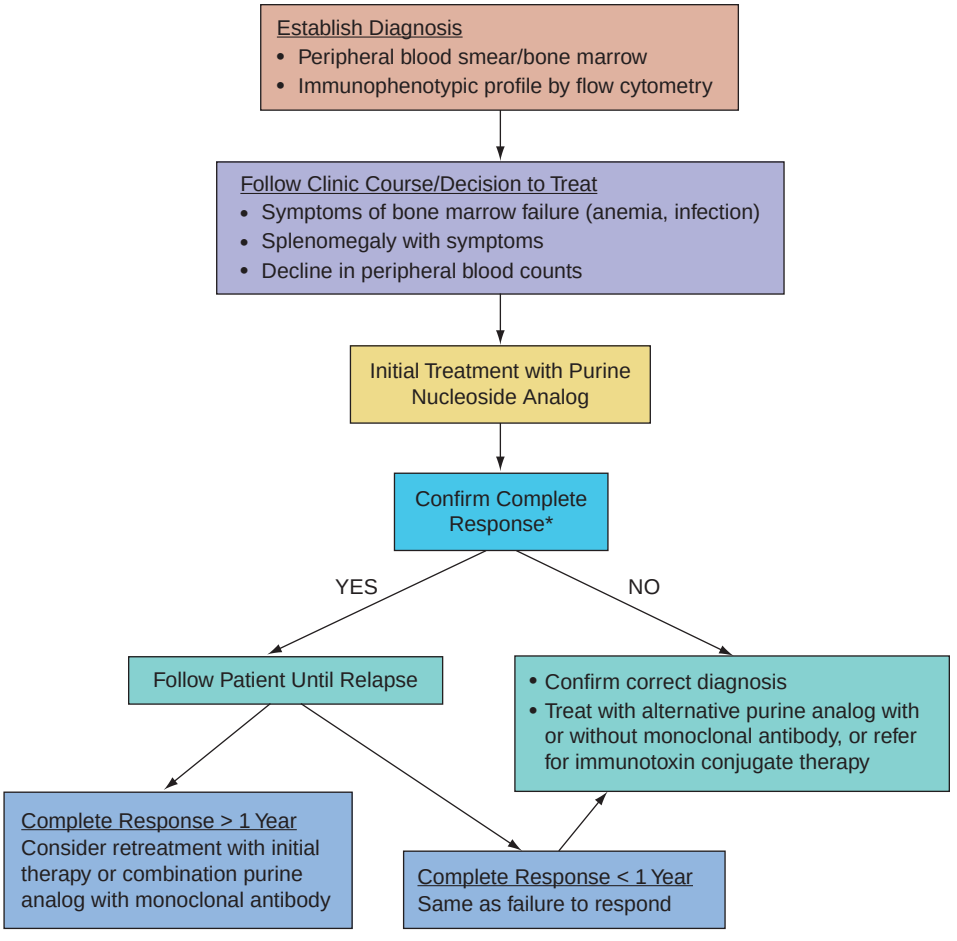

FIGURE 91.13. Recommended treatment schema for hairy cell leukemia (HCL). *Confirmation of a complete response: If patient is participating in a clinical trial, consider using flow cytometry or immunohistochemical stains on bone marrow to document minimal residual disease. It is difficult to require these added studies for patients being treated from a clinical protocol. (From Grever MR. How I treat hairy cell leukemia. Blood 2010;115:21–28, with permission.)

rupture and may be of value for patients with pure "splenic" HCL, as well as for patients who have severe thrombocytopenia with increased numbers of megakaryocytes in the marrow.

SECOND MALIGNANCIES

There has been controversy as to whether patients with HCL have an increased incidence of malignancies and whether this may be related to therapy.[210,224,236,247,248,311–314,315,316] Several studies have demonstrated an increased incidence of second tumors in HCL, and the incidence appears to be highest in the first 2 years after diagnosis. However, the increase may occur before the diagnosis of HCL, or concurrently, suggesting that these patients have an inherent tendency to develop second malignancies.[210,311,312] Kampmeier et al.[312] demonstrated that 19% of 69 patients observed for a median of 91 months after treatment with IFN-α developed a second malignancy, and the authors suggested that the increased incidence was related to the more prolonged survival of these immunocompromised patients rather than an effect of the IFN-α. However, it has been observed that the incidence of second malignancies is lower when patients are treated with pentostatin or cladribine than with IFN-α, suggesting that the second malignancies may be directly related to active HCL.[313] In 379 patients treated with cladribine, 22% developed a second malignancy (primarily solid tumors), a rate 2.03-fold higher than expected.[249] Those patients who had had a malignancy before the diagnosis of HCL had a 3.7-fold increased risk of developing a second cancer compared with those who did not.[249] However, Kurzrock et al.[314] observed a 7.4% incidence of second malignancies in 350 HCL patients after a mean follow-up of 7.1 years, and this incidence was not significantly greater than expected and was not influenced by treatment with IFN-α or the nucleoside analogs. Others have made similar observations.[224,236] In a large multicenter prospective crossover study with pentostatin and IFN-α and a median follow-up of 112 months, there was no increase in the number of second malignancies as compared with that of the control population.[236] However, a large Surveillance, Epidemiology and End Results (SEER) population study of 3,104 HCL patients collected between 1973 and 2002 has demonstrated an increased incidence of Hodgkin lymphoma, non-Hodgkin lymphomas, and thyroid cancer in HCL, but the overall increase in cancer rates was small with the probability of a second cancer being 31.9% at 25 years.[316]

PROGNOSIS

Before the availability of IFN-α and the nucleoside analogs, the median survival of HCL patients was 4.6 years for nonsplenectomized patients and 6.9 years for splenectomized patients.[2] However, the prognosis has improved markedly with present therapies, and the predicted 5- and 10-year survival rates for patients treated with the nucleoside analogs are now similar to those of the general population.[233,234,236] However, long-term follow-up is required to determine the relapse rate, the percentage of patients who become resistant to the nucleoside analogs and, subsequently, the monoclonal antibodies, and whether there will be long-term complications from these treatments.

CHAPTER 92

CUTANEOUS T-CELL LYMPHOMA: MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

John A. Zic, Jeff P. Zwerner, Laura Y. McGirt, Claudio A. Mosse, John P. Greer

Cutaneous lymphomas are a heterogeneous group of non-Hodgkin lymphomas (NHLs) of T- and B-cell origin in which the skin is the primary organ of involvement. Primary cutaneous lymphomas usually present without signs of extracutaneous malignancy at onset of symptoms; they represent an entity distinct from nodal lymphomas with secondary cutaneous involvement. In 1975, Lutzner, Edelson, and associates introduced the term cutaneous T-cell lymphoma (CTCL) to describe the spectrum of skin-based lymphomas of T-cell origin including classical mycosis fungoides (MF) and Sézary syndrome (SS).[1,2] This chapter is a review of the history, epidemiology, clinicopathologic features, and therapy of these lymphomas.

HISTORICAL PERSPECTIVE AND PATHOPHYSIOLOGY

Clinical Description

The first clinical description of MF was provided in 1806 by Alibert, a French physician, who identified a 56-year-old man presenting with skin tumors resembling mushrooms after having had a desquamating rash over several months; the lesions waxed and waned for 5 years before the patient died with a "hectic" fever.[3] In 1832 Alibert first used the term mycosis fungoïde in his treatise on diseases of the skin to describe the mushroomlike tumors.[4] Bazin described the three "classical" cutaneous stages in 1870: (a) the premycotic stage, which can be localized or diffuse with superficial eczematous or erythematous lesions; (b) the infiltrative plaque stage; and (c) the tumor stage.[5] The *mycosis d'emblée* variant, in which tumors develop rapidly without a preceding premycotic or plaque stage, was described by Vidal and Brocq in 1885.[6] In the early 1890s, Besnier and Hallopeau described the erythrodermic variant, which later became known as Sézary syndrome.[7,8]

Histopathology

By the end of the 19th century, most authorities agreed that the small round cells infiltrating the epidermis and forming tumors were lymphoid in origin.[9] Although the French authorities considered the disease lymphadenomatous in nature, the German, English, and American authorities were divided between sarcomatous and granulomatous (infectious) etiologies.[9,10]

The unique appearance of the cells involved in CTCL was identified in 1938 by Sézary and Bouvrain, who reported a triad of erythroderma, leukemia with circulating mononuclear cells that had convoluted nuclei, and adenopathy infiltrated with the same cells.[11] SS was recognized in the English literature by several groups in the 1950s, but it was not described in the United States medical literature until Taswell and Winkelmann at the Mayo Clinic in 1961.[12] In 1968, Lutzner and Jordan extended the light microscopic description of the Sézary cell by using electron microscopy to visualize the "serpentine" or cerebriform cell nucleus.[13]

Immunology

The 1970s witnessed the introduction of cellular immunology into the study of hematopoietic neoplasms, and in 1971 Crossen et al. confirmed the lymphocyte origin of SS.[14] In 1973, Broome et al.[15] and Brouet et al.[16] identified the neoplastic cell as a T-cell, and Broder et al. demonstrated in 1976 that the cells are usually of the helper phenotype ($CD4^+$).[17]

Studies performed in the early 1990s further characterized the circulating malignant T-cells in patients with SS as "memory" helper T-cells because of the expression of $CD45RO^+$.[18] In 1992, Vowels et al. detected a cytokine profile similar to that produced by murine Th2 cells from both stimulated peripheral blood mononuclear cells (PBMCs) and serum from patients with SS.[19] Further studies identified a Th2 cytokine profile (interleukin [IL]-4, IL-5, IL-6, IL-10) to be present in the skin of patients with MF and SS.[20–22] Increased levels of IL-4 and IL-5 produced by the malignant T-cell clone may account for the eosinophilia and increased levels of IgE and IgA in the serum of patients with advanced CTCL.[23] More recently, the Th17-associated proinflammatory cytokine, IL-17, has also been found to be up-regulated in MF skin lesions and appears to be activated through the Jak/Stat pathway.[24]

Immunologic studies have addressed the pathogenesis of MF and SS by examining the complex interactions among malignant cerebriform T-cells, keratinocytes, Langerhans cells, and other immunomodulating cells.[24] Lymphocytes (malignant and inflammatory) that home to cutaneous sites differ from lymphocytes in noncutaneous infiltrates by expressing the cutaneous lymphocyte-associated antigen (CLA), which binds to the endothelial cell adhesion molecule E-selectin (ELAM-1), which is preferentially induced on cutaneous venules.[25] Both circulating and skin-based malignant T-cells from patients with MF have been shown to express CLA, which may explain how the cells preferentially home into the skin (Fig. 92.1).[25,26] In addition, CLA^+ T cells selectively express CC chemokine receptor 4 (CCR4) and CCR10, whose ligands CCL17 (TARC) and CCL27 (CTAK) are generated by the lesional keratinocytes and also on the luminal surface of postcapillary venules in the skin.[25–28] Narducci et al. discovered that SS cells express a functionally active CXCR4 and that the ligand SDF-1 is abundantly produced in the skin, which represents the main destination of SS cell spreading.[29] SDF-1 is normally inactivated by proteolytic cleavage by the CD26/dipeptidylpeptidase IV (DPPIV). The lack of CD26 from the cell surface is a hallmark of circulating SS cells. Additionally, it has been found that fibroblasts from lesional CTCL produce increased levels of the chemokine eotaxin, which is also expressed at increasingly higher levels as the disease advances.[30] The only receptor for eotaxin is CCR3, which is found on Th2 lymphocytes and eosinophils, and may further explain why we see an increase of Th2 polarity as CTCL progresses.[30] Another recent report suggests that low herpes virus entry mediator (HVEM) expression on dermal fibroblasts in advanced CTCL skin attenuates expression of Th1 chemokines, which may contribute to a shift to a Th2-dominant microenvironment as disease progresses.[31]

Within the skin, the specific epidermotropism of the malignant T-cell is partially explained by the discovery of increased expression of intercellular adhesion molecule-1 (ICAM-1 or CD54) by epidermal keratinocytes in early MF lesions. The binding of ICAM-1 to LFA-1 (lymphocyte function-associated protein or CD18) expressed by lymphocytes may explain the histologic finding of atypical lymphocytes nesting within the epidermis.[32] Some authorities speculate that the expression of

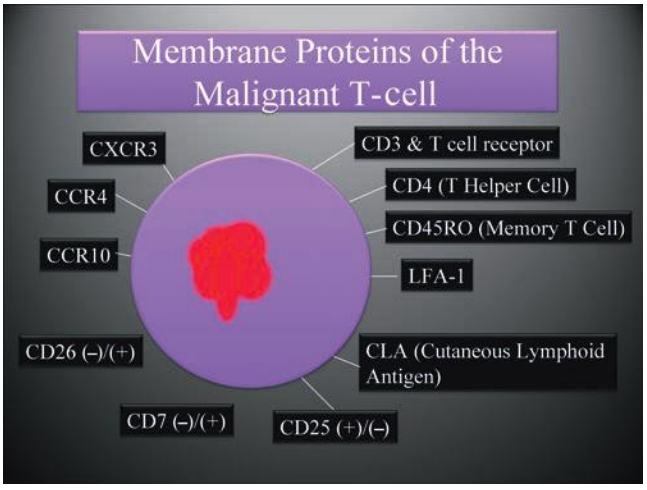

FIGURE 92.1. Membrane proteins of the malignant T-cell. The cutaneous lymphoid antigen (CLA) is a membrane protein expressed by a vast majority of T-cells found in inflamed skin including (CTCL). LFA-1 is a β_2 integrin expressed by all mature white blood cells.

ICAM-1 by keratinocytes is induced by the release of interferon-γ (IFN- γ) from infiltrating $CD8^+$ T-cells or natural killer (NK) cells responding to the malignant T-cell population within the dermis (Fig. 92.2).[23] Adhesion molecules other than ICAM-1/LFA-1 have been implicated in the phenomenon of epidermotropism and include E-cadherins, CD58/CD2, B7/CD28, CD49a (VLA-1), CD49c (VLA-3), and CD49f (VLA-6).[28] Soluble chemotactic factors may also play a role in the epidermotropism of MF. The expression of the CXC chemokine IP-10 (IFN-γ–inducible protein-10), which is chemotactic for $CD4^+$ lymphocytes, has been shown to be markedly increased by basal and suprabasal keratinocytes in MF lesions.[33] Several studies suggest that in early MF, epidermal Langerhans cells convert to hyperstimulatory antigen-presenting cells ($CD1a^+$, $CD1b^+$, $CD36^+$) with a high expression of Class II MHC molecules and adhesion molecules capable of activating tumor-infiltrating lymphocytes.[23]

More advanced lesions of MF, characterized clinically as tumors or generalized erythroderma, often demonstrate a loss of epidermotropism, with malignant T-cells infiltrating the deep dermis.[28] In 1989, Nickoloff et al. found markedly diminished ICAM-1 expression by keratinocytes in a patient with SS,[34] and similar findings in tumor-stage patients were reported by Vejlsgaard et al..[35] Rook et al.[36] have suggested that unknown mechanisms lead to an evasion of the host immune response, with subsequent expansion of the malignant clonal population and increased production of IL-4. Increased levels of IL-4 could inhibit the production of IFN-γ, leading to decreased ICAM-1 expression by keratinocytes and thus reduced binding of malignant T-cells within the epidermal compartment (Fig. 92.3).[36] In addition, CXCR3, a T-cell chemokine receptor, has been shown to be expressed by lymphocytes in early-stage MF but absent in cases of transformed MF, when epidermotropism is often absent.[37] Others have suggested that the expression of CCR7 by some peripheral blood Sézary cells may enhance their ability to home into lymph nodes.[38] Indeed, a recent study revealed a disparate chemokine receptor expression profile in leukemic CTCL cells as compared to CTCL cells isolated from lesional skin. The leukemic cells had strong expression of CCR7, L-selectin, and CCR4, whereas the cells from CTCL skin expressed CCR4 and CLA.[39] The results of these investigators suggest that SS is a malignancy of central memory T-cells and MF is a malignancy of skin-resident effector memory T-cells.[39]

As the disease progresses, cell-mediated immunity, critical for tumor cell recognition and destruction, is slowly dismantled. IL-4 and IL-10 secreted by the malignant T-cell may inhibit Th1 cells responsible for coordinating cell-mediated immune functions.[23,40,41] Also, the inhibition of IL-12 secretion from macrophages may diminish the cytokine's stimulatory effect on CD8-cytotoxic T-cells.[23] With Th1 cells, CD8-cytotoxic T-cells, macrophages, and NK cells partially disabled, the malignant clone can escape immune surveillance and proliferate.[40,41]

Molecular Genetics

Clonality in T-cell lymphoma was difficult to establish before the development of molecular genotyping methods in the 1980s. Initial evidence of clonality in MF/SS was provided by cytogenetic analysis.[42,43] Several of these early studies demonstrated the same abnormal clone in separate lesions from skin, peripheral blood, lymph nodes, and bone marrow.[42,43]

The identification of a defined cytogenetic abnormality would be a major advance in the diagnosis and our understanding of the pathogenesis of MF/SS. Unfortunately, to date, no such abnormality has been identified consistently in MF, with most reported findings being largely of a random nature.[44,45] Some of the specific chromosomal deletions and amplifications that have been identified in CTCL include 8q gains, 10q and 17p deletions,

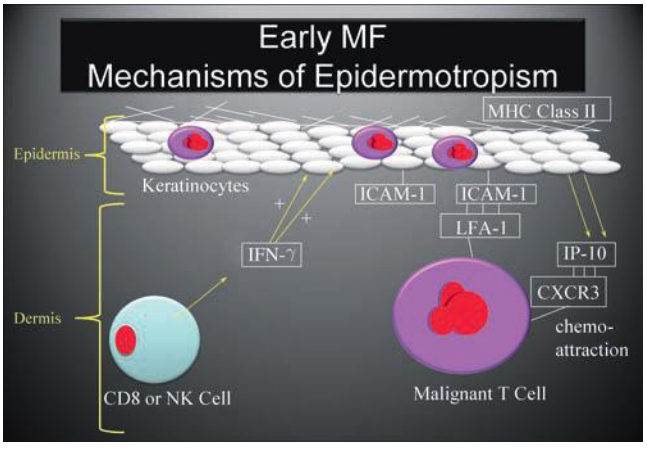

FIGURE 92.2. Early (CTCL): mechanisms of epidermotropism. The release of interferon (IFN) γ by early, reactive CD8 cytotoxic T-cells or natural killer (NK)-cells leads to increased keratinocyte expression of intercellular adhesion molecule-1 (ICAM-1) and release of the CXC chemokine IP-10, which binds to the CXCR3 receptor, and may lead to nesting of CTCL cells within the epidermis.

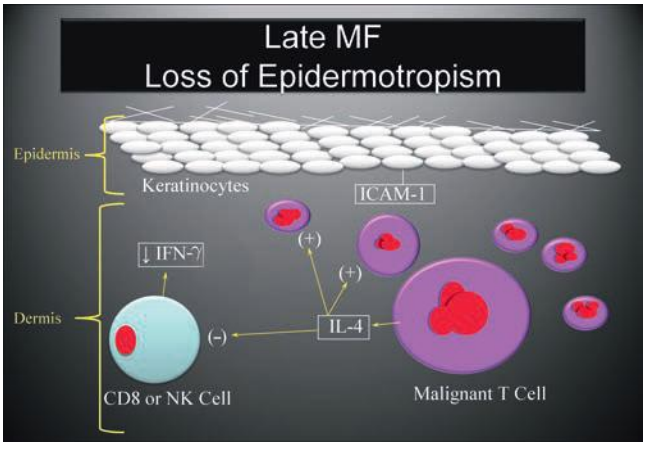

FIGURE 92.3. Late cutaneous T-cell lymphoma (CTCL): loss of epidermotropism. As the clonal population of CTCL cells expands, more IL-4) is released which drives autocrine-induced proliferation of the CTCL cells and inhibition of CD8 cytotoxic T-cells and natural killer (NK)-cells. The impaired release of interferon (IFN) γ may lead to less ICAM-1) expression and decreased keratinocyte-CTCL cell adhesion. MF, mycosis fungoides.

and 17q gains (isochromosome 17).[46–50] Abnormalities in chromosome 10 have been correlated with progression to tumor stage, including loss of heterozygosity on 10q and microsatellite instability.[51] Salgado et al. demonstrated through comparative genomic hybridization oligonucleotide array that in tumor-stage MF, loss of 9p21.3 (encodes *CDKN2A* and *CDKN2B*) and 10q26qter, and gain of 8q.24.21 were associated with decreased survival.[52] Additionally, $p16^{INK4a}$, a protein coded at the 9p21 locus, has been shown to be silenced in tumor-stage MF.[53] Microsatellite instability was detected in 16 of 56 patients with CTCL that may be a consequence of *hMLH1* promoter hypermethylation and may prevent transcription in a subset of patients.[54] van Doorn and colleagues reported that the malignant T-cells of patients with CTCL display widespread promoter hypermethylation associated with inactivation of several tumor-suppressor genes involved in DNA repair (*MGMT, MLH1*), cell-cycle (*CHFR*), and apoptosis signaling pathways.[55] Recently, comparative transcriptome analysis was performed on tissue from patients with early-stage MF and benign dermatoses that identified increased expression of the TOX protein in MF. TOX is strongly expressed in thymic tissue but is normally silenced in mature $CD4^+$ T-cells.[56] It may prove to be useful as an immunohistochemical diagnostic marker.

Overexpression of the tumor-suppressor gene *TP53* has been detected in some cases of high-grade CTCL such as cutaneous anaplastic large-cell lymphoma (ALCL), but rarely in low-grade CTCL.[57] Infrequent *FAS* mutations, but no *BAX* or *TP53* mutations, were discovered in a study of 44 patients with early MF.[57] Aberrant expression of the *BCL-2* gene, which normally codes for an inner mitochondrial membrane protein, can suppress apoptosis, an important pathogenic mechanism in lymphomas. Although Dummer and colleagues detected *BCL-2* expression in 22 of 26 MF cases; it was also present in 5 of 6 cases of benign inflammatory dermatoses.[58] A cDNA microarray study of 29 cases of MF and 11 cases of inflammatory dermatoses revealed a signature of 27 genes implicated in the tumorigenesis of MF, including tumor necrosis factor receptor–dependent apoptosis regulators, *STAT4*, *CD40L*, and other oncogenes and apoptosis inhibitors.[59] Loss of SHP-1 tyrosine phosphatase expression appears to correlate with the advanced stages of CTCL.[60] The epigenetic silencing of *SHP-1* is induced by an activated phosphorylated (p)-STAT3 transcription factor in cooperation with DNA methyltransferase 1, the key member of the epigenetic gene silencing machinery.[60] *JUNB* amplification leads to enhanced Th2 cell function, a hallmark of the malignant T-cell in CTCL. Mao and colleagues reported the amplification and overexpression of JUNB in tissue from patients with CTCL.[61] Recently, mutations involving the RAS pathway have been identified in a minority of CTCL.[62]

The small, single-strand, noncoding RNAs, known as microRNAs (miRNAs), have been found to be differentially expressed in MF/CTCL.[63,64] A CTCL miRNA signature (miR-155, miR-203, and miR-205) has been identified in a recent study and is capable of distinguishing between CTCL and benign inflammatory dermatoses with 95% accuracy.[64] It has also been demonstrated that there is a loss of miR-223 and miR-342 in SS versus normal $CD4^+$ T-cells and that the reduced miR-342 leads to inhibition of apoptosis in CTCL cells.[65]

In 1985 Aisenberg et al. and Weiss et al. independently described Southern blot analysis techniques using probes for the β chain of the T-cell receptor (*TCR*) to establish clonality in T-cell lymphoproliferative disorders.[66,67] Because earlier cytogenetic studies suggested that CTCL arises from a single malignant clone of mature T-cells,[42] the presence of *TCR* β-chain rearrangement in pathologically suspicious tissue has been considered strong evidence for the diagnosis of CTCL.[68] However, in early lesions of MF (patch stage), when the number of infiltrating malignant T-cells is minimal, the Southern blot technique fails to detect clonal T-cell populations consistently. Other limitations of the Southern blot technique include its necessity for large amounts of preserved DNA, as well as its extensive time and labor requirement.[69] Therefore, the detection sensitivity of Southern blotting of DNA derived from skin biopsy specimens of early lesions is too low and may fail as a diagnostic test when the clinical and histologic diagnosis is most difficult.[70]

More sensitive techniques involving polymerase chain reaction (PCR) have been developed to evaluate clonality in CTCL and related skin diseases and are now considered the methods of choice.[71,72] The PCR is an in vitro imitation of the enzymatic DNA repair and replication that takes place in all proliferating cells, but it amplifies short specific lengths of DNA of the order of 10^9 to 10^{12} and therefore permits the use of very small amounts of starting DNA. Although the vast majority of CTCL express the α/β *TCR* heterodimer, most labs using the PCR technique take advantage of the fact that all α/β *TCR*-positive T-cells also contain at least one rearranged allele of the *TCR* γ-chain gene.[73] The γ gene contains a very limited number of clinically significant V segments (8) and C regions (2), making it possible to use specific primers for all known *TCR* γ V segments.[74] It is estimated that this PCR-based technique in combination with high-resolution nondenaturing polyacrylamide gel electrophoresis is 10 to 50 times more sensitive than conventional Southern blot analysis in the detection of small T-cell clones.[72] Several studies have shown a sensitivity of 90% to 95% using the PCR technique, indicating that up to 10% of cases of CTCL may show no *TCR* rearrangement even with this sensitive technique.[71,75,76] Given that some *TCR* β rearrangements may be missed with conventional *TCR* γ primers, there are those who recommend use of both *TCR* γ and *TCR* β primers.[77] It is important to note that clonality does not indicate malignancy, as suggested by one study in which 25% of tissue from patients with lichen planus, a benign dermatosis, were found to have *TCR* gene rearrangements using the PCR technique.[75]

In the late 1990s, a European consortium of 45 laboratories (BIOMED-2 Concerted Action BMH4-CT98-3936) was initiated with the aim to establish a highly reliable standard in PCR-based clonality testing, for B-cell as well as for T-cell malignancies.[78] Because of the higher speed, efficiency, and sensitivity of the BIOMED-2 multiplex PCR protocol, it can reliably replace Southern blot analysis in clonality diagnostics in routine laboratory settings.[79] Expertise with clonality diagnostics and knowledge about the biology of *TCR* gene recombination are essential for correct interpretation of *TCR* clonality data.[78] Patel and colleagues recently showed that combining *TCR*-γ primers with *TCR*-β primers significantly improved the sensitivity of *TCR* gene analysis, to 94%.[80] Yang et al. used the strategy of multiple PCR/heteroduplex analysis for *TCR*-γ gene rearrangement combined with a laser-capture microdissection proteinase K approach to increase the detection rate of clonal *TCR*-γ gene rearrangement in early MF cases.[81] This approach could provide strong evidence to confirm the diagnosis of early MF when the diagnosis can be most challenging.

EPIDEMIOLOGY

The incidence of the primary CTCLs has risen dramatically and consistently since 1973.[82] Based on data from the Surveillance, Epidemiology, and End Results (SEER) Program of nine cancer registries, the incidence of CTCL in the United States increased from 2.8 to 6.3 to 9.6 cases per 1 million population in the periods 1973 to 1977, 1988 to 1992, and 1998 to 2002, respectively.[82] During the period 1973 to 2002, the overall annual age-adjusted incidence of CTCL for the original nine SEER registries was 6.4 per million persons, representing 4% of all reported NHLs.[82] Bradford et al. reported an age-adjusted CTCL incidence of 7.7 per million persons from 2004 to 2005.[83] Because the number of patients with early-stage MF often is not reported to tumor registries, the actual incidence may be higher. In one study, missed

cases were estimated to constitute 17% of MF.[84] Thus, using the most recent incidence rate, the incidence of new cases of CTCL in the United States in the first decade of the 21st century is almost 3,000 cases per year. The incidence of MF increases with advancing age, and the median age is usually between 60 and 70 years, with an incidence rate of 24.6 per million for persons 70 to 79 years of age and a peak around 80 years of age.[82,83] It is rare in patients <30 years of age. However, in the 1990s there emerged several reports of children and adolescents affected with MF and SS.[85–87] One study found that 4% to 5% of patients with MF had onset of their eruption before 20 years of age,[87] whereas the more recent epidemiologic study by Criscione and Weinstock showed only 1% of cases of CTCL to be in the <20 years age group.[82] A study from the International Childhood Registry of Cutaneous Lymphoma found the mean age of onset and diagnosis of pediatric cutaneous lymphoma to be 7.5 years (±3.8 years) and 9.9 years (±3.4 years), respectively.[88]

Blacks are more likely to develop MF compared to whites, 9.0 to 10.0 versus 6.1 to 8.1 per million incidence rates, with the greatest racial differences seen among the younger patient populations.[82,83] Both Asian/Pacific Islanders and Hispanic whites have an incidence rate of 5.1 per million.[83] Men are significantly more likely to develop CTCL than women, with an age-adjusted incidence rate almost twice that of women.[82,83] The epidemiologic study by Criscione and Weinstock found the incidence rates of CTCL to be correlated with high physician density, high family income, high percentage of population with a bachelor's degree or higher, and high home values, suggesting that increased detection of CTCL may play a role in the increased incidence rates since 1973.[82]

The etiology of MF/SS remains unknown, but genetic, environmental, and infectious agents have been implicated as possible factors in triggering lymphocyte activation and/or lymphocyte transformation.[89,90] A recent study found that not only did the antioxidative effects of wine consumption fail to protect against the development of MF, but patients who consume >24 g of alcohol per day demonstrated a higher incidence of MF than matched controls (adjusted odds ratio 3.02, 95% confidence interval 1.34 to 6.79).[91] Also significant was that the alcohol effect remained constant regardless of beverage type.

Rare familial clusters of CTCL cases have been reported,[92] and an increased incidence has been noted in patients with certain histocompatibility antigens.[93,94] A rare case of transformed CTCL developing in a husband and wife suggested a common environmental or infectious exposure in the etiology of their disease.[95] Early reports implicated an increased risk of developing CTCL in people employed in a manufacturing occupation, particularly those related to petrochemicals, textiles, or metals, or in farming, with exposure to pesticides or herbicides.[96] However, two case-control studies have failed to confirm these observations.[97,98] Results of other studies have suggested that patients with MF have increased contact allergies, but Whittemore et al. were unable to substantiate the association in a case-control clinical study.[98]

Human retroviruses have been suggested as possible etiologic agents in CTCL. HTLV-I was described initially in a CTCL patient who had an aggressive clinical course; however, this disease was later identified as adult T-cell leukemia/lymphoma (ATL), which is endemic to Japan, the Caribbean, and other areas of the world but can have cutaneous lesions similar to CTCL (see ATL in Chapter 88).[99] Serologic findings for HTLV-I/II in patients with CTCL are negative in the vast majority of patients.[100–102] In support of the association of HTLV-I/II and MF, virus particles indistinguishable from HTLV-I have been identified using electron microscopy on immortalized MF cells,[103] and combined PCR/Southern blot analyses have demonstrated HTLV *pol*, *tax*, and/or *rex* sequences in PBMC lysate extracts and lesional skin from patients with MF/SS.[100,104–106] Further support of a potential HTLV-1/CTCL association was suggested after inoculation of immunosuppressed rats with PBMC extracts from patients with MF/SS. A novel anti-HTLV-I antibody was detected in the serum of 29% of the animals, whereas PBMC from healthy controls did not elicit an anti-HTLV-1 antibody response. These findings lend further support to the role of HTLV-1 as being at least a co-factor in the pathogenesis of CTCL.[107] Based on these studies, some authors contend that the strongest evidence of an etiologic/pathogenic factor for CTCL relates to the presence of a defective or variant HTLV-I virus.[70,104] Other authorities,[101,102,108,109] however, disagree, citing seven series that found no proviral HTLV-I sequences in 332 CTCL patients[101,110–115] and four studies that detected the proviral sequences in 10% of 176 patients.[116–119] Future development of advanced molecular techniques should eliminate the difficulty of establishing with certainty the presence or absence of HTLV-I proviral sequences in patients with CTCL.[108,120] More recently, there have been studies evaluating the presence of HHV-8 and the Merkel cell polyoma virus, but neither of these infectious agents has been significantly identified.[121,122] A separate group evaluated MF skin samples for the presence of multiple infectious agents (HTLV, Epstein-Barr virus, and *Borrelia burgdorferi*) and found that 21/83 MF samples had two or more infectious agents identified as compared to 1/83 healthy controls.[123]

CLINICAL PRESENTATION

MF usually evolves over a long period, so patients often have a long premycotic or pre-malignant phase with eczematous skin eruptions between 4 and 10 years before a histologic diagnosis is established.[70] The differential diagnosis during this period includes chronic eczematous, atopic or contact dermatitis, which may evolve slowly into eruptions clinically suggestive of parapsoriasis *en plaque*, poikiloderma atrophicans vasculare, or other benign papulosquamous skin diseases.[124] Failure of the lesions to respond to standard topical therapy may be an early clue of a different diagnosis. However, initial lesions occasionally appear to improve following topical steroid application, which masks early recognition of the underlying malignancy.[125] Because of the difficulty in diagnosis in the premycotic phase of MF, careful follow-up with serial skin biopsies is warranted in patients with suspect lesions (see section "Diagnostic Evaluation").

The earliest diagnostic phase of MF is the patch phase, characterized by persistent scaly macules and patches that vary in size, shape, and color, tend to involve sun-protected sites, and are occasionally associated with pruritus (Fig. 92.4A).[5,124,126] Early MF patches and plaques, unlike other eczematous eruptions, are usually asymptomatic. Other, less common early skin findings in MF include poikiloderma,[127] hypopigmentation,[128] hyperpigmentation (Fig. 92.4B), alopecia, pruritus alone,[129–131] and porokeratosis-like lesions.[132] Recently, several cases of "invisible MF" were described. Afflicted patients presented only with persistent, generalized pruritus and no clinical eruption.[129–131] Random biopsies of "normal" skin confirmed the diagnosis of MF.

Plaques are sharply demarcated, scaly, elevated lesions that may have annular, arcuate, or serpiginous borders (Fig. 92.4C). Plaques with thick scale can mimic psoriasis or nummular eczema, whereas annular lesions with central clearing may be confused with tinea corporis.[124] Ultraviolet radiation occasionally induces regression of patches and plaques, further delaying correct diagnosis. Prominent involvement of the palms and/or soles may result in hyperkeratosis, fissuring, or frank keratoderma (Fig. 92.4D).[133]

The tumor phase is heralded by the onset of dome-shaped, deep red to violaceous nodules emerging in areas of uninvolved skin or in pre-existing plaques.[124] The tumors may ulcerate and become secondarily infected (Fig. 92.4E), and there is a predilection for the body folds and face, where dermal

See text for full description.

thickening, coalescing plaques, and tumors may result in characteristic "leonine facies" (Fig. 92.4F). The tumor stage is more clinically aggressive than the patch and plaque stages, and may be associated with histologic transformation to a large cell process with a vertical growth phase (see section "Histopathology and Prognosis").[124] Rarely, patients with MF will present initially with tumors without the preceding patch and plaque phases (the MF *d'emblée* variant).[6,134] It is very common for more advanced patients to have patches, plaques, and/or tumors present simultaneously on different areas of their skin.[70]

Generalized erythroderma may develop as the initial presenting sign of MF/SS or may accompany plaques and tumors.[70] In SS, the leukemic variant of CTCL, erythroderma, and circulating tumor cells (Sézary cells) in the peripheral blood may be accompanied by generalized lymphadenopathy, splenomegaly, keratoderma, vitiligo-like hypopigmented patches,[135] alopecia,

ectropion, nail dystrophy, and ankle edema.[136] Intense pruritus and cutaneous pain are common in SS, and when the palms and soles are affected with scaling and fissuring, walking and manual dexterity become difficult.[136]

CLASSIFICATION OF CUTANEOUS T-CELL LYMPHOMAS

The term cutaneous T-cell lymphoma or CTCL is a general term that encompasses a variety of diseases, including MF and SS. In addition, there are other cutaneous T-cell lymphoproliferative disorders that appear to be specific entities with unique clinical, histologic, and prognostic features. In an effort to recognize the separate disease processes, a new classification of primary cutaneous lymphomas was formulated jointly by the World Health Organization (WHO) and the European Organisation for Research and Treatment of Cancer (EORTC) in 2005 (Table 92.1).[137] The most recent WHO classification of tumors of hematopoietic and lymphoid tissues presented in 2008 essentially mirrors, with a few exceptions, the 2005 WHO-EORTC classification scheme.[138,139] MF is the most common subtype, accounting for almost 50% of all CTCL, and this term should be used only for patients with the classic presentation of patches and plaques with slow progression as described by Alibert and Bazin.[137] The WHO-EORTC classification recognizes three variants of MF and the T-cell lymphoproliferative disorder lymphomatoid papulosis (LyP) as a distinct subtype of CTCL for the first time. The following sections focus on the histopathology and immunopathology of MF, SS, and the other types of primary CTCLs.

TABLE 92.1

WHO-EORTC CLASSIFICATION OF CUTANEOUS LYMPHOMA

Cutaneous T-cell Lymphomas
Mycosis fungoides[a]
Variants of MF:
Folliculotropic mycosis fungoides[a]
Pagetoid reticulosis[a]
Subtype of MF:
Granulomatous slack skin[a]
Sézary syndrome[b]
$CD30^+$ lymphoproliferative disorders of the skin
Lymphomatoid papulosis[a]
Primary cutaneous anaplastic large-cell lymphoma[a]
Subcutaneous panniculitis-like T-cell lymphoma[a]
Primary cutaneous T-cell lymphoma, unspecified[c]
Provisional entities:
Primary cutaneous epidermotropic $CD8^+$ T-cell lymphoma (provisional)[b]
Cutaneous $\gamma\delta$-positive T-cell lymphoma (provisional)[b]
Primary cutaneous $CD4^+$ small/medium-sized pleomorphic T-cell lymphoma[a]
Extranodal NK-/T-cell lymphoma, nasal type[b,d]
Adult T-cell leukemia/lymphoma[d]
Cutaneous B-cell Lymphomas
Primary cutaneous marginal zone B-cell lymphoma (MALT-type)[a]
Primary cutaneous follicle center lymphoma[a]
Follicular, follicular and diffuse, diffuse growth patterns
Primary cutaneous diffuse large B-cell lymphoma, leg type[e]
Primary cutaneous diffuse large B-cell lymphoma, other[e]
Intravascular large B-cell lymphoma[d,e]
Precursor Hematologic Neoplasm
Blastic plasmacytoid dendritic cell neoplasm (previously $CD4^+$/ $CD56^+$ hematodermic neoplasm)

EORTC, European Organization for Research and Treatment of Cancer; MALT, mucosal associated lymphoid tissue; MF, mycosis fungoides; NK, natural killer WHO, World Health Organization.

[a]Indolent (5-year disease-specific survival >75%).

[b]Aggressive (5-year disease-specific survival <25%) clinical behavior.

[c]Aggressive (5-year disease-specific survival <25%) clinical behavior (excluding provisional entities).

[d]Typically, an extracutaneous lymphoma with skin as a secondary site.

[e]Intermediate (5-year disease-specific survival 25% to 75%).

Modified from Willemze R, Jaffe ES, Burg G, et al. WHO-EORTC classification for cutaneous lymphomas. Blood 2005;105:3768–3785.

DIAGNOSTIC EVALUATION

Tissue Handling

Skin biopsies for diagnosis of MF/SS must be properly handled to maximize the diagnostic information obtained. These studies include routine histology, immunophenotyping, and molecular genotyping. Communication between the clinical staff, dermatologists, and pathologists is essential to ensure that the appropriate types of biopsies are done and are properly handled. In general, 6-mm punch biopsies are recommended. Multiple biopsies from different skin lesions may be necessary to establish a definitive diagnosis of MF/SS, particularly in early-patch–stage lesions. Topical steroids may blunt many of the histologic features of MF/SS and should be discontinued for 2 to 3 weeks prior to biopsy. A careful drug history should be taken prior to biopsy, because certain drug eruptions can closely mimic early MF, particularly phenytoin and other anticonvulsants.[140] Although advancements in immunohistochemical protocols and molecular diagnostics allow most studies to be performed on formalin-fixed tissue, optimally skin biopsies for possible CTCL should be sent to the pathology or dermatopathology lab fresh, on saline-soaked gauze or in tissue culture media such as RPMI. These biopsies can then be divided for the various diagnostic studies. Punch biopsies can be divided into halves, one half for routine histology and the other half for immunophenotyping and/or molecular diagnostic studies. Sections for routine histology should be fixed in a good nuclear fixative such as B5 to facilitate evaluation of nuclear morphology and recognition of characteristic cerebriform cells. If it is a large biopsy of a cutaneous tumor or a lymph node biopsy, it may provide adequate tissue to prepare cell suspensions for immunophenotyping by flow cytometry and for cytogenetic studies. The tissue for immunophenotyping by flow cytometry should be promptly delivered to the appropriate laboratory in cell culture media. Tissue for molecular studies should be snap-frozen in liquid nitrogen and stored at –70°C. For leukemic infiltrates, cytochemical stains can be performed on air-dried touch imprints from freshly cut surfaces. A small sliver of the biopsy can be shaved off and fixed in glutaraldehyde for electron microscopy if needed. Lymph nodes should be worked up as previously described.[141]

Histopathology

Cutaneous Features of Mycosis Fungoides/Sézary Syndrome

In general, the histologic diagnosis of MF/SS in skin biopsies is based on criteria similar to those used for the diagnosis of other lymphoid neoplasms, including the presence of an infiltrative or destructive growth pattern and cytologic atypia. The distribution of the infiltrate within the skin biopsy is also important (Fig. 92.5A). The characteristic atypical lymphocytes in MF and SS are dysplastic cerebriform T-cells with enlarged hyperchromatic nuclei and complex nuclear folding. Demonstration of cerebriform nuclear

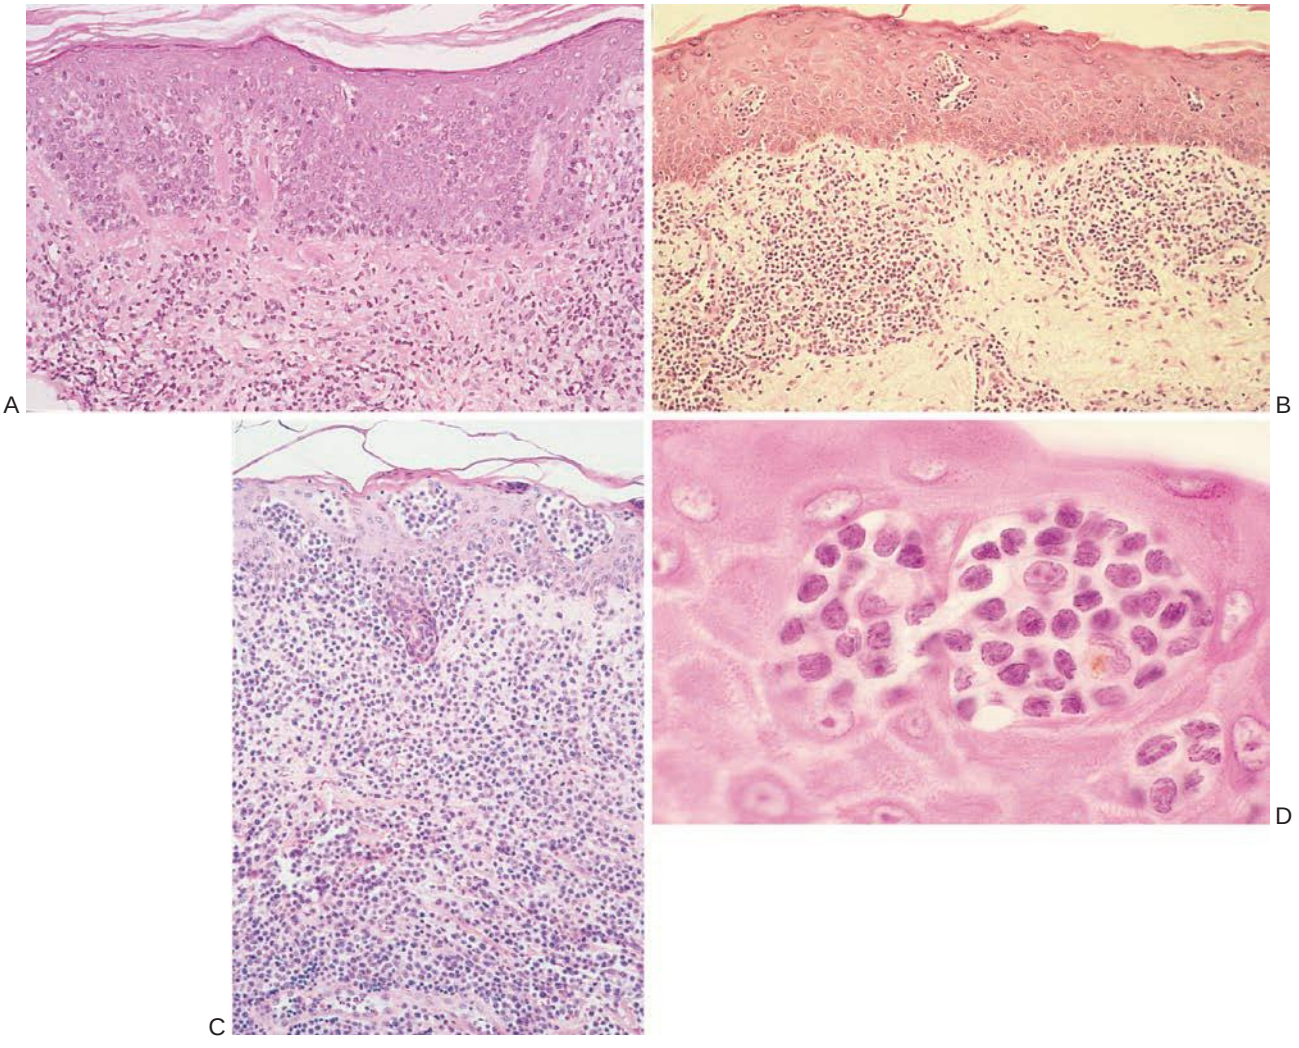

FIGURE 92.5. A: Mycosis fungoides (MF), patch stage. A bandlike lymphocytic infiltrate occupies the superficial papillary dermis with single-cell epidermotropism by atypical, "haloed" cerebriform T-cells, preferentially involving the basal layer (hematoxylin and eosin, ×50). **B:** MF, plaque stage. A bandlike lymphocytic infiltrate occupies the papillary dermis with epidermotropism by atypical cerebriform T-cells, focally forming small Pautrier microabscesses (hematoxylin and eosin, ×25). **C:** MF, thick plaque. A dense bandlike lymphocytic infiltrate fills the papillary dermis and extends into the reticular dermis. Prominent epidermotropism by atypical, enlarged cerebriform T-cells creates large Pautrier microabscesses (hematoxylin and eosin, ×25). **D:** MF, Pautrier microabscess. High magnification of a Pautrier microabscess shows characteristic small to medium cerebriform T-cells with highly convoluted nuclear folding. The Pautrier microabscess recapitulates normal interactions between components of the skin-associated lymphoid tissue, i.e., cutaneous T-cells, Langerhans histiocytes (2 cells with large pale nuclei in the center), and keratinocytes (hematoxylin and eosin, ×500).

folding requires good fixation (such as B5 fixation), thin (4-μm) sections, and examination under 100× oil immersion. Others have used special methods such as 1-μm sections of plastic-embedded tissue, electron microscopy, or nuclear morphometry.[142] Diagnostic criteria for cutaneous involvement by MF are best illustrated in plaque-stage lesions (Fig. 92.5B,C). The essential criteria for diagnosis are (a) a bandlike lymphocytic infiltrate in the superficial papillary dermis, (b) epidermotropism, and (c) atypical cerebriform T-cells in the dermal and epidermal infiltrates.[143,144] Pautrier microabscesses (Fig. 92.5D) are characteristic of MF but are often absent in patch-stage lesions, erythroderma, and nonepidermotropic tumors. Diagnosing early-patch–stage lesions is often difficult. In a morphologic study of >700 early-patch–stage lesions by Massone et al., the histologic features most helpful for diagnosing MF were (a) epidermotropism, particularly with a basilar lymphocytosis (23%) or with "haloed" lymphocytes (40%); (b) a dermal lymphocytic infiltrate that is bandlike (30%) or patchy lichenoid (66%); and (c) interface dermatitis (59%).[145] Large convoluted lymphocytes in the epidermis were found only in 9% of cases, and Pautrier microabscesses were found in 19%. The authors noted that although these cytologic changes are highly specific, the architectural abnormalities (infiltrate, epidermotropism) were more sensitive in diagnosing MF, as has also been suggested by others.[146] Earlier studies have shown similar criteria as being valuable in diagnosing MF "haloed" epidermotropic cerebriform T-cells along the basal layer of the epidermis, disproportionate epidermotropism (intraepidermal lymphocytes without accompanying spongiosis), and medium to large cerebriform cells in the epidermis and clustered in the dermis.[143,147,148] Several studies have pointed to the association of papillary dermal fibrosis with MF/SS; however, at least one study found that in a carefully selected population of early, untreated MF patients this finding argued against a lymphoma diagnosis.[149]

Spongiosis should be minimal in relationship to epidermotropism in MF and SS. Biopsies with prominent spongiosis must be differentiated from eczematous or spongiotic dermatitis. Microvesiculaion and Langerhans cell microabscesses are rarely present in MF/SS and would point toward a spongiotic process. Eosinophils and plasma cells are often present in early patch- and plaque-stage MF, and represent a nonspecific reactive component.

It is important to understand that a definitive diagnosis of MF may not be possible in some early-patch–stage lesions. Multiple biopsies of separate skin lesions, immunophenotyping, and *TCR* gene rearrangement studies may help confirm the diagnosis in difficult cases. Even these ancillary studies may be inconclusive in early lesions. The reported range of sensitivity of T-cell clonality detection is large, with some studies reporting as few as 20% of early-patch–stage lesions being clonal[150] to as many as 71%.[151] Likely, this variability reflects variability in density of infiltrate in early lesions, variability in source material for DNA extraction (frozen vs. paraffin), and variability of the clonality assay [Southern blot vs. PCR vs. denaturing gel electrophoresis vs. capillary electrophoresis]. In later plaque- and tumor-stage lesions, T-cell clonality can typically be detected in >90% of cases.[151,152] Recently, a PCR-based clonality protocol has been proposed and validated (BIOMED-2) in an attempt to provide some degree of standardization.[77,153] In addition, several techniques have been advocated, such as comparing clonality studies from disparate clinical lesions and using complementary clonality studies (*TCR* β and *TCR* γ) that may increase the specificity and sensitivity of the molecular studies.[154,155] Despite these advancements, however, a lack of demonstrated clonality in a histologically or clinically suspicious lesion should not prevent a diagnosis of CTCL. Likewise, the presence of a clonal population does not equate with malignancy as many benign dermatoses may demonstrate clonality.[156]

Tumor-stage MF is characterized histologically by a dense dermal infiltrate involving the papillary and reticular dermis, often with extension into the subcutis. In contrast to patch- and plaque-stage lesions, MF tumors are often nonepidermotropic and may spare the dermal—epidermal interface. Furthermore, the malignant T-cells in tumor-stage MF often display various degrees of histologic transformation, with medium and large pleomorphic cells, immunoblastic large cells, and anaplastic large cells.[157,158] The diagnosis of malignancy in the tumor stage is rarely in question, but recognition of MF origin for tumors with large-cell transformation may be obscured by their resemblance to other NHLs. A careful search for dysplastic cerebriform T-cells and residual foci of epidermal infiltration near the edges of tumors often provides histologic evidence of MF origin in difficult cases.[157] Previous or concurrent biopsies of earlier-stage MF lesions may also help confirm the diagnosis in these cases.

Generalized exfoliative erythroderma is characteristic of SS but may also occur in MF.[159] Cutaneous biopsies of erythroderma in MF/SS often lack many of the hallmark features found in patch/plaque MF, such as epidermotropism and lymphocytes aligned along the basement membrane.[160] In fact, in one study, up to 17% of skin biopsies of patients with established SS were considered nondiagnostic because of insufficient epidermotropism.[161] Evaluation of the peripheral blood for circulating tumor cells and/or molecular analysis of the skin and peripheral blood for a clonal rearrangement of the TCR may help establish the diagnosis of MF/SS in cases for which skin biopsies are histologically suspicious, but nondiagnostic. In addition, the finding of identical clonal populations in the skin and peripheral blood is very supportive of a lymphoma diagnosis.[162]

Large-cell Transformation of Mycosis Fungoides/Sézary Syndrome

Approximately 20% of low-grade MF and SS undergo secondary transformation to high-grade large-cell lymphoma with a predominance (>25%) of large transformed lymphocytes (Fig. 92.6).[157] Secondary large-cell transformation of MF/SS may resemble immunoblastic large-cell lymphoma, pleomorphic large-cell lymphoma, or ALCL.[157,163] It has been shown that secondary large-cell lymphoma is immunophenotypically and clonally related to earlier MF/SS biopsies taken prior to transformation.[164]

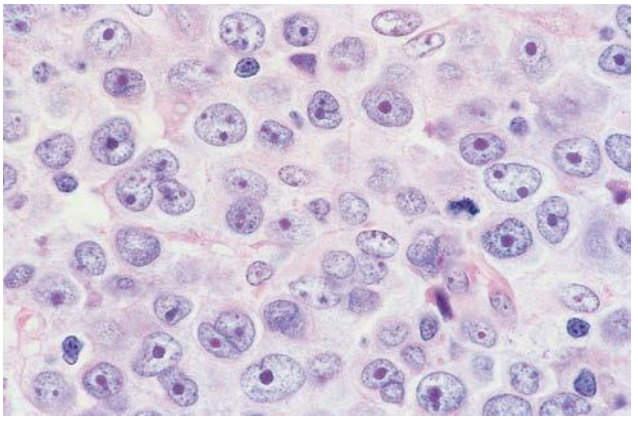

FIGURE 92.6. Large-cell transformation of mycosis fungoides (MF). This represents secondary transformation of low-grade MF to high-grade immunoblastic large-cell lymphoma. This tumor is composed of sheets of large transformed cells or immunoblasts with round to oval nuclei, dispersed chromatin, and prominent nucleoli. Several mitoses are present (hematoxylin and eosin, ×500).

Cutaneous large-cell transformation usually occurs late in tumor-stage lesions, but it can occasionally be seen in plaques or erythrodermic MF and may be present in the initial diagnostic biopsy (mycosis *d'emblée* variant). Lymph nodes are the most common site of extracutaneous large-cell transformation, but it may also occur in other extracutaneous sites. Approximately 50% of secondarily transformed large-cell lymphomas express CD30.[165] In MF patients with large-cell transformation the absence of CD30 expression has been associated with a reduced disease-specific survival.[166] It is important to distinguish secondary large-cell transformation of MF/SS from unrelated primary cutaneous large-cell lymphoma, LyP, and secondary cutaneous involvement by systemic large-cell lymphoma because of prognostic differences.[167] This is particularly true for secondary $CD30^+$ large-cell lymphoma resulting from transformation of MF/SS, which has a poor prognosis, in contrast to primary cutaneous $CD30^+$ ALCL and LyP, both of which have a favorable prognosis.[168,169] Differentiating these entities is often impossible on histologic grounds alone and requires close collaboration between the clinician and pathologist to establish the correct diagnosis in the WHO-EORTC classification scheme.

Extracutaneous Mycosis Fungoides/Sézary Syndrome

Extracutaneous dissemination is generally considered to be a late occurrence in MF/SS because the disease is clinically limited to the skin for prolonged periods of time in most patients. Using more sensitive techniques such as cytogenetics, electron microscopy, and immunophenotypic studies, extracutaneous disease has been found in nearly 90% of MF/SS patients at initial staging in one case series.[170] There is evidence that nodal involvement as detected with highly sensitive molecular techniques can segregate otherwise low-stage patients into high-risk and low-risk groups;[171] however, assessment of regional lymph nodes is not standard practice in early-stage MF patients. Although autopsy studies have histologically documented widespread extracutaneous disease in most patients,[172] most series were performed several decades ago, when detection of early disease was difficult.

Extracutaneous MF/SS has histologic features that are usually similar to those seen in the skin. Dysplastic cerebriform T-cells are the most helpful diagnostic feature for recognition as extracutaneous disease. Almost every organ has been involved by MF/SS in autopsy series, but the most frequent sites are the lymph

nodes, liver, spleen, and lungs, which may be involved in >50% of more advanced cases.[172] Other common sites include kidney, bone marrow, thyroid, heart, pancreas, gastrointestinal tract, and central nervous system. Lymph nodes represent the most frequent site of extracutaneous disease in pathologic staging studies; up to 50% of lymph nodes are positive by light microscopy at initial staging.[173] Several series from the 1980s found visceral involvement present in ~15% of initial staging liver and bone marrow biopsies.[157,173,174] When staging laparotomies were routinely performed in the past, ~30% of spleens were microscopically involved by MF/SS.[175] Extracutaneous CTCL, particularly visceral disease, is strongly associated with advanced-stage skin disease (tumors and erythroderma) and SS.[174] Because tumor-stage MF and generalized erythroderma are frequently nonepidermotropic, it has been suggested that loss of epidermotropism may play an important role in systemic dissemination.

Lymph Node Pathology

With up to 50% of staging lymph node biopsies being microscopically involved by MF/SS, lymph nodes are the earliest and most common site of extracutaneous dissemination.[173] Nevertheless, the ISCL guidelines only recommend excision of lymph nodes if they are either >1.5 cm in greatest transverse diameter or are palpably irregular, firm, or fixed lymph nodes regardless of size.[176] Partially effaced nodes often have an interfollicular pattern with preservation of reactive follicular centers, but eventually most lymph nodes become completely effaced. As lymph nodes become progressively infiltrated, the cerebriform T-cells tend to become larger and more pleomorphic, with increased numbers of large transformed cells.[177] Over 35% of positive nodes will show complete large-cell transformation with pleomorphic, immunoblastic, or anaplastic large-cell morphology.[157,177,178] In contrast to MF, lymph nodes from patients with SS tend to be effaced by more monomorphic infiltrates of small to medium cerebriform T-cells,[179] but may also undergo large-cell transformation in some cases.[157,165]

Bone Marrow Involvement

The bone marrow in MF and SS is generally thought to be spared until late in the course of the disease, including in patients with large numbers of circulating Sézary cells.[70,170] Early studies suggested that antemortem marrow involvement occurred in <3% of MF/SS patients,[170] yet the marrow was involved in nearly 50% of patients at autopsy in several series from the 1970s.[172,180] Marrow involvement typically manifests as nonparatrabecular lymphoid aggregates with cerebriform lymphocytes. Molecular studies have shown that in patients with a defined clonal T-cell rearrangement in the skin, approximately 20% will have an identical T-cell clone detected in their blood or bone marrow. Moreover, all patients with bone marrow involvement by molecular studies had blood involvement as well, but only 76% of patients with blood involvement had bone marrow involvement.[181] Sibaud et al. were unable to demonstrate that bone marrow involvement was associated with a worse prognosis in a multivariate analysis of their data; however, blood involvement was an independent variable for disease progression. In patients with SS, subtle small interstitial clusters of Sézary cells have been identified in up to 90% of cases, suggesting that most patients with circulating Sézary cells have early systemic dissemination of disease.[174] Detection of these subtle interstitial infiltrates of Sézary cells requires careful examination under oil immersion (100×) to identify the cells with abnormal cerebriform nuclear folds. Identification can be facilitated with immunoperoxidase studies for T-cell markers such as CD3, CD4, and CD7. Flow cytometry using a broad array of T-cell markers including CD3, CD4, CD8, CD7, and CD26 is also useful for detecting marrow involvement.

Other Extracutaneous Sites

Splenic and hepatic involvement by MF and SS is common and can be staged using imaging criteria rather than by invasive methods.[182] Liver involvement in initial staging procedures has been found in 8% to 16% of cases.[173] Disseminated MF and SS tend to form nodular infiltrates of atypical cerebriform T-cells within the portal tracts or hepatic lobules. Cerebriform T-cells within the hepatic sinusoids without formation of focal aggregates are not considered diagnostic of liver involvement in the presence of peripheral blood involvement. Splenic infiltration was documented in 31% of staging laparotomies in one series.[175] The atypical cerebriform T-cells usually infiltrate the red pulp diffusely, but they may home to the periarteriolar lymphocyte sheath.[180] Splenic rupture has been reported in a rare case with massive splenic involvement by CTCL.[183]

All other suspected sites of visceral involvement should be confirmed by biopsy if possible. Antemortem pulmonary manifestations of MF and SS are generally uncommon but may occasionally present clinically as interstitial or nodular pulmonary infiltrates.[184] However, the lungs are frequently involved by MF/SS at autopsy.[172] Infiltrates of atypical cerebriform T-cells usually spread along the alveolar septae with preservation of the alveolar architecture. In some cases, the infiltrates may also fill alveolar spaces.

Blood Involvement

The ISCL has defined three stages of blood involvement for MF/SS.[176] Patients with B2 peripheral blood involvement have >1,000 Sézary cells/mm^3, where the Sézary cells are distinguished by their large nuclear size (>15 μm) and high nuclear contour index (Fig. 92.7).[185] In one study, increased large Sézary cells correlated significantly with poorer survival.[186] However, size criteria alone would fail to recognize the small Sézary cell variant, which is similar in size to a normal resting lymphocyte. Because of the inherent difficulties in diagnosing peripheral blood involvement by MF/SS on peripheral smear review, additional technologies are now used including flow cytometry and molecular studies such as PCR. The ISCL considers a positive clonal *TCR* rearrangement in the blood coupled with either a CD4:CD8 ratio >10:1 or abnormal immunophenotype by flow cytometry ($CD4^+CD7^-$ or $CD4^+CD26^-$) as adequate evidence to constitute a positive peripheral blood for staging purposes.[185] It has been shown that patients with B2 blood involvement have a statistically worse survival than those with B1 or B0 staging.[186] ISCL B0 is defined as no increase in Sézary cells (<5% of peripheral blood lymphocytes). B0 cases with molecular detection of T-cell clonality (B0b) have a worse prognosis than

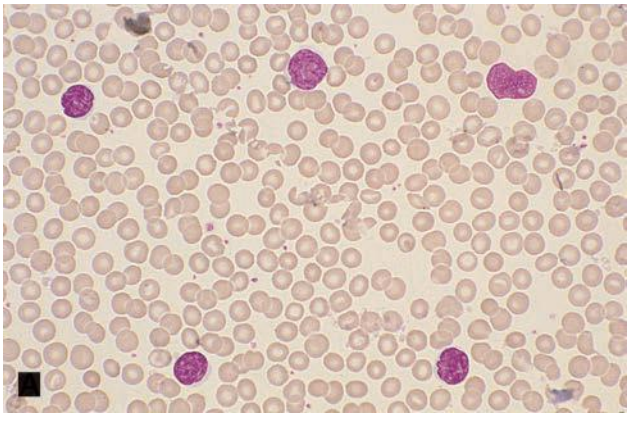

FIGURE 92.7. Sézary syndrome. The peripheral blood shows lymphocytosis. Most lymphocytes are Sézary cells with enlarged, highly convoluted nuclei and scant cytoplasm (hematoxylin and eosin, ×250).

molecularly negative (B0a) cases even when the histologic criteria for blood involvement have not been met.[162,187,188] In fact, T-cell clonality in the peripheral blood even in the absence of increased lymphocytes by morphology or flow cytometry (B0b) has been shown to convey a worse overall survival (OS), disease-specific survival and risk of disease progression.[189] B1 stage is defined as the group of patients who fail to meet criteria for B2 or B1. These patients have >5% atypical T-cells but do not otherwise reach the criteria for B2 involvement. These patients can also be split into B1a molecular clone negative and B1b molecular clone positive cases. Although T-cell clonality is required for diagnosis of B2 stage, the presence of molecularly defined T-cell clones in elderly patients or in patients with other lymphoproliferative disorders is not uncommon[151,190,191] requiring therefore correlation with the clonality of the cutaneous infiltrate or association with MF-associated immunophenotypic abnormalities (increased CD4:CD8 ratio, loss of CD7 or CD26 on CD4 T cells).

Immunophenotyping Studies

T-cell origin of the neoplastic cells in MF and SS is well established as a memory T-cell that expresses CLA, the cutaneous lymphoid antigen homing receptor.[192] The vast majority are derived from T-helper cells that express CD4 and other T-cell–associated antigens including CD2, CD3, CD5, CD45RO, and $\alpha\beta$ TCRs (Fig. 92.8).[193] However, a small number of $CD8^+$ CTCL[194] have been reported as well as $\gamma\delta$ CTCL.[195,196] Of note, clinical presentation and behavior are crucial in distinguishing the $CD8^+$ MF variant from the more aggressive primary cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma described in the updated WHO-EORTC nomenclature as a provisional subtype of peripheral CTCL. Furthermore, it is likely that most $\gamma\delta$ CTCL would be classified as cutaneous $\gamma\delta$ T-cell lymphoma (CGDTCL) in the WHO-EORTC scheme.[137,194,197] Activation-associated (HLA-DR, CD25, CD30, CD38) and proliferation-associated (CD71, Ki-67) antigens are also frequently expressed in MF/SS, particularly in advanced stages.[157]

Aberrant T-antigen expression is often seen in MF and SS, particularly advanced plaque- or tumor-stage lesions, and can be used to help differentiate reactive dermatitis from MF/SS.[198] Often, flow cytometry is used to assess antigen expression on the T-cells present in circulation or directly from involved skin biopsies. Aberrant T-cell phenotypes are defined as diminished or absent expression of pan-T–cell antigens (CD2, CD3, or CD5), absent T-subset antigen expression ($CD4^-$ $CD8^-$), or co-expression of T-subset antigens ($CD4^+$ $CD8^+$). Diminished or absent CD7 expression is one of the most common aberrant T-cell phenotypes in tissue sections of MF and SS.[198] However, the isolated findings of loss of CD7 expression must be considered in the context of other clinical, histologic, and immunophenotypic findings in that expanded populations of CD7-negative T-cells can also be seen in benign dermatitides.[193] More recently, several studies have shown that the loss of CD26 (dipeptidyl-aminopeptidase IV) expression is a characteristic feature of circulating Sézary cells that is likely more sensitive than loss of CD7 expression.[199,200,201] Nevertheless, when considered as a group, loss of any major T-cell antigen (CD2, CD5, CD3, CD4, or CD7) is as or more sensitive a marker for SS and MF than loss of CD26.[202]

For histologic diagnosis of cutaneous lymphomas, immunohistochemistry can reliably differentiate among T-cell lymphomas, B-cell lymphomas, and Hodgkin disease. The most widely used paraffin-reactive T-cell antibodies include CD2, CD3, CD4, CD5, CD7, CD8, CD30, CD43, CD45RO, βF1, and TCR $\alpha\beta$. Although immunohistochemistry for CD7 can be helpful in evaluating early MF biopsies, loss of CD7 can be seen in a wide variety of reactive benign conditions requiring correlation with clinical, histologic, other immunophenotypic and molecular findings.[203,204] NK-cell or cytotoxic lymphocyte markers (CD56, granzyme B, perforin, and TIA-1) can be used as well if non-MF NK-/T-cell lymphomas are in the differential. CD20, CD79a, CD5, CD10, BCL-6, BCL-2, κ, λ, MUM1, and CD138 are the most widely used B-cell paraffin-reactive antibodies. When used in panels, these antibodies allow subclassification of most cutaneous lymphomas.

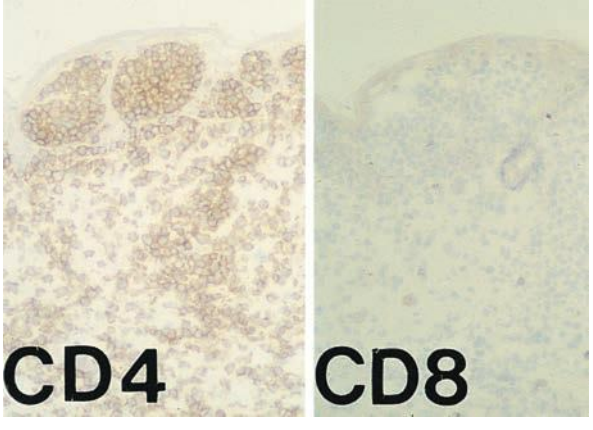

FIGURE 92.8. Frozen section immunohistochemistry of a cutaneous plaque in a patient with MF shows a marked predominance of $CD4^+$ T-helper cells within Pautrier microabscesses and within the dermis. CD8 is essentially negative (Diaminobenzidine-hematoxylin, ×50). MF, mycosis fungoides.

DIFFERENTIAL DIAGNOSIS

The clinicopathologic differential diagnosis for MF/SS includes several forms of benign dermatitis, other primary low-grade CTCLs, and secondary cutaneous involvement by disseminated lymphomas or leukemias (Table 92.2). Differentiation of these mimickers from CTCL often requires careful correlation of clinical, histopathologic, immunophenotypic, and genotypic characteristics, and may require multiple or serial biopsies. The following discussion describes methods to differentiate MF/SS from similar benign conditions, indolent CTCL, and other primary CTCLs.

To assist clinicians with the diagnosis of early MF, Pimpinelli et al. proposed an algorithm using clinical, histopathologic, molecular biologic, and immunopathologic criteria in which a total of 4 points from any of the four categories was necessary to make the diagnosis of early MF.[126] The scoring system would allow, for example, a patient with persistent patches in nonsun-exposed areas with size/shape variation (2 points) and histologic findings of a superficial lymphocytic infiltrate, epidermotropism without spongiosis, and lymphocyte atypia (2 points) to meet criteria for early MF diagnosis without any immunostains or T-cell–receptor gene rearrangement analysis of the skin tissue.

Benign Conditions

Benign inflammatory skin lesions are most likely to be confused with early patch-stage MF. In general, these conditions have clinical presentations and courses that are different from MF, lack enlarged atypical cerebriform T-cells, and lack epidermotropism that is disproportionately increased in relationship to spongiosis. However, in difficult cases, immunophenotypic analysis and gene rearrangement studies may be necessary to look for aberrant T-cell phenotypes or clonal *TCR* gene rearrangements. The benign inflammatory dermatoses that most closely resemble CTCL include small and LPP, PVA, pityriasis lichenoides, pigmented purpuric eruption, lichenoid keratosis, benign erythroderma, contact dermatitis, persistent arthropod bite reactions, drug eruptions, LyP, and actinic reticuloid (AR).[205]

Despite the name, the chronic skin diseases under the term parapsoriasis are unrelated to the much more common skin

TABLE 92.2

BENIGN AND MALIGNANT CONDITIONS THAT CAN MIMIC MF AND SÉZARY SYNDROME

Benign Conditions
Small and large plaque parapsoriasis
Poikiloderma vasculare atrophicans
Pityriasis lichenoides et varioliformis acuta
Benign erythroderma
Chronic spongiotic dermatitis
Contact dermatitis
Drug eruption
Arthropod bites
Actinic reticuloid
Follicular mucinosis
$CD30^+$ Lymphoproliferative Disorders
Lymphomatoid papulosis
Primary cutaneous anaplastic large-cell lymphoma
Other Primary Cutaneous T-Cell Lymphomas
Pagetoid reticulosis
Folliculotropic mycosis fungoides
Granulomatous slack skin
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous $\gamma\delta+$ T-cell lymphoma
Primary cutaneous CD8+ T-cell lymphoma
Primary cutaneous pleomorphic small/medium-sized CTCL
Primary Cutaneous B-Cell Lymphomas
Primary cutaneous follicle center lymphoma
Primary cutaneous marginal zone lymphoma
Primary cutaneous large B-cell lymphoma
Intravascular large B-cell lymphoma
Secondary Lymphoma/Leukemia
Leukemia cutis
Extramedullary myeloid tumor
Adult T-cell leukemia/lymphoma
Peripheral T-cell lymphoma
Hodgkin lymphoma

CTCL, cutaneous T-cell lymphoma

disease psoriasis. Most dermatologists separate parapsoriasis into one of two types. The benign subtype is known as small plaque parapsoriasis, digitate dermatosis, or chronic superficial dermatitis. The other type is considered pre-malignant and is most often called LPP or parapsoriasis *en plaques* (having in the past been called pre-reticulotic poikiloderma).[206,207] LPP is clinically indistinguishable from patch-stage MF.[126] However, the patches of MF tend to be fixed whereas the patches of LPP tend to wane in the summer and flare in the winter. Because of clinical and histologic overlap, some authorities consider LPP to be an early stage of MF.[208] Others consider LPP to be a latent form of MF[209] because ~10% of patients eventually develop overt MF.[210] A retrospective review documented a higher rate of evolution to MF in 12 of 36 (33%) patients with LPP.[211] This view is supported by the demonstration of clonal *TCR* gene rearrangement in 50% of LPP biopsies.[73] Furthermore, demonstration of clonal *TCR* gene rearrangements in small plaque or digitate parapsoriasis has suggested that this may be an abortive form of MF.[212,213] Histologically, the lymphoid infiltrate of LPP is perivascular and less dense with less epidermotropism than in MF; Pautrier microabscesses are not seen in LPP. Furthermore, cytologically atypical cerebriform T-cells with highly convoluted nuclei are inconspicuous or absent in LPP. However, immunophenotypic analysis is usually not helpful for differentiating LPP from patch-stage MF as both have a predominance of $CD4^+$ helper cells with absent CD7 and CD62L expression.[127] One study found the presence of HECA-452 immunostaining higher in MF than LPP, which may be helpful in distinguishing the two diseases and predicting which cases of LPP may evolve into MF.[214]

PVA can also present similarly to early MF, so much so, that most experts believe PVA to be a rare variant of MF.[215–217] The macules and patches of PVA show the poikilodermatous features of hypopigmentation, hyperpigmentation, atrophy, and telangiectasias. PVA macules/patches tend also to be localized to sun-protected sites, most commonly appearing on the buttocks, breasts, and flexural areas. And, like LPP, some clinicians believe that PVA may potentially precede or co-exist with MF.[125] Histologically, PVA is characterized by an atrophic epidermis, chronic, ill-defined inflammatory changes and dilated capillaries. Often, lymphoid cells form a bandlike pattern in the superficial dermis, with only rare epidermotropism.[215–217]

Pityriasis lichenoides is considered a spectrum of diseases including an acute and a chronic form: pityriasis lichenoides et varioliformis acuta (PLEVA) and pityriasis lichenoides chronica (PLC), respectively. Many patients demonstrate lesions of both forms during their disease course. PLEVA, also known as Mucha-Habermann disease, is a benign cutaneous disorder characterized by recurrent, self-healing papulonecrotic lesions that may resemble LyP, which is discussed later.[218] PLC, which is a benign eruption with lymphocytic infiltrates of the skin, presents as a persistent, erythematous, papular eruption with scale.[219] Biopsies may show slightly atypical cerebriform T-cells with some epidermotropism, but vacuolar degeneration of the epidermal basilar layer, necrotic keratinocytes, and dermal hemorrhage in PLEVA distinguish it from MF. The lymphoid infiltrate is composed predominantly of $CD8^+$ cells as opposed to the typical $CD4^+$ phenotype of MF.[220] The histology of PLC is similar to PLEVA, although the findings are muted with only focal basal vacuolar change and limited lymphocytic exocytosis. The intraepidermal lymphocytes tend to be $CD4^+$, which further complicates the distinction from early MF. As in PLEVA, the lymphocytes lack significant cytologic atypia. Some consider pityriasis lichenoides to be a T-cell lymphoproliferative disorder or a form of indolent cutaneous T-cell dyscrasia related toLyP, and clonal *TCR* gene rearrangement has been demonstrated.[221–224] Although cases of patients with pityriasis lichenoides progressing to MF have been described, this is definitely a rare event.[220,224,225]

Pigmented purpuric dermatoses (PPD) are a group of chronic and benign skin disorders categorized by rupture of the small capillaries in the superficial papillary dermis. Clinically, patients present with petechiae and bronze discoloration of the skin on the lower extremities.[226] Histologically, there is a superficial perivascular infiltrate that may be dense and lichenoid in nature. Dermal hemorrhage and hemosiderin deposition is present to varying degrees. Lymphocytic exocytosis is often present, however, cytologic atypia and intraepidermal lymphocytic microabscesses are generally absent. Immunohistochemical and molecular studies are typically not helpful in differentiating PPD from MF. Lichen aureus, a rare type of PPD, can mimic MF both clinically and histologically and progress to MF in very rare cases.[227] One study showed that of 43 cases of PPD, 21 showed a clonal population of T-cells. Only 40% of the cases with demonstrated clonality, however, had clinical and pathologic features consistent with MF. In addition, loss of CD7 was frequently observed in both

the polyclonal and monoclonal groups.[228] Other studies have documented the frequent occurrence of T-cell clonality in cases of PPD that fail to develop disease typical of MF.[229] The presence of extensive PPD-like skin disease, especially when present outside the lower extremities, should raise the suspicion of MF regardless of the histologic features.

Lymphomatoid keratosis is a benign epithelial skin neoplasm related to an inflamed seborrheic keratosis or lichenoid keratosis. Patients generally demonstrate scattered small hyperkeratotic plaques on the trunk and are biopsied to rule out the possibility of a nonmelanoma skin cancer. The histologic features can be indistinguishable from MF with a lichenoid infiltrate and extensive lymphocytic exocytosis. Additionally, clonal populations of T-cells have been detected.[230] The presence of epidermotropic $CD20^+$ B-cells is suggestive of a lymphomatoid keratosis; however, clinicopathologic correlation is paramount in arriving at the correct diagnosis.[231]

Erythroderma may occur in a variety of benign dermatologic disorders including psoriasis, pityriasis rubra pilaris, eczematous dermatitis, seborrheic dermatitis, severe contact dermatitis, and drug eruptions.[232,233] These patients may also have circulating cerebriform cells and lymphadenopathy, further complicating the diagnosis. Erythroderma secondary to drug reactions, especially anticonvulsants such as phenytoin, can be particularly difficult to distinguish from MF/SS because of the presence of convoluted cerebriform T-cells and the formation of Pautrier microabscesses.[140] Several studies have compared the histologic features of erythrodermic MF/SS with other causes of reactive erythroderma. Although not present in all cases, Pautrier microabscesses and a dense, often lichenoid, dermal lymphocytic infiltrate were more commonly associated with erythrodermic MF/SS.[234–236] Differentiation of benign erythroderma from erythrodermic CTCL can usually be accomplished through careful evaluation of the history, skin biopsy of the more typical lesions of the underlying disease, and molecular genetic analysis of both skin and blood.[235,236] Numerous eosinophils favor a drug reaction. Aberrant T phenotypes or clonal *TCR* gene rearrangements are usually not present in benign erythroderma.

Subacute or chronic spongiotic dermatitis and interface dermatitis resulting from contact dermatitis, drug eruption, and persistent arthropod bite reaction may have atypical cerebriform T-cells with epidermotropism and Pautrier-like microabscesses mimicking MF.[205] Caution should be exercised in interpretation of epidermotropism associated with significant spongiosis, especially microvesiculation, which is only rarely observed in MF.[143] The Pautrier-like microabscesses seen in spongiotic processes typically have a flask shape and are composed of Langerhans cells and keratinocytes. Immunophenotyping may be helpful in this differential diagnosis because cutaneous T-cell pseudolymphomas rarely show aberrant loss of CD2, CD3, or CD5 expression, especially a combination of these markers.[205] CD7 and CD62L (Leu 8) are not as helpful as their expression is commonly lost in both MF and reactive dermatoses.[205] Typically, T-cell–predominant pseudolymphomas are characterized by perivascular, "sleeve-like" infiltrates around vessels in the dermis, with accompanying plasma cells, eosinophils, and macrophages. The T-cells are typically a mixture of $CD4^+$ and $CD8^+$ cells as opposed to the $CD4^+$-predominant population characteristic of most cases of MF. The utility of gene rearrangement studies in this setting is unclear as clonal *TCR* gene rearrangements have been reported in some cutaneous T-cell pseudolymphomas.[237–239] The following drugs have been implicated as causing pseudolymphoma: alprazolam, amitriptyline, atenolol, carbamazepine, cefixime, chlorpromazine, cimetidine, clarithromycin, clonazepam, clonidine, cotrimoxazole, cyclosporine, desipramine, diltiazem, doxepin, fluoxetine, furosemide, gemfibrozil, gold, lamotrigine, lithium, lorazepam, losartan, methotrexate, nizatidine, perphenazine, phenytoin, ranitidine, sulfamethoxazole, sulfasalazine, and thioridazine.[240]

B-cell–predominant pseudolymphomas are notable for reactive follicle formation with tingible-body macrophages, centroblasts, and centrocytes in the germinal centers surrounded by distinct mantle zones. There are polyclonal plasma cells, a mix of $CD4^+$ and $CD8^+$ T-cells and often eosinophils in the accompanying inflammatory infiltrate.[241,242] $CD21^+$ follicular dendritic cells (DCs) can be found in the follicles as well.

AR is a severe form of photosensitive dermatitis that may closely mimic MF or SS clinically and histologically when fully developed.[243–245] AR is a chronic persistent eruption that can be induced by a broad spectrum of light wavelengths (ultraviolet A [UVA], UVB, and visible wavelengths of light).[243] The skin lesions are typically plaques and papules on the sun-exposed areas of the face and hands, but may extend to covered areas or even become generalized erythroderma.[246] In contrast to MF, epidermotropism is not prominent, but small Pautrier microabscesses may be found in some cases. Severe cases of erythrodermic AR may have generalized lymphadenopathy and circulating Sézary cells mimicking SS. Preferential involvement of sun-exposed areas, absence of large dysplastic cerebriform T-cells, and a $CD8^+$ phenotype help distinguish AR from MF/SS. AR does not appear to be associated with progression to malignant lymphoma, and clonal *TCR* rearrangements have not been reported.[245]

$CD30^+$ Lymphoproliferative Diseases

The differential diagnosis for suspected MF also includes a variety of related conditions, which are equally concerning for their malignant or pre-malignant clinical course. LyP and primary cutaneous ALCL (pcALCL) are both characterized by the presence of $CD30^+$ T-cells; together, they represent the poles of a continuous disease spectrum. Both LyP and pcALCL are now considered subtypes of the CTCLs.[137] There is no clear-cut boundary between the diseases, however, and many patients fall into a borderline category when definitive diagnosis is not possible based on the current clinicopathologic features.

LyP is a CD30 (Ki-1)-positive T-cell lymphoproliferative disorder characterized by chronically recurring, self-healing crops of mildly pruritic papulonodular lesions that are clinically benign but histologically malignant.[247] LyP initially presents with crops of erythematous papules that wax and wane, becoming hemorrhagic and necrotic before undergoing spontaneous regression with scar formation. Individual lesions range from 2 mm to 2 cm in diameter (usually <1 cm) and have an average duration of 5 weeks, ranging from 2 weeks to 6 months.[248] LyP is classically divided into three histologic types, type A, type B, and type C. More recently a fourth histologic presentation, termed LyP type D, has been described.[249] Any of the histologic types may occur simultaneously in the same patient or during the course of the disease and the individual histologic type provides no prognostic significance.[250] LyP type A, the most common type, is characterized by a polymorphous infiltrate of eosinophils, neutrophils, and scattered anaplastic large transformed lymphocytes and binucleate Reed-Sternberg-like cells (Fig. 92.9).[251,252] LyP type B is characterized by small to medium cerebriform T-cells resembling MF. LyP type C is characterized by sheets of large, anaplastic $CD30^+$ cells and can be histologically identical to pcALCL but follows a waxing and waning clinical course. The atypical cells in LyP types A, B, and C are typically $CD4^+$. LyP type D is characterized by an extensively epidermotropic population of cytologically atypical CD8+ lymphocytes in a pattern that is nearly identical to that observed in primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma (see below).[249,253,254] The atypical cells in all of the types often have clonal rearrangement of the T-cell–receptor gene, and absent or diminished expression of pan-T–cell antigens.[255] However, CD30 expression differs among the types; the large transformed cells in types A, C, and D are $CD30^+$, similar to $CD30^+$ ALCL, whereas the atypical cerebriform T-cells in type

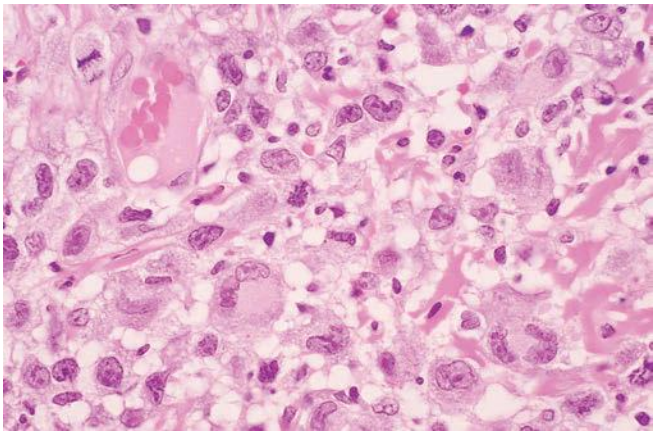

FIGURE 92.9. Lymphomatoid papulosis, type A. Anaplastic large cells with abundant cytoplasm, reniform nuclei, and prominent nucleoli are scattered among small lymphocytes and eosinophils. Note occasional binucleate Reed-Sternberg-like cells (hematoxylin and eosin, ×250). The large cells were strongly positive for CD30 (not shown).

B LyP typically do not express CD30.[256] Vonderheid and Kadin have suggested that the papular variant of MF and type B LyP are the same entity[256] although Kodama and colleagues point to the lack of spontaneous resolution of papules in papular MF.[257] Clinical behavior of LyP is usually benign; however, overt lymphoma has been documented in ~10% to 25% of patients, usually MF, pcALCL, or Hodgkin lymphoma.[248,258] The cumulative risk for the development of another lymphoma in patients with LyP over 15 years of disease may be as high as 80%.[259] A retrospective review of 31 patients with LyP over a 27-year span identified 60% who developed a co-existing lymphoma.[258] No clinical, histologic, immunophenotypic, or molecular genetic features have been identified that can predict which patients will develop lymphoma, but two studies suggest that malignant transformation is more strongly associated with type A than with type B LyP.[256] Onset of LyP at a younger age may be associated with increased cumulative risk for overt lymphoma and therefore all LyP patients should be closely monitored throughout their lives.[221,259,260] The benign or malignant nature of LyP is controversial, but the WHO-EORTC considers LyP to be a latent or low-grade stage of the primary cutaneous $CD30^+$ lymphoproliferative disorders that are considered to be malignancies.[137,261] Its clinical, histologic, and immunophenotypic similarities to pcALCL, aberrant T-cell–antigen expression, clonal *TCR* gene rearrangements, and increased risk for transformation to malignant lymphoma support this view.

Differentiation of primary cutaneous ALCL from LyP and secondary $CD30^+$ LCL resulting from large-cell transformation of MF/SS is important because of differences in prognosis and therapy.[137,261] pcALCL has a good prognosis and can be effectively managed with local excision and/or radiation therapy,[262] whereas secondary $CD30^+$ LCL due to large-cell transformation of MF/SS has a very poor prognosis requiring systemic therapy that often includes aggressive combination chemotherapy.[167,263] LyP also has an excellent prognosis and can often be managed with no therapy, topical chemotherapy, phototherapy, and low-dose methotrexate without the need for aggressive therapy.[264,265] Furthermore, pcALCL must be differentiated from secondary cutaneous involvement by extracutaneous ALCL.[266,267] Primary nodal ALCL and secondary cutaneous involvement by extracutaneous ALCL are more aggressive than pcALCL.[266,267] In malignant cells, the presence of anaplastic lymphoma kinase-1 protein (ALK-1) from the t(2;5) (p23;q35) chromosomal translocation favors primary nodal ALCL.[268] A thorough dermatologic examination, history, and staging for extracutaneous disease are necessary to exclude secondary large-cell transformation of low-grade MF or secondary cutaneous involvement by extracutaneous lymphoma before a case is accepted as pcALCL. pcALCL is differentiated from LyP type A by cohesive sheets or >75% $CD30^+$ large transformed cells, fewer admixed neutrophils and eosinophils, a diffuse infiltrate that extends into the deep dermis versus a more superficial wedge-shaped infiltrate, larger solitary or localized nodules or tumors instead of crops of papules, and higher frequency of persistent or progressive cutaneous lesions with less frequent or incomplete spontaneous regression.[263,268,269] Recently it has been shown that translocations in the interferon regulatory factor-4 (*IRF4*) gene are specifically associated with pcALCL and may be used to differentiate it from the other previously mentioned entities.[270] Other aspects of ALCL are discussed in more detail in Chapter 88.

Other Primary Cutaneous T-cell Lymphomas

Using the WHO-EORTC classification for cutaneous lymphomas as a guide, other primary CTCLs need to be considered in patients with atypical lymphocytic infiltrates of the skin.[137,139,271] These lymphomas include: three variants of MF (pagetoid reticulosis [PR], granulomatous slack skin [GSS] disease, and folliculotropic MF); subcutaneous panniculitic T-cell lymphoma; extranodal NK-/T-cell lymphoma, nasal type; and primary cutaneous peripheral T-cell lymphomas (PTCLs), unspecified, which include: (a) primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma, (b) CGDTCL, and (c) primary cutaneous $CD4^+$ small/medium-sized pleomorphic T-cell lymphoma.

PR and folliculotropic MF are variants of MF implying minor clinicopathologic differences from classical MF, whereas GSS is a subtype of MF with more significant differences from classical MF.[272] As in classical MF, these diseases are low-grade clonal T-cell lymphomas that generally follow a benign course but may behave aggressively over time. PR is a rare epidermotropic variant of MF that usually presents as localized, hyperkeratotic, verrucous plaques on the hands or feet (Woringer-Kolopp disease)[273] but may also present with disseminated cutaneous plaques (Ketron-Goodman disease).[274] Given its more aggressive clinical course, Ketron-Goodman disease would currently be better classified as tumor-stage MF, CGDTCL, or aggressive epidermotropic $CD8^+$ CTCL.[137,275,276] PR may mimic a more unusual variant of MF localized to the palms and soles known as MF palmaris et plantaris.[277] Skin biopsies of PR show pagetoid epidermotropism by enlarged, atypical cerebriform T-cells, with relative sparing of the dermis (Fig. 92.10). The malignant cells in PR may be $CD8^+$ or, less commonly, $CD4^+$and rarely, $CD4^-CD8^-$.[278] In contrast to conventional MF and SS, there is often co-expression of $CD30^+$. Although the original classification of PR allowed for $\gamma\delta$ TCR expression of the neoplastic cells, these cases are best classified

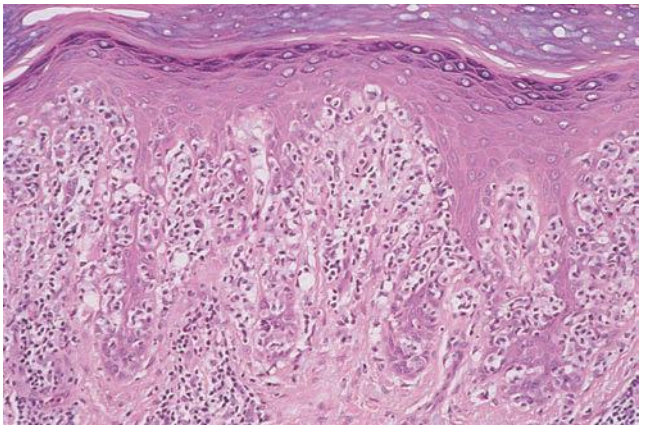

FIGURE 92.10. Pagetoid reticulosis. Note the pronounced pagetoid pattern of epidermotropism by enlarged, atypical cerebriform T-cells (hematoxylin and eosin, ×50).

as CGDTCL according to the WHO-EORTC guidelines. Clonal *TCR* gene rearrangement and aberrant T-cell–antigen expression support classification of PR as a form of CTCL;[279] however, PR has a clinically benign course, with only rare reports of cutaneous dissemination of localized PR.[276] Further studies are needed to confirm whether phenotypic differences in PR have clinical relevance. Local excision or radiation therapy is generally adequate treatment for PR, especially the localized form.

Folliculotropic or follicular MF (FMF) is another uncommon variant of CTCL first reported in 1985 with preferential perifollicular and folliculotropic infiltration by atypical cerebriform T-cells with minimal or absent epidermotropism and mucin (Fig. 92.11).[280–282] The follicles may show plugging, cystic dilatation, and mucinous degeneration, as seen with mucin stains such as Alcian blue. Folliculotropic cerebriform T-cells are $CD4^+$[282,283] and may express an aberrant T-cell phenotype with loss of CD7 and other T-cell antigens.[282] Differential up-regulation of ICAM-1 (CD54) on follicular epithelium instead of epidermal keratinocytes has been implicated in the folliculotropic homing pattern of folliculotropic MF.[282] Lymph node involvement and large cell transformation have also been described.[282] Folliculotropic MF, whether or not exhibiting follicular mucinosis, has shown a more aggressive course than classic MF.[189,284] Approximately 7% of reported cases have demonstrated rapid lymph node involvement.[285,286] In a large series of patients with FMF (n = 51), the disease-specific survival was 68% at 5 years and 26% at 10 years.[286] This poor prognosis has been confirmed by other studies as well.[166,287] Agar and colleagues completed an outcome analysis on 1,502 patients with MF/SS concluding that folliculotropic MF was one of several independent predictors of poor survival and increased risk of disease progression.[189]

Follicular mucinosis is frequently associated with folliculotropic MF and less commonly with classical MF. This variant of MF must be differentiated from idiopathic follicular mucinosis or alopecia mucinosa.[288,289] In general, no single clinicopathologic feature can differentiate follicular mucinosis associated with MF from alopecia mucinosa.[288–290] Alopecia mucinosa tends to occur in younger patients with fewer lesions localized to the head and neck as opposed to the more general distribution commonly seen in MF-associated cases. Histologically, alopecia mucinosa tends to have fewer atypical cerebriform T-cells, less epidermotropism and/or lymphocytic infiltration of follicular epithelium, and a normal CD4/CD8 ratio. In follicular mucinosis associated with MF the infiltrate tends to be denser and cytologically atypical with a $CD4^+$-predominant immunophenotype.[288] Clonal *TCR* gene rearrangement can be detected in many cases of alopecia mucinosa thus limiting its usefulness in the differentiation from MF.[290,291] In support of this, a long-term follow-up study of seven patients with follicular mucinosis concluded that despite the presence of a clonal *TCR* gene rearrangement, there was no evidence of progression to CTCL in any patient.[292]

GSS disease is a rare but distinctive subtype of MF that begins with patches and plaques that steadily progress to characteristic pendulous, erythematous skin folds in the axillae and groin.[293,294–298] Several authors stress the importance of distinguishing the mature lesions of GSS from the histologic variant of granulomatous MF, which can be differentiated quantitatively, not qualitatively.[293,298] GSS has histologic features of MF including superficial papillary dermal and epidermotropic infiltrates of atypical cerebriform T-cells, but it also exhibits expansive infiltration into the deep dermis and subcutis with extensive elastolysis and a prominent granulomatous reaction with Langerhans-type multinucleated giant cells (Fig. 92.12). These multinucleated giant cells are histiocytic in origin with 20 to 30 nuclei, frequently show emperipolesis and elastophagocytosis, and express CD68 and CD1a.[293,299,300] Similar to MF, GSS is a clonal proliferation of $CD4^+$ T-helper cells that frequently lack expression of CD7 and CD62L. GSS usually remains localized to the skin, although hypercalcemia, lymph node involvement, and fatal systemic dissemination have been reported.[295–298,301,302] It is important to note that in contrast to other CTCL variants, patients with GSS have an increased incidence of Hodgkin lymphoma at a frequency between 25% to 50%.[293,302,303]

Subcutaneous panniculitis-like T-cell lymphoma (SPTL) presents as tender erythematous nodules or subcutaneous palpable masses, mostly on the legs, trunk, arms, or face. Histologically, this lesion is confined to the subcutis and does not typically

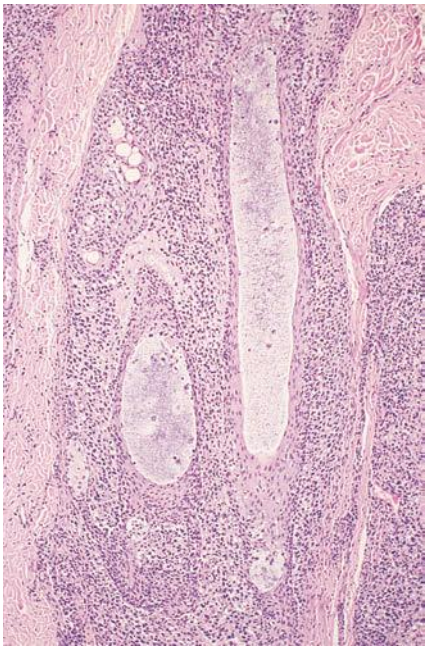

FIGURE 92.11. Folliculotropic mycosis fungoides with follicular mucinosis. Note the preferential pattern of perifollicular infiltration by atypical cerebriform T-cells with prominent folliculotropism forming small Pautrier microabscesses. Also note the bluish pools of mucin within the hair follicles (hematoxylin and eosin, ×25).

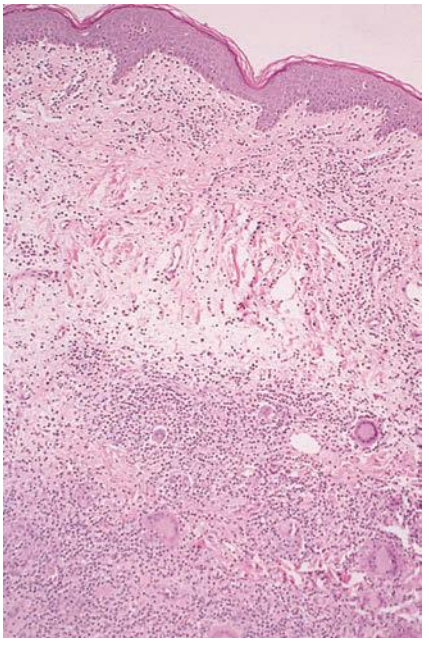

FIGURE 92.12. Granulomatous slack skin. This variant of mycosis fungoides (MF) shows a deep lymphocytic infiltrate with dermal edema, disruption of elastic fibers, and numerous foreign body giant cells (hematoxylin and eosin, ×10).

extend to the dermis or epidermis.[304,305] Classically, T-cells ranging from small and inconspicuous to large and transformed cells with hyperchromatic nuclei rim individual fat cells.[306,307] There is necrosis, karyorrhexis, and cytophagocytosis by the histiocytes that are found interspersed in the lesional tissue. As the name implies, this lymphoma is similar in histology to a lobular panniculitis and, in fact, many patients present with a history of previously biopsied panniculitis. In addition, there is some clinical and histologic overlap with lupus panniculitis and many patients with SPTL will present with or develop evidence of concomitant systemic lupus erythematosus.[308–310] By immunohistochemistry, the neoplastic T-cells express $\alpha\beta$ TCR, CD3, CD8, and cytotoxic granule proteins, although CD56 and CD30 are rarely detected.[304,306,307,311,312] Historically SPTL had been associated with a very poor prognosis often secondary to an aggressive hemophagocytic syndrome (HPS). The more recent WHO-EORTC classifications divided these cases into SPTL with an $\alpha\beta$ phenotype and CGDTCL based both on immunohistologic features and clinical behavior. SPTL with an $\alpha\beta$ phenotype are $CD4^-$, $CD8^+$, $CD56^-$, and $\beta F1^+$; are limited to the subcutaneous fat; are uncommonly associated with a HPS; and have a favorable prognosis (5-year OS 82%). CGDTCL is generally $CD4^-$, $CD8^-$, $CD56^{+/-}$, and $\beta F1^-$; tends to involve the epidermis with resulting ulceration; is commonly associated with HPS; and has a dire prognosis (5-year OS 11%).[313] Repeat biopsies may be necessary to confirm the diagnosis of SPTL. Once confirmed, early induction of combination chemotherapy with or without radiotherapy may yield remission and prevent the development of HPS.[314–316] (For further discussion of SPTL, see Chapter 88.)

Primary cutaneous T-cell neoplasias that do not fit into the other categories of CTCL are diagnosed as primary cutaneous PTCL, unspecified, in the WHO-EORTC classification system. This large category includes three provisional entities that are considered separately here. First, CGDTCL is characterized clinically by disseminated plaques and ulceronecrotic nodules that frequently also involve mucosal sites. The different clinicopathologic presentations may resemble MF, PR, PTCL, unspecified, and SPTL.[307,317–319] Patients presenting with nodules/tumors/plaques localized predominantly to the extremities should alert the clinician to CGDTCL. One series found all 23 of their patients with CGDTCL to have nodules or tumors on the extremities, with less than half exhibiting concurrent truncal lesions.[319] Most reports suggest that CGDTCL is aggressive and poorly responsive to therapy. Whether these lesions are primary to the mucosa or the skin, the prognosis is universally poor,[320] except in rare cases.[321] As mentioned previously, CGDTCL includes subcutaneous lesions previously considered to be $\gamma\delta$ variants of SPTL, which is associated with a potentially very aggressive HPS.[241,319] There are reports of a more indolent subcutaneous form of CGDTCL associated with atypical lymphocytic lobular panniculitis[321] that may be difficult to distinguish without clinical correlation. Histologically, the neoplastic clone of CGDTCL is a mature, activated $\gamma\delta$ T-cell with a cytotoxic phenotype. The subcutis, dermis, or epidermis may be involved by medium- to large-sized cells with irregular nuclei and clumped chromatin. Basal vacuolar interface change and interface dermatitis is common. The background tissue shows apoptosis and necrosis with occasional angioinvasion. Often, one patient may show different histologic patterns at different sites. In contrast to $\alpha\beta^+$ MF and SS, the neoplastic $\gamma\delta^+$ T-cells are typically negative for both CD4 and CD8, with rare $CD8^+$ cases.[318,319] Immunohistochemically, these neoplastic $\gamma\delta$ T-cells express CD3, CD2, CD43, and CD45RO.[322] The T-cells also express cytotoxic granule proteins such as TIA-1, perforin, and granzyme B.[304] Due to the lack of a reliable antibody that could detect either the γ or δ TCR in formalin-fixed tissue, identifying $\gamma\delta$ T-cells has historically been deduced from the lack of CD4, CD8, and TCR βF1 staining. Recently a protocol using commercially available antibodies directed against epitopes on the γ and δ TCR has been described.[323]

Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma (PC8TCL) is a second provisional entity in the primary cutaneous PTCL, unspecified, group. As the name implies, this tumor is comprised of epidermotropic $CD8^+$ T-cells with an aggressive clinical course.[324,325] Patients with this aggressive variant usually present with widespread eruptive ulcerative plaques. Mucosal and genital involvement is common. The disease course is often complicated by spread to the central nervous system, lung, and testis.[324] Of note, the lymph nodes are rarely involved. Histologically, there is a pagetoid pattern or occasionally a linear distribution of T-cells in an atrophic or acanthotic epidermis. Spongiosis may accompany the intraepidermal lymphocytes.[324] Angioinvasion with adnexal destruction are common findings. Immunohistochemically, the neoplastic cells express CD3, CD8, CD45RA, and cytotoxic granule proteins such as perforin, granzyme B, and TIA-1.[194] CD2 and CD5 expression are often lost, but CD7 expression is retained, a pattern that is generally the reverse of what is typically observed in MF.[326] PC8TCL must clinically and histologically be differentiated from CD8 MF, PR, and Type D LyP, all of which tend to follow an indolent course.[194,254,327] Nofal and colleagues have recently proposed diagnostic criteria for PC8TCL that must include these constant features:[324] (1) clinical: a history of onset within weeks to months of an aggressively behaving eruption of widespread papules, plaques, and tumors, that often ulcerate, without any precursor lesions; (2) histopathologic: epidermotropism, often prominent with a nodular or diffuse infiltrates of pleomorphic T-cells; (3) immunohistochemical: $CD8^+$, $CD4^-$ staining pleomorphic T-cells. PC8TCL patients have a poor prognosis with a median survival of 32 months.[324,326] This is further exemplified by an average 5-year survival of 18% as compared with 88% in the more indolent MF.[137]

The third provisional entity classified as a primary cutaneous PTCL is primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma. Primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma typically presents as a solitary plaque or tumor on the trunk or head and neck without preceding erythematous patches or plaques more typical of MF.[328] Uncommonly, the papulonodules, tumors, or deep plaques of primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma can be multiple.[328,329] Histologically, there is a nodular or diffuse infiltrate of small- or medium-sized pleomorphic lymphocytes in the dermis, with minimal or no epidermotropism and without cerebriform nuclei. The infiltrate can extend deeply into the dermis and subcutis and can include histiocytes, plasma cells, and eosinophils. Large atypical lymphocytes should comprise <30% of total cellularity. There have been rare cases with granulomatous features that may be confusing for GSS, yet GSS typically presents with more epidermotropism and shows some cerebriform cells.[328,330] The neoplastic T-cells are by definition $CD4^+$ and also express CD3 and $\alpha\beta$ TCR, but are negative for CD8, CD30, and cytotoxic proteins, and they can show loss of pan-T–cell markers. Several recent studies have shown that the neoplastic cells express the markers PD-1, CXCL13, and BCL-6 consistent with derivation from follicular T-helper cells.[331,332,333] The prognosis is usually excellent; a 5-year survival rate has been reported as 60% to 80% in several series.[328,329,334]

Other Hematopoeitic Neoplasms with Similar Cutaneous Presentations

Other lymphomas and hematopoietic tumors that may involve the skin include HTLV-1^+ ATL (Fig. 92.13), extranodal NK-/T-cell lymphoma, Hodgkin lymphoma, cutaneous B-cell lymphomas, and leukemia cutis or extramedullary myeloid tumor (EMT) (including granulocytic sarcoma and monoblastic sarcoma). Peripheral T-cell and NK/T-cell lymphomas are discussed in Chapters 88 and 89. Hodgkin lymphoma is discussed in Chapters 91 and 92. Cutaneous B-cell lymphoma, leukemia cutis, and EMTs are discussed in the following section.

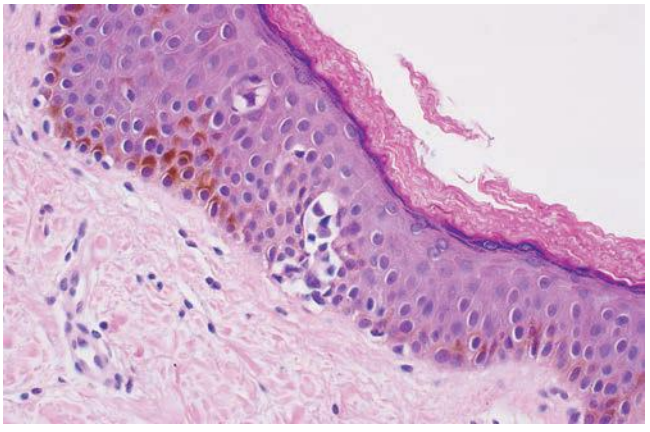

FIGURE 92.13. HTLV-1 (+) adult T-cell leukemia/lymphoma. Cutaneous involvement by HTLV-1 (+) adult T-cell leukemia/lymphoma showing epidermotropism and formation of a Pautrier microabscess (hematoxylin and eosin, ×50). HTLV-1, human T-cell lymphotrophic virus type-I

Primary cutaneous B-cell lymphomas are uncommon (incidence of 3.1 per million person-years), and must be differentiated from secondary cutaneous involvement by systemic B-cell lymphoma and cutaneous lymphoid hyperplasia of B-cell type.[83] The primary cutaneous B-cell lymphomas include: primary cutaneous follicle center lymphoma (PCFCL); primary cutaneous marginal zone B-cell lymphoma (PCMZL); primary cutaneous diffuse large B-cell lymphoma (PCLBCL), leg type; and primary cutaneous large B-cell lymphoma, other.[137,335] Other systemic B-cell lymphomas may involve the skin, including intravascular large B-cell lymphoma, lymphomatoid granulomatosis, chronic lymphocytic leukemia/small-cell lymphoid neoplasm, mantle cell lymphoma, and Burkitt lymphoma.[137,261] Cutaneous B-cell lymphomas usually present as single or multiple violaceous nodules on the head and neck or trunk and tend to infiltrate the deeper portions of the dermis, sparing the epidermis ("bottom-heavy"). PCFCLs are the most common cutaneous B-cell lymphomas. PCFCLs may have a nodular or a nodular and diffuse growth pattern and more frequently have a predominance of large noncleaved cells[336] than their nodal counterparts (Fig. 92.14). The Mann-Berard grading system used for nodal follicular lymphomas is not predictive in PCFCL. In fact, in contrast to the aggressive behavior of nodal large-cell follicular lymphomas, primary cutaneous large-cell follicular lymphomas tend to be localized, follow an indolent course, and can often be managed with local excision, radiation therapy, and more recently rituximab.[335,337–340] However, careful staging must be performed to exclude extracutaneous lymphoma before a case is classified as primary cutaneous B-cell lymphoma. Typically, nodal follicular lymphomas express BCL-2 and are characterized by the chromosomal translocation t(14;18). PCFCLs, on the other hand, rarely show characteristic chromosomal translocations and BCL-2 is uncommonly expressed (Table 92.3).[341,342]

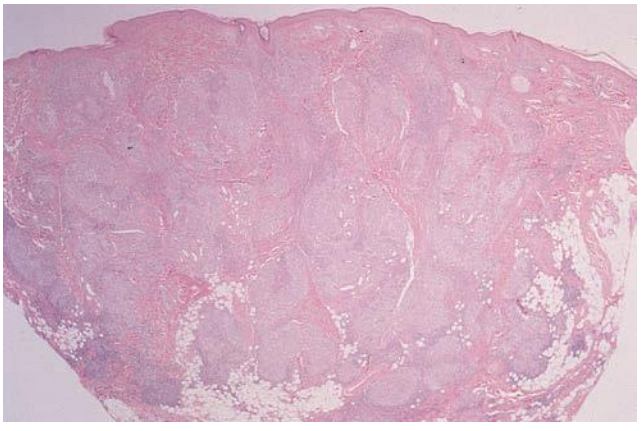

FIGURE 92.14. Primary cutaneous follicle center lymphoma. Note the back-to-back nodular pattern. The infiltrate extends from the superficial reticular dermis to the superficial subcutis in a "bottom-heavy" pattern sparing the papillary dermis and epidermis (hematoxylin and eosin, ×2).

PCMZL is an indolent lymphoma characterized clinically by small purple-pink irregular plaques on the trunk, in contrast to PCFCL, in which the violaceous nodules are usually confined to the head and neck.[343] Histologically, PCMZL is characterized by small, monocytoid, or lymphoplasmacytoid B-cells. Rarely, the infiltrate may be predominantly plasmacytic, and in instances where there is no evidence of systemic disease, these lesions are still considered part of the spectrum of PCMZL. The infiltrates range from nodular to diffuse. Reactive germinal centers may serve as foci for the nodular infiltrate of neoplastic marginal-zone cells. The neoplastic cells typically express CD20 and CD79 and BCL-2 but are negative for CD5, CD10, and BCL-6, the last two markers helping to distinguish it from PCFCL.[343,344] The presence of large clusters of CD123 plasmacytoid DCs has also been proposed as a differentiating feature of PCMZL from the other primary cutaneous B-cell lymphomas.[345] The chromosomal translocation t(14;18) (q32;q21) leading to the fusion of *IGH* and *MALT1* genes as well as the t(3;14) (p14;q32) fusing the *IGH* and *FOXP1* genes have rarely been reported in PCMZLs.[346] Similar to diffuse large B-cell lymphoma, a recent study identified aberrant somatic hypermutation in PCMZL, which leads to genomic instability.[347]

PCLBCL, leg type, typically presents in the elderly (average age of onset, 78 years) with rapidly growing reddish to violaceous nodules and tumors on the lower legs, but they can occur at any cutaneous site.[348,349,350,351] Histologically, the lesion is composed of immunoblasts and centroblasts without the admixed centrocytes that are more often seen in PCFCL. The infiltrate rarely involves the epidermis but can extend into the deep dermis and subcutaneous tissue. Because PCLBCL has a poor prognosis compared to the more indolent course of PCFCL, it is important to be able to distinguish these two entities.[348,349,350,351] As noted earlier, PCFCL and also PCLBCL can have a purely diffuse infiltrate with many centroblasts and immunoblasts, yet PCFCL will also contain centrocytes whereas PCLBCL, leg type, will not. By immunohistochemistry, PCFCL expresses CD10 and BCL-6 and only expresses BCL-2 or MUM1/IRF4 in a minority population, whereas PCLBCL diffusely expresses BCL-2, MUM1/IRF4, and IgM, but does not express CD10 and only rarely expresses BCL-6.[344,350,351–353] Gene chip expression profiling has shown that PCLBCL has an activated B-cell genotype, whereas PCFCL has more of a germinal center B-cell genotype.[354] A further study evaluating apoptosis-related genes identified a strong cellular cytotoxic immune response in PCFCL, whereas PCLBCL, leg type, had constitutive activation of the intrinsic mediated apoptosis pathway and downstream inhibition of apoptosis.[355]

PCLBCL, other, is a WHO-EORTC classification that includes those B-cell lymphomas that do not conform to the PCFCL or PCLBCL, leg type, criteria. This category includes large B-cell lymphoma subtypes such as anaplastic, plasmablastic, T-cell/histiocyte-rich, and intravascular large B-cell lymphoma.[356–362] Although these entities can present initially as cutaneous lesions, they often represent cutaneous involvement by a systemic lymphoma. Of note, some cases of intravascular large B-cell lymphoma appear to be confined exclusively to the venules, capillaries, and arterioles of the skin, without systemic involvement.[362] These rare cases have a better prognosis (56% 3-year OS vs. 22%) than their systemic counterparts.[362] More detailed discussion of the other systemic B-cell lymphomas is in Chapter 88.

TABLE 92.3

IMMUNOHISTOCHEMISTRY PATTERN OF THE PRIMARY CUTANEOUS B-CELL LYMPHOMAS (CBCL)

CBCL Type	BCL-2	BCL-6	CD10	CD20	Ig	MUM1/IRF4
PCFCL	– (10% +)	+	+ follicular pattern; – diffuse pattern	+	–	– (10% +)
Secondary FCCL	+	+	+	+	+	–
PCMZL	+	–	–	+	+	+ on associated plasma cells
PCLBL, Leg type	++	rarely	–	+	+IgM	++

FCCL, follicle center cell lymphoma; PCFCL, primary cutaneous follicle center lymphoma; PCLBL, primary cutaneous large B-cell lymphoma; PCMZL, primary cutaneous marginal zone lymphoma.

Leukemia cutis and EMT are cutaneous infiltrates of myeloblasts and immature myeloid precursors that are often difficult to differentiate from cutaneous lymphoma. EMT, also known as granulocytic sarcoma or chloroma, is an extramedullary tumor composed of immature granulocytic precursor cells. The most common sites of presentation are bone, periosteum, soft tissue, lymph node, skin, and, infrequently, small intestine. The tumor may develop during the course of acute myeloid leukemia, chronic myeloid leukemia, or other myelodysplastic disorders.[363,364] EMT usually presents as nodules or tumors that are often solitary, whereas leukemia cutis presents with multiple skin lesions with a varied clinical appearance, including papules, nodules, plaques, palpable purpura, or ulcers.[364] Histologically, EMT and leukemia cutis tend to infiltrate between collagen bundles and fat spaces in an interstitial pattern (Fig. 92.15). Cytologically, the myeloblasts of EMT and leukemia cutis are medium-sized cells with finely dispersed chromatin, small or inconspicuous nucleoli, and scant cytoplasm. Occasionally, eosinophilic or neutrophilic granules may point to the cells' myeloid lineage. In difficult cases, immunohistochemistry, flow cytometry, and cytochemical stains will usually confirm the diagnosis and exclude lymphoma.[365] CD68, CD43, and lysozyme, although not lineage-specific for monocytes or macrophages, have been shown to be the most sensitive markers for detecting myeloid leukemia cutis.[366,367] Nearly half of the cases may be myeloperoxidase negative; however, a recent study looking at 173 skin biopsies of myeloid leukemia cutis demonstrated a 100% diagnostic accuracy utilizing CD68, CD33, and MPO.[368] If the patient has systemic leukemia, comparing the immunohistochemical profile of the cutaneous infiltrate with that from the peripheral blood or bone marrow can be helpful. It must be kept in mind, however, that many of the immunophenotypic markers used in defining blastic cells in the blood or bone marrow (CD117 and CD34) are often negative in the cutaneous infiltrates.[353] Myeloperoxidase, Sudan black B, and chloroacetate esterase cytochemical stains can be used to confirm myeloid differentiation if air-dried touch imprints are available.

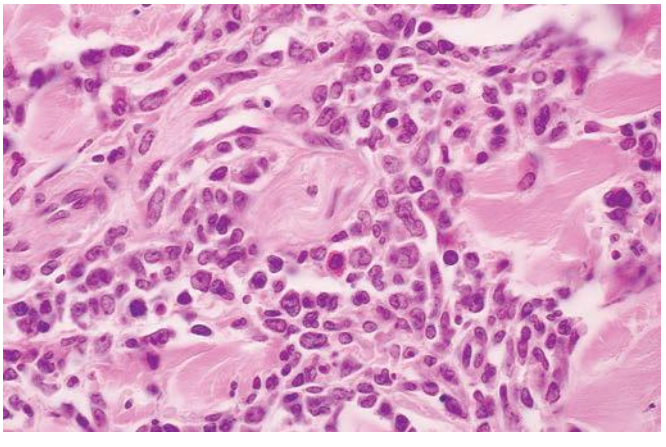

FIGURE 92.15. Leukemia cutis. Clusters of myeloblasts with fine chromatin and scant cytoplasm infiltrate between collagen bundles in the reticular dermis (hematoxylin and eosin, ×250).

STAGING

In 1979, a staging system for CTCL was proposed by an international panel of experts who devised a tumor–node–metastasis (TNM) system.[369] In the original TNM staging system, peripheral blood involvement with >5% atypical circulating cells was indicated by a separate peripheral blood stage B1 (vs. B0) and did not affect the clinical stage designation. Two large series have shown that blood involvement is more commonly seen in higher-stage disease, with 0% to 12% of patients with plaques only, 16% to 27% of patients with tumors, and >90% with erythroderma, demonstrating peripheral blood involvement.[173,370] More recently, Vonderheid et al. have shown that blood involvement has distinct prognostic implications.[371]

In 2007 the ISCL/EORTC recommended revisions to the MF Cooperative Group classification and staging system for CTCL.[176] These revisions are made to incorporate advances related to tumor cell biology, diagnostic techniques, and prognostic variables pertaining exclusively to MF and SS as opposed to non-MF/SS CTCLs (Table 92.4). Stage I refers to patients with patches and plaques without adenopathy and is divided into stage IA for patients with <10% body surface area (BSA) involvement (T1) and stage IB for more generalized patches and plaques (T2). Stage II has two unique categories: stage IIA patients have patches/plaques with palpable adenopathy (histology negative), whereas stage IIB patients have tumors (nodules >1cm in size) with or without palpable adenopathy (histology negative). Patients with erythroderma are placed into stage III with or without palpable adenopathy (histology negative). Stage IV patients have evidence of CTCL beyond the skin. Stage IVA_1 reflects significant blood involvement. Patients with stage IVA_2 have nodal involvement without visceral disease and stage IVB reflects patients with visceral disease. The lymph node staging includes N1 for dermatopathic lymph nodes (NCI grades 0 to 2), N2 for NCI grade 3 lymph nodes, and N3 for NCI grade 4 lymph nodes (Table 92.5). New to the ISCL/EORTC staging system is B2 staging for high blood tumor burden (Table 92.4), B0 for <5% Sézary cells, and B1 blood stage for >5% Sézary cells when criteria for B2 are not met. For the first time, the blood stage is factored into the clinical stage to create a TNMB matrix. Changes also include the creation of clinical stages IIIA (T4N0-2M0B0), IIIB (T4N0-2M0B1), IVA_1 (T1–4N0-2M0B2), and IVA_2 (T1–4N3M0B0–2).[176]

Staging procedures recommended by the international panel in 1979 included lymph node biopsy of a nonpalpable lymph node in patients without adenopathy, and liver and bone marrow biopsies for advanced stages (II, III, IV).[372] These procedures may be considered in patients in clinical trials but are rarely helpful in those patients with limited skin disease and no

TABLE 92.4

2007 ISCL/EORTC STAGING OF MYCOSIS FUNGOIDES/SÉZARY SYNDROME

Stage	Clinical–Pathologic Features
T Skin Stage	
T1	Patches/plaques <10% BSA
T2	Patches/plaques >10% BSA
T3	At least one tumor nodule >1 cm in diameter
T4	Confluence of erythema (erythroderma) covering >80% BSA
N Lymph Node Stage	
N0	No clinically abnormal peripheral lymph nodes (pLNs)
N1	Clinically abnormal pLNs with NCI grade 1 or 2 pathology
N2	Clinically abnormal pLNs with NCI grade 3 pathology
N3	Clinically abnormal pLNs with NCI grade 4 pathology
Nx	Clinically abnormal pLNs with no histologic confirmation
M Visceral Stage	
M0	No visceral involvement
M1	Visceral involvement
B Blood Stage	
B0	Sézary cell count ≤5% lymphocytes
B1	Sézary cell count >5% lymphocytes when B2 criteria are not met
B2	T-cell clone in blood + >1,000 Sézary cells/μl, OR 2 of 3: CD4/CD8 ratio >10, or $CD4^+CD7^-$ >40% lymphocytes, or $CD4^+CD26^-$ >30% lymphocytes AND lymphocytes or CD4 or CD3 count must be elevated.
Clinical Stage	TNMB Stages
Early-Stage Disease	
IA	T1 N0 M0 B0–1
IB	T2 N0 M0 B0–1
IIA	T1–2 N1–2 M0 B0–1
Late-Stage Disease	
IIB	T3 N0–2 M0 B0–1
IIIA	T4 N0–2 M0 B0
IIIB	T4 N0–2 M0 B1
IVA_1	T1–4 N0–2 M0 B2
IVA_2	T1–4 N3 M0 B0–2
IVB	T1–4 N0–3 M1 B0–2
Sézary Syndrome	
$IVA_{1\ or\ 2}$ or IVB	T4 N0–3 M0–1 B2

BSA, body surface area; EORTC, European Organization for the Research and Treatment of Cancer; ISCL, International Society of Cutaneous Lymphomas; NCI, National Cancer Institute; pLNs, peripheral lymph nodes.
Modified from Olsen E, Vonderheid E, Pimpinelli N, et al. Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC). Blood 2007;110:1713–1722.

lymphadenopathy.[182] Because invasive tests such as liver biopsy or staging laparotomy have added little diagnostic information for patients with early and advanced-stage disease,[175,373,374] these staging studies are not recommended by the recent consensus conference.[176] Table 92.6 outlines staging procedures for MF/SS adapted from the ISCL/EORTC guidelines.[176] All patients should have a complete physical examination with special attention to skin and lymph nodes. Careful mapping of skin involvement and/or total-body photographs are recommended to document the initial extent of disease at diagnosis and to assess response to treatment.[375] Laboratory studies should include serum comprehensive metabolic panel, lactate dehydrogenase, and complete blood count with manual differential. In addition, peripheral blood should be examined for abnormal lymphocytes by either a Sézary cell count (number per microliter) and/or flow cytometry with attention to $CD4^+/CD8^+$ ratio and $CD4^+/CD7^-$ or $CD4^+/CD26^-$ gated populations if indicated. *TCR* gene rearrangement of peripheral blood is also recommended, including an attempt to correlate a positive finding with any clone in the skin. A recent study showed no significant benefit to performing bone marrow biopsies for staging purposes.[181] They may be helpful in working up unexplained hematologic abnormalities.

TABLE 92.5

NCI VA GRADING SCHEME FOR LYMPH NODE HISTOLOGY IN CTCL

Grade	Histopathologic Features
LN-1	DL with occasional CTC
LN-2	DL with CTC singly or in small clusters (<6 cells)
LN-3	DL with numerous CTC, singly or in large clusters (>15 cells)
LN-4	Partial or complete effacement by MF/SS ± DL

CTC, cerebriform T-cells; CTCL, cutaneous T-cell lymphoma; DL, dermatopathic lymphadenopathy; LN, lymph node; MF, mycosis fungoides; NCI, National Cancer Institute; SS, Sézary syndrome; VA, Veterans Affairs.
Modified from Sausville EA, Eddy JL, Makuch RW, et al. Histopathologic staging at initial diagnosis of mycosis fungoides and the Sézary syndrome. Definition of three distinctive prognostic groups. Ann Intern Med 1988;109:372–382.

Imaging

The role of diagnostic imaging in the initial staging of CTCL has been examined by several authors.[376–379] Kulin et al. studied the results of gallium citrate Ga-67 scintigraphy, liver–spleen scans, lymphangiography, and computed tomography (CT) used in the initial staging of 62 CTCL patients (85% with stage I or II disease) and found that none of the results added significantly to the information obtained from physical examination and routinely performed lymph node biopsy (73% of 62).[377] In contrast, a study of 63 CTCL patients (78% with stage I or II disease) who had staging body CT scans found positive findings in 18 (29%) patients, one half of whom had clinically unsuspected advanced-stage disease.[376] Eight of these 18 patients had biopsies, with 5 of 8 confirming extracutaneous CTCL. Of the 38 patients with stage I disease, however, only 2 had positive findings on CT scan.[376] Another retrospective study of 33 CTCL patients (70% with stage I or II disease) who had CT scans found that 3 of the 20 patients with initial clinical stage I disease were staged higher on the basis of CT findings as stage II.[378] Subsequent lymph node biopsies confirmed extracutaneous disease in all three patients (stage IVA). In summary, pelvic, abdominal, and thoracic CT scans have a low yield in patients without palpable adenopathy (stage I) and are not necessary for staging these patients. The highest yield of CT scans appears to be in cases of non-MF/SS CTCL (nonepidermotropic, transformed CTCL, ALCL) and stage III disease (erythroderma), in contrast to stage II and IV patients, in whom CT findings often do not change treatment or stage.[376] Therefore, staging CT scans of the chest, abdomen, and pelvis are recommended for patients with generalized plaques, erythroderma, tumors, palpable lymph nodes, or blood involvement.[176]

TABLE 92.6

RECOMMENDED INITIAL STAGING EVALUATION OF MYCOSIS FUNGOIDES/SÉZARY SYNDROME

	Evaluation and Studies
Skin	
Physical exam	Identify primary skin lesion (patches, plaques, tumors, erythroderma) and % BSA involved.
Skin biopsy	Punch biopsy of thickest or oldest skin lesions (>1 skin biopsy)
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.
Lymph Nodes	
Physical exam	Identify abnormal peripheral lymph nodes ≥1.5 cm or irregular.
Radiologic tests	CT scans of chest, abdomen, pelvis except in stage IA or limited IB. PET scans may be helpful to identify which LN to biopsy.
LN biopsy	Complete LN biopsy preferred over core LN biopsy or FNA.
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.
Viscera	
Physical exam	Identify abnormal liver, spleen, or other organs.
Radiologic tests	CT scans of chest, abdomen, pelvis except in stage IA or limited IB. PET scans may be helpful to identify visceral abnormalities.
Liver biopsy	Not indicated, unless involvement would change management.
Spleen biopsy	Not indicated, unless involvement would change management.
Bone marrow biopsy	Not indicated, unless abnormalities would change management.
Other biopsies	Not indicated, unless involvement would change management.
Immunophenotyping	CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30.
Molecular genetics	T-cell receptor rearrangement analysis if needed.
Blood	
Chemistries	Comprehensive panel including liver enzymes, lactate dehydrogenase, HTLV-1 serology if indicated.
Blood cells	Complete blood count and manual Sézary cell count/differential.
Immunophenotyping	Flow cytometry for absolute count and %: CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD26 (if available), CD30. Also include CD4/CD8 ratio, $CD4^+CD7^-$, $CD4^+$ $CD26^-$ (if available).
Molecular genetics	T-cell receptor rearrangement analysis.

BSA, body surface area; CT, computed tomography; FNA, fine-needle aspiration; HTLV-1, human T-lymphotropic virus-1; LN, lymph node; PET, positron emission tomography.
Modified from Olsen E, Vonderheid E, Pimpinelli N, et al. Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC). Blood 2007;110:1713–1722.

Positron emission tomography (PET) may provide an alternative staging and response-assessment tool for patients with CTCL. A recent study evaluated 13 patients with MF and SS at risk for secondary lymph node involvement using integrated PET/CT followed by excisional biopsy of the lymph nodes.[380] Two of seven patients with LN4 effaced lymph nodes had nodes <1.5 cm on CT scan and would have been assigned an N0 classification without the use of integrated PET/CT. The intensity of PET activity correlated roughly with lymph node histologic grade but did not reach statistical significance because of the small sample size. Feeney and colleagues recently evaluated the FDG PET/CT findings in patients with a variety of T-cell lymphomas noting a significant difference in the mean maximum standardized uptake value (SUV) in patients with MF with transformation (SUV, 11.3) compared with patients with MF without transformation (SUV, 3.82; $\pi < 0.05$).[381] Additional studies need to be performed to evaluate the role of CT/PET in the staging of patients with MF/SS.

Lymph Nodes

Although the presence of palpable nodes has prognostic value, lymph node histology is even more important in staging and assessing prognosis, not only at diagnosis but also later in the course of the disease. Enlarged lymph nodes from MF/SS patients either show dermatopathic lymphadenopathy or involvement by MF/SS. Sausville et al. described a system of grading lymph nodes in CTCL patients (NCI VA classification) that correlated well with prognosis: LN1, a few atypical cerebriform T-cells; LN2, dermatopathic lymphadenopathy with small clusters (<6 cells) of atypical cerebriform T-cells; LN3, dermatopathic lymphadenopathy with large clusters (>6 cells) of atypical cerebriform T-cells; and LN4, partial or complete effacement of lymph node architecture.[173] Although clusters of atypical cerebriform T-cells are present in grades LN2 and LN3, lymph node architecture is preserved. Only LN4 lymph nodes are considered involved with CTCL (histology positive) for purposes of the TNM staging system (Table 92.4). The NCI VA classification has been criticized because of the nonspecificity of grades LN1–3 and because lymph nodes from patients with unrelated diseases can show similar findings, and many consider LN3 lymph nodes to be histologically borderline.[163,382]

The ISCL/EORTC consensus staging system for lymph nodes distinguishes stage N3 lymph nodes that show effacement of nodal architecture (grade LN4) from stage N2 lymph nodes that contain clusters of atypical lymphocytes (>6 cells) that do not efface architecture (grade LN3). ISCL/EORTC stage N1 lymph nodes may show dermatopathic lymphadenopathy, or small clusters of atypical lymphocytes (3 to 6 cells) that do not distort nodal architecture (grade LN1–2). In general, there is good correlation between histologic and molecular evaluation of lymph nodes for involvement by MF/SS. Three studies have shown that most histologically negative lymph nodes (LN1–2) do not show T-cell–receptor gene rearrangements, whereas ~90% or more histologically involved LNs (LN4) do show clonal T-cell–receptor gene rearrangements by Southern blot analysis.[383–385] All three studies also showed a mixture of clonal and polyclonal populations in histologically borderline cases (LN3 or histologically equivalent to LN3). Although not statistically significant in all studies, histologically borderline cases that have a positive *TCR* gene rearrangement tend to have a poorer prognosis, similar to cases with histologically involved lymph nodes (LN4).[384]

Fine-needle aspiration of lymph nodes to assess for involvement by MF/SS has been evaluated in a limited number of patients, with good correlation between cytologic grade of the FNA specimen and histologic classification of the lymph node biopsy.[382,386] However, as with other types of lymphomas, there is an inherent risk of sampling only low-grade involvement and missing a focal area of transformation to a large-cell lymphoma. Therefore, excisional biopsy of peripheral lymph nodes >1.5 cm in diameter is recommended, with preference for the largest lymph node draining the involved skin area or, if available, the lymph node with the highest SUVfrom PET scan data.[176]

Peripheral Blood

The 1979 Committee on Staging and Classification of CTCLs defined peripheral blood involvement by MF/SS as >5% peripheral blood lymphocytes with Sézary cell morphology (Fig. 92.7);[372] however, this criterion is not uniformly agreed on. Because Sézary cells can be seen in the peripheral blood of patients with benign dermatitis or erythroderma, investigators have suggested that other criteria be used to define peripheral blood involvement.[176,371] The 2007 ISCL/EORTC staging criteria of peripheral blood involvement includes B2 staging for high blood tumor burden and B1 blood stage for low blood tumor burden (>5% Sézary cells) when criteria for B2 are not met. More specifically, B2 is defined as clonal *TCR* rearrangement in the blood and one or more of the following: (a) absolute Sézary cell count of 1,000 cells/μl or more, (b) CD4/CD8 ratio of 10 or more due to an increase in $CD3^+$ or $CD4^+$ cells by flow cytometry, (c) increase in $CD4^+$ cells with an aberrant phenotype: ≥40% $CD4^+/CD7^-$, or ≥30% $CD4^+/CD26-$ as suggested by Vonderheid and Bernengo.[387]

As discussed earlier, aberrant phenotypes include the absence of T-cell markers such as CD2, CD3, CD5, CD7, and CD26, which are usually expressed on normal T-cells, or co-expression or absence of both CD4 and CD8. A CD4:CD8 ratio of >10:1 or an aberrant phenotype constitutes an abnormal population. Because decreased CD7 expression on T-cells has been seen in patients with benign skin conditions, the ISCL recommends that 40% or more of the $CD4^+$ T cells lack CD7 for it to be considered significant.[176] PCR of peripheral blood has been shown to detect a clonal population of T-cells in approximately one third of patients with stage I to II disease and a majority of patients with stage III to IV disease.[187,388] In addition, loss of CD26 expression on circulating $CD4^+$ T-cells has been reported in most cases of MF and SS.[199,200,389] Therefore, gating of $CD4^+CD26^-$ T-cells may provide a more sensitive way to use flow cytometry to evaluate peripheral blood for involvement by MF/SS.[29,38,235,390] A recent study of CD27 expression in peripheral blood T-cells showed a significantly higher expression of the CD4+CD27+CD45RA- central memory T-cell subset in patients with SS as compared to patients with idiopathic erythroderma patients who showed increased CD4+CD27–CD45RA– effector memory T-cell levels.[391]

Bone Marrow

Studies of bone marrow involvement in MF patients at initial staging found disease in 2% to 22% of patients.[174] Histologic findings in involved marrows include clusters of $CD3^+$ atypical lymphocytes with cerebriform nuclei and occasional large dysplastic cells.[174] Bone marrow involvement by MF is more common in higher-stage disease and correlates with a poorer prognosis; however, when other factors such as skin stage and visceral involvement were considered, bone marrow involvement was not shown to be an adverse prognostic factor.[392] These findings were supported by a recent study that evaluated the prognostic significance of histologic and molecular evidence of bone marrow involvement at the time of diagnosis. This study also showed a correlation between histologic or molecular bone marrow involvement and clinical stage of disease, but bone marrow involvement failed to be an independent prognostic indicator.[181] Therefore, despite being considered in initial staging of non-MF/SS lymphoma patients, routine staging bone marrow biopsies in patients with MF are not currently recommended. The recent ISCL/EORTC consensus conference recommended performing bone marrow biopsies only in patients with B2 blood involvement or unexplained hematologic abnormalities.[176]

PROGNOSIS

Prognosis correlates with the extent of skin disease and status of the lymph nodes, blood, and visceral involvement. MF behaves in a manner similar to other low-grade or indolent NHLs, with prolonged survival despite recurrent relapses (see Chapter 88). Zackheim et al. assessed relative (observed/expected) long-term survival among the four skin stages. Stage and survival data for 489 patients with CTCL was extracted from a University of California, San Francisco, CTCL registry dated 1957 to 1994 and compared to a control group matched for age, sex, race, and geographic variables. Using the control group to generate expected survival values, researchers found a relative survival at 10 years for each group as follows: 100% for T1, 67% for T2, 40% for T3, and 41% for T4.[393]

The TNM staging system has correlated well with prognosis, demonstrating the following 5-year survival rates: 95% for stage I, 76% for stage II, 45% for stage III, and 51% for stage IV.[394] Utilizing the newest staging criteria from the ISCL/EORTC, the 5-year survival rates are similar: 94% for stage IA, 84% for stage IB, 78% for stage IIA, 47% for stage IIB, 47% for stage IIIA, 40% for stage IIIB, 37% for stage IVA_1, 18% for stage IVA_2, and 18% for stage IVB.[189] Data from a retrospective cohort analysis suggest that the long-term (30-year) survival of patients with stage IA (limited patch/plaque) MF is similar to the expected survival of a matched control population.[389,393] Therefore, it is unlikely that stage IA MF will affect the life expectancy of afflicted patients.

Kim et al. performed a retrospective cohort analysis of 525 patients with MF/SS at Stanford University from 1958 through 1999.[389] In the multivariate analysis, patient age, T classification, and the presence of extracutaneous disease were the most important independent factors. The risk for disease progression to a more advanced TNM or B classification, worse clinical stage, the development of extracutaneous disease, or death due to MF correlated with the severity of the initial T classification. None of the patients had T1 disease when their extracutaneous disease was detected.[389]

Using histology to differentiate between patch and plaque predominance within stage T2, one study found plaque predominance to influence relative survival negatively.[395] A retrospective analysis by Sausville et al. of 152 consecutively staged patients at the NCI identified skin stage (T3, T4 vs. T1, T2) and visceral involvement as the most significant independent predictors of survival with palpable adenopathy and lymph node histopathology classification showing marginal significance using multivariate analysis.[173] Three prognostic groups were identified, with the most favorable, low-risk group having limited skin disease without visceral or blood involvement (TNM stages IA, IB, IIA) and the least favorable, high-risk group demonstrating effaced lymph nodes (NCI VA LN4, TNM stage IVA) or visceral involvement (TNM stage IVB).[173,396] The intermediate-risk group included all other patients (TNM stages IIB, III) and stage IVA patients with grade LN3 lymph node histopathology. Several reports suggest that patients with dermatopathic or early lymph node involvement with *TCR* gene rearrangement have a worse prognosis than similar patients without evidence of gene rearrangement.[171,383,384,397]

A study of 57 patients demonstrated serum LDH to reflect tumor burden in erythrodermic CTCL, with levels being inversely related to hematologic stage and survival.[398] This same study used a univariate model, which found lymph node stage and hematologic stage to predict survival. Upon multivariate assessment, however, only lymph node stage served as an important prognostic indicator of survival.

A more recent study that retrospectively analyzed 1,502 MF/SS patients with the revised ISCL/EORTC staging for CTCL found a significant difference in survival between those with patch-only disease (T1a/T2a) versus patch and plaque disease (T1b/T2b).[189] Multivariate analysis revealed that advanced T stage, the presence of a peripheral blood tumor clone without Sézary cells (B0b), increased LDH, and folliculotropic MF were associated with both decreased survival and increased risk of disease progression.[189] The same analysis showed that large-cell transformation was predictive only of increased risk of disease progression, and male sex, increasing age, and poikilodermatous MF were associated with decreased survival.[189]

In a retrospective analysis of 100 patients with transformed MF, Benner et al. identified decreased overall and disease-specific survival in those with folliculotropic MF and those lacking CD30.[166] They developed a "prognostic index" for those with transformed MF based upon the following four negative prognostic factors: CD30 negativity, generalized skin lesions, extracutaneous transformation, and folliculotropic MF. There was a significant decrease in survival in those with 2+ negative prognostic factors versus those with 0 to 1.[166]

Patients with SS have a relatively poor prognosis, with a median survival of ~3 to 4 years.[136,389,399] In a series of 29 patients with SS, features linked with a bad prognosis included fast evolution of the disease (from symptoms onset up to diagnosis) ($p = 0.0274$), raised levels of serum lactate dehydrogenase ($p = 0.0379$), and β_2-microglobulin ($p = 0.0151$), the latter being the most important prognostic factor.[399] Some of these findings were confirmed in another series of 28 patients with SS in whom the detrimental prognostic value of increasing age and LDH level, and the identification of the EBV genome in the skin, were reported.[400]

The prognosis for patients with extracutaneous disease is poor, with median survivals between 1 and 2.5 years.[401] Virtually all patients with extracutaneous disease die of CTCL, compared to nearly one third of patients with generalized plaques and a majority of patients with tumors or erythroderma without visceral involvement.[375,402] Very few patients with limited plaques (T1) actually die of MF, with most deaths due to cardiovascular events or other malignancies.[375,389,393] Overall, illnesses attributed directly to CTCL or indirectly implicated via CTCL-related complications contribute up to a mere 19% of deaths in CTCL patients.[394] More recently, Agar et al. found that 26% died due to their cutaneous lymphoma.[189] Overall, the bulk of patients with CTCL do not die from their malignancy.[401,403] Second malignancies other than skin cancers include NHL, HD, colon cancer, and lung cancer.[404] Infection remains the most common cause of death in patients who succumb to CTCL, with *Staphylococcus aureus* and *Pseudomonas aeruginosa* being the most common pathogens infecting the skin, leading to bacteremia and sepsis.[402,403] Visceral involvement with CTCL may lead to organ failure and ultimately death.

THERAPY

The mainstay of treatment of CTCL has been control of the cutaneous manifestations of disease with topical therapies in the hope of preventing spread to extracutaneous sites. However, because of the risk of progression to extracutaneous sites and worsening cutaneous symptoms, systemic agents alone or in combination with topical therapies have been studied to control more advanced disease. Therapy in MF/SS is based on the extent of disease, age, performance status, potential for remission, availability of treatments, efficacy, and treatment toxicity.[405,406] Because MF usually behaves as a low-grade or indolent lymphoma, controversial issues have involved the timing, selection, and intensity of systemic therapy. Unfortunately, there are few randomized clinical trials comparing the efficacy of the numerous therapeutic options available for patients with MF/SS. The following discussion summarizes the efficacy and toxicity of each therapy, and relates these parameters to disease stage (Fig. 92.16).

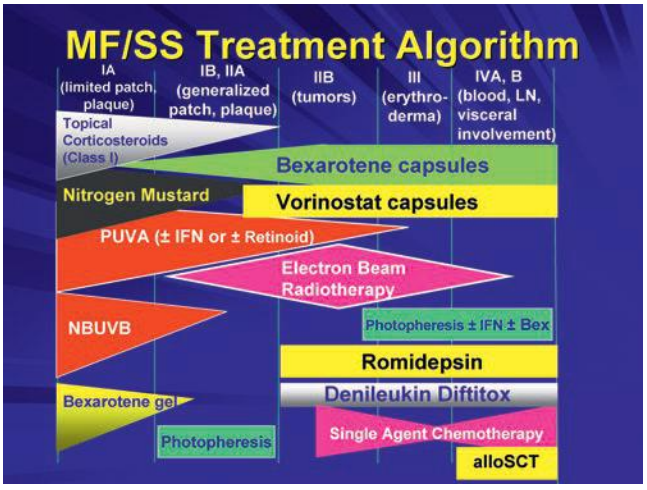

FIGURE 92.16. Cutaneous T-cell lymphoma (CTCL) treatment algorithm. alloSCT, allogeneic stem cell transplant; Bex, bexarotene capsules; IFN, interferon; LN,lymph node; MF/SS, mycosis fungoides/ Sézary syndrome; NBUVB, narrow beam ultraviolet B phototherapy; PUVA, psoralen + ultraviolet A phototherapy. Note that single-agent chemotherapeutic agents with impressive benefit/risk ratios include pegylated liposomal doxorubicin, gemcitabine, and pralatrexate.

Topical Chemotherapy

Mechlorethamine hydrochloride, or nitrogen mustard (HN2), was introduced in 1947 as the first topical agent to demonstrate activity in treating MF[407] and remains one of the major therapies of choice for early-stage MF. In 1942, HN2 became the first chemotherapy agent to be infused into a human being for the treatment of cancer.[408] HN2 is an alkylating agent that undergoes rapid degradation to an active ethylenimonium ion that has high antimitotic activity and a brief half-life.[401] Several studies have suggested that the mode of action of HN2 may involve induction of G_2 arrest,[409] gene-specific DNA cross-links,[410,411] and blockage of transcription factor–binding sites.[412] Some investigators have suggested that immunogenic properties of HN2 demonstrated by its propensity to induce delayed-type hypersensitivity contribute to its antineoplastic activity.[413] Topical HN2 may be prepared in a variety of ways; initial studies involved dissolving HN2 in water to reach a concentration of 10 to 20 mg/dl,[414] whereas more recently HN2 has been suspended in an emollient such as Aquaphor or a gel at concentrations of 0.01% and 0.02%.[415,416] Topical HN2 is usually applied once daily to the entire skin surface with relative sparing of the eyelids, genitalia, rectum, lips, and intertriginous areas. The length of treatment is variable but usually involves daily applications until the patient achieves a complete or significant clearing of skin lesions, followed by a maintenance regimen of daily or every-other-day applications for a period of 6 months to 2 years. No author has advocated a maintenance regimen of indefinite HN2 applications. Recently, Kim et al. found that longer maintenance regimens had no impact on the relapse rate in patients treated with topical HN2.[417] Treatment may be intensified for localized lesions by increasing either the concentration or frequency of application.

The response rate of topical HN2 is related to the morphology (patch/plaque vs. tumor) and extent of disease (T1 vs. T2). Several large series with >100 patients have been reported.[417,418,419] It is difficult to compare overall response rates among these studies because of differences in the clinical stages treated, adjunctive therapies, and staging systems. The percentage of patients with early-stage MF achieving an initial complete response (CR) ranged from 64%[418] to 75%[419] in stage I disease. Including more advanced stages, the complete response ranged from 37% in stage I/IIA disease to 50% in stage I to III disease.[417] The median time to achieve CR is shorter for stage I patients than for those with more advanced stages.[417,418] Vonderheid et al. found a durable CR to HN2 lasting more than 8 years occurring in 34 of 324 (10%) patients with early-stage MF,[419] and Kim et al. demonstrated that freedom-from-progression rates at 10 years were 85% and 83% for T1 and T2 patients, respectively.[417] Relapse is common, as Kim et al. observed relapses in 42% of 107 patients after an initial CR, all of which occurred within 5 years, and disease progression to a higher skin stage has been recently reported in 12% and 17% of T1 and T2 patients, respectively.[417] However, among patients who had an initial response to HN2 and relapsed, 67% achieved a CR after receiving HN2 salvage therapy. In summary, HN2 is effective in achieving an initial response in early-stage disease. Relapse occurs frequently but can often be treated with a second course of therapy.

The side effects of topical HN2 include local allergic reactions, xerosis, hyperpigmentation, and secondary cutaneous cancers.[413] Immediate hypersensitivity reactions manifesting as urticaria are rare but do occur in ~5% of patients using topical HN2 and necessitate discontinuing treatment to avoid a potentially life-threatening anaphylactic reaction.[413,420,421] Delayed-type hypersensitivity reactions (allergic contact dermatitis) manifesting as erythematous eczematous patches occur in up to 64% of patients treated with aqueous HN2[418,419,422] but occur less frequently (<10%) with the ointment-based preparation.[417] Some investigators have suggested that the delayed-type hypersensitivity reaction to topical HN2 may have a beneficial effect in clearing MF lesions[413] and advocate topical desensitization[414,418,423] rather than discontinuation of the HN2 when delayed-type hypersensitivity reactions occur.[413] Despite this, discontinuation of the medication can occur in up to 19% of patients.[422] Hyperpigmentation of the skin, especially in sites of MF involvement, occur commonly in patients using topical HN2, and patients should be reassured that the hyperpigmentation will resolve spontaneously within several months.[413]

In their study of 331 patients treated with HN2, Vonderheid et al. calculated an 8.6-fold (n = 31, 9%) and 1.8-fold (n = 27, 8%) increased risk for the development of squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) of the skin, respectively, when compared to the general US population.[419] In contrast, Kim et al. found BCC or SCC skin neoplasms in only 8 of 203 (4%) CTCL patients treated initially with HN2.[417] Melanoma occurred in 1 patient in the Kim et al. cohort. This patient had Fitzpatrick skin type 1 and had had a previous BCC.[417] Because HN2 is a known radiomimetic agent, its carcinogenic potential may be amplified with the simultaneous use of other agents, most notably ultraviolet therapy.[413,424] To help minimize this risk, patients using HN2 should adhere to strict protection from sun exposure. The risk of environmental contamination from topical HN2 appears to be minimal, as there are no epidemiologic data of increased malignancy in family members of treated patients; however, treatment assistants should wear latex gloves and wash accidentally exposed skin thoroughly.[425,426]

Topical carmustine (BCNU), a nitrosourea compound that causes DNA damage through alkylation at an O6 site of guanine and interstrand cross-linkage, is also used to treat early-stage MF, although experience is more limited than with topical HN2.[427,428] The use of topical nitrosoureas for the treatment of MF was first reported in 1972.[429] Patients mix a 5-ml (10-mg) aliquot of a 0.2% alcoholic stock solution with 60 cc of tap water and apply the solution to only the involved areas of MF.[413] Applications are repeated daily for no more than 8 to 10 weeks at a time. Zackheim et al. reported a CR in 86% of T1 stage patients and 48% of T2 patients treated with BCNU solution.[427] In their follow-up report of 188 early-stage MF patients treated with topical BCNU, 91% of stage T1 patients and 62% of stage T2 patients had not failed treatment after 36 months, and 5-year survivals were 97% and 80%, respectively.[413] Very recently, a phase 1 clinical trial evaluating the use of topical carmustine and intravenous

O6-benzylguanine was reported.[428] Given the likelihood of a potentiating effect from the two therapies, O6-benzylguanine and systemic carmustine have been used to treat solid tumors. The therapeutic combination, now utilizing topical carmustine was initiated in 21 patients with refractory early-stage MF (IA-IIA). The minimal toxic effect was seen at the 40-mg dose of carmustine, and there was also a 76% overall clinical response noted.[428] Side effects from carmustine include erythema and skin tenderness in a great majority of patients, telangiectasia following less common severe cutaneous reactions, allergic cutaneous reactions (<10%), and mild leukopenia (4%).[428]

Phototherapy

Psoralen photochemotherapy was introduced in 1974 for refractory psoriasis[430] and has been used extensively in the early stages of CTCL. Psoralen and ultraviolet A light therapy (PUVA) involves the ingestion of 8-methoxypsoralen (8-MOP), a photosensitizing compound, which is activated after exposure to ultraviolet A (UVA) light (320- to 400-nm wavelength). More recently, 5-methoxypsoralen has been used as the photosensitizing agent in PUVA, and early studies indicated similar efficacy.[431] Because of the similar efficacy of narrow-band ultraviolet B (NBUVB) phototherapy as compared to PUVA phototherapy in the treatment of psoriasis, the availability of UVA light boxes in dermatology offices is diminishing. Psoralen intercalates with DNA and, after UVA exposure, forms mono- or bifunctional adducts to pyrimidine bases and cross-links between strands of DNA. In addition to interfering with DNA synthesis and the subsequent death of neoplastic T-cells,[432] PUVA may have other effects, including a direct cytotoxic effect, immunomodulation,[433] and the induction of apoptosis in peripheral blood lymphocytes.[434]

Approximately 1 to 2 hours after ingesting 8-MOP, patients are exposed to increasing doses of UVA light, initially in the range of 1.5 to 3.0 J/cm^2 based on the patient's skin type (I to VI) determined from skin color and sun sensitivity or, less commonly, based on the direct measurement of a patient's minimal phototoxic dose.[432] Treatments are given at a frequency of two to three times per week until complete clearing occurs, followed by a maintenance regimen with increasing intervals between treatments over 2 to 7 months.[432,435] Some authors recommend a once-monthly treatment indefinitely to decrease recurrences,[435] whereas others discontinue PUVA treatments in stage I patients after the maintenance regimen.[436] In a small study, the number of patients in the relapse versus the nonrelapse group receiving maintenance therapy was the same.[437] Therefore, the risk of increased cumulative UVA dose in patients treated with maintenance therapy must be balanced against the potential side effects.

In their combined analysis of five recent studies[435,436,438–440] reflecting the response of 244 CTCL patients to PUVA, Herrmann et al. reported the following complete response rates for each stage: IA, 54/60 (90%); IB, 88/116 (76%); IIA, 7/9 (78%); IIB, 16/27 (59%); III, 11/18 (61%); IVA, 4/10 (40%); IVB, 0/4 (0%).[432] Median time to complete response was 3 months in the study of Herrmann et al..[435] Patients with early-stage disease readily respond to PUVA, but relapse among complete responders is common, affecting ~31%, 56%, and 71% of stage IA, IB, and IIA patients, respectively.[435] In a retrospective review of 104 patients with early-stage MF treated with PUVA, Querfeld et al. reported a 63% CR rate, although 50% relapsed on maintenance PUVA therapy.[437] Even higher relapse rates were seen in erythrodermic patients treated with PUVA alone. Tumor-stage (IIB) patients usually require localized radiation therapy or systemic chemotherapy to achieve a significant response and PUVA should play only an adjunctive role. Approximately one third of relapsing stage IA patients will achieve a second long-lasting disease-free remission with re-initiation of PUVA, whereas ~22% of stage IB patients can be expected to do the same.[432,435] Hermann et al. reported the same 5- and 10-year survival rates of 89%, 78%, and 100% for stages IA (n = 19), IB (n = 49), and IIA (n = 6) patients, respectively, and a 5-year survival rate of 80% for stage III (n = 6) patients.[435] In an attempt to minimize side effects, Weber et al. evaluated 16 patients who received bath PUVA. Patients were treated with 30 ml of 0.5% alcoholic 8-MOP in 150 l of water; all 16 patients achieved a CR.[441]

Acute side effects of PUVA include delayed (24 hours) burning and erythema (10%), pruritus (7%), nausea due to psoralen (4%), and reactivation of herpes simplex (2%).[432] The photosensitivity due to psoralen may last up to 24 hours, and patients should wear protective clothing and sunscreens to prevent sunburn. Potential complications to long-term PUVA therapy include cataract formation, nonmelanoma skin cancer (8% to 10%), benign solar lentigos (4%), actinic keratoses, keratoacanthomas (3%), and vitiligo (2%).[432,435] Because of the potential of PUVA to induce cataracts, patients are instructed to wear ultraviolet light-blocking eyeglasses for 24 hours. BCC and SCC of the skin can be expected to occur in 8% to 10% of patients receiving PUVA after several years, with a clear predominance of SCC, unlike the general population.[432,435]

Wide-band ultraviolet B phototherapy (WBUVB) (280- to 320-nm wavelength) has also been used effectively to treat stage I CTCL patients,[442,443] but has largely been replaced by NBUVB phototherapy.[444] Resnik and Vonderheid reported the 15-year follow-up results of 31 patients with MF (68% stage IA, 29% stage IB, one patient stage IIA) treated with alternate-day home ultraviolet B phototherapy using a commercially available cabinet of Westinghouse FS40 lamps for 3 to 12 months beyond the date of initial remission (median = 5 months).[443] Overall, 23 of 31 (74%) patients achieved a CR, and available long-term follow-up data from 19 complete responders showed that 7 of 19 had a median disease-free sustained remission of >94 months. Ramsay et al. reported similar results in 37 patients (32 with CTCL, 5 with parapsoriasis *en plaques*), most of whom (73%) had received home UVB therapy, the rest receiving WBUVB phototherapy in an outpatient setting.[442] None of the 4 patients with infiltrated plaques responded, whereas 25 of 30 (83%) patients with erythematous patches achieved a CR, with 5 (20%) relapses and a median CR duration of 22 months.[442] Although burning and erythema may occur, adverse effects from UVB phototherapy are minimal.[432] No cutaneous SCC tumors and four BCC tumors were noted in the previous studies.[442,443]

More recently, studies have emerged on the effectiveness of NBUVB phototherapy (311 to 312-nm wavelength). NBUVB was first introduced in 1984 with the Philip TL-01 lamp as the optimal wavelength for antipsoriatic activity.[445] NBUVB treatment has a lower carcinogenic potential and is associated with less erythema than PUVA and broad-band UVB (BBUVB), respectively.[446–448] One in vitro study, however, reported cyclobutane pyrimidine dimer (CPD) formation, a sign of carcinogenicity, following a minimum erythema dose by NBUVB was significantly higher than that following 1 MED by WBUVB, whereas the formation of (6-4) photoproducts and 8-oxoG following WBUVB was significantly higher than those following NBUVB exposure. These results suggest that CPD formation is closely related to higher carcinogenic characteristics of NBUVB.[449] In the initial clinical report, Clark et al. reported a CR in 6 of 8 patients with MF treated with NBUVB.[450] Since that time, several larger studies have emerged. Gathers et al. evaluated 24 patients with stage IA/IB disease. A total of 13 (54%) achieved a CR, 7 (29%) achieved a PR, and 4 (17%) had no response. In the 4 patients who achieved a CR and discontinued therapy, the average time to relapse was 12.5 weeks.[451] In two comparative studies of NBUVB to PUVA in stage IA/IB disease, no difference in CR rates was observed in patients receiving NBUVB or PUVA.[452,453] Pavlotsky et al. conducted a retrospective analysis of patients with stage IA/IB disease receiving NBUVB and WBUVB. CR was seen in 84% and 89% of stage

1A patients receiving NBUVB and WBUVB, respectively. The CR dropped to 78% and 44% in patients with stage IB disease. Once maintenance therapy was stopped, 65% were relapse-free at 27 weeks. The study found no difference in relapse rates regardless of use of maintenance therapy.[454] Other recent small series of patients with early-stage MF treated with NBUVB therapy have been reported, with CR rates of 57% to 100% (for patch-stage disease) and relapse rates of ~50%.[446,455–457] Side effects of NBUVB therapy were minor and did not require discontinuation of therapy. Gathers et al. report erythema in 42% of patients and pruritus in 29% of patients.[451] Permanent tan freckles (lentigines) and white macules (idiopathic guttate hypomelanosis) have also been reported recently as side effects of NBUVB.[458–460] In early MF, there is no statistically significant difference between the response to oral PUVA and NBUVB.[461] NBUVB is a safe and effective treatment for stage IA/IB MF, especially patch-stage disease. In addition, several studies have confirmed the safety of NBUVB in children as opposed to PUVA phototherapy which should be avoided.[462–464]

Retinoids

Retinoids are a class of pharmaceuticals whose structure and function resemble vitamin A and its metabolites. Vitamin A and its analogs, the retinoids, have antiproliferative activity, may induce cellular maturation, and probably modulate immune response.[465] Isotretinoin (13-*cis*-retinoic acid) and etretinate, a monoaromatic retinoid compound no longer available, have demonstrated similar efficacy in the treatment of CTCL.[466] Three clinical trials have demonstrated overall objective clinical responses in 66 of 113 patients (58%) treated with isotretinoin or etretinate and a CR in 19%.[466–468] Median duration of response, however, has ranged from 3 to >8 months.[468] Etretinate is no longer available and has largely been replaced with its metabolite, acitretin, because of its superior safety profile. Acitretin may reduce the thick palmoplantar keratoderma of advanced MF or SS.[465]

In 1999 the FDA approved the use of bexarotene capsules, a novel retinoid, for the treatment of CTCL. Unlike isotretinoin and acitretin, which bind to nuclear retinoic acid receptor (RAR), bexarotene binds to and activates the nuclear retinoid X receptor RXR and is therefore referred to as a "rexinoid." RXRs are unique in that they form heterodimers with a vast array of nuclear receptors including the RARs, liver X receptors (LXR), and peroxisome proliferator activator receptors.[469,470] The ultimate antiproliferative effect is mediated, in part, by the induction of apoptosis and expression of adhesion molecules.[471,472] Two multicenter clinical trials established the optimal dose of 300 mg/m^2/day, with an overall response rate of 45%.[473,474] Higher response rates were seen in patients with higher initial doses (up to 650 mg/m^2), but side effects of hypertriglyceridemia were dose-limiting. Subsequent pancreatitis occurred in 4 of the 152 patients enrolled in the two clinical trials.[473,474] The advanced-stage CTCL trial showed a relapse rate of 36% but an impressive median duration of response of 299 days.[473]

Talpur et al. recently summarized the experience of treating 70 patients with CTCL using bexarotene capsules as monotherapy and combined with other modalities.[475] Many of the patients participated in the two pivotal clinical trials. The overall response rate seen in the monotherapy group (n = 54) was 48%, in contrast to the 69% response rate in the combination-therapy group. Bexarotene was safely added to photopheresis (extracorporeal photochemotherapy [ECP]), ECP/IFN, IFN/PUVA, and ECP/IFN/PUVA. Adverse effects were similar between the clinical trials and included hypertriglyceridemia (87%), central hypothyroidism requiring thyroid supplementation (80%),[476] neutropenia (41%), skin peeling (43%), hypercholesterolemia (20%), and pancreatitis (3%). Of the monotherapy group, 78% (n = 54) and 100% of the combination-therapy group (n = 16) required at least one lipid-lowering agent (LLA). Of the 10 patients with diabetes, 3 had hypertriglyceridemia that could not be controlled with an LLA.[475] In this series, atorvastatin and fenofibrate were the LLAs of choice. It is interesting that 9 of 10 (90%) patients on bexarotene monotherapy taking two LLAs responded, which was significantly higher than those groups on one or no LLA (p = 0.0001). The explanation for this finding is not clear, but using two LLAs may allow patients to maintain maximum doses of bexarotene.[475] Vigilance should be exercised when combining atorvastatin and fenofibrate to monitor for rhabdomyolysis. Gemfibrozil and drugs that inhibit the CYP 3A4 enzyme are contraindicated with bexarotene, to avoid elevated drug levels and worsened side effects. Although patients taking bexarotene are at increased risk for elevated triglycerides, elevated LDL, and decreased HDL, there are no reports to date indicating an increased risk of cardiac events. Several animal studies have shown that bexarotene may have a favorable pharmacologic effect on atherosclerosis despite the induction of hypertriglyceridemia via LXR,[477] due to a beneficial action on intestinal absorption and macrophage efflux,[478] inhibition of the initial inflammatory response that precedes the atherogenic process by targeting different steps of the mononuclear recruitment cascade,[469] and protective effects against H_2O_2-induced apoptosis in H9c2 rat ventricular cells through antioxidant and mitochondria-protective mechanisms.[479]

Bexarotene is also available as a 1% gel. The gel formulation is most helpful in early-stage patients (IA) without prior therapies. In a phase I/II multicenter trial, bexarotene 1% gel was applied to lesional skin with increasing frequency, once daily the first week and twice daily the second week, with a goal of four times daily if tolerated.[480] Patients achieved an overall response rate of 63% and a clinical CR of 21%. Median projected time to onset of response was 20.1 weeks (range, 4.0 to 86.0 weeks), and the estimated median response duration from the start of therapy was 99 weeks.[480] The most common side effect was irritation (retinoid "paint splatter" dermatitis) at the sites of application, which might make it difficult to assess response to the drug. The study was followed by a phase III study that included patients with stages IA/B and IIA disease. The overall response rate was 44% according to the Physicians Global Assessment. Similar to the previous study, the median time to response was 142 days (range, 28 to 505 days), and the relapse rate in responding patients was 26%. The most frequent adverse response was irritant dermatitis, which occurred more frequently in patients applying the drug more frequently.[481] Overall, topical bexarotene is a moderately effective and well-tolerated treatment for early-stage MF most often used for refractory patches or thin plaques. The retinoid dermatitis may obscure evaluation of the patches of MF so patients should be instructed to avoid enlarging the original treatment area and to stop applying the gel 1 to 2 weeks before clinical evaluation.

Interferon

IFNs are glycoproteins, naturally occurring or synthesized by recombinant DNA technology. These agents act as immunomodulators with both cytostatic and antiviral activity.[482] Although three classes, IFN-α, IFN-β, and IFN-γ, are described, the α-IFNs have been most extensively studied in MF and SS, and their efficacy was first reported by Bunn et al. in 1984.[483] The exact mechanism of action of IFN in MF and SS is unknown. IFN may act to inhibit IL-4 and IL-5 production by normal and aberrant T-cells in patients with SS, induce myelomonocytic My7 antigen (CD13) in epidermal basal cells,[484] induce the ds-RNA–dependent enzyme 2′5′-oligoadenylate synthetase leading to cleavage of cellular RNAs, and phosphorylate eIF-2, a peptide elongation initiation factor that blocks protein synthesis.[482] The pharmacokinetics of IFN delivered via the intramuscular and subcutaneous routes are equivalent, allowing patients the opportunity to self-administer the drug subcutaneously.

The phase II National Cancer Institute (NCI) trial reported by Bunn et al. in 1984 used high doses of recombinant IFN-α2a (50×10^6 U/m^2 = 50 MU/m^2 subcutaneously three times per week) in 20 heavily pretreated MF patients and demonstrated an objective response in 45%, including 3 patients (15%) who achieved a CR.[485,486] Treatment of MF and SS with IFN-α has been reported in >200 patients and the results have been summarized.[482] The overall response rate for IFN-α alone was 52%, with a 17% CR among 207 MF and SS patients, summarized by Bunn et al.[487] Over three quarters of the patients received IFN-α2a, which is no longer available in the United States, although there were no apparent differences in clinical efficacy between IFN-α2a and IFN-α2b (Intron-A, Schering-Plough Research Institute).[482,487] However, interpretation of pooled data is complicated by variations in initial dose, target dose, frequency, and length of therapy among study centers.[482] A trial evaluating PUVA and IFN-α2a versus PUVA and IFN-α2b in CTCL patients demonstrated increased myelosuppression and liver toxicity, but also reduced constitutional effects, reduced study drop-out, and increased overall response (89% versus 50%) in the IFN-α2b arm.[488] There are conflicting reports regarding the impact of clinical stage on the likelihood of response to systemic IFN-α.[482,489,490] In their study of 51 MF and SS patients, Jumbou et al. found that patients with early disease (stages I and II) demonstrated a higher response rate to IFN-α than those with advanced disease.[491]

In an attempt to define the optimal dose of IFN-α in CTCL, a randomized study from Duke and Northwestern Universities was designed comparing low-dose (3 MU/day) to escalating doses (up to 36 MU/day); however, because of slow patient accrual, the proposed study was terminated.[489] For the 22 patients evaluated, the objective response rate was 64% and was greater, although not statistically significant, for those receiving high doses (11 of 14) than for those receiving low doses (3 of 8), in part because of late responses in unresponsive patients who crossed over into the higher-dose arm.[487,489] Of interest, two of the three CR patients were induced by the low-dose regimen, suggesting that patients could achieve a CR with 3 MU daily of IFN-α2a.[482,489] An intermediate daily dose of 18 MU of IFN-α2a for 3 months followed by the same dose three times a week resulted in an impressive 80% objective response rate (27% CR, 53% PR) in 15 CTCL patients reported by Tura et al.[492]

Daily dosing of IFN-α2a for an induction period of several months was used by all of the larger studies of IFN-treated CTCL patients,[490,493] whereas many fewer patients have been studied using an initial three times a week schedule.[494–496] Nonetheless, some authorities[487] recommend an optimal dose of 3 MU of IFN-α2a three times a week, based in part on randomized dose studies in B-cell indolent NHL showing no benefit of higher-dose IFN with respect to response rate or duration.[497] Maximum daily dosing is dependent on several patient factors but, in general, should not exceed 15 M.[498] Two to five months is generally necessary to obtain an objective response with IFN, but a complete or maximal response can take much longer.[482,490] Treatment is generally continued for ~1 year after a CR to prevent the high potential for relapse when treatment is discontinued before clearing.[482] Three studies have reported a median duration of response to IFN-α as follows: 6 months,[485] 8 months,[493] and 14 months.[490] Olsen et al. noted a mean duration of PR while on therapy of 7.9 months (range, 2.1 to 26.5 months) and durations of CR off therapy ranging from 4 to 28 months.[482] Two NCI phase II trials combined IFN-α2a with the adenosine analogs DCF and fludarabine to treat CTCL and demonstrated no clear advantage over either drug alone.[499] The numerous side effects associated with IFN have led to dose reductions in 50% to 86% of patients in some studies.[489,492]

Besides producing anti-IFN antibodies, patients with MF can also exhibit decreased responsiveness to IFN through acquired resistance to IFN-α–induced gene expression. Specifically, a resistant CTCL cell line exhibits disrupted signal transduction in a pathway that is normally activated by IFN-α when therapeutic. In particular, STAT1 expression is reduced in these cells, which interrupts the JAK/STAT signaling pathway.[500]

Recombinant IFN-γ and IFN-β have been studied in many fewer CTCL patients, as they appear to offer no major advantage over IFN-α.[501–503] IFN-β has reportedly shown little effectiveness in treating CTCL,[501] and IFN-γ has been linked with more intense and frequent side effects than IFN-α.[482] Interestingly, it has been demonstrated in vitro that the combination of IFN-γ and a Toll-like receptor (TLR) 7/8 agonist increases natural-killer–cell cytotoxic activity against CTCL cell lines.[504] This combination of the two therapies led to an increase in IL-12 and IFN-α levels which was regulated through the IRF8.[504]

Electron Beam Radiotherapy and Photon Beam Irradiation

Radiation was one of the earliest effective treatments for MF, first reported in 1902.[505] In 1953, Trump et al. were first to suggest using accelerated electrons for treatment.[506] Modern total-skin electron beam radiotherapy (TSEBRT) is among the most effective and well-studied therapies for MF.[200,507,508] The total skin surface can be treated by linear accelerator, generated electron beams that are scattered by a penetrable plate at the collimator site.[509] The usual depth of penetration is <10 mm and is proportional to the energy of the electrons generated, allowing effective dosing to the skin and adnexal structures without internal organ toxicity.[507] The most common technique uses a dual fixed-angle 6-field or rotation methods with 4- to 9-MeV electrons, with total doses in the range of 2,400 to 3,600 cGy over an 8- to 10-week period.[507,510] With this technique, relatively lower doses are delivered to the scalp, soles, and areas of self-shielding such as the ventral penis, perineum, upper medial thighs, perianal skin, inframammary folds, and folds under any pannus.[507] Only the eyes are routinely shielded, and unless there is involvement of the head and neck, a scalp shield is used after a dose of 2,500 to 2,600 cGy has been delivered, to decrease the degree of alopecia.[507] The hands, forearms, ankles, and dorsal penis may receive doses >100%, and shielding all of these structures for part of TSEBRT is not uncommon.[507]

The long-term results of 561 MF patients treated at Stanford University and Hamilton Regional Cancer Centre from the mid-1950s to 1993 with TSEBRT alone were summarized by Jones et al.[507] Over 80% of stage IA patients can be expected to achieve a CR after TSEBRT, with 40% to 60% remaining relapse-free at 5 years.[507] Two more recent studies showed similar CR rates, ranging from 80% to 90% for IA and IB disease.[511,512] Less encouraging were the relapse-free rates, at 2.5 years for stages IB (35% to 40%), IIA (21% to 37%), IIB (7% to 26%), and III (10% to 23%).[507] However, most patients who relapse with what is usually minimal disease will re-enter remission with other topical therapies.[507] In these studies, a new diagnosis of MF, low stage, lack of blood involvement, and intensity of TSEB were independently associated with progression-free survival (PFS).[507,511] TSEBRT was less effective in advanced-stage disease (II to IV), with a CR rate of 60%.[511] Another report suggests that prognosis for tumor-stage patients with <10% skin involvement treated with TSEBRT is significantly better than for patients with >10% involvement.[513]

Acute cutaneous side effects, peaking 1 to 2 weeks after TSEBRT, include erythema, edema, dry or moist desquamation, tenderness, and rare blister formation that is most severe at sites of disease.[507,514] Total-body alopecia and loss of nails will occur in all unshielded patients, but the skin appendages will normally regrow within 6 months.[507] During the first year, heat intolerance may develop as a result of the suppression of sweat gland production, which may be permanent.[403,515] Patients with erythroderma (T4) may experience more severe acute side effects

from TSEBRT; however, radiation may be effective in stage III, especially with no blood involvement.[516] When there is blood, lymph node, or visceral involvement in patients with erythroderma, combined-modality therapies, in particular photopheresis, should be explored.[516,517] Chronic cutaneous side effects most commonly include xerosis, superficial atrophy, telangiectasia, and dyspigmentation.[507,515] The role of TSEBRT in the development of secondary cutaneous malignancies has not been clearly established, as most patients have received a variety of therapies that could contribute to the development of skin cancer.[507]

Several studies have evaluated the response and toxicity of multiple courses of TSEBRT for CTCL, with similar results.[512,518,519,520] Wilson et al.[518] reported on 14 CTCL patients, 5 receiving three courses of TSEBRT and 9 patients who received two courses. The total median dose was 5,700 cGy (range, 4,500 to 8,200 cGy) with 86% (n = 12) achieving a CR after the second course of therapy (median relapse-free interval, 11.5 months) and 3 of 5 (60%) achieving a CR after a third course (limited follow-up).[518]

Because of the toxicities of TSEBRT and the effectiveness of topical therapies, most authorities recommend using TSEBRT for patients with progressive disease, those failing topical therapies, or patients with extensive, deeply infiltrated plaques and tumors.[511,521] Because of the high relapse rates after TSEBRT, post-treatment with nitrogen mustard, PUVA, or photopheresis have been studied to maintain remissions.[511,517,522] A recent retrospective study of patients with MF that received TSEBRT (n = 180, T2 and T3 skin stage) from Stanford University found no difference in outcomes between those that received adjunctive topical nitrogen mustard to prevent relapse and those patients that did not.[520]

Small-field megavoltage photon beam irradiation can be applied as palliation to either deep-seated cutaneous lesions in the tumor phase or for extracutaneous disease.[523] Nearly all cutaneous lesions respond completely, with the risk of relapse (up to 45%) being inversely proportional to the dose, and with recurrence usually developing within 2 years of treatment.

Photopheresis or Extracorporeal Photochemotherapy

Because of the development of resistance to conventional chemotherapy and radiation and the high potential for relapse in advanced-stage patients, new modalities to treat CTCL have been developed. Leukapheresis, which had been used in patients with high Sézary cell counts,[524] was the forerunner for a new adaptation of PUVA called extracorporeal photochemotherapy (ECP) or photopheresis. In the original protocol, patients ingested 8-MOP prior to undergoing fractionation of their blood. A leukocyte-enriched blood fraction was then isolated and exposed to UVA in an extracorporeal system, which photoactivated the psoralen.[525] The photopheresis procedure currently performed uses liquid 8-MOP injected directly into the collection bag containing the enriched white blood cell fraction to achieve a concentration of 340 ng/ml within the collection bag. All treated and untreated blood products were then returned to the patient.

In 1987, Edelson et al. were the first to report responses in 27 of 37 patients (64%) with resistant CTCL treated with ECP, including 8 of 10 patients with lymph node involvement and 24 of 29 patients with erythroderma. However, patients with extensive plaques or tumors did not respond as well (3 of 8 patients).[525]

The immunomodulatory mechanism underlying patient response to ECP is still under debate. However, evidence currently supports the following two simultaneous and synergistic processes occurring during ECP: induction of apoptosis in malignant T-cells, and a mass conversion of blood monocytes to DCs.[434,526,527] Animal studies demonstrate that ECP induces a $CD8^+$ T-cell response against expanded clones of pathogenic T-cells,[528] as well as an increased synthesis of class I MHC molecules on murine T-cell lymphoma cells.[529] Recent in vitro studies using family-specific monoclonal antibodies and magnetic bead technology demonstrated a tumor-specific cytolytic $CD8^+$ T-cell response to distinctive Class I surface peptides on CTCL tumor cells of four patients with advanced disease. These results suggest that reduced Class I expression of relevant tumor antigen epitopes may limit the extent of $CD8^+$ T-cell–mediated cytolysis.[530] In support of this hypothesis, investigators have found a favorable response to correlate with the following two scenarios at the onset of ECP: normal or near-normal numbers of $CD8^+$ peripheral blood T-cells[531] and a lower CD4/CD8 ratio in the peripheral blood.[532]

Other investigators have found that ECP and in vitro PUVA induce apoptosis in peripheral blood lymphocytes but not in monocytes.[434] The apoptosis induction mechanism remains unknown, but may be explained by the observation that a significant amount of tumor necrosis factor-α (TNF-α), which mediates various antitumor effects, is produced by macrophages following ECP.[533] Berger et al. identified monocytes transitioning to immature DCs during overnight incubation in gas-permeable bags of ECP-treated WBCs from five patients with intractable CTCL.[534] Both the initial leukapheresis step as well as the subsequent passage through the narrow photoactivation plate initiated and contributed to monocytes-to-DC differentiation.[534,535] Edelson proposed that the innumerable encounters of monocytes with the plastic surface of the photoactivation plate activated the cells to begin differentiation to immature DCs.[526] An immature DC can engulf an apoptotic T-cell and present tumor antigen via MHC Class I molecules, which stimulates a potent antitumor CD8 T-cell response.[526,527,534–536]

Treatment of CTCL with ECP has been reported in >400 patients and has been recently summarized.[537] The majority of CTCL patients treated with ECP have exhibited generalized erythroderma (skin stage T4), a finding most likely due to the encouraging preliminary study results of Edelson et al.[537] A combined analysis of >400 patients treated with ECP and adjunctive therapies showed an overall response rate for all stages of CTCL of 55.7% (244 of 438), with 17.6% (77 of 438) achieving a complete response[537] Efficacy in treating certain clinical stages (IB, IIA, III, and IVA) and skin stages (T2 and T4) of MF and SS is favorable, although randomized trials comparing ECP to other standard therapies are needed. Combined analysis of five North American series[525,538–542] of ECP-treated CTCL patients (N = 157) demonstrates an objective response (>25% improvement of skin lesions) in 67 of 111 stage T4 patients (60%), with ~20% achieving a CR. A long-term follow-up study of the original 29 erythrodermic CTCL patients in the report of Edelson et al.[525] demonstrated a median survival of 60 months, which compared favorably to historical controls.[532] Many authorities recommend that ECP be considered the first line of treatment for erythrodermic-stage patients.[543–545] However, other authorities differ in their opinions regarding the role of ECP in the treatment of CTCL, stating that the data have been inconsistent and the need for prospective randomized studies.[546,547,548]

Preliminary and long-term follow-up studies by Zic et al. on 20 refractory CTCL patients treated with ECP and adjunctive therapies demonstrated an objective response (>50% clearing of skin lesions) in 9 of 14 (64%) early-stage T2 patients, with CR in 4.[538,549] Talpur and colleagues reported the results of a prospective study of 19 patients with MF stages IA, IB, and IIA who were treated with photopheresis administered 2 days every 4 weeks for 6 months.[550] Patients with partial responses by skin weighted assessment continued for an additional 6 months and nonresponders added oral bexarotene and/or IFN-α. The overall response rate was 42% and the authors concluded that ECP is effective for patients with early-stage MF alone or in combination with biologic response modifiers with low toxicity and improved quality of life.[550] Observations by other investigators question

the use of ECP to treat stage IB patients when less expensive and more widely accessible therapies are available.[551,552,553]

ECP is well tolerated, with few complications or adverse effects.[537,545] Uncommon adverse reactions are usually vascular-related and include the fluid-responsive hypotension and venipuncture-site hematomas.[549] Rarely, adverse reactions have included exacerbation of congestive heart failure or arrhythmias,[543] superficial thrombophlebitis,[543] catheter-related sepsis,[554] herpes infections,[543] disseminated fungal infection,[543] and a single episode of hemolysis.[538]

Several studies have focused on the effects of combining ECP with systemic chemotherapy, PUVA, IFN and other cytokines,[555–558] radiation therapy, bexarotene with and without IFN,[559,560] and nitrogen mustard. Recently, Raphael and colleagues summarized their experience treating 98 patients with SS with at least 3 months of photopheresis and one or more systemic immunostimulatory agents (IFN-α, oral retinoids, IFN-γ, granulocyte-macrophage colony-stimulating factor).[561] A total of 73 patients (75%) responded (30% CR, 45% PR) and a lower CD4/CD8 ratio, a higher percentage of monocytes, and lower numbers of circulating abnormal T-cells at baseline were the strongest predictive factors for complete response compared with nonresponse.[561] A much smaller cohort of patients with SS (n = 12) showed a lower response rate of 42% and the parameters that correlated best with response were number of Sézary cells, CD4/CD8 ratio, and white blood cell count.[562] McGirt and colleagues found increased eosinophils and decreased percentages of Sézary cells were associated with a favorable clinical response to ECP, but they were not able to identify the predictors of ECP response within the first 3 months of treatment.[563]

Systemic Chemotherapy

Single agent and combination chemotherapy are reserved for patients who have advanced stage (IIb–IVb), relapsed or refractory disease or are part of a clinical trial.[564] Treatments that maintain or augment the immune response, such as IFN, bexarotene, and ECP may be preferable over chemotherapy which is immunosuppressive. Sequential use of single agents should be considered over combinations inasmuch as CTCL is chronic and the clinical goals are control of the disease, amelioration of pruritus, and prevention of skin breakdown; however, combination chemotherapy may be warranted if the disease is progressive, extensive, or in stage IV.[565,566] There is no consensus about the optimal combination of agents.[564]

Previously, single agents used for MF/SS were the same as those used in all types of NHL and included oral corticosteroids, alkylating agents, methotrexate, doxorubicin, bleomycin, vinka alkaloids, cisplatin, and etoposide, and resulted in an objective response in a majority of patients with CR rates ranging from 15% to 20%.[559,567] However, median relapse-free intervals were usually short and lasted less than 6 months with a range from 3 to 22 months.[567] Daily or pulse chlorambucil with a steroid has been used to successfully treat SS.[568,569] In two retrospective series using weekly low-dose oral methotrexate, Zackheim et al. reported a 33% response rate (12% CR) in T2 skin disease and a 55% response rate (41% CR) in erythrodermic CTCL with time to progression and OS of 15 months and 31 months, respectively.[570,571]

Novel chemotherapy agents have been evaluated for therapy of CTCL and include nucleoside analogs, liposomal doxorubicin, histone deacetylase inhibitors, the antifolate pralatrexate, the proteasome inhibitor bortezomib, and a novel alkylating agent, temozolomide. In a phase II trial of gemcitabine, a pyrimidine antimetabolite, in refractory patients, Zinzani et al. reported a 70% ORR, including 10% CR and a median response duration of 8 months.[572] Gemcitabine was given at a dose of 1,200 mg/m^2 on days 1, 8, and 15 of a 28-day cycle for a total of three courses. One to two cycles were sufficient to induce tumor reduction in 83% of patients with stage IIB MF. Side effects with gemcitabine included neutropenia (34%), thrombocytopenia (25%), cutaneous hyperpigmentation (17%), and elevated liver enzymes (13%).[572] Duvic et al. demonstrated a similar response rate (68%) and side-effect profile in another phase II trial, with dosing 1,000 mg/m^2 on days 1, 8, and 15 for 6 cycles.[573] Marchi et al. reported a 78% ORR, including 22% CR, in previously untreated patients.[574] Isolated cases of cardiotoxicity, including atrial fibrillation, myocardial infarction, and congestive heart failure; and of pulmonary toxicity suggest that patients with CTCL may be prone to unusual, nonhematopoietic side effects of gemcitabine.[575]

The purine nucleoside analogs, 2-deoxycoformycin (DCF or pentostatin), 2 chlorodeoxyadenosine (2CdA or cladribine), and fludarabine monophosphate (FAMP) have activity in CTCL.[576,577] DCF inhibits adenosine deaminase, preventing the transformation from adenosine to inosine, which is found in high concentrations of T lymphocytes. Accumulation of metabolites blocks DNA synthesis by inhibiting ribonucleotide reductase. Dosing of DCF has varied among studies and yields an ORR of 33% to 71% with approximately one third of the responses being CR.[578] The median time to progression ranges from 1.3 to 8.3 months, and there appears to be a better response in SS than in MF.[578–580] The most common side effects are granulocytopenia, renal insufficiency, and prolonged CD4 lymphopenia. A combination study of DCF with high-dose IFN resulted in an ORR of 41% with a median PFS of 13.1 months.[581]

2CdA is a chlorinated purine analog that is activated by phosphorylation and accumulates in lymphocytes with high deoxycytidine kinase, resulting in DNA strand breaks and cell death. 2-CdA was initially given by continuous infusion over 5 to 7 days and resulted in an ORR of 28% to 41% with a median duration of response of 4 to 5 months in pretreated patients.[577,582,583] Toxicity included leukopenia (62%) with grade 3 or 4 neutropenia (24%), thrombocytopenia (33%), and infections (62%) of both bacterial and opportunistic types.[582]

FAMP is activated by phosphorylation and inhibits DNA repair to induce cell death in lymphocytes. The ORR of FAMP as a single agent in relapsed CTCL has been 19% to 29.5%;[584,585] however, response rates improved in small series when FAMP was combined with IFN (51%), cyclophosphamide (42%), or ECP (63%).[499,585,586] The median PFS for IFN and ECP were 5.9 months and 13 months, respectively.[499,585] Grade 3 or 4 cytopenias occurred in 60% of FAMP+IFN but only 5% of FAMP+ECP.

Forodesine is a selective purine nucleoside phosphorylase inhibitor and causes increased levels of deoxyguanosine and deoxyguanosine triphosphate, which inhibit T-cell proliferation.[587,588] In a phase I intravenous trial of 13 patients with CTCL, there were 4 responses (3 CR, 1 PR) and 6 with stable disease (SD). In a phase I/II trial using an oral formulation at 80 mg/m^2 once daily, the objective response rate was 53.6% (2 CR, 13 PR and 22 SD).[589] Forodesine was well tolerated with primarily mild (grade 1 or 2) side effects, including nausea, dizziness, headache, peripheral edema, and fatigue.

Altering a drug's vehicle can improve its efficacy and lower its toxicity, as evidenced by the pegylated liposomal preparation of doxorubicin.[590] In an open clinical trial, 10 patients with relapsing CTCL were treated with pegylated liposomal doxorubicin at a dosage of 20 mg/m^2 once a month, with an upper limit of 400 mg or 8 infusions.[591] A total of 60% of patients experienced a CR, 10% PR, and 10% SD following this monotherapy. These results were supported by a retrospective review of 34 patients using doses of 20 to 40 mg/m^2 every 2 to 4 week.[592] They demonstrated an overall response rate of 88% (44% CR + CRu [patients who achieved a CR defined by clinical criteria only with no biopsy] and 44% PR), an OSof 17.8 months and event-free survival of 12 months. Adverse events were reported in 41% of patients with 17% grade 3/4, including only one with palmar-plantar erythrodysesthesias.

Histone deacetylase (HDAC) inhibitors (HDI) were discovered serendipitously to have activity in T-cell lymphomas in phase I trials by Piekarz et al. at the NCI and by O'Connor et al. at Memorial Sloan Kettering Cancer Center (MSKCC).[593,594] HDI cause histone hyperacetylation, alter chromatin structure, and modulate gene expression.[595] They also acetylate nonhistone proteins such as p53 and down-modulate cytokines such as IL-10, both of which contribute to apoptosis of cancer cells.[595–597] HDI can be divided into 6 groups based on their chemical structures, and it is unknown whether pan-HDAC inhibition (HDACi) or more selective HDACi is better in treating malignancies.[598] Two HDI have been approved for therapy in relapsed CTCL, vorinostat (Zolinza, Merck & Co, Whitehouse Station, NJ, suberoylanilide hydroxamic acid [SAHA]), a relatively nonselective inhibitor of HDAC, and romidepsin (Istodax, formerly depsipeptide, Celgene Corp, Summit, NJ), a specific inhibitor of class I HDAC enzymes.[596]

Vorinostat was approved for the treatment of relapsed CTCL in October 2006. The maximum tolerated daily oral doses of vorinostat were determined to be 400 mg. In a phase II trial of 33 heavily treated patients with CTCL (median number of prior systemic therapy = 5), Duvic et al. reported an ORR of 24% (all PR) and an additional 33% had SD, pruritus relief, or both.[599] In a multicenter phase II trial in 74 patients treated with at least two previous systemic therapies, the ORR was similar at 29.7%.[600] The median time to progression was 4.9 months and 9.8 months for responders with stage IIB–IVB disease. The adverse effects for the two phase II trials were diarrhea (49% to 60%), fatigue (46% to 78%), nausea (43% to 60%), thrombocytopenia (22% to 54%), and dysgeusia (24% to 51%). Grade 3/4 adverse events were thrombocytopenia (5% to 19%), dehydration (1% to 8%), and pulmonary embolism (5%).[599,600] Cardiac complications have been reported including QT prolongation.[601] Vorinostat is being evaluated in combinations with bexarotene, bortezomib, and lenalidomide.[595,602]

Romidepsin achieved orphan drug status in 2007 and was approved for the treatment of relapsed CTCL in November 2009.[603,604] It is a natural product and a stable prodrug that is converted into its active form by a glutathione-mediated step. Thus, a benefit of romidepsin lies in its ability to counteract glutathione-mediated drug resistance.[593,605] In two phase II trials in relapsed CTCL patients (n = 71 and 96), the ORRs were 34% in both, including 6% CR in both and the median durations were 13.7 and 15.4 months.[606,607] Both studies used the same dose and schedule derived from the NCI phase I study: 14 mg/m^2 as a 4-hour infusion once weekly times 3 out of 4 weeks.

Most of the adverse events with romidepsin were mild (grade 1 or 2) and were gastrointestinal symptoms or fatigue. Adverse events (all grades) were nausea (52% to 54%), fatigue (41% to 42%, emesis (19% to 26%), anorexia (20% to 21%), diarrhea (8% to 14%), and ageusia (13% to 19%). Grade 3/4 cytopenias were more pronounced in the NCI study: neutropenia (14%), lymphopenia (21%), thrombocytopenia (6%),[608] and anemia (6%).[606] There was concern that HDI, including romidepsin, would have significant prolongation of the QT interval and risk of arrhythmia, but the studies found minimal risk; however, antiemetics which prolong QT should be limited and the potassium and magnesium levels should be normalized before romidepsin infusion.

The potential to alter the expression of a more focused, disease-related subset of genes and to limit adverse effects has prompted the development of isoform-specific HDAC inhibitors in various stages of study.[597,609] Belinostat is an intravenous hydroxamic acid with an ORR of 14% in CTCL and 25% in PTCL.[610–613] Panobinostat is a hydroxamic acid with both intravenous and oral formulations and had a 60% ORR in a study of 10 patients with CTCL;[614] however, a larger study of 95 patients reported only 16% ORR.[615] Clinically relevant QTc prolongation is not associated with current dose schedules of panobinostat.[616]

Pralatrexate (Folotyn; Allos Therapeutics Inc.) is a novel antifolate with a high affinity for the reduced folate carrier-1 which is overexpressed in neoplastic cells. Pralatrexate inhibits dihydrofolate reductase, an enzyme involved in the synthesis of deoxythymidine and the purine DNA nucleotides, and promotes apoptosis. Pralatrexate received approval in September 2009 for relapsed or refractory PTCL at a dose of 30 mg/m^2 weekly for 6 of 7 weeks.[617] A de-escalation trial identified an effective dose of 15 mg/m^2 weekly for 3 of 4 weeks in patients with relapsed CTCL.[618] The ORR was 45% (13/29: 1 CR, 12 PR); 73% of responses were continuing at 6 months by Kaplan–Meier estimate. The main toxicities were mild except for mucositis (48% all grades, 17% grade 3). To reduce mucositis, vitamin B12 and folate supplementation are started before therapy with pralatrexate. Ongoing trials are investigating combination therapies that incorporate pralatrexate. Although in vitro studies suggested synergy with sequential gemcitabine, the toxicities, primarily marrow suppression, were excessive.[619,620] Pralatrexate is synergistic with bortezomib in both in vitro and in vivo models of T-cell malignancies.[621]

Bortezomib (Velcade; Millennium Pharmaceuticals, Boston, MA); a proteasome inhibitor, down-regulates NF-κB activation and causes apoptosis of CTCL cell lines.[622] In a phase II trial of 12 relapsed patients (10 MF, 2 PTCLU with skin involvement), the ORR was 67% (2CR, 6PR) and all responses were durable, lasting from 7 to >14 months.[623] There were no grade 4 toxicities, and the grade 3 toxicities were neutropenia (n = 2), thrombocytopenia (n = 2), and sensory neuropathy (n = 2). Bortezomib is synergistic with other agents. A phase I trial of bortezomib, gemcitabine, and liposomal doxorubicin reported a PR in 6 of 7 relapsed CTCL patients.[624] The combination of bortezomib with the HDAC inhibitor, vorinostat, induced apoptosis in CTCL and was associated with an up-regulation of cell cycle regulating proteins p21 and p27, an increased expression of phosphorylated p38, and a suppression of vascular endothelial growth factor by tumor cells.[625]

Temozolomide, an oral derivative of dacarbazine that causes DNA damage by methylating nucleotide bases, has demonstrated some efficacy in the treatment of CTCL. This alkylating agent produces O6-alkylguanine adducts, which are deactivated by O6-alkylguanine-DNA alkyltransferase (AGT), a DNA repair enzyme often found in tumor cells. Dolan et al. found that patients with MF demonstrated lower than expected levels of AGT in tumor cells, thus emphasizing temozolomide's potential therapeutic efficacy in this specific malignancy.[626] In a phase II trial, 9 patients were treated with 150 mg/m^2 of temozolomide orally for 5 days for the first 4-week cycle and then 200 mg/m^2 of temozolomide for 5 days for the second and third 4-week cycles. A total response rate of 33% was observed with 2 patients developing grade 3 hematopoietic toxicities.[627] In a larger trial of 26 relapsed patients using the 200 mg/m^2 dosing schedule, the ORR was 27% (2CR, 5 PR); the median disease-free survival (DFS) and OS were 4 and 24 months, respectively.[628] The response did not correlate with levels of AGT. The most common grade 1/2 toxicities were gastrointestinal and treatment was stopped in three patients due to grade 3 thrombocytopenia, lymphopenia, and skin reaction.

Combination chemotherapy regimens tend to be reserved for relapsed, aggressive, and advanced-stage MF/SS. Responses occur in the 40% to 89% range but are brief with PFS in the 5 to 9 month range.[629–631] In a phase II trial of EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin) in 15 refractory patients with CTCL, including 4 ALCL, the ORR was 80% (4 CR, 8 PR); the median PFS was 8.0 months and the median OS was 13.5 months.[631] Infectious complications, including staphylococcal bacteremia related to open skin lesions, are a significant problem for patients receiving combination chemotherapy.

Combined-modality Therapy

Because there is no single therapy for CTCL that can consistently induce long-lasting remissions, various combinations of therapeutic modalities have been studied. The results of several small studies suggested that better survival could be achieved by combining TSEBRT with chemotherapy.[632,633] Hallahan et al. evaluated TSEBRT followed by combination chemotherapy for 21 patients with tumor-stage CTCL demonstrating an objective response in 19 (90%) with a median duration of remission of 12 months, but all patients relapsed within 25 months.[632] Two nonrandomized studies suggested a benefit for early-stage CTCL patients who receive TSEBRT followed by chemotherapy.[633,634]

Following TSEBT, subsequent PUVA therapy appears to aid in maintaining remission status in patients with CTCL. A significant benefit in DFS but no statistically significant improvement in OS was observed. However, prospective, randomized data are needed to confirm these results. Incidentally, PUVA has also demonstrated effectiveness as a salvage therapy after TSEBT in early-stage patients with recurrence, with acceptable toxicity.[635]

The most significant study to evaluate the role of combined-modality therapy was that of Kaye et al. at the NCI who compared TSEBRT and combination chemotherapy (cyclophosphamide, doxorubicin, etoposide, and vincristine) to conservative topical therapy (beginning with topical HN2 followed sequentially, if needed, by PUVA, TSEBRT, and combination chemotherapy) in a randomized trial of 103 patients with MF.[636] Although the rate of CR was significantly increased in the combined-modality arm (38% vs. 10%, $p = 0.032$), toxicity was greater and no significant difference was noted between the groups in disease-free or OS (Fig. 9.17). Thus, this study indicated that, similar to other low-grade lymphomas, early aggressive therapy in MF does not have a major impact on survival.

A nonrandomized study from Yale University compared relapse-free survival (RFS) and OS between CTCL patients who achieved a CR following TSEBRT, with subsequent treatment consisting of either adjuvant chemotherapy (cyclophosphamide and doxorubicin; $n = 77$), photopheresis ($n = 11$), or no adjuvant therapy ($n = 43$).[637] Adjunctive therapy was also offered to 32 patients who achieved a "good PR" to TSEBRT. The statistical analysis found no appreciable impact on RFS among the patients receiving adjuvant chemotherapy or photopheresis when compared to patients receiving no adjuvant therapy. However, a marginally significant ($p < 0.06$) improvement on OS was demonstrated when stage T3/T4 patients treated with adjuvant photopheresis ($n = 7$) were compared to stage T3/T4 patients receiving no adjuvant therapy ($n = 22$).[637]

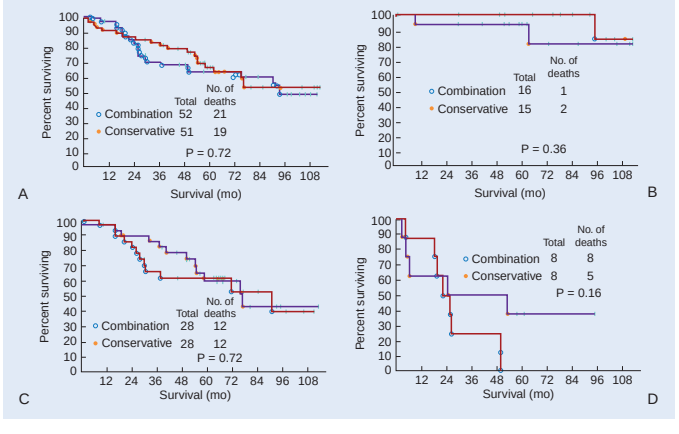

FIGURE 92.17. Survival curves from randomized study at the National Cancer Institute comparing intensive combined therapy. A: Overall survival. **B:** Survival among low-risk patients (stage IA, IB, or IIB). **C:** Survival among intermediate-risk patients (stage IIB, III, or IVA). **D:** Survival among high-risk patients (stage IVB). (From Kaye FJ, et al. A randomized trial comparing combination electron beam radiation and chemotherapy with topical therapy in the initial treatment of mycosis fungoides. N Engl J Med 1989;321:1784, with permission.)

Retinoids and IFN-α have been combined to treat CTCL in several open studies.[638–640] Combined analysis of the results of 102 reported patients treated with retinoids and IFN-α showed that approximately 60% of patients respond and 10% achieve a CR similar to the response for IFN-α alone.[487] PUVA therapy has been combined with systemic retinoids to treat CTCL in two studies.[641] demonstrating response rates similar to PUVA alone. Bexarotene has been combined with ECP, PUVA phototherapy, and IFN-α in several patients with potential beneficial effects, as well as no increased toxicity.[475,642]

The combination of PUVA and IFN-α is well tolerated and generates impressive complete response rates.[643–645] In the combined analysis of the phase I and phase II trials of IFN-α and PUVA for CTCL at Northwestern University, 39 CTCL patients (Stage IB, $n = 14$; IIA, $n = 5$; IIB, $n = 6$; III, $n = 8$; IVA, $n = 5$; IVB, $n = 1$) received intramuscular or subcutaneous IFN-α2a three times a week at initial intermediate doses (6MU, $n = 3$; 12MU to 18MU, $n = 13$; 21MU to 30MU, $n = 23$) with subsequent dose reduction in 19 patients due to apparent toxicity.[643] IFN-α was continued for the planned 2-year period in only 10 of 39 patients (26%) with 8 patients receiving 4 or less months of IFN-α due to tumor progression, toxic effects, or patient request. PUVA was initiated three times per week and tapered to 1 monthly treatment indefinitely for patients achieving a CR. The overall objective response rate was 90% with 24 patients (62%) achieving a pathologically confirmed CR, 15 of whom had early-stage disease (Stage IB/IIA). A total of 19 patients (54%) relapsed demonstrating a median duration of response of 28 months (range, 1 to 64 months). Median survival for the entire cohort was 62 months with mean survivals for stage I/II and stage III/IV patients of 55 and 35 months, respectively.[643] Thus, although patients respond impressively, a majority of patients will relapse despite maintenance PUVA and experience nontrivial toxicities at higher doses of IFN. The overall impact on survival of combined PUVA and IFN-α has yet to be determined.

A prospective phase II trial examined escalating doses of IFN-α2a combined with PUVA in 63 symptomatic patients representing all stages of MF and SS.[645] A total of 51 patients achieved a CR (74.6%) or PR (6%), with a median response duration of 32 months. The 5-year OS rate was 91% and included 17 patients with advanced disease.[645]

Rupoli et al. completed a multicenter prospective phase II clinical study on 89 patients with early-stage IA to IIA MF treated for 14 months with low-dose IFN-α2b (6 to 18 MU/wk) and PUVA.[646] Complete remission (CR) was achieved in 84% and an overall response rate in 98% of cases. Long-term CR was associated with high epidermal CD1a$^+$ dendritic-cell density ($P = 0.030$) and high CD8$^+$ lymphoid T-cell density was associated with a lower relapse rate ($P = 0.002$).[646]

Stadler and colleagues completed a prospective randomized multicenter trial to compare IFN plus PUVA and IFN plus acitretin in stage I and II patients with CTCL ($n = 82$ evaluable patients).[647] IFN-α2a was administered subcutaneously at 9 MU three times weekly and combined with either PUVA at an initial interval of five times weekly, or with acitretin up to 50 mg daily. IFN-α + PUVA ($n = 40$) was significantly superior to the IFN + acitretin ($n = 42$), as marked by a 70% complete remission rate in the former, versus a 38.1% complete remission rate in the latter.[647] A recent report appeared to suggest that elevated levels of the cutaneous T-cell attracting chemokine CTACK/CCL27 in skin and sera after combined PUVA and IFN-α2b therapy might be correlated with risk of recurrence.[26] Reports have emerged of the successful combination of low-dose bexarotene and phototherapy. Narrow-band UVB phototherapy has been combined with oral bexarotene with success in one recent case.[648]

The successful combination of low-dose bexarotene with PUVA phototherapy has also been reported.[475,642,649–654]

Immunotherapy

Over the past decade, researchers have developed immunotherapies to correct abnormalities in the immune response, and cellular growth and differentiation pathways in patients with CTCL. As described in previous sections, recombinant forms of natural cytokines such as IFNs and immunomodulation with photopheresis have shown promise in the treatment of CTCL, with tolerable toxicity profiles and reasonable efficacy. This section focuses on other cytokines and monoclonal antibody therapies for the treatment of CTCL.

Fusion toxin therapy takes advantage of the preferential expression of specific receptors on the surface of malignant cells. Recombinant fusion of a plant or bacterial toxin gene to a specific receptor ligand can guide the toxin gene to the target cell, where it can be internalized via receptor-mediated endocytosis and translocated into a toxic moiety in the cytosol.[655] The interleukin-2 receptor (IL-2R) is present in low-, medium-, and high-affinity forms. The high-affinity form of IL-2R is a three-subunit peptide, and one of the three subunits contains CD25. The high-affinity IL-2R has been a specific target that is commonly present on cells in ATLL,[656] and on mature, activated T-cells. Approximately 60% of patients with CTCL will show expression of IL-2R on their mature T-cells, but there is both interpatient and intrapatient variability of expression.[657]

DAB_{486}IL2 and DAB_{389}IL2 were the first fusion toxins to be used in clinical trials and are composed of the nucleotide sequence of the enzymatically active and the membrane translocating domains of diphtheria toxin conjugated to the amino acid sequence of human IL-2.[655,658,659] In a phase II trial of DAB_{486}IL2 reported by Foss et al.,[660] 3 of 14 CTCL patients demonstrated an objective response (1 patient with a PR and 2 patients with slightly less than 50% improvement). The authors observed that IL-2R expression was necessary, but not sufficient, to predict response. DAB_{389}IL2 (denileukin diftitox), a second-generation molecule, replaced DAB_{486}IL2 because it showed a more favorable pharmacokinetic profile.

A pivotal phase III trial evaluated the safety, efficacy, and pharmacokinetics of two dose levels of denileukin diftitox.[661] This randomized, blinded, parallel-grouped study focused on the use of denileukin diftitox in the treatment of 71 patients with persistent or recurrent stage IB to IVA CTCL. For study inclusion, patients had to have detectable CD25 on ≥25% of their tissue biopsy lymphocytes via immunoperoxidase assay. Following therapy, 30% of patients experienced an objective response (20% PR and 10% CR), 32% experienced SD, and 3% demonstrated progressive disease. Both 9- and 18-μg/kg/day doses were compared, and showed similar tolerability and no evidence of cumulative toxicity. No statistically significant difference was found between the two dosing regimens with respect to response rate and duration of response (median 6.9 months, range 2.7 to 46.1 + months).[661] Upon stratification with respect to disease stage, 18 μg/kg/day of denileukin diftitox proved more effective in treating stage IIB patients (36% OR) than the lower dose (23% OR).[661] Denileukin diftitox was approved by the FDA in 1999 for the treatment of patients with persistent or recurrent CTCL whose malignant cells express the CD25 component of the IL-2 receptor. A phase III, placebo-controlled trial, again evaluating the two dosing regimens of 9- and 18-μg/kg/day doses was performed with 144, CD25 CTCL patients of any stage.[662] The overall response rate was higher in the 18-μg/kg/day group as compared to the 9-μg/kg/day group (49.1% vs. 37.8%) and both were higher than placebo (15.9%).[662] There was also increased estimated PFS in the 18-μg/kg/day group versus the 9μg/kg/day group (32.4 months vs. 26.5 months), but the adverse events were similar for both dosing arms.[662] Not surprisingly, the placebo group had significantly fewer adverse events and reduced PFS.

The effectiveness of denileukin diftitox in patients with <20% of their lymphocyte population expressing CD25 has not been determined, but a study of 24 patients treated without prior knowledge of their CD25 status showed a significant difference in patients achieving a partial response when patients with high CD25 expression were compared to patients with intermediate to minimal CD25 expression. In this study, no patient experienced acomplete response, and the side-effect profile was similar to that of previous studies.[663]

Another small phase III study focused on the use of steroid pre-medication to improve the tolerability of denileukin diftitox. Fifteen CTCL patients received prednisone or dexamethasone immediately prior to each dose of denileukin diftitox, which was administered at two dose levels (9 or 18 μg/kg/day) for 5 consecutive days, every 3 weeks. This cycle was repeated up to eight times. Following therapy, a significant decrease in the incidence of acute hypersensitivity reactions was noted, and a 60% response rate was observed. These findings prompted the authors to conclude that steroid pre-medication not only made denileukin diftitox more tolerable, it also performed this task without compromising clinical response.[664]

Side effects of denileukin diftitox have included reversible elevated hepatic transaminases (61% total, 15% with grade 3 or 4) and flu-like symptoms (fever/chills, nausea/vomiting, and arthralgias/myalgias) seen in 92% of patients in the pivotal trial. A delayed vascular leak syndrome (hypoalbuminemia, edema, and hypotension) was seen in 25% of patients in the same patient population. Increasing hydration may decrease the incidence of vascular leak syndrome, but this theory currently lacks supporting data. Acute hypersensitivity reactions during infusion may show as dyspnea, back pain, chest pain, and hypotension. As noted above, pre-treatment of these patients with steroids make acute hypersensitivity reactions less likely. Bone marrow suppression or secondary immunosuppressive effects have not been noted as significant adverse events related to denileukin diftitox.[655,661] Infections were seen in 56% of subjects. However, 80% of these infections were typical in patients with advanced-stage or heavily pretreated CTCL and were thus not attributed to therapy.[661]

Alemtuzumab (CAMPATH-1H), a monoclonal antibody directed against CD52, has been studied in the treatment of advanced, low-grade NHLs, including CTCL. This humanized antibody targets T and B lymphocytes, and it appears to have a predilection for circulating cells, relatively sparing those localized within lymph nodes.[665,666] Two small phase II studies evaluated the safety and efficacy of alemtuzumab in stage IIB to IV disease. Kennedy et al. reported a 38% overall response rate, and Lundin reported a 55% overall response rate. Both studies used 30 mg twice-weekly dosing. The time to progression and the time to treatment failure were short in both studies, at <4 and 12 months, respectively.[667,668] A more recent open-label trial from Querfeld et al. treated 19 erythrodermic CTCL patients with escalating IV doses of alemtuzumab up to a maximum of 30 mg, three times weekly, for 4 weeks, followed by 8 weeks of subcutaneous administration.[669] The overall response rate was 84%, with 47% having a complete response. Similar to previous studies, the median PFS was 6 months. Significant side effects occurred, including grade 3 to 4 cytopenias and severe infections.[669] There are also reports of cardiac toxicity in several patients that resolved with the discontinuation of treatment;[670] however, Lundin et al. did not experience any adverse cardiac events in their study patients.[671] The side-effect profile for CAMPATH-1H includes significant neutropenia with subsequent increased susceptibility to opportunistic infections and bacterial septicemia, thus limiting its utility in the treatment of advanced-stage patients with compromised immune systems.[667,668,672,673] Although subcutaneous low-dose alemtuzumab shows promise in the setting of SS, larger clinical trials

are needed to clarify the role of alemtuzumab in the treatment of CTCL.[136,673,674,675,676]

Another monoclonal antibody that targets CD4 (zanolimumab) has undergone phase II trials in CTCL patients. Kim et al. reported the use of zanolimumab in 47 treatment-refractory CTCL patients.[677] Seventeen weekly infusions at a dose of either 280, 560, or 980 mg were utilized. An objective response was seen in 15 of the 41 patents (36.6%), but evaluation of the two higher dosing regimens had an objective response of 56% with a median response of 81 weeks.[677]

An antibody to CD30 (SGN30) had minimal activity until it was conjugated to a cytotoxic drug monomethyl auristatin E (MMAE). Brentuximab vedotin (SGN35; Adcetris, Seattle Genetics) is an antibody–drug conjugate that consists of three components: a chimeric immunoglobulin G1 mAb cAC10 specific for human CD30, the microtubule disrupting agent MMAE, and a protease cleavable covalent linker that attaches the antibody to MMAE.[678] Brentuximab vedotin was approved by the FDA in August 2011 for relapsed patients with Hodgkin lymphoma or systemic ALCL. A phase II trial in 58 patients with relapsed ALCL (72% ALK-negative) reported an objective response in 86% of patients including 57% CR and 29% PR.[679] The median durations of overall response and CR were 12.6 months and 13.2 months, respectively. Grade 3 or 4 adverse events were neutropenia (21%), thrombocytopenia (14%), and peripheral sensory neuropathy (12%).

CCR4 is expressed on tumor cells from most patients who have ATLL, which is relatively resistant to chemotherapy. KW-0761 is humanized anti-CCR4 monoclonal antibody, which enhances antibody-dependent cellular cytotoxicity. In a phase II trial of 26 patients with relapsed CCR4-positive ATL, the overall response rate was 50%, including 31% CR.[680] Median PFS and OS were 5.2 and 13.7 months, respectively. Adverse events were manageable in fusion reactions (89%) and skin rashes (63%). Clinical trials are investigating KW-0761 in CTCL.

In addition to monoclonal antibodies, there have been efforts to harness the patients' own immune system to enhance the cytotoxic antitumor response. Utilizing TLRs, and additional cytokines to stimulate NK cells, in vitro studies have shown increased cellular death in CTCL lines.[504] A phase I trial initially evaluated the use of a TLR9 agonist in treatment-refractory CTCL patients (Stage IB-IVA), using a dose escalation ranging from 0.08 to 0.36 mg/kg in 24 weekly subcutaneous injections.[681] Common side effects included rigors, cytopenias, and pyrexia, among others. Although the trial was not designed to evaluate for efficacy, they did identify a 32% overall response rate, of which most lasted for the duration of the study (24 weeks).[681] More recently, a phase I/II study combined an intratumoral injection of a TLR9 agonist with radiation (to enhance tumor immunogenicity) in a cohort of 15 MF patients (stage IA–IVA) who had failed at least one standard therapy.[682] They again found a 33% overall response rate and the therapy was well tolerated with mild injection site reaction or flu-like symptoms.[682]

Hematopoietic Stem Cell Transplantation

Inasmuch as patients with advanced CTCL have a poor prognosis with only a small chance of sustained remission, treatments as invasive as hematopoietic stem cell transplantation (HSCT) have been increasingly explored using various donor sources, donor sites, and therapeutic conditioning regimens. See Chapters 102 and 104 for a full discussion of HSCT.

Autologous stem cell transplant (autoSCT) has an advantage over allogeneic SCT (alloSCT) with a lower treatment-related mortality, but has a disadvantage with a higher relapse rate. AutoSCT has been done in a small number of heavily pretreated CTCL patients, but relapses have occurred quickly in the majority of patients.[683–685] In a report of six patients, five achieved a CR, but three relapsed within 100 days and two remained in CR at 12 months.[683] Using T-depletion and $CD34^+$ stem cell selection in nine patients with tumor stage or more advanced MF, Olavarria et al. reported CR in eight patients, but seven relapsed at a median of 7 months (range, 2 to 14 months), one died of sepsis and one remained in CR at 10 months.[685] Four of the relapsed patients had a less aggressive disease course and responded to conventional therapy. Most experts agree that autoSCT offers little advantage for patients with CTCL due to the high rate of relapse and the increased risk of infectious complications.

In the era of alternative donors and reduced intensity conditioning (RIC), alloSCT is more readily available, but it remains controversial in CTCL due to the indolent course, an increasing number of novel therapies, and the risk and expense of alloSCT. An advantage of alloSCT is an apparent graft-versus-tumor effect. Molina et al. obtained a CR in all eight patients receiving alloSCT (4 matched related donor [MRD] and 4 matched unrelated donor [MUD]).[686] The clonal T-cell population originally found in six patients became undetectable within 60 days post-SCT and had not recurred within a mean follow-up of 56 months. One patient died of respiratory syncytial viral pneumonia at day +34, and a second patient expired from graft-versus-host disease at 16 months. Six patients remained in remission at a median of 53 months (range, 33 to 108 months).

European investigators, retrospectively, analyzed 60 patients (36 MF, 24 SS; median age = 46.5 years [range, 22 to 66 years]) who underwent alloSCT (45 MRD; 15 MUD); 44 received RIC regimens, and 25 underwent T-cell depletion.[687] The PFS was 42% and 34% and the OS was 66% and 53% at 1 and 3 years, respectively. Nonrelapse mortality was 20% at 1 year. A total of 26 patients relapsed (REL) at a median of 3.8 months (range, 1 to 37 months) and the incidence of relapse was 47% at 3 years. There were 17 REL patients who received donor lymphocyte infusions (DLI) and 10 achieved either a CR (8; 47%) or PR (2; 12%). RIC and MRD SCT had better survival than myeloablative and MUD SCT, respectively.[687]

Duvic et al. reported the MD Anderson experience in 19 patients with advanced CTCL (median age = 50 years; range, 21 to 63 years) who received total skin EBRT prior to a RIC alloSCT (12 MRD; 7 MUD).[688] Of 18 evaluable patients 7 experienced relapse or progression in the skin at a median of 50 days (range; 28 to 718 days). Of 8 that experienced relapse in the skin, 5 regained CR with reduced immunosuppression of DLI. Two-year PFS was 53% and OS was 79%. Of the 19 patients 11 (58%) were in CR at a median follow-up of 1.7 years (range, 0.8 to 7.9 years).

More studies are required to define the role of SCT in the treatment of advanced CTCL. An expanding donor pool, including umbilical cord and mismatched family; the decreased mortality of RIC, and improvements in supportive care are increasing the applicability of alloSCT for hematologic cancers. Based on preliminary findings in a limited number of patients, alloSCT warrants further study in CTCL.

SUMMARY AND FUTURE INVESTIGATIONS

Molecular studies are unraveling the complex interactions of cytokines, adhesion molecules, and the immune system responsible for the pathogenesis of CTCL and are continuing to provide insight for novel approaches to treatment. As with other indolent lymphomas, an array of therapies can produce responses in CTCL, but are generally not curative. In contrast to other lymphomas, however, is the high degree of efficacy of topical treatments (NM, TSEBRT, NBUVB, and PUVA phototherapies) for patients with early-stage MF/SS. Because CTCL is not cured by systemic chemotherapy, initial management of early-stage disease should include skin-directed therapy.[689] Ongoing clinical trials may define the roles of systemic therapy in managing more advanced-stage patients including combinations of skin-directed therapies, chemotherapy

agents, photopheresis, retinoids, monoclonal antibodies, IFN, and stem cell transplantation.

CHAPTER 93

HODGKIN LYMPHOMA IN ADULTS

David S. Morgan, Kristie A. Blum

Hodgkin lymphoma (HL) is a lymphoproliferative malignancy that accounts for only 1% of newly diagnosed malignancies in the United States; however, the disease's importance to the field of medical oncology is out of proportion to its clinical incidence. From an historical point of view, HL was the first cancer in which the curative potential of combination chemotherapy was demonstrated. Second, because affected patients are often young, there is a great potential for adding years of productive life by giving curative therapy. Third, because patients with HL are often cured, HL serves as a clinical laboratory for investigating the late effects of cancer therapy.

HL usually presents as solitary or generalized lymphadenopathy and most commonly occurs in young adults, although persons in any age group may be affected. The disease tends to spread in a contiguous fashion, and most patients present with disease limited to the lymph nodes or to the lymph nodes and spleen. Even patients with advanced disease have a reasonable chance of cure. Overall, cure can be achieved in approximately 80% of patients with HL. Treatment of limited disease often incorporates radiation therapy and combination chemotherapy, whereas treatment of advanced disease is generally limited to combination chemotherapy alone.

The evaluation of data and conclusions from clinical trials in HL requires certain caveats. The first issue is that salvage therapy for relapsed HL patients has a relatively high rate of cure. This fortunate fact can complicate the interpretation of trials of initial therapy for HL. In contrast to the situation in many other areas of oncology where salvage therapies generally do not lead to cures, progression-free survival (PFS) in HL trials must not be used as a surrogate marker for overall survival (OS). Conversely, because late complications, including malignancy, can compromise the long-term efficacy of treatments that appear superior in the short run, therapies that produce superior PFS at 5 years may not be associated with superior OS at 15 years. In some situations, then, treatment plans with built-in contingencies may be appropriate. As an example, consider two hypothetical treatment strategies: treatment *A* is moderately effective but nontoxic, and failures can be salvaged effectively with treatment *X*. The alternate treatment, *B*, is very effective but failures are only rarely salvaged with treatment *Y*. The combination of the (less-effective) treatment *A* and salvage with × if needed may lead to superior long-term results as opposed to starting out with the (more effective) treatment *B* and salvage with treatment *Y*. This may be especially true if one considers short- and long-term toxicities of treatment. When considering initial therapy for patients with HL, one must realize that valid alternatives exist in addition to what may be considered the "best therapy" based on short-term observations, and that individualized approaches may be appropriate to accommodate individual risks, especially for long-term toxicity.[1]

EARLY HISTORY

In 1832, Thomas Hodgkin presented a paper entitled, "On Some Morbid Appearances of the Absorbent Glands and Spleen."[2] His report was an autopsy description of seven patients, and the major original thesis presented in the paper was that the entity he was describing was a *primary* process involving the lymph glands and spleen rather than a *reactive* inflammatory condition. In 1856, Samuel Wilks published a series of cases involving enlargement of the lymph glands[3] and noted Hodgkin's original description. In 1865, Wilks wrote, "Cases of Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease) with Remarks," updating and extending his findings.[4] Thus, Thomas Hodgkin's name became linked to the disorder. Of note, some of the cases included in Hodgkin's initial report were cases of tuberculous lymphadenopathy and non-Hodgkin lymphoma.

After these gross pathologic descriptions, the first microscopic description of HL was reported by Langhans[5] in 1872. This report was followed by independent reports by Sternberg in 1898[6] and by Reed in 1902[7] describing the characteristic giant cells that came to be known as *(RS) cells*. At the time of these early reports, all comments regarding the cause of HL were purely speculative. Not surprisingly, these early authors were divided over whether HL represented an infectious disease, an inflammatory disorder, or a malignancy involving the lymph glands.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that 9,060 new cases of HL will be diagnosed in 2012.[8] The male-to-female ratio is 1.2:1.[8] In most economically developed countries, there is a bimodal age distribution, with one peak occurring in the third decade of life and the second, smaller, peak occurring after age 50 years.[9] The occurrence of HL in patients between the ages of 15 and 39 has been positively associated with increased maternal education, decreased numbers of siblings and playmates, and single-family dwellings in childhood.[10] In less economically developed countries, HL is less common but affects children, most of whom are boys; mixed cellularity HL and lymphocyte-depleted HL are more commonly seen.[11] These data have been interpreted as supporting the hypothesis that HL is caused by an infectious agent, and it has been postulated that malignancy is more likely to occur when exposure to the agent in question is delayed until late adolescence or early adulthood.[11–14]

Epstein-Barr virus (EBV) has been proposed as contributing to the development of some cases of HL, and the circumstantial evidence is considerable. The incidence of HL is elevated among patients with a history of EBV infection.[15–17] EBV has been associated with other related malignancies, including Burkitt lymphoma and lymphomas developing in immunocompromised patients. Using modern molecular biology techniques, EBV genome fragments have been found in RS cells from approximately 40% of patients with HL,[18–20] more commonly in cases of mixed cellularity HL.[23] In addition, the EBV DNA associated with RS cells in HL has been shown to be monoclonal, establishing that EBV preceded the development of HL.[18,19] Interestingly, prognosis appears to be better in HL that is EBV-positive, as compared to cases that are EBV-negative.[21–23]

HL occurring in early childhood or in older adults is more likely to be EBV-associated than are cases of HL occurring in young adults.[24] However, in an important 2003 study, 38,555 patients with documented EBV-positive infectious mononucleosis were followed for an extensive period.[25] In this selected population, 29 cases of HL developed and 16 (55%) were positive for EBV. The risk of EBV-positive HL was increased by a factor of 4 as compared to patients who never had documented EBV-positive infectious mononucleosis; the median latency for HL after EBV infection was 4.1 years. There was no increase of EBV-negative HL in this population. These data do not prove causality: the data are equally compatible with the theory that EBV pre-disposes

patients to the development of HL. If there is a causal role for EBV, additional factors must be required for the development of HL.

The idea that HL may represent an uncommon host response to a common agent has received additional support in a study of monozygotic and dizygotic twins. Monozygotic twins, who would be expected to have similar immune responses, had a 99-fold increased risk of being concordant for having HL, supporting a role for genetic susceptibility or abnormal immune response, or both, in the etiology of HL.[26] The incidence of HL in patients with the acquired immunodeficiency syndrome or with human immunodeficiency virus infection is elevated over the incidence in the general population (although not to the extent of the increase in the incidence of non-Hodgkin lymphoma), perhaps lending further plausibility to the concept that HL represents a disordered immune response to antigens.[27,28] An increased incidence of HL has been noted in recipients of allogeneic bone marrow transplants.[29] In addition, a patient has been reported with reversible methotrexate-associated lymphoproliferative disorder that eventually evolved into HL.[30]

HISTOPATHOLOGY

The diagnosis of HL requires biopsy of an involved lymph node or, rarely, of an involved extranodal site (Chapter 86). It is important to note that inflammatory nodes may be interspersed among nodes harboring HL. In general, a larger node with more abnormal features on imaging is a better target for biopsy than a smaller, perhaps more accessible, node. Inguinal nodes, although generally fairly easily biopsied, are often enlarged from current or past inflammation, and biopsy may be misleading. A fine needle aspiration (FNA) should generally be considered an inferior diagnostic approach and will only rarely yield a firm diagnosis; most diagnoses will require an excisional lymph node biopsy (although occasionally a diagnosis can be made on generous core biopsy). Flow cytometry is noninformative in HL, as the majority of cells in a specimen reflect the inflammatory background, with the malignant RS cells being relatively rare. This fact can occasionally falsely reassure a clinician who gets a flow cytometry result of "reactive" and a nondiagnostic FNA on a patient with unexplained adenopathy; the correct response is to go on to an excisional biopsy. Fortunately for clinicians, concordance between pathologists regarding the diagnosis of HL is high, often exceeding 90%.[31]

HL can be confused with atypical inflammatory reactions that can occur in some patients with infectious mononucleosis[32] or in patients receiving phenytoin.[33] Among the lymphomas, HL is sometimes mistaken at the histologic level for anaplastic large cell lymphoma, mediastinal large cell lymphoma, or T-cell–rich B-cell lymphoma. Correct classification can usually be achieved using immunohistochemistry and cytogenetic techniques. Recently identified and listed as a provisional entity in the World Health Organizations classification was:[34] "B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma (cHL)," also known as "Grey Zone Lymphoma."[35,36]

Pathologically, HL is distinguished from other lymphomas by the presence of large binucleated or multinucleated cells (RS cells) generally surrounded by a benign reactive response consisting of lymphocytes, histiocytes, granulocytes, eosinophils, and plasma cells. RS cells are large cells with abundant cytoplasm and generally contain two or more nuclei and two or more inclusionlike nucleoli. Molecular evidence (clonal immunoglobulin rearrangements) has shown that the cell of origin for RS cells is a germinal center or post-germinal center B-cell. The RS cell does not express the common B-cell transcription factors and thus its B-cell phenotype (including the B-cell receptor) because of down-regulation and because of epigenetic silencing.[37,38] Commonly such nonfunctional B-cells would undergo apoptosis, and activation of several antiapoptotic pathways (including the nuclear factor [NF]-κB pathway)[39] has been proposed as mechanisms for the molecular pathogenesis of HL. The molecular mechanisms involved in the development of HL have been the subject of several reviews,[40,41] and further discussion of these intracellular pathways is beyond the scope of this clinical chapter.

Variant forms of RS cells exist, especially in the nodular sclerosis subtype of HL and the nodular form of lymphocyte-predominant HL (LPHL). RS cells are not specific for HL and have been noted in cases of infectious mononucleosis[42] and other malignancies including lymphoma, carcinomas, and sarcomas.[43] Therefore, RS cells are not sufficient to establish the diagnosis of HL because that diagnosis depends on the presence of both the characteristic RS cells and the characteristic cellular environment in which the RS cells are found. In addition to the histologic criteria, immunostaining, the RS cells or variants in classical HL should be positive for CD15 (85%) and CD30 (100%), and negative for most pan-B–cell and pan-T–cell antigens. If a B-cell antigen is present, it is usually CD20 and it is variable in intensity.[44,45]

The subclassification of HL depends in large part on the ratio of neoplastic to reactive cells and their orientation. The current subtype classification stems from the classification of Lukes and Butler,[46] as modified at the Rye Conference in 1966.[47] These investigators described RS cell and their variants (Fig. 86.16), one of which they called the L and H cell, ("lymphocytic and histiocytic" because of the associated background) seen primarily in the LPHL. Later these multilobated cells were referred to as "popcorn cells."[48] It was later shown through immunohistochemistry studies that classic RS cells and L and H cells were distinct, with RS cells or variants of other subtypes of HL being CD30 and usually CD15 positive and negative for pan-B–cell markers (Fig. 86.17), and with the L and H cells of LPHL being CD20 pos and CD30 and CD15 negative (Fig. 86.23). Likewise it is now clear on clinical, immunophenotyping, and gene expression profiling grounds that LPHL is a clinicopathologic entity distinct from the other types of HL.[49–52] Thus the current WHO classification[34] distinguishes cHL from LPHL.

cHL is comprised of four subtypes: nodular sclerosis HL, mixed cellularity HL, lymphocyte-rich classical HL (LRCHL), and lymphocyte-depleted HL. In the past, the subtype of HL was felt to give the clinician valuable prognostic information; however, it is now recognized that the histologic subtype co-varies with stage, and that much of the reported differences in prognosis previously attributed to histologic subtypes may be attributed to stage. When patients are stratified by stage and receive equivalent therapy, differences attributable to histologic subtype are either trivial or nonexistent.[53–56]

The incidence of HL cases with respect to histologic subtype is shown in Table 93.1. The data are taken from one large tumor registry[57] and three large series of referred patients,[31,58,59] and are subject to biases in the selection process. However, the general agreement among the series suggests that this is a fairly reliable estimate regarding the relative incidence of the subtypes of HL.

In nodular sclerosis HL, nodularity is produced by dense collagenous bands that divide the cellular portion of the node into sections (Fig. 93.1). In this type of HL, RS cell variants, rather than classic RS cells, are commonly found in the cellular areas. These lacunar RS cells have faintly stained cytoplasm and appear separated from adjacent cells by empty space, an artifact of formalin fixation (Figs. 93.2 and 86.20). Nodular sclerosis HL is the most distinctive form of HL. Although the other subtypes of HL may be regarded as a histologic continuum and transformation among other subtypes is commonly seen, when patients with the nodular sclerosis subtype undergo repeat biopsies, the nodular sclerosis form of HL is confirmed in more than 90% of cases.[60] This form of HL classically presents as stage I or II disease with cervical and mediastinal involvement in young adults, although more advanced stages of disease are not uncommon (Table 93.2).

TABLE 93.1

RELATIVE INCIDENCE OF HISTOPATHOLOGIC SUBTYPES OF HODGKIN LYMPHOMA

Medeiros et al.[57]	7	63	26	4

Note: Percentages refer to "classified" cases, as some studies contain cases of unclassified Hodgkin disease.

A "syncytial variant" of nodular sclerosis HL has been recognized in which numerous RS cell variants have been observed in sheets and clusters. This variant of HL may be confused with NHL, thymoma, or metastatic cancer.[61]

HL of the mixed cellularity pattern is a diffuse lymphoma composed of a mixture of cells including RS cells (Figs. 93.3 and 86.18). Distinguishing mixed cellularity HL from diffuse mixed forms of NHL may be difficult on the basis of histology alone, but should be resolved with modern immunohistochemical stains. This subtype of HL has a greater tendency than nodular sclerosis HL to be advanced at the time of presentation and to be associated with symptomatic disease. Mixed cellularity and nodular sclerosis HL make up the majority of HL cases.

Lymphocyte-depleted HL is composed predominantly of histiocytes and lymphocytes with varying numbers of eosinophils and RS cells (Figs. 93.4 and 86.21). The host reaction is often scant relative to the number of malignant giant cells, and a varying amount of fibrosis is generally present. The disease is the least common type of HL and tends to be advanced at diagnosis (i.e., stage III or IV). Most patients have B symptoms,[62] retroperitoneal nodal involvement is common, and approximately one half of patients have bone marrow involvement.[63–65] Many older case series contain cases that would now be classified as peripheral T-cell lymphomas[66] or anaplastic large cell lymphomas.[67,68] Therefore the older literature regarding this entirety must be treated cautiously.

LRCHL[51] is characterized by rare RS cells or variants dispersed in a background of predominantly small lymphocytes. The tumor cells have the appearance of classic RS cells as well as the immunophenotype of classic RS cells ($CD30^+$, $CD15^+$, but CD20 negative) (Figs. 93.5 and 86.19).

LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

Nodular lymphocyte-predominant HL (NLPHL) is an uncommon subtype of HL, representing about 5% of cases,[69] with unique pathologic features distinguishing it from classical HL.[70] The neoplastic cell is a large cell, the LP cell, otherwise known as a popcorn cell due to its single, large, folded or multilobulated nucleus that typically has a smaller nucleus than observed in RS cells (Figs. 93.6 and 86.22). However, unlike the RS cell, these cells are typically CD30 and CD15 negative, with CD19, CD20, CD45, and CD79a positivity (Fig. 86.23). These cells are also PAX-5 and Oct-2 positive. The surrounding background lymphocytes are predominantly small CD20 B-cells, with rare eosinophils, neutrophils, or plasma cells. Surrounding the LP cells, $CD4^+$ t-cell rosettes are found and CD21-positive follicular dendritic cells are present, consistent with the germinal center derivation of this malignancy.[70]

Due to the rare occurrence of this malignancy, presentation, treatment, and patient outcomes are not well described in this disease. In a retrospective analysis of 8,298 patients enrolled on clinical trials for HL through the German Hodgkin Study Group,

Gross appearance of the cut surface of a resected node shows a thickened capsule, white fibrous bands, and yellow parenchymal nodules. **B:** Nodular sclerosing Hodgkin lymphoma. Low magnification shows a fibrous capsule and bands of sclerosis circumscribing abnormal lymphoid nodules.

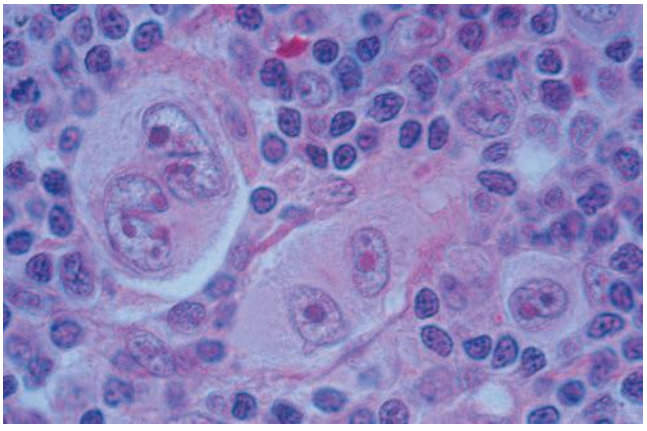

FIGURE 93.2. Nodular sclerosing Hodgkin lymphoma. High magnification shows Reed-Sternberg cells and lacunar variants in B5 fixed material.

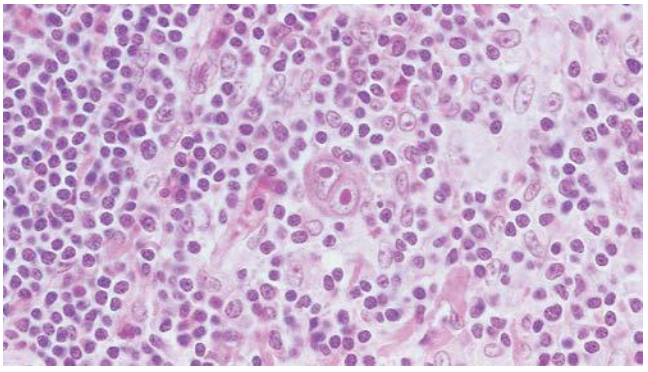

FIGURE 93.3. Mixed cellularity-type Hodgkin lymphoma. High magnification shows a classic Reed-Sternberg cell in a mixed background of small lymphocytes, plasma cells, and eosinophils.

394 patients had NLPHL.[69] In this series, the median age at diagnosis was 37, 75% patients were male, and 79% of patients had early stage disease. Clinically, there appear to be two age peaks, one in children and another in patients aged 30 to 50. The presence of B-symptoms or bulky disease is unusual, observed in <10% of patients.[70] Unlike classical HL, patients with NLPHL typically have peripheral adenopathy (axillary or inguinal) at diagnosis rather than central or mediastinal involvement and nodal spread does not track from LN basin to LN basin as typical for classical HL. In NLPHL, nodal involvement is not contiguous and extranodal involvement is uncommon.

An association exists with this subtype of lymphoma and a benign condition, progressive transformation of germinal centers, as well as with NHL, particularly T-cell–rich B-cell lymphoma and diffuse large B-cell lymphoma. Progressive transformation of germinal centers is described as lymph nodes with large, well-defined nodules with an excess of B-cells, or germinal centers overrun by lymphocytes.[70] This entity may be observed prior to, simultaneous with, or following a diagnosis of NLPHL. This entity is thought to be a benign condition, but as it occurs concurrently or following a diagnosis of NLPHL, biopsy of recurrent adenopathy is always required in this disease to confirm relapse. Likewise, T-cell–rich B-cell lymphoma and NLPHL can occur simultaneously or in succession, and frequently T-cell–rich B-cell lymphoma can be pathologically confused for NLPHL. With T-cell–rich B-cell lymphoma, large atypical B-cells that are CD20 positive are surrounded by an abundant background of T-cells and histiocytes. As about 5% of NLPHL eventually develop NHL including T-cell–rich B-cell NHL or diffuse large cell lymphoma, biopsy of recurrent lymph nodes is necessary to determine therapy at relapse. In a series of 22 patients treated with rituximab for NLPHL, 9 patients relapsed, including 5 who underwent biopsy at recurrence and of these 2 had diffuse large cell NHL within 13 months of follow-up.[71]

CLINICAL EVALUATION

Physical Examination: Sites of Disease

Staging, the basis for treatment planning in HL, begins with the physical examination. HL almost always presents with lymphadenopathy, and the involved nodes are usually freely movable with a rubbery consistency. Cases in which the microscopic appearance reveals fibrosis or sclerosis can be associated with hard firm nodes. Although any lymph node group can be involved (Table 93.3), cervical and supraclavicular adenopathy are the most common physical findings, and axillary presentations are not rare.[72,73]

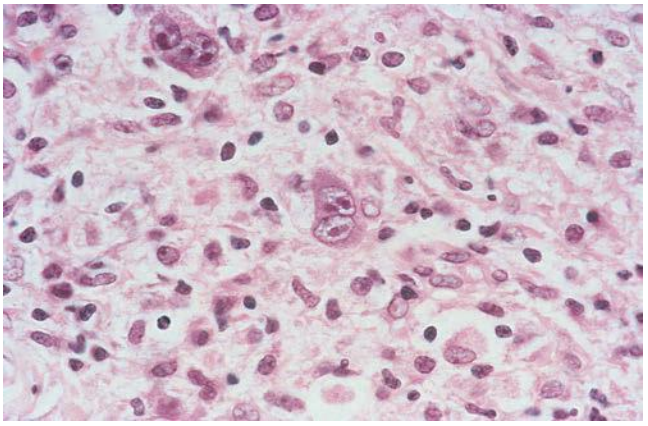

FIGURE 93.4. Lymphocyte-depleted type Hodgkin lymphoma, diffuse fibrosis subtype. Reed-Sternberg cells are easily found, and the background is depleted of cellularity and composed of amorphous eosinophilic connective tissue.

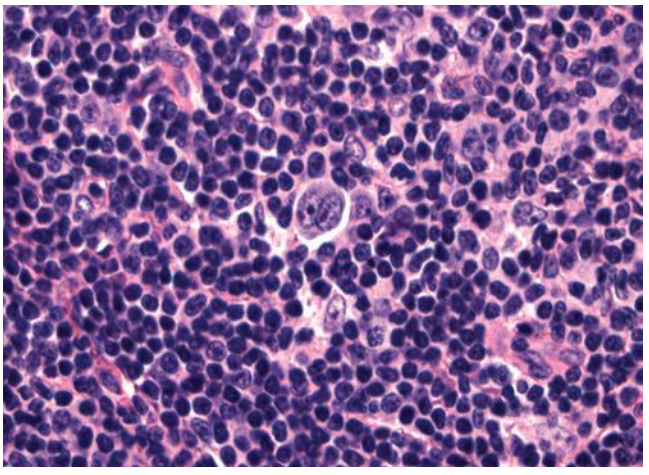

FIGURE 93.5. Lymphocyte-rich "classic" Hodgkin lymphoma. The background is primarily lymphocytes, and the Reed-Sternberg cells are usually $CD15^+$ and $CD30^+$ and negative for the B-cell marker CD20.

Mediastinal disease is often present, but it is rarely the only site of disease because it usually occurs in conjunction with cervical or supraclavicular disease. HL can present with iliac, inguinal, or femoral adenopathy, and in approximately 3% of cases, only subdiaphragmatic disease is present.[74,75] However, in a large series of cases in which the original diagnosis of HL was not confirmed on review, two features that predicted errors in diagnosis were primary extranodal disease and primary subdiaphragmatic disease.[76] Thus, the pathologic diagnosis of HL should be questioned in cases with subdiaphragmatic presentation. A complete physical examination of the patient with HL should include an evaluation of Waldeyer's ring and epitrochlear nodes even though these sites are only rarely involved.

Splenomegaly is noted at presentation in approximately 10% of cases of HL. However, splenomegaly may be a nonspecific manifestation of the HL, and in only one half of patients with splenomegaly was splenic involvement confirmed at laparotomy[73] in a study from the era of staging laparotomies. Additionally, splenic involvement may occur in 20% to 30% of patients in the absence of splenomegaly[73] even when abdominal computed tomography (CT) scans are used to assess splenomegaly by three-dimensional measurements.[77] This latter fact should not be surprising, because splenic involvement may be limited to a few microscopic nodules.

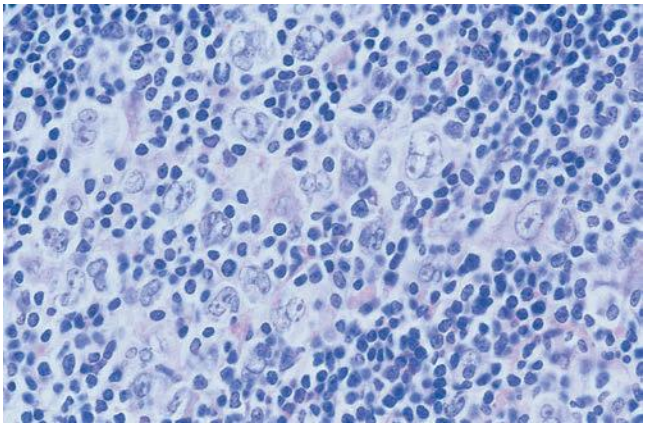

FIGURE 93.6. Lymphocyte-predominant Hodgkin lymphoma. High magnification shows variant lymphocytic and histiocytic cells (L and H cells), which have "popcorn" nuclei. A background of small lymphocytes and histiocytes is present.

TABLE 93.3

FREQUENCY OF INVOLVEMENT OF NODAL SITES IN HODGKIN LYMPHOMA

Site	Frequency of Involvement (%)	Frequency of Involvement as Only Site of Disease (%)
Left cervical and/or supraclavicular nodes	70	7
Right cervical and/or supraclavicular nodes	62	4
Mediastinum	60	1
Spleen[a]	36	0
Para-aortic nodes[a]	34	<1
Left axillary nodes	25	1
Right axillary nodes	25	1
Hilar nodes	21	0
Iliac, inguinal, femoral nodes	16	1

[a]Data based on surgically staged patients.

Modified from Kaplan HS. Contiguity and progression in Hodgkin's disease. Cancer Res 1971;31:1811–1813; and Kaplan HS, Dorfman RF, Nelsen TS, et al. Staging laparotomy and splenectomy in Hodgkin's disease: analysis of indications and patterns of involvement in 285 consecutive, unselected patients. Natl Cancer Inst Monogr 1973;36:291–301.

Extranodal disease can occur at any site. However, the central nervous system and the testis, which are not uncommon sites for NHL, are exceptionally rare sites for HL. At presentation, lung, liver, bone, and bone marrow are the most common extranodal sites of disease, with each of these sites seen in approximately 5% to 10% of cases.[78,79] Disease at other individual sites occurs in <5% of cases. Primary extranodal HL should always lead the clinician to consider the possibility of an incorrect pathologic diagnosis.

Pattern of Spread

HL tends to spread in a contiguous fashion.[72,80] In fact, when one considers that the left supraclavicular area and the upper abdomen are contiguous (via the thoracic duct), a contiguous pattern of disease can be established at presentation in more than 90% of cases.[72] For patients with only right supraclavicular involvement at presentation, abdominal disease is found in only 8% of cases; for patients with left supraclavicular involvement at presentation, the incidence of abdominal involvement is 40%. Hilar involvement with HL does not occur unless mediastinal disease is present. Pulmonary involvement by HL does not occur in the absence of mediastinal and hilar involvement.[81]

The spleen is the most commonly involved abdominal site of disease, possibly representing hematogenous spread. Liver involvement is uncommon at presentation in patients with HL, and it is exceptionally rare in the absence of splenic involvement.[72,82] Within the abdomen, the pattern of disease detected at staging laparotomy suggests spread from the spleen in a contiguous fashion. In a series in which staging laparotomies were performed with rigorous attention to biopsy of all nodal groups, the spleen and contiguous nodes were involved in 71% of cases, the spleen and noncontiguous nodes were involved in 16% of cases, and lymph nodes were involved in the absence of splenomegaly in only 13% of cases.[83] It is unknown whether the cases of apparent discontiguous spread represent cases in which early hematogenous dissemination has occurred or cases in which HL has spread through a node without involving the node.

Initial Evaluation of the Hodgkin Lymphoma Patient

Clinical History

An accurate clinical history facilitates the management of HL patients in a number of ways. The presence of certain symptoms is associated with a less favorable prognosis and may be a clue to more advanced disease than otherwise suspected. Other symptoms may point out the need for additional studies (such as a bone scan or neck CT) for accurate staging. The discovery of additional sites of disease because of symptoms may lead to a modification of therapy and establish the need for additional follow-up studies on completion of treatment. A history of heart disease or lung disease may prompt closer assessment of those organs before chemotherapy or during its course. A history of HIV infection may affect choice of chemotherapy or infection prophylaxis. A history of smoking or autoimmune disease or a family history of breast cancer may influence the decision to incorporate radiation therapy into the treatment plan and may influence the follow-up plan.

The constitutional symptoms that are known to have prognostic value are unexplained fever to >101°F, drenching night sweats, and weight loss equal to 10% of the patient's weight. These are the only symptoms that are accounted for in the Cotswold staging system (and whose presence is denoted by *B* appended on the numerical stage). Fever in HL can have any pattern, including continuous low-grade fever or occasional fever spikes. The pattern of recurrent episodes of daily high fevers separated by days without fever, Pel-Ebstein fever, was first associated with HL in 1885.[84,85] However, in the modern era it is a rare manifestation of HL and, although limited to patients with very advanced disease, it is uncommon even in those patients. Rarely, fever may be the only clinical manifestation of HL, for instance, in the case of patients with the lymphocyte-depleted HL who present with fever and disease limited to retroperitoneal nodes or the bone marrow, or both.[86]

Before designating a patient as having the symptom of night sweats, the clinician should verify that the patient's sweating is abnormal. The night sweats of HL are drenching and not simply associated with increased ambient temperature. Perimenopausal women should be asked if they have vasomotor symptoms before the sweating, as flushing is not generally a symptom of the sweats of HL.

Pain at the site of HL in association with the ingestion of alcohol is well described and can be the first hint of a recurrence. The mechanism of this phenomenon is unknown and it does not have prognostic significance. The occurrence of alcohol-induced pain has become less common in recent decades, perhaps in association with earlier diagnosis and more effective therapy. Generalized pruritus may be a nonspecific manifestation of HL, and it may be an early manifestation of the disease in up to 10% to 15% patients. It also has no known prognostic implication. Similarly, fatigue and weakness may occur in patients with HL but do not cause a patient to be classified as symptomatic.

Although the staging classification divides patients into categories A and B for asymptomatic and symptomatic, respectively, clinicians are well aware that this binary classification is an oversimplification and that the presence 0 of symptoms varies along a continuum[87,88] with respect to their clinical significance. When patients with stage IB and stage IIB HL were reviewed, it was found that the presence of fevers was associated with a relative risk of relapse after treatment of 4.3. For weight loss alone, the relative risk of relapse after treatment was 2.4; for night sweats, the relative risk of relapse was 0.8 (i.e., not increased).[87] Nevertheless, the presence of symptoms may suggest advanced disease. Symptoms are found in <10% of patients with stage I disease and in approximately two thirds of patients with stage IV disease.[89] The presence of B symptoms in a patient with apparent stage I disease is, therefore, suggestive that further evaluation will lead to the discovery of a more advanced-stage disease.

The Cotswold Staging System

The stage of the patient is the main determinant of therapy and prognosis in HL. The current classification system is the Cotswold classification system[90,91] (Table 93.4). Although the modalities used to stage patients have changed since the Cotswold conference in 1990 (e.g., PET and improved CTs have replaced staging laparotomy and gallium scans), and treatment algorithms have changed, the current staging system remains the backbone for clinical decision making and for clinical trial design.

Stage I disease is the involvement of a single lymph node region (or a single lymphoid structure). Stage II disease is the involvement of multiple lymph node regions (e.g., cervical nodes, supraclavicular nodes) but on only one side of the diaphragm. Stage III disease is the involvement of lymph node regions on both sides of the diaphragm and is further subdivided as to anatomic substage. Disease limited to the upper abdomen (i.e., spleen, splenic hilar nodes, celiac nodes, or porta hepatis nodes) in a patient with stage III disease is defined as substage III_1. Patients with stage III disease in whom abdominal nodal involvement includes para-aortic, iliac, or inguinal nodes are classified as substage III_2. The distinction between stages III_1 and III_2 is largely obsolete as all patients with stage III are now treated similarly with chemotherapy. Stage IV disease is visceral involvement (e.g., lung, liver, or bone marrow) that is not due to direct extension from a nodal site. The subscript E represents extension from a nodal site, such as extension of a mediastinal mass directly into the lung, for example, II_E.[78] The designations *A* and *B* are used to represent the absence and presence of symptoms (e.g., unexplained fever, drenching night sweats, and weight loss of 10% of body weight), respectively. The presence of "bulky" disease, defined as a mediastinal mass with a diameter greater than one-third the diameter of the chest as measured at the T5–T6 interspace on a postero-anterior chest radiograph, or any nodal

TABLE 93.4

COTSWOLD STAGING CLASSIFICATION FOR HODGKIN LYMPHOMA

Stage I

Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring)

Stage II

Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes are lateralized); number of anatomic sites should be indicated by a suffix (e.g., II_3)

Stage III

Involvement of lymph node regions of structures on both sides of the diaphragm

III_1	With or without splenic hilar, celiac, or portal nodes
III_2	With para-aortic, iliac, or mesenteric nodes

Stage IV

Involvement of extranodal site(s) beyond that designated *E*

A	No symptoms
B	Fever, drenching sweats, weight loss
X	Bulky disease, greater than one-third widening of the mediastinum, >10 cm maximum dimension of nodal mass
E	Involvement of a single extranodal site, contiguous or proximal to a known nodal site
CS	Clinical stage
PS	Pathologic stage

TABLE 93.5

DISTRIBUTION OF HODGKIN LYMPHOMA CASES WITH RESPECT TO STAGE AND SYMPTOMATIC STATUS

Stage	A (%)	B (%)	A and B (%)
I	11.4	0.8	12.2
II	34.1	12.4	46.5
III	17.5	13.1	30.6
IV	3.3	7.4	10.7
Total	66.3	33.7	100.0

Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980.

mass with a greatest diameter of more than 10 cm, is represented by the designation *X*.[92–94] The relative incidence of each stage of HL is shown in Table 93.5.

Required and Suggested Studies for Initial Evaluation

As treatment recommendations for HL depend heavily on stage, accurate staging is crucial. Staging also establishes a baseline so that the completeness of remission can be assessed on completion of therapy. The evaluation begins with a clinical history (see above) and a physical examination. The physical exam should focus on accessible lymphoid tissues, including Waldeyer's ring, all palpable lymph node areas, including the epitrochlear and popliteal nodes, as well as the spleen.

The role of radiographic imaging in HL patients is to determine the stage accurately, as stage determines treatment. A second role is to establish a baseline for comparison to mid-treatment or post-treatment scans. There is now a general agreement that positron emission tomography with integrated CT scanning (PET/CT) can supplant other imaging studies in the initial assessment of most patients with HL. PET/CT is reported to have very high sensitivity and specificity in HL. CT alone relies on size criteria to distinguish normal nodes from involved nodes and thus may understage patients with small but involved nodes. It is also poor at identifying a diffusely involved organ such as the spleen or liver, unless those organs are enlarged. It is reported that PET/CT (as compared to CT alone) changes the stage in up to 20% to 40% of cases and changes the treatment in 5% to 15%.[95,96,97] The majority of these cases are upstaging. Some argue for omitting PET/CT in favor of CT alone for certain "clearly limited-stage" patients,[98] however, most clinicians and most guidelines (e.g., the National Comprehensive Cancer Network) favor initial PET/CT as a routine study for initial evaluation of HL. If a PET/CT is unavailable, or otherwise unused, patients should have CT scans of the chest, abdomen, and pelvis. A neck CT should be included if there is any clinical suspicion of involvement of neck nodes. A chest radiograph is performed in a patient with a mediastinal mass to assess whether the patient's disease meets the criteria for bulky mediastinal disease. Certain situations and patients may warrant other radiographic studies, for example, the patient with bone pain may be evaluated with bone scan or MRI.

A marrow biopsy is usually performed on any patient with B symptoms or abnormal blood counts, and on any patient with stage III or IV disease. Although the chance that an early stage asymptomatic patient with normal blood counts will have marrow involvement is low,[79,99] some clinicians perform a marrow biopsy on all patients with HL. Recent data suggest that PET/CT accurately identifies or rules out marrow involvement,[100] and clinicians may be able to decrease their use of marrow biopsy accordingly in the future.

Blood tests should include a complete blood count with differential and platelets, erythrocyte sedimentation rate, liver function tests including alkaline phosphatase, lactate dehydrogenase, albumin and bilirubin (abnormal liver function tests are not diagnostic of liver involvement, but are sometimes nonspecifically elevated and may complicate the use of certain chemotherapy agents); BUN and creatinine, and thyroid function tests as a baseline (if neck radiotherapy is contemplated). Serology for human immunodeficiency virus is appropriate in selected cases. A pregnancy test should be performed for women of childbearing potential.

Patients should be counseled about fertility preservation. An assessment of ejection fraction by echocardiogram or radionuclide study is appropriate if anthracycline chemotherapy will be used. Pulmonary function tests with diffusing capacity should be ordered if bleomycin-containing chemotherapy will be used.

A summary list of suggested initial procedures and tests is presented in Table 93.6.

Prognostic Indicators

As noted above, stage is the major prognostic factor in HL and the major basis on which therapy is determined. However, patients can be stratified for risk on the basis of prognostic factors in addition to stage. In a study of 5,141 patients with "advanced" HL, primarily stage III and IV disease, Hasenclever and Diehl[101] performed a multivariate analysis of risk factors (Fig. 93.7). Seven independent factors that predicted freedom from progression (FFP) were identified: albumin <4.0 g/dl; hemoglobin <10.5 g/dl; male sex; 45 years of age or more; stage IV disease; leukocytosis at or above 15,000/mm^3; and lymphocytopenia (lymphocytes ≤600/mm^3 and/or lymphocytes <8% of total white count). For patients with no risk factors (7% of all patients), FFP was 84%. For

TABLE 93.6

RECOMMENDED INITIAL EVALUATION FOR PATIENTS WITH HODGKIN LYMPHOMA

History and Physical Examination, Including
Past medical history: including B symptoms (fever, night sweats, weight loss of >10% in past 6 mo), alcohol intolerance, itching, HIV risks, cardiac, renal, liver impairment
Family history: including lung cancer, coronary disease, breast cancer
Personal history: smoking
Examination of all peripheral lymph node regions (including epitrochlear, popliteal, Waldeyer's ring), liver, and spleen
Radiologic Studies
Chest radiograph
PET/CT
Assessment of EF (optional in younger patients)
Pulmonary function tests (optional in younger patients)
Laboratory Studies
Hematocrit, white blood cell count, differential, platelet count
Erythrocyte sedimentation rate, lactic dehydrogenase
Liver function tests including albumin, alkaline phosphatase transaminases, bilirubin
Bilirubin, alkaline phosphatase, liver function tests
Thyroid function tests if radiation to neck is contemplated
Bone scan (selected patients)
HIV serology
Bone Marrow Aspiration and Biopsy (Optional Unless Stage III)

CT, computed tomography; HIV, human immunodeficiency virus; PET, positron emission tomography.

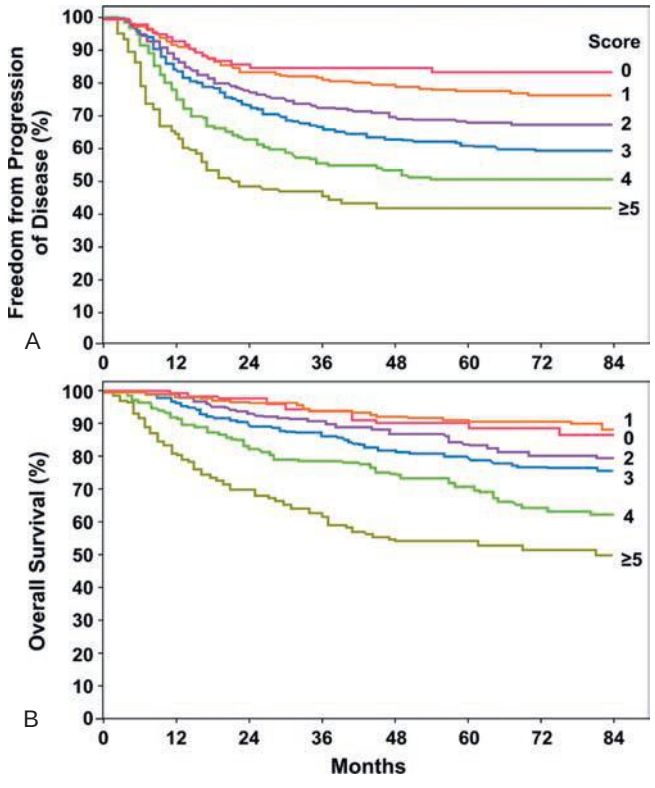

FIGURE 93.7. Progression-free survival (A) and survival (B) as related to number of risk factors. (From Hasenclever D, Diehl V. A prognostic score for advanced Hodgkin's disease. N Engl J Med 1998;339:1506–1514, with permission.)

patients with one risk factor (22% of all patients), FFP was 77%. For patients with two risk factors (29% of all patients), FFP was 67%. For patients with three risk factors (23% of all patients), FFP was 60%. For patients with four risk factors (12% of all patients), FFP was 51%. For patients with five or more risk factors (7% of all patients), FFP was 42%. Of note, B symptoms did not have independent prognostic value in this model. At present this model is validated only for advanced-stage patients.

A number of prognostic classifications have been used for early-stage HL and have been used to tailor therapy further in clinical trials. These commonly employ some combination of age, erythrocyte sedimentation rate, mediastinal bulk, and number of involved nodal sites. See Table 93.7, "Unfavorable Prognostic Factors for Stage I–II HL, by Three Cooperative Groups."

OVERVIEW AND HISTORICAL PERSPECTIVE OF RADIATION THERAPY

Six years after the discovery of x-rays by Roentgen in 1895, Pusey reported that x-rays could shrink enlarged nodes in patients with HL.[102] However, given the orthovoltage techniques of the day, therapy was only palliative. The modern radiotherapy era began with the Swiss radiotherapist Gilbert in 1925.[103] Based on observed patterns of spread in patients with HL, Gilbert advocated treatment of both involved areas and adjacent, apparently uninvolved, areas. This approach was also adopted by Peters, who, in 1950, was the first to report that radiation therapy of HL could produce cures.[104] Over the next two decades, the curability of HL was confirmed by Peters,[105,106] Easson and Russell,[107] and Kaplan,[108,109] the latter investigator establishing the critical relationship between radiation dose and the risk of recurrence in the treatment field (Fig. 93.8).

TABLE 93.7

UNFAVORABLE CHARACTERISTICS FOR STAGE I AND II HL, PER THREE COOPERATIVE GROUPS

Risk Factor	GHSG	EORTC	NCIC
Age		≥50	≥40
Histology			NC or LD
ESR and B symptoms	>50 if A; >30 if B	>50 if A; >30 if B	50 or any B
Mediastinal mass	MMR > .33	MTR > 35	MMR >.33 or >10 cm
# Nodal sites	>2[a]	>3	>3
E lesions	any		

GSHG, German Hodgkin Study Group ([a]uses alternate definition of nodal sites); EORTC, European Organization for the Research and Treatment of Cancer; NCIC, National Cancer institute of Canada; MMR, mediastinal mass ratio: maximal width of mass/maximal intrathoracic width; MTR, mass to thoracic width at T5–T6 interspace on standing PA chest radiograph.

As originally suggested by Gilbert, the principle of treating involved and adjacent apparently uninvolved areas (i.e., extended field therapy) became a standard radiotherapeutic approach to HL. With the advent of staging laparotomy and evidence that the retroperitoneum could represent a potentially involved adjacent area of disease, the concept of extended field therapy came to include the standard mantle, para-aortic/splenic, and pelvic radiation ports shown in Figure 93.9.[110]

Although the radiotherapy pioneers were the first to cure HL, and they did so by conducting elegant and groundbreaking clinical trials, the era of radiation as single modality for the initial treatment of HL has passed. However, HL is a very radiation-sensitive disease, and radiation remains a useful component of the treatment of certain patients. Currently the most well documented role for radiation is in the early stage setting, discussed below.

Complications of radiation therapy depend on technique, dose, and the volume of irradiated tissue. Common complications include hair loss within the treatment fields, radiation pneumonitis, radiation pericarditis, mediastinal fibrosis, and pulmonary fibrosis. Symptoms of radiation pneumonitis generally occur within 1 to 3 months of completing therapy and are nonspecific because they include dyspnea, cough, and fever. Such

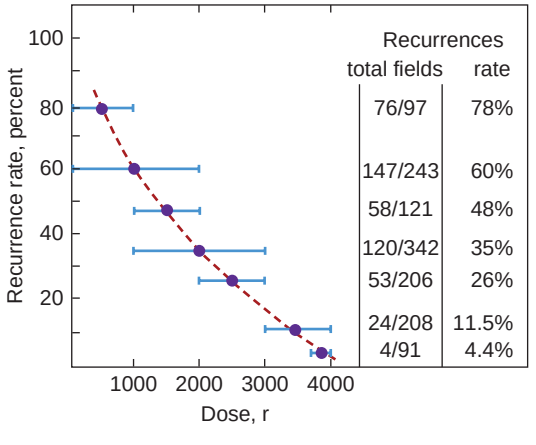

FIGURE 93.8. Rate of recurrence in a given treatment field as a function of radiation dose delivered to that field. (From Kaplan HS. Evidence for a tumoricidal dose level in the radiotherapy of Hodgkin disease. Cancer Res 1966;26:1221–1224, with permission.)

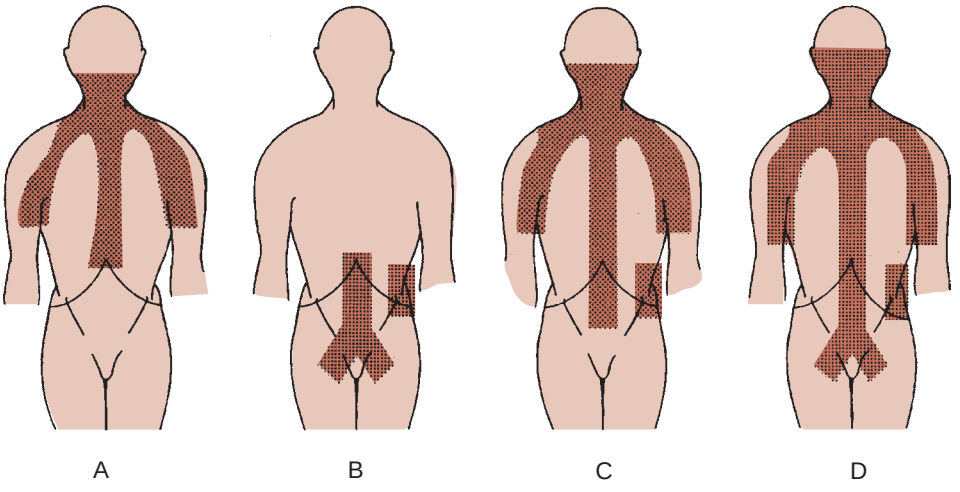

FIGURE 93.9. Treatment fields used as extended field irradiation of Hodgkin disease. A: Mantle field. **B:** Inverted Y field. **C:** Mantle and para-aortic field (extended mantle field). **D:** Total nodal field. The spleen is irradiated in conjunction with the fields in **B, C,** and **D,** unless it has been surgically removed.

complications are rarely seen at lung doses <15 Gy and occurred in <5% of patients receiving routine mantle irradiation. The presence of a large mediastinal mass or the concomitant use of chemotherapy essentially doubles the risk of radiation pneumonitis.[111,112] Although infection and recurrent HL must be considered in the differential diagnosis of radiation pneumonitis, radiation injury is likely to be confined to the area of the lung that was irradiated. Infiltrates with sharp borders, representing the edge of the radiation field, strongly suggest the presence of radiation pneumonitis. Because HL and its therapy are both associated with immunosuppression, whenever radiation injury is considered in the differential diagnosis of a patient with HL, one must also consider the diagnosis of *Pneumocystis jiroveci* pneumonia.

Cardiac toxicity of radiation therapy can include myocarditis, arrhythmias, pericarditis (rarely including constrictive pericarditis and tamponade), valvular heart disease, and coronary artery disease.[113,114,115,116–118] Although an increased risk of myocardial infarction appears to exist after radiation therapy,[117] this risk is greater for patients who received radiation therapy before 1966, suggesting that modern treatment techniques have minimized this risk.

Spinal cord injury should not occur with modern radiation therapy techniques but may occur if radiation fields overlap. Splicing of fields over the spinal cord should be done with great care. The one neurologic problem that may occur despite the use of appropriate technique is the Lhermitte sign,[89] which includes numbness and tingling in the arms, legs, or both and electrical sensations up and down the spine made worse by flexion of the head. This complication is usually transient and of no clinical consequence.

Hypothyroidism is a common complication of radiation therapy,[119] with actuarial analysis indicating that 52% of patients develop hypothyroidism 20 years after radiation.[119] Thyroid cancer is an uncommon complication, but, based on the hypothesis that chronic elevations of thyroid-stimulating hormone in patients after thyroid irradiation may lead to thyroid tumors, the administration of thyroid replacement has been advocated in patients with an elevated thyroid-stimulating hormone even if they are clinically euthyroid.[119]

In addition to thyroid cancer, an increased risk of second malignancies, including lung cancer,[120,121] stomach cancer,[120] melanoma,[120,122] and breast cancer,[123,124,125] has been noted in patients receiving radiation therapy for HL. These malignancies generally occur 10 to 20 years after radiation therapy, with the risk of second malignancies being increased in patients who have also received chemotherapy. The relative risk of breast cancer secondary to radiation is age related. The relative risk of developing breast cancer is 38 for patients radiated before age 20; the relative risk is 17 for patients radiated between the ages of 20 and 29; the relative risk is 4 for patients radiated after the age of 30, a relative risk that is not significantly different from 1.[123] Fortunately, the baseline risk of breast cancer in patients younger than age 30 is low, muting the quantitative impact of this increase in relative risk. Nevertheless, it has been recommended that women who receive radiation therapy for HL should receive mammography starting 8 years after completion of therapy because 95% of such tumors occur more than 10 years after radiation.[124]

It should be recognized that radiation therapy developed as a primary treatment approach to HL when no other modalities were available. In the 1960s, 1970s, and 1980s, when chemotherapy and radiotherapy were both rational treatment options, radiotherapy was often seen as the simpler approach with minimal side effects. Over the last 10 to 15 years, however, there has been increased recognition of the fact that radiation therapy is associated with an increased incidence of late deaths and that for limited-stage patients those deaths eventually exceed the number of deaths from HL. At the same time, chemotherapy has become more tolerable. The result is an overall trend to use radiation therapy less often and to use chemotherapy more often.[126] This is discussed in detail in the sections on treatment.

OVERVIEW AND HISTORICAL PERSPECTIVE OF CHEMOTHERAPY

The development of cancer chemotherapy arose from the observation of lymph node necrosis in soldiers exposed to nitrogen mustard gas during World War I. Therefore, it is not surprising that HL and NHL were among the first disorders treated with nitrogen mustard when the drug was developed for therapeutic use.[127,128,188,189] Since then, several chemotherapeutic agents in several classes of drugs have been shown to be effective in HL. Single agents generally produced partial rather than complete remissions, and unmaintained remissions rarely lasted more than 3 months, with maintained remissions lasting 8 to 10 months (Table 93.8).[129–132] During the 1960s, efforts were made to combine effective agents,[133] culminating in the landmark demonstration by DeVita et al. that MOPP (Mustargen [mechlorethamine], Oncovin [vincristine], procarbazine, and prednisone) combination chemotherapy could cure advanced HL.[134] In the initial publication reporting results achieved with the MOPP regimen,[135] 81% of patients with advanced HL achieved a complete remission, and by actuarial analysis, 47% were projected to be long-term disease-free survivors. Follow-up studies[136,137] confirmed that these long-term disease-free survivals (DFSs) were equivalent to cure and projected cure rates of 56%.[137]

TABLE 93.8

RESULTS OF SINGLE-AGENT THERAPY IN HODGKIN LYMPHOMA

Agent	Representative Dose and Route	Response Rate (%)	
		CR	CR and PR
Nitrogen mustard	0.2–0.4 mg/kg IV, q4–6wk	13	65
Vincristine	0.2 mg/kg/wk IV	36	58
Procarbazine	50–150 mg/kg/d PO	38	69
Prednisone	40–60 mg/d PO	0	61
Cyclophosphamide	2 mg/kg/d PO	12	54
Chlorambucil	0.2 mg/kg/d PO	16	60
Vinblastine	0.2 mg/kg/wk IV	30	68
Bischloroethyl nitrosourea	100–200 mg/m^2 IV, q6wk	4	47
Doxorubicin	30–60 mg/m^2 IV, q3–4wk	8	41
Bleomycin	5 mg/m^2 IV, varying schedules	6	37
DTIC	200 mg/m^2 IV, daily ∞5, variable	6	56
Etoposide	50–120 mg/m^2 IV, daily ∞5, variable	7	25
Cisplatin	75 mg/m^2 IV, q3–4wk	8	35

CR, complete response; PR, partial response.
Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980:199–201.

This study of MOPP in advanced HL[135] established combination chemotherapy as the treatment of choice for advanced HL (Table 93.9).[135–140,141,142–145] Additionally, by demonstrating the cumulative and synergistic efficacy of combining drugs with different mechanisms of action and—to a degree—separate toxicities, it established the rationale for the use of combination chemotherapy in other malignancies. Subsequent investigations, as detailed below in the section on front-line therapy of advanced disease, have established alternative regimens as superior to MOPP with respect to efficacy and toxicity.

The primary toxicity of combination chemotherapy is hematologic, with neutropenia being more common than thrombocytopenia. Drug toxicity tends to be cumulative, with neutropenia having an increased degree and duration with each cycle of chemotherapy. Because there is evidence that optimal dose intensity (dose /time) is essential to achieving the best therapeutic results,[137,140,146,147] many clinicians have used a granulocyte colony-stimulating factor to avoid delays in therapy. However, a recent report showed increased lung toxicity in HL patients treated with filgrastim along with ABVD (26% vs. 9% without G-CSF)[148] and has led to some concerns about this approach although patients with testis cancer treated with bleomycin and using filgrastim support had no increase in lung toxicity as compared to a no-filgrastim group. Evens and colleagues reported their experience with proceeding with ABVD every 14 days without regard to neutrophil count and without administering colony-stimulating factors. They retrospectively compared the 61 patients treated in this manner to 23 patients treated with routine empiric filgrastim. Only 0.44% of the treatments given without filgrastim or dose reductions were complicated by neutropenic fever, and over 99% of the planned dose intensity was maintained.[149] Whether or not there is an increase in lung toxicity in HL patients treated with bleomycin and filgrastim, it seems reasonable to treat younger healthier patients without dose reductions or delays and without the routine use of colony-stimulating factors.

A major long-term complication of the MOPP regimen was myelodysplasia and leukemia, occurring in 2.6% at 5 years[150] and in more patients with longer follow-up. The addition of radiation may increase the risk to as much as 7% to 10% during the first 10 years.[151–158] ABVD does not seem to cause myelodysplasia.

Vincristine, and to a lesser extent vinblastine, cause a dose-dependent sensory neuropathy. This should not lead to dose modifications unless the sensory neuropathy involves the entire fingers or limits function. Motor neuropathy and obstipation are indications for dose reduction, but to limit the need for this dose modification, patients receiving vincristine should receive prophylactic laxatives.

Bleomycin may produce pulmonary fibrosis, and doxorubicin may produce cardiac toxicity. However, these toxicities are related to total dose administered. Bleomycin lung toxicity is seen in approximately 10% of patients receiving more than 250 mg/m^2 of bleomycin.[159] Clinical evidence of cardiac toxicity is observed in a similar percentage of patients receiving more than 450 mg/m^2 of doxorubicin.[160–162] Thus, these toxicities are uncommon even when ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) is used. For patients receiving eight cycles of ABVD, the total cumulative doses would be 160 mg/m^2 of bleomycin and 400 mg/m^2 of doxorubicin, which approaches the toxic threshold. The threshold for drug toxicity is not absolute, and evidence of drug toxicity may be observed at lower doses, especially in older patients or in patients who have received radiation therapy to ports that include the lung or heart.

If the history or physical examination during ABVD therapy raises the suspicion of bleomycin pulmonary toxicity, a chest radiograph should be obtained, and tests such as a chest CT scan and pulmonary function tests with diffusing capacity of lung for carbon monoxide should be considered. Absolute criteria for the discontinuation of bleomycin have not been established, but we strongly caution against the continuation of bleomycin in the face of a corrected diffusing capacity of lung for carbon monoxide of ≤50%. In making a decision about further use of bleomycin, the clinician must consider the risks of further therapy as well as the risk of early discontinuation of an effective agent.

Sterility is another toxicity of HL treatment that must be considered in planning therapy because this complication may have a significant impact on a patient's quality of life. Although the formerly standard MOPP chemotherapy produced long-term azoospermia in 90% to 100% of patients,[163–166] limited data suggest that ABVD is associated with only transient azoospermia.[167] For men, permanent sterility is related primarily to the use and dose of alkylating agents; with ABVD, sterility is rare. In women, age, alkylating agent, and dose are important.[168] Many women become amenorrheic during chemotherapy, with hormonal findings consistent with ovarian failure.[169,170] In younger women, recovery of menses and recovery of fertility are generally seen. In women older than age 35, menses may resume, but menopause may occur prematurely. In women who are perimenopausal at the time of chemotherapy, menses may cease permanently. Although cryopreservation of semen before chemotherapy and artificial insemination have been successful in achieving pregnancy,[171] the presence of decreased sperm counts and abnormal sperm motility before therapy in patients with HL limit this approach.[172] In vitro fertilization for embryo cryopreservation is an option for some patients, but requires a delay in treatment. The cryopreservation of oocytes and of ovarian tissue is under investigation. Oral contraceptives or gonadotropin-releasing hormone-analogues have not been protective of fertility.[173] Offering information about fertility preservation should be considered even for those in whom limited ABVD is planned, as a minority of patients will progress and will go on to more intensive therapy.

TABLE 93.9

CHEMOTHERAPY REGIMENS UTILIZED IN ADVANCED-STAGE HODGKIN LYMPHOMA

ABVD	Adriamycin 25 mg/m^2	IV	Days 1 and 15	Q28d
	Bleomycin 10 units/m^2	IV	Days 1 and 15	
	Vinblastine 6 mg/m^2	IV	Days 1 and 15	
	Dacarbazine 375 mg/m^2	IV	Days 1 and 15	
BEACOPP (baseline)	Bleomycin 10 mg/m^2	IV	Day 8	Q21d
	Etoposide 100 mg/m^2	IV	Days 1–3	
	Adriamycin 25 mg/m^2	IV	Days 1	
	Cyclophosphamide 650 mg/m^2	IV	Day 1	
	Vincristine 1.4 mg/m^2 (capped at 2.0 mg)	IV	Day 8	
	Procarbazine 100 mg/m^2	IV	Day 1–7	
	Prednisone 40 mg/m^2	IV	Day 1–14	
BEACOPP (escalated)	Bleomycin 10 mg/m^2	IV	Day 8	Q21d
	Etoposide 200 mg/m^2	IV	Days 1–3	
	Adriamycin 35 mg/m^2	IV	Days 1	
	Cyclophosphamide 1,200 mg/m^2	IV	Day 1	
	Vincristine 1.4 mg/m^2 (capped at 2.0 mg)	IV	Day 8	
	Procarbazine 100 mg/m^2	IV	Day 1–7	
	Prednisone 40 mg/m^2	IV	Day 1–14	
Stanford V	Adriamycin 25 mg/m^2	IV	Weeks 1, 3, 5, 7, 9, 11	
	Vinblastine 6 mg/m^2	IV	Weeks 1, 3, 5, 7, 9, 11	
	Vincristine 1.4 mg/m^2 (capped at 2.0 mg)	IV	Weeks 2, 4, 6, 8, 10, 12	
	Bleomycin 5 units/m^2	IV	Weeks 2, 4, 6, 8, 10, 12	
	Mustard 6 mg/m^2	IV	Weeks 1, 5, 9	
	Etoposide 60 mg/m^2	IV	Weeks 3, 7, 11	
	Prednisone 40 mg/m^2	PO QOD	Weeks 1–9, taper by 10 mg QOD weeks 10 and 11	

Although the detrimental effects of combination chemotherapy on fertility are well documented, neither the occurrence of infertility nor its persistence can be predicted with certainty. Because of the risk of birth defects, adequate contraception during chemotherapy is essential. Both during and following chemotherapy, patients desiring to avoid pregnancy should be advised not to rely on chemotherapy as their only form of contraception. In addition to decreased fertility, hormonal effects of chemotherapy have been associated with decreased libido in both men and women receiving chemotherapy for HL.[169,174,175]

Limited-stage Disease

Limited- or early-stage HL is further stratified into two groups for the purpose of clinical trials and for treatment planning. *Favorable early-stage HL* is defined as stage I or II HL without unfavorable features or risk factors, and *unfavorable early-stage HL* is defined as the stage I or II with one or more risk factors. The risk factors have been variously defined by different groups, (see Table 93.7) but generally include (1) a greater number or nodal sites, (2) elevated erythrocyte sedimentation rate, (3) B symptoms, (4) a large mediastinal mass or other bulky disease, and (5) age over 40 or 50 years. Unfavorable early-stage HL may also be thought of as comprising two further groups: those unfavorable on the basis of bulky disease, and those unfavorable on the basis of another risk factor.

Treatment of Favorable Early-stage Hodgkin Lymphoma

Favorable early-stage HL has traditionally been treated with extended field radiotherapy, with cure rates as high as 80%. Long-term follow-up of patients treated and cured with radiotherapy has now made clear that such patients suffer from high rates of life-threatening and/or debilitating late effects, such as early atherosclerosis and myocardial infarction, valvular heart disease, and secondary malignancies. Over the last 2 decades this recognition has led to a general move toward using chemotherapy for early-stage patients and simultaneously reducing the fields and doses of radiotherapy, and even eliminating radiotherapy entirely for certain highly susceptible patients (e.g., young women with mediastinal disease who would have a high risk of breast cancer with mediastinal irradiation). Reducing the fields and doses of radiotherapy has been shown to reduce the risk of at least some of the late side effects of radiation exposure.[176,177–179,180]

In the last 15 years, a number of publications have shown the excellent results and tolerability of a treatment paradigm for favorable early-stage HL consisting of a limited number of courses of chemotherapy (generally ABVD) and limited radiotherapy at reduced total dose.[181–184] Although there is a paucity of randomized data comparing a modern combined modality regimen (i.e., a limited number of cycles of ABVD followed by involved field radiotherapy with relatively low total dose) to radiotherapy alone or to ABVD alone, the single-arm PFS rates of over 90% and short-term tolerability, and the expected low rate of long-term side effects have made combined modality therapy a de facto standard for favorable early-stage HL. Extended field radiotherapy is no longer a standard of care, and chemotherapy alone is used primarily when there is particular concern about long-term side effects of radiation. A number of randomized trials have evaluated combined modality treatment, although most have used noncurrent radiotherapy, noncurrent chemotherapy, or both. As is the case in many trials of initial treatment of HL, a difference in OS is difficult to prove, presumably because of the efficacy of salvage therapy and the long survival times of patients. However, at least one randomized trial, the EORTC's H8F trial, which compared three cycles of MOPP/ABV (mechorethamine, vincristine, procarbazine, prednisone, doxorubicin, bleomycin, and vinblastine) hybrid and involved field radiotherapy to subtotal nodal irradiation, shows an OS for the combined modality treatment advantage at 10 years follow-up (97% vs. 92%, $P = 0.001$).[183] Likewise a meta-analysis of trials comparing chemotherapy alone to combined modality therapy demonstrated an advantage in both tumor control and OS for the combined modality approach.[185]

Most recent investigations of combined modality therapy of favorable early-stage HL have used ABVD, based on its superiority to earlier regimens, although some studies incorporate the BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) or Stanford V regimens (see section "Advanced Therapy Treatment"). A currently accruing trial of the German Hodgkin Study group, HD13, randomizes favorable early-stage patients to ABVD versus ABV versus ABD versus AV.

Within the paradigm of combined modality therapy for favorable early-stage HL, several key questions remain, including the following. (1) What is the optimal number of cycles of chemotherapy? (2) What is optimal dose of RT? (3) Can radiotherapy be eliminated entirely?

Four cycles of ABVD followed by involved field radiotherapy has been used as a comparator arm in a number of studies and has emerged as a standard treatment for favorable early HL. For example Bonadonna and colleagues reported a study comparing radiotherapy fields in stages I and II HL (29% were unfavorable). The ABVD × 4 and involved field radiotherapy arm had a 12-year FFP of 94% and an OS of 94%.[184] The HD 10 study of the German Hodgkin Study Group randomized favorable early-stage patients to either four or two cycles of ABVD, and later to one of two doses of radiation. A total of 1,190 patients from 329 institutions were analyzed for the comparison of ABVD × 4 versus ABVD × 2. At 5-year follow-up, there was no difference in OS (97.1% vs. 96.1%, NS) or PFS (93.1% vs. 91.2%, NS).[186] It is important to note that the inclusion criteria for this trial selected patients likely to be especially favorable, as compared to the study population in other favorable early-stage HL trials. In particular, the patients had two or fewer nodal groups involved (as opposed to three or fewer), and the definitions of the nodal groups are unique to the GHSG and not precisely concordant with the Cotswold definition. Details are available in the appendix to the paper online at http://www.nejm.org/doi/suppl/10.1056/NEJMoa1000067/suppl_file/nejmoa1000067_appendix.pdf. Thus the HD10 trial may be read as identifying a "very favorable" subgroup for whom ABVD × 2 is adequate before involved field radiation therapy.

The appropriate dose of involved field radiation therapy in the combined modality approach to favorable early-stage HL has also been a topic of investigation. The Italian trial above[184] used a dose of 36 Gy with excellent 12-year results, and a Stanford trial of abbreviated chemotherapy (Stanford V × 8 weeks), followed by involved field radiotherapy used a dose of 30 Gy with 10-year OS and PFS of 94%. The EORTC H9F trial (reported in abstract only) used the alternative chemotherapy EBVP (epirubicin, bleomycin, vinblastine, and prednisone) × 6 followed by involved radiotherapy 30 Gy versus 20 Gy versus no radiotherapy. There was no significant difference between the 30 Gy and 20 Gy groups by 4-year freedom from treatment failure (FFTF, 87% vs. 84%).[187] The HD10 study of the German Hodgkin Study Group randomized patients (selected for two or fewer involved nodal groups, as above) to either 30 Gy or 20 Gy involved field radiation. There was no difference between the two doses of radiotherapy at 5 years (PFS 93.7% vs. 93.2% and OS 97.7% vs. 97.5%).[186]

A number of groups have reported using chemotherapy alone for favorable early-stage patients. In a prospective single-arm study from Spain, investigators reported on stage I and II patients treated with ABVD × 6 for early-stage HL. Among 49 patients who were favorable by EORTC criteria, the PFS and OS were 88% and 100% at 78-months follow-up.[188] Canellos et al reported a retrospective series of 75 patients with nonbulky early-stage HL who were treated with ABVD alone (the majority with 6 cycles). All patients attained a complete response (CR), and the PFS at 60 months was 92%.[189] It is important to note that this is a retrospective study: presumably those not achieving a CR would have been considered for RT and if they received radiation would not have been included in the study. Strauss et al. randomized 152 nonbulky stage I, II, and IIIA patients to ABVD × 6 versus ABVD x6 and 36 Gy of extended or involved field radiation therapy. At 60 months, FFP was 81% versus 86% (NS) and OS was 90% versus 97% (NS).[190] The inclusion of stage III patients and the use of "full-course" chemotherapy complicates the interpretation of this trial. The authors point out the trial is not powered to detect difference smaller than 20%. The HD6 trial of the National Cancer Institute of Canada randomized nonbulky early-stage patients to either ABVD alone (4 to 6 cycles) or a strategy in which favorable (<40 years, ESR <50, no MC or lymphocyte-depleted histology, <4 sites of disease) patients received extended field radiation alone and unfavorable patients received ABVD × 2 followed by radiation. Comparing the chemotherapy-only patients to the patients treated with a strategy including radiation, there is an advantage in PFS for the latter (93% radiation vs. 87% ABVD, $P = 0.006$) but no difference in event-free survival (EFS) and OS. Five-year PFS for the favorable patients receiving ABVD only (59 patients) is 87%. In this study, the only patients who were randomized to chemotherapy-only or combined modality therapy were unfavorable (though nonbulky), and thus the utility of these data for evaluating combined modality therapy versus chemotherapy alone are limited.[191]

In summary, the standard treatment of favorable early-stage HL is combined modality treatment, with two to four cycles of ABVD followed by 20 to 30 Gy of involved field radiation therapy. The lower limits of the above guideline are validated for the somewhat selected group identified in the HD10 study with two or fewer involved sites. Chemotherapy alone has a 5-year PFS rate of 81% to 92%. Although the PFS is likely somewhat lower than with combined modality therapy, chemotherapy alone might be preferred when radiation is deemed more dangerous or otherwise unsuitable. The most common of these situations is the case of a young woman who would be placed at higher risk of breast cancer if she underwent chest irradiation. Other scenarios include smokers in whom chest irradiation would further increase the risk of lung cancer or fibrosis, and anatomic situations where a vital structure such as the heart would be irradiated. A reasonable question for the clinician to ask himself is whether the additional margin of PFS after an initial combined modality approach is worth any extra toxicity over a chemotherapy-alone approach, especially if there is a reasonable chance of salvage for the small number of patients who relapse as a result of not receiving radiation therapy. In the future, an early response by PET may identify patients who do not have an additional benefit from post-CR radiation; this is a focus of a current intergroup trial, C50604.

Treatment of Unfavorable Early-stage Hodgkin Lymphoma

Many patients who are classified as having unfavorable early-stage HL (also known as *intermediate stage HL*) have a bulky mediastinal mass, although others will qualify as unfavorable on the basis of a high erythrocyte sedimentation rate or multiple nodal sites.

Combined modality therapy has long been the recommended therapy for this group of patients. The EORTC/GELA (Groupe d'Etude des Lymphoma de l'Adulte) H8U[183] study randomized patients to one of three treatment strategies, two of which were MOPP/ABV × 6 followed by involved field radiation and MOPP/ABV × 4 followed by involved field radiation. There was no statistical difference in 5-year FFTF (84% vs. 88%) or the 10-year OS (88% vs. 85%). The same group's H9U study[187] randomized patients to ABVD × 6, ABVD × 4, or baseline BEACOPP, each followed by involved field radiation. The ABVD arms were

equivalent, with 4-year FFTF of 94% and 89%, respectively, and 4-year OS of 96% and 95%. BEACOPP was not more effective (4-year FFTF 91%) and was more toxic. These studies established ABVD × 4 followed by 30 Gy involved field radiation as a standard for unfavorable early-stage HL.

The HD11 study of the German Hodgkin Study Group randomized 1,395 patients to either ABVD or baseline BEACOPP and further randomized them to involved field radiotherapy of 20 Gy or 30 Gy. Of these, 19.5% had a bulky mediastinal mass and 9.9% had an extranodal lesion. ABVD × 4 and 30 Gy was as effective (5-year PFS 87.2%) as BEACOPP and 30 Gy (87.9%) or BEACOPP and 20 Gy (87.0%), but ABVD × 4 and 20 Gy was inferior (82.1%). BEACOPP arms were more toxic. The authors concluded that ABVD × 4 and 30 Gy should be the standard in unfavorable early-stage HL because of superior tumor control and lower toxicity.[192]

In an attempt to improve on the HD11 results, the German Hodgkin Study Group's HD 14 trial compared ABVD × 4 to escalated BEACOPP × 2 followed by ABVD × 3 ("2 + 2"), each followed by 30 Gy involved field radiation; 1,528 patients entered the study. The 2 + 2 arm was superior in PFS at 5 years (95.4% vs. 89.1%, $p = <0.001$) and OS was not significantly different. Toxicity was higher in the 2 + 2 arm as compared to the ABVD arm (at least one grade 3 or 4 toxicity 87.1% vs. 50.7%) and 4 patients (0.52%) died from toxicity in the 2 = 2 arm.[193] Despite the higher efficacy of the 2 + 2 arm, many would question the utility of the small increase in PFS without an increase in OS in this relatively short follow-up.

The current intergroup trial C50604 includes nonbulky unfavorable patients. Those who have a negative PET after two cycles will omit radiotherapy.

Therapy for lymphocyte predominant Hodgkin lymphoma is addressed after the section on Pregnancy.

FRONT-LINE THERAPY FOR ADVANCED-STAGE HODGKIN LYMPHOMA

Adriamycin (Doxorubicin), Bleomycin, Vinblastine, and Dacarbazine

Since the early 1990s, the treatment of patients with advanced-stage HL has relied on combination chemotherapy with ABVD (see Table 93.9). ABVD was first introduced by Bonadonna and colleagues in the late 1970s as an effective, non-cross–resistant chemotherapy option for patient with relapsed HL.[141] Unlike MOPP (mechlorethamine, vincristine, procarbazine, and prednisone), the first successful combination chemotherapy regimen used in the treatment of HL, ABVD was not associated with sterility or secondary myelodysplasia or leukemia.[154,167] The success of ABVD in the second line setting eventually led to efforts to combine MOPP and ABVD in 12 alternating treatment cycles (MOPP/ABVD alternating regimen). As front-line therapy in patients with stage IV HL, MOPP/ABVD proved superior to MOPP alone with a FFP at 8 years of 64.6% versus 35.9% ($P< 0.005$) and 8-year OS rates of 83.9% versus 63.9% ($P < 0.06$).[143] In 1982, the Cancer and Leukemia Group B (CALGB) in the United States initiated a randomized multicenter trial in 361 patients with stage III–IV previously untreated HL, comparing MOPP for 6 to 8 cycles ($n = 123$), ABVD for 6 to 8 cycles ($n = 115$), and alternating MOPP/ABVD for 12 cycles ($n = 123$).[200] In this trial, CR rate (67% MOPP, 82% ABVD, and 83% MOPP/ABVD, $P = 0.006$) and 5-year failure-free survival (FFS) (50% MOPP, 61% ABVD, and 65% MOPP/ABVD, $P = 0.02$) were superior in the ABVD and MOPP/ABVD arms, with less neutropenia, thrombocytopenia, and infectious toxicity in the ABVD arm (18%, 2%, and 2% ABVD, 47%, 36%, and 11% MOPP, and 53%, 28%, and 12% MOPP/ABVD, respectively).[200] A subsequent randomized phase III US Intergroup trial compared ABVD and MOPP/ABV hybrid (combined MOPP and ABV drugs in each cycle rather than alternating cycles of MOPP and ABVD) for 8 to 10 cycles in 856 patients with stage III–IV HL. CR rates (76% vs. 80%, $P = 0.16$) and 5-year FFS rates (63% vs. 66%, $P = 0.42$) were similar in patients receiving ABVD or MOPP/ABV, respectively.[150] In this study, the 5-year FFS for patients with 0, 1, 2, 3, 4, and ≥5 risk factors by the International Prognostic Score (IPS),.[101] were 76%, 72%, 81%, 69%, 64%, and 67%, respectively; the 5-year OS was 82% using ABVD; and ABVD resulted in fewer pulmonary and hematologic toxicities, treatment-related deaths, and second malignancies including acute leukemia than observed with MOPP/ABV.[150] In a UK study comparing ABVD to other combination hybrid regimens (ChlVPP/PABIOE and ChlVPP/EVA), the 3-year EFS and OS with ABVD were 75% and 90%, respectively, once again similar to multidrug regimens, with less infectious and neurologic toxicity than observed with the hybrid regimens.[201] As a result of these trials, ABVD became the standard of care for initial therapy of advanced-stage HL; however, recently, two other combination chemotherapy regimens, Stanford V and BEACOPP (see Table 93.9), have challenged the role of ABVD as the standard front-line regimen in this patient population.

Stanford V

Stanford V, a multiagent combined modality regimen consisting of doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone administered weekly over 12 weeks followed by 36 Gy consolidative radiotherapy to bulky mediastinal disease, tumor masses or lymphadenopathy ≥ 5 cm, and macroscopic splenic nodules, was designed to reduce the total doses of bleomycin and adriamycin. In initial phase II trials, respectively, the 5-year FFP utilizing this regimen was 85% to 89% in patients with bulky stage I–II and advanced-stage HL.[202,203] In a randomized Italian trial in 355 patients with stage IIB, III, and IV HL comparing six cycles of ABVD ($n = 122$), 12 weeks of Stanford V ($n = 107$), and six cycles of MOPPEBVCAD (mechlorethamine, vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine), 5-year FFS were 78%, 54%, and 81%, respectively ($P < 0.01$).[204] However, in this trial, radiation was only given to sites of initial bulky disease or sites of residual disease post-chemotherapy, and only 66% of patients receiving Stanford V also received radiation in the Italian study, compared to 91% in the prior single institution trial.[202,204] At 10 years of follow-up, 10-year FFS were 75%, 74%, and 49% ($P < 0.001$) and 10-year OS were 87%, 80%, and 78% ($P = 0.4$) for the ABVD, MOPPEBVCAD, and Stanford V arms, respectively; however, in looking at Stanford V patients treated with and without radiotherapy, 10-year DFS was statistically in favor of those patients receiving radiation (76% vs. 33%, $P = 0.004$).[205] In a subsequent multicenter UK study in 520 patients with stage IIB, III, IV, or bulky stage I-II HL, there were no differences in 5-year FFS and OS in patients receiving six to eight cycles of ABVD (53% patients received radiation to sites of residual disease) or 12 weeks of Stanford V (73% patients received radiation to disease sites >5 cm or splenic nodules).[206] More pulmonary toxicity was observed in the ABVD arm in this trial, although myelosuppression and neuropathy were slightly worse with Stanford V. A randomized phase III US Intergroup trial, conducted from 1999–2006, demonstrated no significant difference in 5-year FFS (73% vs. 71%, $P = 0.29$) or 5-year OS (88% vs. 87%, $P = 0.87$) in 812 patients with bulky stage I–II, III, or IV HL receiving six to eight cycles of ABVD with radiation to bulky mediastinal disease or 12 weeks of Stanford V chemotherapy with radiotherapy to disease >5 cm or splenic nodules, respectively.[207] With median follow-up of 5.25 years, 26 second malignancies were observed (14 ABVD and 12 Stanford V). Therefore, as a result of these trials, six cycles of ABVD has remained the standard treatment for patients with advanced-stage HL; however, Stanford V may be acceptable in patients

where a shortened treatment duration or reduction in cumulative doses of bleomycin or adriamycin is desirable. Long-term follow-up is needed from the UK and US intergroup trials to determine the risks of second malignancies, particularly with Stanford V, as additional radiotherapy is required per the treatment protocol in the majority of patients.

Bleomycin, Etoposide, Doxorubicin, Cyclophosphamide, Vincristine, Procarbazine, and Prednisone

Intensification of initial therapy is one approach to improving outcomes in patients with advanced-stage HL. However, this approach may lead to increased short-term and long-term toxicity that may ultimately have a negative impact on OS, particularly in lower-risk patients. The German Hodgkin study group HD9 trial randomized patients ages 15 to 65 with stage IIB, III, and IV HL to either eight cycles of COPP/ABVD (cyclophosphamide, vincristine, procarbazine, and prednisone alternating with ABVD), BEACOPP-baseline, or BEACOPP-escalated (esc).[208] With 10 years of follow-up, FFTF was 64%, 70%, and 82% with OS of 75%, 80%, and 86% in the COPP/ABVD, BEACOPP-baseline, and BEACOPP-esc arms, respectively.[209] By IPS, FFTF at 5 years was 92%, 87%, and 82% with BEACOPP-esc for patients with 0 to 1, 2 to 3, and 4 to 7 risk factors, respectively.[208] However, it is important to note that only 13% of patients receiving BEACOPP-esc had 4 to 7 risk factors on this trial, and although differences in FFTF were significantly in favor of BEACOPP-esc among all three risk groups, statistically significant improvements in OS were only observed in patients with IPS scores of 2 to 3 ($P = 0.27$ for IPS 0–1, $P < 0.0027$ for IPS 2–3, and $P = 0.16$ for IPS 4–7).[209] When analyzed by age, there was not a significant improvement in FFTF and OS for patients ages 60 to 65 and increased toxicity occurred with BEACOPP-esc. Therefore, BEACOPP-esc is not recommended in patients over the age of 60.[208] In an attempt to reduce toxicity, the HD12 trial examined eight cycles of BEACOPP-esc versus four cycles of BEACOPP-esc plus four cycles of BEACOPP-baseline.[210] Five-year FFTF and OS were 86.4% and 92%, respectively with eight BEACOPP-esc compared to 84.8% and 90.3% with 4 + 4 arm, and toxicities were not significantly reduced with the 4 + 4 approach.[210]

In a randomized Italian study comparing six cycles of ABVD with four cycles of BEACOPP-esc plus two cycles BEACOPP-baseline,[211] 5-year PFS was superior for BEACOPP (81%) compared to ABVD (68%), although there were no differences in OS perhaps due to the smaller numbers of patients[150] on this trial compared to the 1,201 patients on the previous German HD9 trial. In a second Italian cooperative group study, the 7-year rate of freedom from first progression was 85% in patients receiving four cycles of BEACOPP-esc plus four cycles BEACOPP-baseline compared to 73% in patients receiving six to eight cycles of ABVD ($P = 0.004$).[212] In this same trial, the 7-year rate of freedom from second progression was 88% in the BEACOPP group compared to 82% in the ABVD group ($P = 0.12$), suggesting that long-term outcomes may not differ between the two regimens when one factors in the efficacy of salvage chemotherapy and autologous stem cell transplant following ABVD.[212]

Despite the success of the BEACOPP-esc regimen compared to hybrid regimens and ABVD in patients ≤60 years of age, this regimen is associated with infertility and a 6.0% second malignancy rate, including a 3.2% incidence of secondary AML/MDS.[209,213] In addition, BEACOPP-esc is associated with more acute toxicities including hematologic and infectious complications than observed with ABVD.[211] Therefore, although several studies demonstrate the superiority of BEACOPP-esc with respect to PFS in patients with advanced-stage HL, it remains unclear if the risks of second malignancies, infertility, and acute infections associated with BEACOPP-esc are justified to improve patient outcomes in all patients with advanced-stage HL, especially if relapsing patients after ABVD can be effectively salvaged with high-dose therapy and stem cell transplantation. Current studies are examining the role of reduction of total cycles of BEACOPP-esc and PET-directed approaches that may maintain the advantage of improved disease control observed with BEACOPP-esc while reducing acute and late toxicities or at least limiting exposure to those patients at highest risk. However, these approaches utilizing interim PET/CT to reduce total number of cycles of BEACOPP-esc in patients who have negative interim PET/CT or to limit exposure to BEACOPP-esc to only the most unfavorable patients with interim positive PET/CT remain under investigation and long-term follow-up will be needed to assess for late toxicities that affect OS. Currently ABVD, Stanford V, and BEACOPP-esc are all accepted front-line therapy in patients with advanced-stage HL.

Radiation Therapy as Consolidation in Stage III–IV Hodgkin Lymphoma

Several studies have examined the role of consolidative radiotherapy in patients with advanced-stage HL, and to date, no study has demonstrated a clear OS advantage with combined modality therapy in patients achieving a CR or PR with chemotherapy alone. The H89 GELA study randomized 533 patients with stage III–IV HL to six cycles of MOPP/ABV hybrid or six cycles of ABVPP followed by either two more cycles of chemotherapy or subtotal nodal radiation for patients achieving a CR or PR after six cycles.[214] In the chemotherapy alone arms 10-year OS was superior (90% for ABVPP × 8, 78% for MOPP/ABV × 8, 82% for MOPP/ABV × 6 with radiation, and 77% for ABVPP × 6 with radiation, $P = 0.03$). Using an ABVD backbone, Laskar and colleagues demonstrated an improvement in 8-year EFS and OS with chemotherapy and involved field radiotherapy in patients achieving a CR; however, this trial was small with only 179 patients randomized to observation versus radiotherapy and included all stages ($n = 80$ with stage III–IV disease).[215] A larger, although nonrandomized, UK study restricted to advanced-stage HL patients analyzed outcomes in 807 patients treated with six cycles of ABVD, CHLVPP/PABlOE, or CHLVPP/EVA, and involved field radiotherapy to sites of residual masses or bulky disease. A total of 300 patients (43%) received involved field radiotherapy, and although non-RT patients tended to be more often in CR, 5-year EFS was 86% with RT and 71% without RT ($P < 0.001$) and 5-year OS was 93% with RT and 87% without RT ($P < 0.001$).[216] In contrast, a randomized study of 739 patients with advanced-stage HL assigned patients with a CR after six to eight cycles of MOPP/ABV hybrid to observation or involved field RT, and demonstrated no difference in 5-year OS ($P = 0.07$) or EFS ($P = 0.35$) in the radiotherapy ($n = 172$, OS of 85% and EFS of 79%) group compared to the observation group ($n = 161$, OS of 91% and EFS of 84%).[217] The HD12 trial randomized responding patients after BEACOPP with stage IIB, III, and IV HL and with bulk or residual tumor on CT imaging to either additional consolidative RT or no RT.[210] In this trial, 1,085 patients received initial BEACOPP therapy, 207 required no RT due to lack of bulky disease or CR; 148 received RT due to less than a PR to chemotherapy (less than 50% tumor reduction); and 730 patients were randomized to RT or no RT. At 5 years, FFTF was 87% in those patients who did not receive RT, compared to 90.4% in the RT arm ($P = 0.08$).[210] Therefore, based on these studies, it appears that consolidation with IFXRT does not improve outcomes in patients achieving a CR after combination chemotherapy, although additional studies need to be done in patients with a PR, particularly utilizing a PET-based response determination. In one such trial, the HD15 trial, patients with stage IIB, III, and IV HL received involved field radiotherapy after six to eight cycles of BEACOPP if they had residual disease more than 2.5 cm and were PET positive. In this study, 311 of 1,788 enrolled had residual disease

>2.5 cm on CT and PET was positive in 66 of these patients.[218] With 1 year of follow-up, PFS for the PET-negative patients who were not radiated was 96% and for the PET-positive patients was 85% ($P = 0.011$), and therefore PET-directed radiotherapy may be feasible in this population.[218] In addition, as demonstrated by the GELA study,[214] prolonged follow-up beyond 10 years is needed from these trials to determine if OS is adversely affected with the incorporation of involved field radiotherapy at the end of therapy in patients with advanced-stage HL due to the potential late complications of second malignancies and cardiovascular disease related to the radiotherapy.

Autologous Transplant as Consolidation in Stage III–IV Hodgkin Lymphoma

Several trials have examined the role of autologous transplant to improve outcomes in patients with high-risk, advanced-stage HL, and to date none have demonstrated a role for this following standard ABVD chemotherapy. A European intergroup trial randomized 163 patients with stage III–IV HL and two risk factors (elevated LDH, bulky disease, stage IV with two or more extranodal sites, anemia, or inguinal involvement) achieving a CR or PR after four cycles of ABVD or doxorubicin containing induction (MOPP/ABVD, MOPP/ABV, CVPP/ABV) to either four additional cycles of the same induction chemotherapy or autologous stem cell transplantation after BEAM (carmustine, etoposide, cytarabine, and melphalan) or CBV (cyclophosphamide, carmustine, and etoposide) conditioning regimens.[219] The 5-year FFS with continued chemotherapy was 82% compared to 75% ($P = 0.4$) with consolidative autologous transplantation, and the 5-year OS were 88% and 88% ($P = 0.99$), demonstrating no clear benefit from early high-dose consolidation in high-risk advanced-stage HL. Two other studies using hybrid induction chemotherapy regimens versus chemotherapy followed by myeloablative transplant in 126 to 158 high-risk patients also similarly demonstrated no difference in OS with front-line transplantation.[220,221]

Future Directions/Upcoming Studies in Front-line Therapy for Stage III–IV Hodgkin Lymphoma

In the future, therapy for advanced-stage HL may be tailored based on a patient's pre-treatment risk factors (clinical or selected biologic markers) or on results of interim PET/CT. In previous studies, 2-year PFS for patients with a positive PET/CT after two cycles of ABVD were 12.8% compared to 95% for interim PET/CT negative patients ($P < 0.0001$), and interim PET/CT results were more predictive of outcome than IPS score in multivariate analysis.[222] Although the prognostic potential of PET/CT may be dependent on initial treatment, timing of scans, and definitions of PET negativity, PET/CT does represent an important tool that may in the future direct therapy. To date, altering therapy based on interim PET/CT results remains investigational; however, a number of trials are ongoing examining this question in patients with advanced-stage HL. Risk-adapted therapy was first described by Dann et al., who prospectively assigned 108 patients with unfavorable HL (stages I–II with risk factors, B-symptoms, or bulky disease and stages III–IV) to either two cycles of BEACOPP-esc if IPS score ≥3 or BEACOPP-baseline if IPS <3 followed by interim PET/CT or gallium scan.[223] Patients with a positive interim scan received four more cycles of BEACOPP-esc and those with a negative interim scan received four cycles of BEACOPP-baseline. Using this IPS and imaging directed therapeutic approach resulted in 5-year EFS and OS of 85% and 90%, respectively.[223] Currently, UK and US intergroup studies are exploring intensification of therapy in patients who are interim PET/CT positive after two cycles of initial ABVD therapy, and the German Hodgkin Study Group HD18 trial is reducing therapy after two cycles of initial BEACOPP-esc in patients who are interim PET/CT negative. Central review of interim PET/CT is critical in these studies using PET/CT to alter treatment approaches.

In addition to efforts to risk-stratify therapy based on initial high-risk features or interim PET/CT, efforts are also being made to incorporate promising new therapies into traditional ABVD backbones to improve outcomes in advanced-stage HL further. Brentuximab vedotin, a CD-30 antibody-drug conjugate, which is FDA-approved for the treatment of relapsed and refractory HL and is further described below, has recently been added to the ABVD regimen.[224] In this phase I trial, patients with stage III–IV HL received ABVD with escalating doses of brentuximab vedotin ranging from 0.6 to 1.2 mg/kg on days 1 and 15 of each 28-day cycle. Initial toxicities included significant pulmonary toxicity, leading to removal of bleomycin from the regimen and treatment of an expanded cohort of patients with AVD plus brentuximab.[224] Randomized studies in patients with bulky stage II, III, and IV HL comparing the AVD plus brentuximab regimen to traditional ABVD are planned, but this may offer an alternative strategy for improving therapy in high-risk patients using a novel targeted agent and may ultimately become an attractive option in young, high-risk patients with less risk of secondary malignancies or infertility than intensification with BEACOPP-esc. However, long term follow-up will be needed from randomized studies comparing AVD plus brentuximab with ABVD and BEACOPP-esc to determine the efficacy and risks with AVD plus brentuximab before this approach to therapy is accepted in advanced-stage patients.

THERAPY FOR RELAPSED OR REFRACTORY HODGKIN LYMPHOMA

Salvage Therapy and Autologous Hematopoietic Cell Transplant

Salvage chemotherapy followed by autologous stem cell transplant is the standard of care for patients with relapsed or refractory HL (Chapter 104). With respect to salvage regimens prior to autologous transplant, patients typically receive two to three cycles and then proceed to transplant. However, there are no randomized data on optimal salvage regimens and numerous options exist. Regimens include ICE (ifosfamide, carboplatin, etoposide), GVD (gemcitabine, vinorelbine, liposomal doxorubicin), DHAP (dexamethasone, cytarabine, cisplatin), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), GDP (gemcitabine, dexamethasone, and cisplatin), IGEV (ifosfamide, gemcitabine, vinorelbine, prednisolone), mini-BEAM (carmustine, etoposide, cytarabine, melphalan), and Dexa-BEAM (dexamethasone, carmustine, etoposide, cytarabine, melphalan; see Table 93.10) with responses ranging from 70% to 90%.[225–228,229,230,231–233] Ideally, the salvage regimen chosen should result in a high overall response rate with acceptable toxicity and not impair stem cell mobilization if transplantation is planned.

In 1997, physicians at Stanford University compared outcomes for 60 patients with relapsed or refractory HL treated with a non-cross–resistant combination therapy until maximal response followed by autologous transplant with 103 matched historical patients receiving chemotherapy alone.[234] The 4-year OS, EFS, and FFP were 54% versus 47% ($P = 0.25$), 53% versus 27% ($P < 0.01$), and 62% versus 32% ($P < 0.01$), respectively, favoring transplant compared to conventional salvage therapy. The British National Lymphoma Group randomized 40 patients with relapsed HL to either BEAM (carmustine, etoposide, cytarabine, and melphalan) followed by autologous transplant or mini-BEAM alone, demonstrating a significant PFS benefit ($P = 0.005$) with transplantation.[235] A larger trial of 161 chemosensitive patients randomized to two cycles of Dexa-BEAM and autologous transplant

TABLE 93.10

SALVAGE COMBINATION CHEMOTHERAPY REGIMENS UTILIZED FOR RELAPSED OR REFRACTORY HODGKIN LYMPHOMA

GVD (not previously transplanted)[227]	Gemcitabine 1,000 mg/m^2	IV	Days 1 and 8	
	Vinorelbine 20 mg/m^2	IV	Days 1 and 8	Q21d
	Liposomal doxorubicin 15 mg/m^2	IV	Days 1 and 8	
GVD (previously transplanted)[227]	Gemcitabine 800 mg/m^2	IV	Days 1 and 8	
	Vinorelbine 15 mg/m^2	IV	Days 1 and 8	Q21d
	Liposomal doxorubicin 10 mg/m^2	IV	Days 1 and 8	
ICE[226]	Ifosfamide 5,000 mg/m^2	IV over 24 h	Day 2	
	Mesna 5,000 mg/m^2	IV over 24 h	Day 2	Q14d
	Etoposide 100 mg/m^2	IV	Days 1–3	
	Carboplatin AUC = 5 (maximum dose of 800 mg)	IV	Day 2	
DHAP[231]	Dexamethasone 40 mg	IV/PO	Days 1–4	
	Cisplatin 100 mg/m^2	IV over 24 h	Day 1	Q21d
	Cytarabine 2,000 mg/m^2	IV every 12 h	Day 2	
ESHAP	Etoposide 40 mg/m^2	IV	Days 1–4	
	Methylprednisolone 500 mg	IV	Days 1–5	Q21d
	Cytarabine 2,000 mg/m^2	IV	Day 5	
	Cisplatin 25 mg/m^2	CIV	Days 1–4	
Mini-BEAM[232]	BCNU (carmustine) 60 mg/m^2	IV	Day 1	
	Etoposide 75 mg/m^2	IV	Days 2–5	Q21–28d
	Cytarabine 100 mg/m^2	IV every 12 h	Days 2–5	
	Melphalan 30 mg/m^2 (maximum of 50 mg)	IV	Day 5	
Dexa-BEAM[233]	Dexamethasone 24 mg	PO	Days 1–10	
	BCNU (carmustine) 60 mg/m^2	IV	Day 2	Q28d
	Melphalan 20 mg/m^2	IV	Day 3	
	Etoposide 200 mg/m^2	IV every 12 h	Days 4–7	
	Cytarabine 100 mg/m^2	IV ever 12 h	Days 4–7	
	GCSF 300–480 μg	SQ	Day 9 until WBC >2,500/μl	
IGEV[225]	Ifosfamide 2,000 mg/m^2	IV	Days 1–4	
	Gemcitabine 800 mg/m^2	IV	Days 1 and 4	Q21d
	Vinorelbine 20 mg/m^2	IV	Day 1	
	Prednisolone 100 mg	PO	Days 1–4	
GDP[232]	Gemcitabine 1,000 mg/m^2	IV	Days 1 and 8	
	Cisplatin 75 mg/m^2	IV	Days 1 and 8	Q21d
	Dexamethasone 40 mg	PO	Days 1–4	
ChlVPP[248]	Chlorambucil 6 mg/m^2	PO	Days 1–14	
	Vinblastine 6 mg/m^2	IV	Days 1 and 8	Q28d
	Procarbazine 100 mg/m^2	PO	Days 1–14	
	Prednisone 40 mg	PO	Days 1–14	
Brentuximab Vedotin[194]	1.8 mg/kg (capped at maximum of 100 kg)	IV	Day 1	Q21d

or two further cycles of Dexa-BEAM demonstrated a 3-year FFTF of 55% with transplantation compared to 34% without transplant ($P = 0.019$).[229] However, neither trial demonstrated an OS benefit perhaps due to limited follow-up or small patient numbers.

For patients who are refractory to front-line or salvage therapy, PFS of 25% to 38% with high-dose therapy and hematopoietic cell transplantation (HCT) have been reported,[236–238] suggesting that these patients also benefit from transplantation, although not unexpectedly with inferior outcomes compared to patients with chemosensitive disease. These studies are limited by differing definitions of refractory disease, the fact that many of the patients received MOPP containing inductions which is inferior to standard ABVD, and that few patients who did not respond to salvage therapy were transplanted. For example, in 86 patients of whom 91% failed to achieve a CR with front-line hybrid regimens and 9% had disease progression within 3 months of completing front-line therapy, 62% responded to salvage therapy and 24% progressed.[238] All patients did undergo HCT and 5-year EFS and OS were 25% and 35%, respectively, with response to salvage therapy significantly associated with survival in multivariate analysis.[238] In a retrospective review of 122 patients who failed to achieve a CR after at least one induction combination chemotherapy regimen and underwent autologous transplant between 1989–1995 at centers participating in the Autologous Bone and Marrow Transplant Registry, 56% had a CR or PR with pre-transplant salvage and 44% had less than a PR.[237] Similar to the previous trial, 3-year PFS and OS were 38% and 50%, respectively.[237] A retrospective study from Vancouver also demonstrated 15-year OS of 39% in patients with refractory disease to initial induction therapy, compared to 67% in chemosensitive patients.[239] In a retrospective analysis of 175 patients with SD or PD to initial induction and who also failed to respond according to CT findings to salvage therapy, 5-year OS and PFS were 36% and 32%.[236] In multivariate analysis, > 18 months interval between diagnosis and HCT was favorably associated with OS. Therefore, in patients with primary refractory disease defined either as failure to achieve a CR on CT (not PET/CT) with front-line chemotherapy or a short remission duration who respond to salvage therapy, high-dose therapy with HCT may lead to prolonged durable remissions. Fewer data are available in those patients who fail to respond to salvage therapy.

Although the study by Sweetenham suggests that some patients who are refractory to salvage therapy may benefit from HCT,[236] PET/CT may be helpful in guiding treatment approaches for these patients. A number of studies have recently demonstrated the prognostic value of FDG PET/CT pre-transplant, with EFS/PFS of

10% to 31% in patients who are PET positive compared to 68% to 93% for patients with a negative PET/CT prior to HCT.[240–242] Using PET/CT to determine eligibility for HCT remains investigational, however, it is reasonable to recommend two to three cycles of salvage chemotherapy, confirmation of response by PET/CT, and then autologous stem cell transplantation in responding patients. For those patients with clearly progressive disease on PET/CT, alternative salvage regimens should be offered and if patients respond, autologous transplant could be considered. For those patients with improving disease on CT scan, but persistent PET positivity prior to autologous transplant, HCT is still recommended based on previous retrospective data and possibility of false-positive PET/CT[237,238]; however, further prospective study is needed in this patient population that incorporates centrally reviewed PET/CT into the response assessment and transplant determination.

Tandem transplantation or sequential high-dose therapy has also been evaluated with poor risk or refractory disease and remains investigational. In the largest multicenter trial of 247 patients, 105 patients with primary refractory (defined as less than a PR or progression within the first 90 days from induction doxorubicin containing chemotherapy) or at least two risk factors (time to relapse <12 months, stage III–IV at relapse, or relapse within irradiated sites) underwent tandem ASCT and 95 patients with intermediate risk disease (only 1 risk factor) received a single transplant. In this study, 5-year FFP and OS were 73% and 85%, respectively, in the intermediate risk group; and 46% and 57%, respectively, for the high-risk group who underwent tandem transplant which compares favorably to historically observed 3- to 5-year PFS of 25% to 39% in primary refractory patients.[243] However, in a second trial, use of sequential high-dose conditioning regimens (i.e., high-dose cyclophosphamide, methotrexate, and etoposide followed by BEAM and then HCT) did not improve FFTF or OS over standard BEAM and HCT.[244] Therefore, single versus tandem transplant and use of sequential high-dose conditioning regimens remains investigational in patients with relapsed HL.

Therapeutic Options for Patients Relapsing after Autologous Hematopoietic Cell Transplantation

Although many of the previously discussed combination salvage regimens including ICE, GVD, DHAP, ESHAP, GDP, and IGEV have significant activity in patients with HL that has progressed after autologous HCT, often the goals in this patient population are palliation, with minimization of symptoms as well as treatment-related toxicity. Furthermore, prolonged therapy over several months rather than two to three cycles may be necessary to control disease. Therefore, single-agent regimens are often preferred and combination regimens reserved for patients with organ involvement or significant disease-related symptoms. A number of single-agent regimens can be utilized in this setting and include vinblastine, etoposide, gemcitabine, and vinorelbine. With vinblastine, 4 to 6 mg/m^2 weekly or every 2 weeks until disease progression or toxicity, response rates as high as 59% and median EFS of 14 months have been reported.[245] Gemcitabine and vinorelbine both have single-agent activity in 39% to 50% of patients.[246,247] Combination therapy with ChlVPP (chlorambucil, vinblastine, procarbazine, and prednisone) also has activity in this patient population.[248] Selected patients with nonbulky lymphadenopathy and no organ involvement who are otherwise asymptomatic could also be observed in this setting.

Radiotherapy should also be considered in the setting of relapsed HL. In a retrospective analysis of salvage radiotherapy used in 100 patients at first treatment failure, typically after COPP/ABVD initial therapy, 5-year FFTF and OS were 28% and 51% with radiotherapy alone.[249] Advanced stage at relapse and B-symptoms adversely affected OS in multivariate analysis.[249] Therefore, in highly selected patients with limited-stage disease at relapse who may not be eligible for autologous HCT due to age and co-morbid conditions, involved field radiotherapy may lead to prolonged remissions. For younger patients with relapsed HL, due to potential risks of second malignancies within the radiation field and improved survival with autologous stem cell transplantation, radiotherapy alone is not recommended at first relapse. However, involved field radiotherapy should be considered in these patients as consolidation post-autologous transplant to bulky, nonirradiated sites or to sites of relapsed limited-stage disease in previously nonirradiated fields. For those patients with limited-stage relapse post-transplantation, radiotherapy may lead to prolonged remissions and delay the need for palliative chemotherapy.

Brentuximab Vedotin (SGN-35)

Recently, the Food and Drug Administration approved brentuximab vedotin, a novel anti-CD30 drug–antibody conjugate for the treatment of patients with relapsed or refractory HL after previous stem cell transplant. Brentuximab vedotin is comprised of a CD30 antibody conjugated by a plasma-stable linker to the antimicrotubule agent, monomethyl auristatin E. In phase I testing, the maximum tolerated dose was 1.8 mg/kg every 3 weeks with an overall response rate of 38% in 45 patients, including 11 CRs.[250] In a pivotal phase II study with 102 patients with relapsed (29%) or refractory (71%) HL who had previously received a median of 3.5 prior therapies (range 1 to 13), the ORR was 75% with a 34% CR rate.[194] The median duration of response was 20.5 months in this trial and grade 3 to 4 toxicity consisted of sensory neuropathy (5%), fatigue (2%), neutropenia (14%), and thrombocytopenia (3%).[194] Therefore, with its significant single-agent activity and tolerability, brentuximab vedotin should be considered as initial therapy for patients with relapsed HL post-autologous transplantation. Brentuximab vedotin may be administered for up to 16 cycles, with dose reductions or delays if needed for myelosuppression or neuropathy.

On the basis of this striking efficacy and tolerability in a heavily pre-treated relapsed and refractory patient population, brentuximab vedotin has recently been added to ABVD chemotherapy in a phase I trial in patients with stage IIB, III, and IV previously untreated HL.[224] Due to increased risks of bleomycin toxicity (40% incidence in 25 patients treated with ABVD + brentuximab vedotin), the study has dropped bleomycin from the combination and is currently examining AVD in combination with brentuximab vedotin utilizing brentuximab vedotin at 1.2 mg/kg days 1 and 15 of each cycle.[224a] There are 26 patients who have received AVD + brentuximab vedotin without bleomycin and no pulmonary toxicity has been observed now that the bleomycin has been dropped from the treatment regimen. An international study sponsored by Seattle Genetics/Millennium randomizing patients with stage III and IV HL to ABVD × 6 cycles versus AVD + brentuximab vedotin × 6 cycles is in development as are multicenter phase 2 studies using this agent alone and in combination with ICE as pre-transplant salvage therapy, and in the future it is hoped we will determine if it is safe to incorporate this agent into front-line therapy, the effect of this agent on stem cell mobilization, and if PFS and OS are improved with the addition of brentuximab to front-line or pre-transplant therapy.

Allogeneic Transplant

Allogeneic HCT has been used for patients with relapsed HL after prior autologous transplant, although the presence of a graft-versus-Hodgkin lymphoma effect remains controversial.[251] Most trials of allogeneic transplant in HL demonstrate 2-year PFS rates of 30% and OS of 35% to 60%. A European Blood and Marrow Transplantation trial compared reduced intensity

(n = 89) to myeloablative (n = 79) allogeneic HCT.[252] In this trial, with reduced intensity conditioning, 1-year treatment-related mortality (TRM) was 23% and 5-year OS was 28%, compared to 46% 1-year TRM and 5-year OS of 22% with myeloablative conditioning. In the reduced intensity group 5-year PFS was 18%. Other prospective and retrospective studies have reported 2- to 3-year PFS of 25% to 32% and OS of 43% to 64% with reduced intensity conditioning allogeneic stem cell transplantation in patients with relapsed HL.[253,254] Overall, these studies and others demonstrate that in selected patients with available donors, reduced intensity allogeneic stem cell transplantation is an option for patients with relapsed or refractory HL after prior autologous transplantation and may lead to prolonged DFSs in 18% to 30% of patients.

HODGKIN LYMPHOMA IN THE ELDERLY

Older patients with HL have generally been underrepresented in clinical trials. Outcomes in this population are inferior to those in younger patients, most likely because of more frequent co-morbid conditions in older patients. This may lead to dose attenuation and loss of dose density and thus inferior outcomes.

Fit older patients without limiting co-morbidities may be candidates for treatment with standard ABVD-based protocols, as long as there is normal cardiac and pulmonary function. Data regarding the outcome and toxicity of this approach is limited, however. The GHSG reported that grade 3 to 4 toxicity occurred in 67% and 69% of patients with a median age of 65 and 64 years receiving ABVD × 4 on the HD 10 and HD 11 studies;[255,256] they included a prospective stratification of elderly (age 66 to 75 years) patients randomized to COPP/ABVD or BEACOPP (standard dose). The complete remission rate and OS rate were similar; however, the rate of toxic death during the treatment was 21% (9 of 42 patients) in the BEACOPP group as opposed to 8% in the COPP/ABVD group. Thus most would consider BEACOPP inappropriate for even the fit elderly.

Recently the GHSG published their experience with PVAG (prednisone 40 mg/m^2 days 1–5, vinblastine 6 mg/m^2 day 1, doxorubicin 50 mg/m^2 day 1, and gemcitabine 1,000 mg/m^2 day 1, repeated every 21 days) in patients 60 to 75 years old with early unfavorable or advanced HL. Patients received six to eight cycles of PVAG and radiotherapy was added for patients not in complete remission after chemotherapy.[257] PFS and OS were 58% and 66% of 59 patients. Grade 3 or 4 toxicity was reported in 73%, but there was only one toxic death.

HODGKIN LYMPHOMA AND HUMAN IMMUNODEFICIENCY VIRUS

Although HL is not considered an AIDS-defining illness, the incidence of HL is increased perhaps tenfold among patients with HIV infection.[27,28,258,259] In contrast to patients without HIV infection, HL in patients with HIV infection is most commonly of the mixed cellularity subtype and is associated with B symptoms and with advanced stage, commonly due to bone marrow involvement.[260] Despite the excellent results seen in patients with advanced-stage HL in the absence of HIV infection, early in the AIDS epidemic, median survival in HIV-positive patients with HL was poor, generally <2 years.[260] With the advent of immune reconstitution with highly active antiretroviral therapy, outcomes approach those in the HIV-negative population using standard chemotherapy.[261,262,263] As in the general population, an interim PET scan is highly predictive of good outcome.[264]

HODGKIN LYMPHOMA AND PREGNANCY

Because HL is commonly seen in women of childbearing years, it is not surprising that HL may occur in women who are pregnant. This problem has been extensively reviewed;[168] although agreement regarding optimal management of these patients does not exist, several key observations have been made, and guidelines for therapy have been advocated. Pregnancy does not affect the course of HL as compared to age-adjusted controls with Hodgkin disease who are not pregnant.[265]

Staging of the pregnant patient with HL must be modified to decrease the risks associated with radiation exposure of the fetus. Such an evaluation must be performed in the context of treatment planning. If the overall plan is to delay treatment until after delivery, unless bulky disease is found, then a modified approach to staging is reasonable. A chest radiograph, complete blood counts, liver and renal function tests, serum lactic dehydrogenase, and bone marrow biopsy are indicated. Abdominal ultrasound is probably adequate to establish or rule out the presence of extensive abdominal disease, but more accurate staging must be deferred until after pregnancy as pregnancy precludes the use of CT or PET scans.

The risk of fetal malformations is approximately 15% when chemotherapy is given in the first trimester, but there is no evidence of an increase in fetal malformations when chemotherapy is given in the second and third trimester.[266] The risk of late sequelae of chemotherapy to the fetus is unknown. Therefore, unless disease is clearly bulky and symptomatic, one can consider following patients to term if disease is diagnosed in the late second or third trimester.

If a decision is made to delay therapy until after delivery, the patient should be monitored closely, and the clinical plan should be re-evaluated if progressive disease is noted. If chemotherapy is given during pregnancy, it is probably best to avoid chemotherapy during the 3 weeks before delivery to avoid having the baby be neutropenic at birth.

THERAPY FOR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA

With respect to treatment for NLPHL, no standard front-line or relapsed therapy exists, although a number of options are available. In the large German Hodgkin Study Group series, outcomes for these patients appears to be excellent, with ORR of 85% to 91% in patients with early-stage NLPHL compared to ORR of 83% to 86% in patients with early-stage classical HL treated with the same regimens.[69] For advanced-stage patients, outcomes are similarly good with ORR of 78% in patients with NLPHL compared to 78% in patients with stage III–IV classical HL. FFTF at 50 months was 88% in patients with NLPHL and 82% for patients with classical HL. Interestingly, late relapses >1 year after therapy are observed more commonly in patients with LPHL (7.4%) compared to classical HL (4.7%). Adverse prognostic factors in LPHL include advanced stage, hemoglobin < 10.5 g/dl, age ≥ 45 years, and lymphopenia (< 8% of total white cell count).[69]

For early-stage NLPHL, typically involved field radiotherapy alone or in combination with rituximab or chemotherapy is recommended. However, given the excellent long-term survivals of these patients, the risks of late secondary malignancies and cardiovascular disease must be considered. In a single institution study of 113 patients with stage I–II NLPHL, 93 patients were treated with radiation alone, 13 patients received combined-modality therapy, and 7 received

chemotherapy alone.[194a] Of 106 patients receiving radiotherapy, 20 relapsed (19%), compared to 6 of 7 patients treated with chemotherapy alone; 10-year PFS for stage I and II patients treated with radiotherapy were 89% and 72%, respectively. No differences were observed in patients treated with extended field, regional, or limited field radiotherapy and the use of combined modality therapy did not improve PFS or OS over radiotherapy alone. However, 12 patients receiving radiotherapy did develop second cancers, 5 of which were fatal. The GHSG evaluated 131 patients with stage IA LPHL treated with extended field (n = 45), involved field (n = 45), and combined modality treatment (n = 41), and found a FFTF rate of 95% and OS of 99% at 43 months, with no differences with respect to FFTF or OS among the three treatment arms.[69a] In this series, only one secondary cancer was observed, gastric carcinoma in the extended field group. In a retrospective evaluation from the Australasian Radiation Oncology Group of 202 patients with stage I–II NLPHL treated with radiotherapy alone, the 15-year FFP and OS were 83% and 82%, respectively.[195] Second malignancies included NHL (n = 9), acute leukemia (n = 1), and 18 carcinomas including breast, lung, GI, melanoma, and unknown primary carcinomas. Deaths due to cardiac and respiratory complications after radiotherapy occurred in 9 patients. In contrast to these three trials demonstrating excellent PFS and OS with RT alone in early-stage NLPHL, a retrospective comparison of 32 patients treated with RT alone versus 56 patients receiving combined modality therapy with ABVD × 2 cycles and RT demonstrated improved PFS survival (65% vs. 91%, P = 0.0024) with combined modality therapy as compared to radiation alone.[196] Therefore, although most series support very favorable outcomes with radiotherapy alone in early-stage NLPHL with the exception of late second malignancies and cardiovascular disease, at least one series advocates treating these patients similarly to current classical HL treatment approaches with combined modality therapy and both approaches are standardly utilized. Due to the risks of second malignancies and the excellent long-term outcomes observed in patients with LPHL, in selected patients where the disease is completely resected, observation may also be a suitable alternative to involved field radiotherapy.[197]

Chemotherapy is typically reserved for those patients with advanced-stage disease or where the risks of late complications of radiotherapy are increased due to field or dose of radiotherapy required. In early-stage patients, where the risks of secondary malignancies with radiotherapy are of concern, chemotherapy alone is occasionally utilized. For example, a study conducted in the United Kingdom and France prospectively examined the results of three cycles of cyclophosphamide, vinblastine, and prednisolone (CVP) in children and adolescents with stage I–II NLPHL. In this trial, the ORR was 100% and the 40-month FFTF and OS were 75% and 100%, respectively.[198] In a study of single-agent rituximab as front-line therapy in 28 patients with stage IA NLPHL, the ORR was 100% and at 36 months the PFS was 81%.[199] Therefore, although the FFTF may be slightly lower with chemotherapy alone compared to radiotherapy or combined modality therapy, these early-stage patients who relapse can be effectively salvaged with additional chemotherapy and radiotherapy and such an approach may reduce the rates of second malignancies.

In the advanced-stage setting, chemotherapy options include six cycles of ABVD, alkylator regimens (CVP or CHOP), or rituximab. Due to the CD20 expression on LP cells, rituximab is increasingly utilized in the front-line treatment of advanced-stage NLPHL. In one of the initial series examining the activity of this agent, Ekstand and colleagues reported an ORR of 96% in 22 patients, 12 with previously untreated NLPHL; however, response duration is limited, with a median freedom of progression of 9.2 months.[71] With the notable activity of single-agent rituximab in relapsed and previously untreated HL, it is frequently combined with ABVD or alkylator-based (CHOP or CVP) therapy as part of initial treatment with those for stage III–IV disease. Limited data exist comparing ABVD to alkylator therapy either alone or in combination with rituximab, and therefore, these regimens are all frequently utilized as front-line and salvage therapy for relapsed stage III–IV NLPHL.

FOLLOW-UP OF PATIENTS WITH HODGKIN LYMPHOMA

Follow-up of patients with HL must address both the risk of relapse as well as potential late complications of therapy (Fig. 93.10). In a study of 1,261 patients treated for HL before the age of 41 from 1965–1987, 534 patients died, including 54% due to HL and 22% from second malignancies.[267] The likelihood of HL recurrence declined after 5 years, whereas the incidence of second malignancies and cardiovascular disease continually increased beginning 10 to 15 years from the start of treatment.[267] Within the first 5 years from diagnosis, patients are typically monitored for HL recurrence with history- and symptom-directed evaluation, physical examinations, and laboratory testing (CBC, platelets, chemistries, and ESR if elevated at initial diagnosis) every 2 to 3 months for the first 2 years and every 3 to 6 months during years 3 to 5. However, limited data exist regarding the utility of routine blood work in detecting relapsed disease, and in one series, relapse was detected in 55% of patients by history, 23% by CXR, and 1% by laboratory findings.[268] In a second study of 107 patients, 22 patients relapsed and 64% were detected clinically, 9% detected by laboratory testing, and 9% by CT imaging.[269]

With respect to imaging studies, although the convention has been to recommend CT of initially involved sites every 6 to 12 months during the first 5 years from diagnosis, several previous studies have demonstrated no survival benefit with routine CT surveillance and it does not appear to be cost effective.[269–271] A more recent examination of follow-up PET/CT demonstrated a high false-positive rate, with an overall positive predictive value of only 28%, limiting its utility as a follow-up tool for HL.[272] In this study, 161 patients had 299 routine or clinically indicated follow-up PET/CTs (defined as PET/CT performed based on clinical suspicion) and in this setting the true positive rates were only 5% and 13%, respectively.[272] Therefore, with the low risk for relapse in most patients with HL, and no demonstrated survival benefit with routine surveillance CT or PET/CT, follow-up should consist

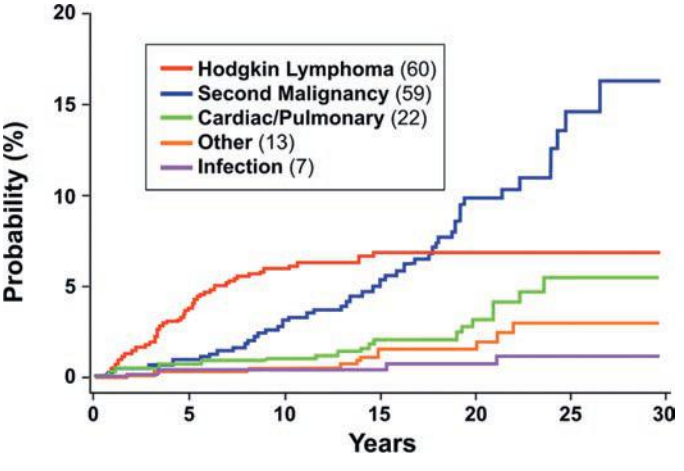

FIGURE 93.10. Causes of death in limited-stage Hodgkin lymphoma. At approximately 15 years Hodgkin lymphoma is not the major cause of death. (From Ng A, Bernardo M, Weller E. Long-term survival and competing causes of death in patients with early-stage Hodgkin's disease treated at age 50 or younger. J Clin Oncol 2002;20:2101–2108, with permission.)

of history and physical exam with only symptom-directed imaging during the first 5 years after HL diagnosis.[271] The risks of routine laboratory and imaging studies including false-positive findings should be discussed with the patients and the use of routine imaging limited without clinical suspicion. Routine surveillance PET/CT finding is currently not recommended[271] based on low positive predictive value and associated costs of this testing and work-up of false-positive results.

Secondary late therapy-related effects in HL survivors include hypothyroidism, fertility issues, secondary cancers, and cardiovascular disease. The risks of second malignancies and cardiovascular disease continue even beyond 30 years from diagnosis;[267,273] and therefore, monitoring of late complications is a lifelong endeavor for HL survivors. In a meta-analysis, second cancers were more commonly encountered in patients receiving chemoradiation or radiation alone compared to chemotherapy alone, and no significant differences in the second malignancy rate were observed with involved field versus extended field radiotherapy.[274] Therefore, any patient receiving previous radiotherapy should be monitored for second malignancy and cardiovascular disease. Specifically, annual breast screening (typically mammography) is recommended 8 to 10 years after completion of treatment or at the age of 40, whichever comes first, in women who received chest or axillary radiation.[271,273] The risk of secondary breast cancers is associated with young age at the time of radiation, particularly women under the age of 30.[267,271,275] Lung cancer risk is also increased in patients receiving mediastinal radiation, particularly patients with a smoking history, and chest imaging annually should be considered for these patients at greatest risk.[271] Cardiovascular disease including increased risk of coronary artery disease, pericardial disease, cardiomyopathy, and valvular disease is also observed in HL survivors, particularly after mediastinal radiation or anthracycline-based chemotherapy, starting about 5 years after treatment and is also associated with age at treatment.[267] Although optimal screening strategies are unclear, monitoring and aggressive management of cardiovascular risk factors including smoking, hypertension, diabetes, and hyperlipidemia is recommended along with consideration of a baseline stress test or echocardiogram.

Other late toxicities associated with radiotherapy include hypothyroidism which can occur in up to 50% of patients and radiation pneumonitis or lung fibrosis, which is fairly uncommon occurring in 3% to 10% of patients.[271] Annual thyroid function tests are recommended for patients with radiation to the neck or upper mediastinum and evaluation for pulmonary fibrosis should be considered in symptomatic patients.

Secondary leukemia is rarely associated with ABVD chemotherapy, but can be observed in up to 3.2% of patients treated with eight cycles of BEACOPP-esc.[209] It remains to be seen with prolonged follow-up if efforts to reduce the total cycles of BEACOPP using PET-directed approaches or to alternate escalated and baseline BEACOPP will reduce this secondary leukemia rate. However, patients treated with BEACOPP or who have received MOPP should have a CBC monitored annually for this risk. Lastly, with respect to fertility, several studies have demonstrated no impact of ABVD on gonadal function and most patients are able to maintain their fertility; however, patients treated with MOPP or BEACOPP typically become infertile[213] and should be counseled about this risk and referred for sperm banking or reproductive endocrinology evaluation if interested prior to treatment.

Finally, in addition to the risks discussed above, patients who undergo autologous HCT for relapsed disease should also be monitored for risks of secondary leukemia, other secondary malignancies, hypogonadism and its complications including declines in bone mineral density, and also considered for re-vaccination. In a retrospective study of 153 patients treated with autologous HCT for relapsed HL, the relative risk of second malignancies was 6.5 compared to the general population and 2.4 compared to nontransplanted patients with HL.[276] Second malignancies occurred in 15 patients, at a median of 9 years post-transplantation and consisted of AML/MDS (n = 6), NHL (n = 3), non-small cell lung cancer (n = 2), colon cancer (n = 2), gastric cancer (n = 1), and adenocarcinoma of unknown primary (n = 1). All patients with AML/MDS had MOPP as part of their initial treatment regimen. In 100 patients treated with autologous HCT in Vancouver, second malignancies occurred in 7 patients at median time of 4.2 years from transplantation and consisted of AML/MDS, glioblastoma, renal cell carcinoma, colon carcinoma, NHL, and breast cancer.[239] In this series, 5 patients developed cardiovascular disease including myocardial infarctions 4 to 11 years post-transplant, arrhythmia, and aortic stenosis. In the largest retrospective series of outcomes post-autologous transplantation, 16 of 494 patients who underwent autologous HCT for relapsed or refractory disease developed second malignancies and second malignancy was associated with use of total body irradiation as part of conditioning, age $\geq$ 40, or use of radiation prior to transplantation.[277] Therefore, all survivors of HL who are transplanted should be monitored lifelong for second malignancies, with close attention to those treated with radiation either pre- or post-transplant or with TBI during transplant conditioning.

In addition, patients typically experience hypogonadism post-transplantation and monitoring for consequences of hormonal deficiency is recommended including monitoring for bone mineral density reduction using DEXA scanning. Lastly, immunity typically wanes post-autologous transplantation, and it is recommended that patients receive pneumococcal, tetanus, Haemophilus influenza type B, hepatitis B, and annual influenza vaccinations. Measles, mumps, and rubella and varicella vaccinations can be considered in immunocompetent patients no sooner than 24 months post-transplantation.

SUMMARY

HL is a success story of modern medical and radiation oncology. A disease once universally fatal is now cured in 80% of patients. The study of this disease has led to major advances in our understanding of the use of noncross-reactive chemotherapy to cure patients with advanced malignancies and of the long-term effects of radiotherapy and chemotherapy.

Despite this success, some patients are not cured, and others may be overtreated by the current treatment paradigms. A major remaining question is how to tailor our treatment not only to subgroups of patients but to individuals. Two current US intergroup studies nearing completion, SWOG 0816 and CALGB 50604, address this question through the investigation of response-adapted therapy. Patients with an FDG-PET positivity after two cycles of ABVD go on to more intensive therapy.

In the future the two objectives of increasing efficacy of treatment and of lessening late effects will be increasingly the focus of trials. New agents and individualized therapy may be the key to simultaneously achieving these goals.

CHAPTER 94

HODGKIN LYMPHOMA IN CHILDREN

Debra L. Friedman

INTRODUCTION

The first description of Hodgkin lymphoma (HL) was in 1832 when Thomas Hodgkin described seven patients with enlarged lymph glands and spleen. This was followed with histologic descriptions of multinucleated giant cells, by Sternberg in 1898[1] and Reed in 1902.[2] In the 1960s, the clonality of the Reed-Sternberg cell was established.[3] More recently, work has focused on the molecular biology of the disease, including the role of immunoglobulin genes, transcription factors, apoptotic pathways, and Epstein-Barr virus (EBV) incorporation.[4–7]

Therapeutic advances in HL began in 1902 when Pusey reported on the use of radiotherapy,[8] followed by the use of single-agent chemotherapy, mechlorethamine (nitrogen mustard) in 1946,[9] then combination chemotherapy with MOPP in 1964,[10] and ABVD in the 1970s.[11] Donaldson and colleagues at Stanford introduced the concept of combined modality therapy for pediatric patients using the MOPP backbone and low-dose radiation therapy (RT)[12] (see Table 94.1 for acronyms of treatment protocols). Multimodality, risk-adapted therapies are now the standard of care for pediatric and adolescent HL. The goals of contemporary clinical trials are to balance short- and long-term toxicity with efficacy, in order to maximize cure and minimize adverse sequelae of treatment simultaneously.

EPIDEMIOLOGY

Incidence

Supported by data from United States Surveillance, Epidemiology End Results [SEER],[13] HL makes up 8.8% of all childhood cancer under the age of 20 years, but 17.7% of cancer in children between ages 15 and 17 years. The overall annual incidence rate in the United States is 12.1 per million for children under 20 years and increases to 32 per million when limiting the analysis to adolescents between 15 and 19 years. Overall there is a slight female predominance when considering all children less than 20 years (M:F = 0.9). The Caucasian:African American ratio is 1.3:1.[13]

Adolescent and young adults are most likely to have disease of the nodular sclerosing subtype. Although among children <20 years of age, the nodular sclerosing subtype accounts for 70% of cases, this subtype accounts for 74% of cases in those 15 to 19 years of age. Under the age of 20 years, the mixed cellularity subtype accounts for 16% of cases, but under the age of 10 years, 32% of cases and across the pediatric age group, it is more common in males.[13]

TABLE 94.1

COMMON CHEMOTHERAPY PROTOCOLS AND ACRONYMS

Acronym	Chemotherapy Agents
ABV	Doxorubicin, bleomycin, vinblastine
ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine (DTIC)
BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone
CHOP	Cyclophosphamide, doxorubicin, vincristine, prednisone
COP (P)	Cyclophosphamide, vincristine, procarbazine (prednisone)
COPDAC	Cyclophosphamide, vincristine, prednisone, dacarbazine
D(A)BVE (PC)	Doxorubicin, bleomycin, vincristine, etoposide (prednisone, cyclophosphamide)
MOPP	Mechlorethamine (nitrogen mustard), vincristine, procarbazine, prednisone
VAMP	Vincristine, doxorubicin, methotrexate, prednisone
VEPA	Vinblastine, etoposide, prednisone, doxorubicin
OEPA	Vincristine, etoposide, prednisone, doxorubicin
OPPA	Vincristine, procarbazine, prednisone, doxorubicin
ICE	Ifosfamide, carboplatin, etoposide
IV	Ifosfamide, vinorelbine
BEAM	Carmustine, etoposide, cytarabine, melphalan

Risk Factors

There are several factors that are known to increase the risk of HL, which include family history of HL, Epstein-Barr virus (EBV) infections, socioeconomic status, and social contacts. For young adult disease (ages 16 to 44 years), there is a 99-fold increased risk among monozygotic twins and a seven-fold increased risk among other siblings.[14–16] There is a fascinating interaction between EBV and HL epidemiology and biology. EBV-associated HL, with incorporation of the EBV in the genome, is most commonly reported with the mixed cellularity histologic subtype in children from underdeveloped and developing nations and in young adult males. Conversely, in young adult HL, incorporation of EBV in the tumor genome is unusual but a history of infectious mononucleosis and high-titer antibodies to EBV are associated.[7,17–19,20] Interestingly, the association between HL and socioeconomic status also differs by age. In children under 10 years, the disease is associated with lower socioeconomic status and large sibship.[21,22] In contrast, risk in young adult patients increases with socioeconomic status and with the related characteristics of a small nuclear family, single-family housing, and fewer siblings or childhood playmates. These findings may be related to an association with infections, where increased infections in early childhood may reduce risk of young adult HL.[23,24] There are inconsistent data regarding clustering of young adult cases.[25,26]

Biology

The hallmark of classical HL is Reed-Sternberg (RS) cell which most commonly derives from a neoplastic clone originating from B-lymphocytes in lymph node germinal centers, but is then embedded within a reactive infiltrate of lymphocytes, macrophages, granulocytes, and eosinophils.[27] The RS cell is a binucleated or multinucleated giant cell that is often characterized with a bilobed nucleus, with two large nucleoli, described commonly as an owl's eye appearance.[28] Sequence analyses of RS cell clones reveal rearrangements of immunoglobulin variable-region genes resulting in deficient immunoglobulin production. RS cells then evade the apoptotic pathway, leading to the genesis of HL, and perhaps the paraneoplastic immune-mediated phenomena that sometimes accompany the disease.[4,5] The B lymphoid cells from which RS arise have high levels of constitutive nuclear NF-*k*B, a transcription factor known to mediate gene expression related to inflammatory and immune responses, and deregulation of NF-*k*B has been postulated as a mechanism by which RS cells evade apoptosis.[6,29] NF-*k*B dimers are held in an inactive cytoplasmic complex with inhibitory proteins, the I*k*Bs.[29] B-cell stimulation by

diverse signals results in rapid activation of the I*k*B kinase (IKK). The IKK complex phosphorylates two critical serine residues of I*k*Bs,[30,31,32] thereby targeting them for rapid ubiquitin-mediated proteasomal degradation. Active NF-*k*B dimers are then released and translocated to the nucleus, where they activate gene transcription. Activation of NF-*k*B appears to be a final common effect of co-stimulatory interactions, genetic aberrations, or viral proteins that operate in HL.[33]

RS cell survival is dependent on several downstream pathways. RS cells express CD40 and CD40 ligand (CD40L) is expressed on inflammatory T and dendritic cells that surround them. CD40/CD40L interactions normally provide a second signal from activated helper T-cells to normal B-cells, resulting in activation of NF-*k*B. NF-*k*B in turn causes proliferation and induces expression of BCL-x_L, which protects B-cells from apoptosis.[34] Tumor necrosis factor receptor-associated factor 1 (TRAF 1) is overexpressed in EBV-transformed lymphoid cells and RS cells[35] and is associated with activation of NF-*k*B and protection of lymphoid cells from antigen-induced apoptosis. Activation of NF-*k*B, in turn, leads to expression of TRAF1, thereby establishing a positive feedback loop that maximizes NF-*k*B–dependent gene expression.[36] EBV latent membrane protein 1 (LMP1) interacts with TRAF1, and tumors with TRAF1-LMP1 aggregates exhibit high NF-*k*B activity.[37,38] LMP1 activates NF-*k*B by promoting I*k*Ba turnover.[39] RS cells express CD30 and CD30 ligation promotes proliferation of HL-derived cells with constitutive activation of NF-*k*B.[40]

EBV genome fragments can be found in approximately 30% to 50% of HL specimens, and may play a role in the rescue and repair of RS cells, further aiding in their evasion of apoptosis and enhanced survival.[7,41,42,43] Three latent viral antigens are expressed in EBV-positive HL in RS cells: Epstein-Barr nuclear antigen-1 (EBNA1), required for viral episome maintenance, LMP1 with transforming properties, and LMP2, which is nontransforming.[44,45]

Histology

HL can broadly be divided into two pathologic classes: classical Hodgkin lymphoma (CHL) and nodular lymphocyte predominant Hodgkin lymphoma (NLPHL).[46,47] In turn, CHL can be further divided into four subtypes: lymphocyte rich (LRCHL), nodular sclerosis (NSHL), mixed cellularity (MCHL), and lymphocyte depleted (LDHL). See Chapter 86 for descriptions of the subtypes. As noted above, different cell types are more common in younger or older children and adults with HL.

In CHL, the RS cells do not express B-cell antigens such as CD45, CD19, and CD 79A, but virtually all express CD30 and approximately 70% express CD15, with only 20% to 30% expressing CD20.[48] In comparison, in NLPHL, the tumor cells do express B-cell antigens such as CD19, CD20, CD22, and CD79A, may or may not express CD30 and do not express CD15.[49] In addition, the OCT.2 and BOB.1 oncogenes are down-regulated in CHL but not in NLPHL, correlating with immunoglobulin transcription.[50]

CLINICAL CONSIDERATIONS

Presentation and Staging

The most common presentation of HL, occurring in 80% of patients, is painless adenopathy. Mediastinal involvement is present in approximately 76% of adolescents but only in 33% of children 10 years of age and younger. A large mediastinal mass with a maximum diameter that is greater than one third of the chest diameter and/or a node or nodal aggregate greater than 10 cm occurs in about 20% of patients.[51,52] B symptoms, defined as (1) unexplained loss of >10% of body weight in the 6 months preceding the diagnosis; (2) unexplained fever with temperatures >38°Celsius for more than 3 days; or (3) drenching night sweats, are seen in 20% of patients at the time of initial disease presentation.[52,53,54] Staging is performed clinically, based on the Ann Arbor staging system[55] as revised in 1989.[53] Approximately 80% to 85% of children and adolescents with HL have involvement limited to or with direct extension from the lymph nodes and/or the spleen (Stages I to III), whereas 15% to 20% of patients are Stage IV with involvement of the lung, bone marrow, bone, or liver.[55] Although staging definitions by nodal region, B symptoms, and definition of extranodal involvement are well defined, bulk disease and substaging have not been consistent across studies (Table 94.2).

Diagnostic Evaluation

A detailed history is required to elucidate B symptoms, which becomes important in risk stratification. A thorough physical evaluation should be performed, documenting the location and size of adenopathy, presence of splenomegaly and any evidence of organ dysfunction. This should be complemented by computed tomography (CT) scans of the neck, thorax, abdomen, and pelvis. FDG-PET imaging is the standard of care in HL and response to disease is now judged by FDG-PET alone or in combination with CT. With the advent of combined CT-PET scans, areas of disease can be evaluated simultaneously with both modalities in an overlapping fashion.[56,57,58,59] Technicium-99 bone scintigraphy can be considered in patients with bone pain or elevated alkaline phosphatase, although PET may obviate the need for this. In addition, an upright chest radiograph (CXR) with posteroanterior (PA) and lateral views has traditionally been required for documentation of a large mediastinal mass (bulk mediastinal disease) for clinical trials, defined as tumor diameter >1/3 the thoracic diameter (measured transversely at the level of the dome of the diaphragm on a 6-foot upright PA CXR),[60] although the ongoing value of this remains unclear.

Bone marrow biopsy is recommended for all Stage III and IV patients or patients with B symptoms. There are less consistent recommendations for lower-stage patients without B symptoms.[61,62] Laboratory studies include a complete blood count, blood chemistries to evaluate hepatic and renal function and may include acute phase reactants such as ferritin, erythrocyte sedimentation rate, and serum copper, which may be seen as nonspecific markers of tumor activity, but may correlate with prognosis or response.

Prognostic Factors

Adverse prognostic markers established from clinical trials often form the basis for risk stratification and subsequent modification of therapeutic algorithms. In sequential trials, as treatment is then risk-based, these adverse factors are abrogated by the changes in therapy. Pre-treatment factors that have been shown to be associated with adverse outcome include advanced stage, B symptoms, bulk disease, extranodal extension, male sex, and elevated erythrocyte sedimentation rate; and in some studies, hemoglobin <110 g/L or white blood cell count >11.5 × 10^9/L, age 5 to 10 years, and increased numbers of sites of disease.[63–66,67,68,69] Patients with NLPHL appear to have an overall better prognosis than those with CHL, and among those with CHL, histologic subtype is not consistently associated with prognosis.[67,70] Serum markers that may confer adverse prognostic risk include soluble vascular adhesion molecule-1, tumor necrosis factor, soluble CD-30, beta-2 microglobulin, transferin, serum IL-10, and serum CD 8 antigen.[71,72,73,74,75,76] High RS cell levels of caspase 3 may be associated with a more favorable outcome.[77] Early response to treatment, which may be a correlate for biology, may also be an important prognostic factor, allowing titration of therapy to the individual.[68,78–80]

TABLE 94.2

CLINICAL AND STAGING CRITERIA FOR HODGKIN LYMPHOMA

A. Stage Grouping

Stage I: Involvement of single lymph node region (I) or localized involvement of a single extralymphatic organ or site (IE).

Stage II: Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized contiguous involvement of a single extralymphatic organ or site and its regional lymph node(s) with involvement of one or more lymph node regions on the same side of the diaphragm (IIE).

Stage III: Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized contiguous involvement of an extralymphatic organ or site (IIIE), by involvement of the spleen (IIIS), or both (IIIE+S).

Stage IV: Disseminated (multifocal) involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement, or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement.

B. Symptoms and Presentations

"A" Symptoms: Lack of "B" symptoms.

"B" Symptoms: At least one of the following:

Unexplained weight loss >10% in the preceding 6 mo

Unexplained recurrent fever >38°C

Drenching night sweats.

X Bulk disease (see C below)

E Involvement of a single extranodal site that is contiguous or proximal to the known nodal site.

C. Bulk disease

One or both of the following presentations are considered "bulk" disease:

- *Large mediastinal mass:* tumor diameter >1/3 the thoracic diameter (measured transversely at the level of the dome of the diaphragm on a 6-foot upright PA CXR) In the presence of hilar nodal disease the maximal mediastinal tumor measurement may be taken at the level of the hilus. This should be measured as the maximum mediastinal width (at a level containing the tumor and any normal mediastinal structures at the level) over the maximum thoracic ratio.
- *Large extramediastinal nodal aggregate:* A continuous aggregate of nodal tissue that measures >6 cm[a] in the longest transverse diameter in any nodal area.

[a]Some studies use 10 cm for definition of extramediastinal bulk disease.

INITIAL TREATMENT FOR PEDIATRIC HODGKIN LYMPHOMA

To our knowledge, the biology and natural history of HL does not differ between children and adults. As a result, early therapeutic approaches for pediatric HL were similar to or modeled after those developed for adults with HL. This seemed particularly logical and HL is most commonly a disease of adolescents as opposed to adults. However, with high cure rates, contemporary standard approaches to adolescent and young adult HL include multiagent chemotherapy with or without low-dose involved field radiotherapy. The overriding principles of these treatment regimens are to balance efficacy with both acute and, perhaps, more important, long-term toxicities.[81–83] A summary of common protocols for upfront therapy is found in Table 94.3. Figure 94.1 shows the timeline of evolution of therapy for pediatric HL.

Challenges inherent in comparing data across pediatric HL trials are differing patient populations, with differing definitions of stratification. However, overall, results are quite good with 3- to 10-year EFS rates ranging from 67% to 94% for combined modality therapy and 60% to 91% for chemotherapy alone, as reviewed by Olson and Donaldson.[84]

Chemotherapy regimens have largely built upon the MOPP and ABVD backbones and have been quite successful overall. To decrease alkylator therapy and potential cardiotoxicity and to provide dose-intensive treatment, the Pediatric Oncology Group (POG) developed a series of studies built upon the ABVD backbone, substituting dacarbazine with etoposide. The use of vincristine instead of vinblastine allowed for escalation of doxorubicin and etoposide. POG 9226 piloted therapy with 4 cycles of DBVE followed by low-dose IFRT in patients with Stages I, IIA and IIIA. The 5-year EFS was 89%.[85] This pilot was followed by a Phase III study using the same therapy (POG 9426) in a nonrandomized response-based manner. Those with a rapid response

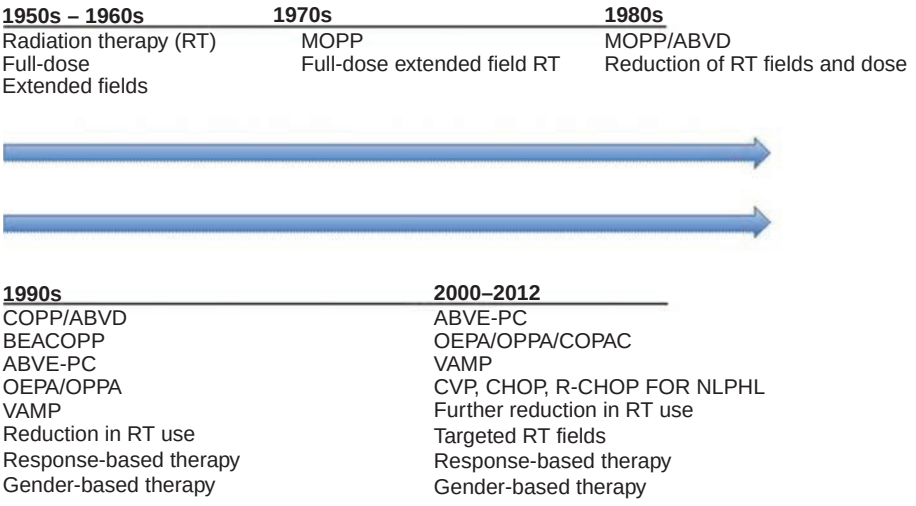
TABLE 94.3

SOME COMMON STANDARD THERAPY PROTOCOLS FOR PEDIATRIC CLASSICAL HODGKIN LYMPHOMA

Stage and Presentation	Commonly Accepted Chemotherapy Regimens
IA, IIA < 4 nodal regions without B symptoms, bulk disease, or extranodal extension	VAMP × 4 COPP/ABV hybrid × 4 ABVE × 4 OEPA or OPPA × 2 CHOP × 3–4 ± Rituximab ABVD × 2–4
IA, IIA with bulk disease, ≥3 nodal regions, or extranodal extension IIB*, IIIA, IVA	COPP/ABV × 6 ABVE-PC × 3–5 OPPA/OEPA × 2 + COPP × 2 OEPA-COPAC ABVD × 4–6
IIB*, IIIB, IVB	ABVE-PC × 3–5 BEACOPP × 8 (or BEACOPP × 4 + ABVD × 2 or + COPP/ABV × 4) OPPA/OEPA × 2 + COPP × 4 OEPA-COPAC Stanford V ABVD × 6–8

All regimens should consider LD-IFRT (low-dose involved field radiotherapy; 15 to 25 Gy), but there are variations in recommendations based on risk and early and complete response to chemotherapy.

FIGURE 94.1. Timeline of Hodgkin lymphoma upfront therapy.



(60% tumor reduction, gallium negative) after 2 cycles proceeded to consolidative IFRT without further chemotherapy; slow responders continued to receive 4 cycles plus IFRT. The overall EFS was 88.3%.[86] In POG 9425 (for patients with advanced stage disease) prednisone and cyclophosphamide were added to the ABVE backbone, with more rapid delivery of therapy to intensify the weekly therapeutic intensity. Response was assessed after three cycles (9 weeks). Those with rapid response did not receive the additional two cycles of chemotherapy. All patients received consolidative regional low-dose (20 Gy) RT. Overall 3-year EFS was 87%.[79] Both studies evaluated the efficacy of dexrazoxane in reducing cardiac and pulmonary toxicity. Although it is still too early to know whether there was a significant benefit, dexrazoxane was associated with an increased risk of acute (hematologic/infectious) toxicities and development of second malignancies, mostly treatment-related leukemia.[87]

With the goal of balancing efficacy with toxicity, and specifically to decrease long-term risk for organ dysfunction and second malignancies, there have been a number of studies conducted to evaluate the avoidance of RT in the POG and Children's Cancer Group (CCG), and more recently in the Children's Oncology Group (COG), representing the merger of those groups. In the Children's Cancer Group (CCG) 521 study, patients were randomized between 12 cycles of alternating MOPP/AVBD versus 6 cycles of AVBD + low-dose regional chemotherapy. Event-free survival was 77% for Stage III and IV patients and there was excess pulmonary toxicity with the ABVD arm.[88] POG 8725 compared eight cycles of MOPP/AVBD with and without IFRT in Stage IIB, III, and IV patients. There was no significant benefit for RT, but patients were exposed to significant doses of alkylating agents and anthracyclines, which are associated with significant long-term risk for gonadal toxicity, cardiac toxicity, and secondary leukemia.[89] Response post three cycles was a strong prognostic factor, with a 94% EFS in the rapid early responders as opposed to a 78% EFS in those who did not respond quickly.[89] In a randomized Phase III trial, CCG 5942 evaluated the avoidance of radiotherapy in patients who had a complete response following chemotherapy. Patients were treated with four cycles of COPP/ABV, six cycles of COPP/ABV, or two cycles each of COPP/ABV, cytarabine/etoposide, and CHOP, depending on the stage of disease and presence of bulk disease. Of the 829 eligible patients, complete response was achieved in 83% and 501 were randomized to receive IFRT or no further therapy. Event-free survival at 3 and 10 years was 87% and 83%, respectively. In all groups, the difference in EFS post randomization was highly significant and overall EFS was 91% at 3 and 10 years for the group who received IFRT and 86% at 3 years and 83% at 10 years for those who did not receive IFRT. Despite the differences in EFS, early evaluation of overall survival is not affected by the inclusion of IFRT.[63,90] A pilot study of 99 patients in CCG 59704 utilized the German Hodgkin Disease Group's BEACOPP backbone for patients with B symptoms or advanced stage disease. Overall the 5-year EFS was 94% with patients receiving six to eight cycles of chemotherapy with or without radiotherapy on the basis of a gender-stratified, response-based therapeutic algorithm.[91]

A series of studies in the COG have just completed accrual and have evaluated the principles of response-based risk-adapted therapy, where therapy is decreased for those at lowest risk and with favorable early responses to chemotherapy and augmented for those with more advanced disease or a slow response to initial chemotherapy. These studies have utilized the ABVE-PC backbone of the POG 9425 and 9,426 studies.

The Dana Farber-Stanford-St. Jude pediatric Hodgkin lymphoma consortium studies have focused efforts on reduction in alkylating agent, anthracycline, and radiotherapy doses. Low-risk patients have been treated with four cycles of an alkylator-free chemotherapy protocol, VAMP, with radiotherapy doses of 15 Gy or 25.5 Gy based upon response to the first two cycles of chemotherapy. This approach resulted in a 5-year EFS of 93% and 10-year EFS of 89%.[92] For patients with higher risk disease, two protocols have been evaluated, VAMP/COP and VEPA, both with IFRT. Results have been less acceptable with 5-year EFS of 74% and 68%, respectively.[93,94] The group is now evaluating the Stanford V regimen[95] that has been successfully employed in adult patients.

In the same era, the German cooperative groups have built upon COPP chemotherapy in both pediatric and adult HL. To decrease gonadotoxicity, which is more prevalent in males exposed to alkylating agents, some of these therapies have been gender-based. The DAL-HL-90 study used OEPA/COPP for males and OPPA/COPP for females, both followed by IFRT. EFS for Stages II, III, and IV was 92%, 86%, and 90%, respectively.[96] The GPOH-95 study was designed to assess elimination of radiotherapy for those with a complete response. It built on the OPPA/OEPA backbones by adding cycles of COPP for patients with more advanced disease. Radiotherapy dose was determined by the post-chemotherapy disease reduction. Complete response was defined as complete resolution of all disease (as opposed to a 70% reduction in CCG 5942 and 59704). Only 22% achieved a complete response. A total of 50% achieved between 75% and 95% disease reduction and were treated with 20 Gy radiotherapy, and 4% had less than a 75% reduction and were treated with 30 Gy. In addition, 20% of patients had residual masses treated with boost doses to 35 Gy. Overall the EFS was 92% for those receiving radiotherapy, compared with 88% in those treated with chemotherapy alone, but for patients with IA, IB, and IIA disease, EFS was not

different among those with a CR to chemotherapy and no other therapy (97%) and those with a partial response, subsequently treated with radiotherapy (94%). However, for all other patients the EFS was 79% for those treated with chemotherapy alone compared with 91% for those treated with combined modality therapy.[97] This was followed by the GPOH-HD-2002 study, where OEPA-COPDAC chemotherapy was tested in males compared with OPPA-COPP in females for intermediate and advanced HL. The 5-year EFS was 89.0% without significant difference between males and females.[98]

For low-risk patients with NLPHL, some patients may be treated with surgery alone. There are multiple small reports in both adult and pediatric HL of patients of successful treatment of completely resected Stage I disease. For those who did relapse, salvage rates were encouraging and death from disease very low.[99–102] This has prompted a study in the COG to formally evaluate surgery only in patients with involvement of a single completely resected lymph node with NLPHL. Although adults with NLPHL may be treated with radiotherapy alone, the dose required without adjuvant chemotherapy exceeds that optimal in children and adolescents, and thus this strategy is not used in pediatric NLPHL. The optimal treatment of patients with advanced stage NLPHL remains undetermined. These patients are traditionally treated with regimens that are used for patients with advanced stage classical HL with outcomes equivalent to or better than those with CHL. However, the biology of NLPHL may be more similar to indolent CD20+ B-cell non-Hodgkin lymphoma (NHL) than classical HL and thus the question remains of whether regimens for NHL would be more effective with potentially less toxicity in these patients. A retrospective analysis at MD Anderson Cancer Center from 1995 to 2010 found that patients with NPLHL treated with R-CHOP had better 5-year progression-free and overall survival compared to those treated on the HL regimen.[103] From 2005 to 2010, a study was conducted in France and the United Kingdom, testing CVP in 55 patients with early-stage NLPHL. The 40-month freedom from treatment failure was 75.4%, but with an overall survival of 100%, respectively.[104]

However, prospective multicenter randomized studies have not been conducted to answer such questions and it is unlikely, given the exceptional overall survival, that such studies will be successfully conducted.

Radiotherapy for Hodgkin Lymphoma

It has been recognized since the 1950s that HL is an extremely radiosensitive disease. Currently, for children and adolescents with HL, radiotherapy is exclusively delivered in the context of multimodality therapy. Doses of 15 to 25 Gy are commonly used, and as noted above, clinical trials have been and continue to be conducted to identify groups of patients for whom the exclusion of radiotherapy is possible, without affecting disease-free survival.

Below are some basic principles for radiotherapy in pediatric and adolescent HL. However, delivery of radiotherapy, particularly in children and adolescents, requires careful considerations of the age, tumor burden and location, response to chemotherapy, and an assessment of both short- and long-term potential toxicity.

Megavoltage energies are now the treatment of choice for pediatric and adolescent HL. Although there are differences in treatment techniques among radiation oncologists and specific institutions, the general technical principles remain constant.[105] Proton beam radiotherapy is currently under investigation at several centers across the United States, but there is insufficient data to know whether this modality will provide the best option for long-term cure, while decreasing adverse long-term effects of treatment.[106,107]

Radiotherapy fields must be designed with the goal to deliver the optimum volume of radiotherapy for disease control, while avoiding normal tissue damage. Customized shielding blocks should be utilized as appropriate to protect normal tissue. Blocking the genitalia is of specific importance when pelvic fields are included. In females, oophoropexy results in doses of 8% to 10% and 4% to 5%, respectively, of the pelvic dose,[108] which will be compatible with the preservation of fertility. For males, a frog leg position and an individually fitted shield will provide the greatest shielding to the testes, reducing scatter to approximately 0.75% of the pelvic lymph node dose.[109]

TREATMENT FOR RELAPSED HODGKIN LYMPHOMA

HL may be cured even if it has recurred after initial treatment. Potentially curative options include conventionally dosed combined modality protocols: radiotherapy alone for those relapsing in a limited nodal pattern, re-induction chemotherapy followed by autologous hematopoietic stem cell transplantation (HSCT), full and reduced intensity allogeneic transplants, and evolving targeted antibodies.[110,111] Some common retrieval regimens are shown in Table 94.4 and the choice of regimen is dependent on previous treatment and patterns of relapse. Two ifosfamide-based regimens have been used with good response rates, ICE and IV with EFS exceeding 75%.[112,113] Gemcitabine has also been used in combination with vinorelbine with excellent overall response rates in recurrent HL with similar EFS.[114,115,116,117]

Autologous HSCT is most commonly used for recurrent or refractory HL, particularly when used following dose-intensive regimens or for high-risk disease.[115,116–119,120–125,126,127,128] However, an allogeneic effect has been observed, and full and reduced intensity allogeneic approaches as well as immune modulation and induction of autologous graft versus host disease have been explored to enhance the allogeneic effect.[129–131,132,133–136]

The most promising new agent in the treatment for HL is brentuximab vedotin (SGN35), which is also being utilized in the earlier relapse period with several recently reported as well as ongoing trials, although pediatric experience is quite limited.[137] In a recent Phase 2 study, the efficacy and safety of brentuximab vedotin was evaluated in 102 patients with relapsed or refractory HL after ASCT. Reductions in tumor size were observed in 94% of patients. The overall response rate was 75%, with complete remission achieved by 34% of patients and partial response in 40%.[138] A retrospective analysis by the German Hodgkin Study Group with brentuximab vedotin as single agent was reported in 45 patients with refractory or relapsed CD30 (+) HL, with an objective response rate of 60%, including 22% complete remissions.[139] A case series of 20 transplant-naive patients who either refused or were ineligible for transplant, enrolled in two Phase I multicenter studies, reported six responses.[140] In a study of

TABLE 94.4

COMMON TREATMENT OPTIONS FOR RECURRENT HODGKIN LYMPHOMA

ICE (Ifosfamide, carboplatin, and etoposide)
DECA (Dexamethasone, etoposide, cisplatin, cytarabine)
IV (Ifosfamide and vinorelbine)
GV (Gemcitabine and vinorelbine)
IEP–ABVD–COPP (Ifosfamide, etoposide, prednisone–doxorubicin, bleomycin, vinblastine, dacarbazine–cyclophosphamide, vincristine, procarbazine, prednisone)
APE (Cytosine arabinoside, cisplatin, etoposide)
SGN-35 (brentuximab vedotin)—antibody-drug conjugate targeting CD30

These therapies can be used as stand-alone therapy or as re-induction prior to planned stem cell transplant. Radiotherapy can be considered together with this therapy.

25 patients with recurrent HL post-allogeneic transplant, who had received a median of 9 (5–19) prior regimens, overall and complete response rates were 50% and 38%, respectively, among 24 eligible patients, with a median progression-free survival time of 7.8 months.[141] These data led to accelerated approval of brentuximab vedotin for the treatment of patients with HL after failure of autologous stem cell transplantation (ASCT) or after failure of at least two prior multiagent chemotherapy regimens in patients who are not ASCT candidates.[142] Studies are now ongoing evaluating brentuximab vedotin as part of multiagent protocols in the upfront and recurrent setting.

ADVERSE LONG-TERM OUTCOMES OF THERAPY

In pediatrics, a significant consideration when deciding therapy is the risk of adverse long-term risks of therapy, which include organ dysfunction and second malignancies.[143] The common potential long-term effects of radiotherapy and chemotherapy for HL are summarized together with general monitoring recommendations in Table 94.5. In a review from the Childhood Cancer Survivor Study (CCSS), among 2,633 HL 5-year survivors, initially treated between 1970 and 1986, there were 500 deaths with the following causes: HL, 35%; second malignancies, 23%; cardiovascular disease, 14%; pulmonary disease, 4%; external cause, 7%; other and unknown cause, 17%. Adjusting for demographics and medical conditions, treatment with radiotherapy or alkylating agents were independent risk factors for overall mortality and those same exposures as well as anthracycline treatment for second malignancies. In this cohort, the 30-year cumulative incidence for second malignancy was 18.7%. Based on self-report, the 30-year cumulative incidence of grade 3 to 5 chronic health conditions in the cohort were as follows: cardiovascular,11%; pulmonary, 5%; and thyroid, 51%.[144] Other studies of subsequent malignancy cite female gender, radiotherapy field and dose, and follow-up time since diagnosis as risk factors. The most significant risk is for secondary breast cancer in female survivors treated with thoracic radiotherapy, where even lower doses of radiotherapy, with ongoing follow-up now are associated with increased risk.[145–149] Thyroid dysfunction and thyroid cancer are also of concern in this population. In the CCSS, self-report thyroid status was assessed in 1,791 HL survivors treated from 1970 to 1986. Of the entire cohort, 34% have been diagnosed with at least one thyroid abnormality. Hypothyroidism was the most common disturbance, with a relative risk of 17.1 compared to sibling controls. Hyperthyroidism was reported by 5% of survivors, which was 8-fold greater than the incidence reported by the controls. The risk of thyroid nodules was 27 times that in sibling controls. Female gender and higher radiation dose increased risk for thyroid abnormalities.[150] In a pooled cohort of childhood cancer survivors including 16,757 patients, with 187 developing primary thyroid cancer, radiation-dose–related relative risks increased approximately linearly for <10 Gy, leveled off at 10 to 15-fold for 10 to 30 Gy and then declined, but remained elevated

TABLE 94.5

GENERAL GUIDELINES FOR RISK AND SURVEILLANCE FOR ADVERSE LONG-TERM OUTCOMES

System	Therapeutic Exposure	Potential Effects	Monitoring Recommendations[a]
Cardiac	Thoracic RT Doxorubicin	Cardiomyopathy Pericarditis Coronary artery disease Valvular disease	Electrocardiogram and echocardiogram
Pulmonary	Thoracic RT Bleomycin	Pulmonary fibrosis Restrictive lung disease	Pulmonary function tests (PFTs) (including DLCO and spirometry)
Thyroid	Neck RT	Overt or compensated hypothyroidism Thyroid nodules or cancer Hyperthyroidism	Free T4; TSH
Gonadal (female)	Pelvic RT Alkylating agents	Delayed/arrested puberty Early menopause Ovarian failure	FSH, LH, estradiol
Gonadal (male)	Pelvic RT Alkylating agents	Germ cell failure Infertility/Azoospermia Leydig cell dysfunction Hypogonadism Delayed/arrested puberty	FSH, LH, testosterone Semen analysis
Bone	Corticosteroids	Decreased bone mineral density	Bone density evaluation (DEXA or quantitative CT)
Second Malignancies	Radiotherapy	Sarcomas CNS tumors Breast cancer Melanoma Nonmelanoma skin cancer Thyroid cancer Other solid tumors	Routine cancer screening per general population guidelines Mammography to screen for female breast cancer at age 25 y or 10 y post RT exposure, whichever is later
	Doxorubicin Etoposide Mechlorethamine Cyclophosphamide	Therapy-related myelodysplasia and acute leukemia	Annual cbc with differential for 10-y post exposure

[a]Monitoring recommendations all include a risk-adapted health history and physical examination. The frequency with which diagnostic studies should be performed is dependent on many factors including radiotherapy dose, chemotherapy exposures, age at exposure, and other clinical parameters. See Children's Oncology Group guidelines for more details (www.survivorshipguidelines.org).

DEXA, Dual-energy X-ray absorptiometry; DLCO, Diffusing capacity; FSH, follicle stimulating hormone; LH, luteinizing hormone; RT, radiation therapy; TSH, thyroid stimulating hormone.

for doses >50 Gy. Dose-related excess relative risks increased with decreasing age at exposure but did not vary with attained age or time-since-exposure, remaining elevated 25+ years after exposure. Gender and number of treatments did not modify radiation effects. In another pooled analysis, three models of assessing absolute risk for secondary thyroid cancer were developed and validated. Model M1 included self-reported risk factors, model M2 added basic radiation and chemotherapy treatment information abstracted from medical records, and model M3 refined M2 by incorporating reconstructed radiation absorbed dose to the thyroid. All models were associated with elevated relative risks (*M1* = 10.8; *M2* = 6.8; *M3* = 8.2) and had good discriminatory ability. Past thyroid nodule was consistently the strongest risk factor in the models.[151,152] Cardiac toxicity following anthracycline therapy and mediastinal radiotherapy is well recognized among survivors.[144,153] Among 1,132 survivors of HL treated between 1978 and 1995, treated with a relatively low doxorubicin dose (160 mg/ m^2), at a median of 19.5 years, cardiac diseases had been diagnosed in 50 patients. Valvular defects were diagnosed most frequently, followed by coronary artery diseases, cardiomyopathies, conduction disorders, and pericardial abnormalities. Multivariate analysis showed the mediastinal radiotherapy dose to be the only significant variable associated with cardiac disease.[154] In a cohort of 1,362 5-year survivors diagnosed between 1966 and 1996, with 50 cardiac events reported, cumulative incidence of anthracycline (dose), cardiac irradiation (dose), combination of these treatments, and congenital heart disease were significantly associated with developing a cardiac event.[155] Reproductive outcomes have been examined for all survivors in the CCSS, but risk factors for impairment are generally those seen with HL therapy. Sklar and colleagues evaluated premature menopause and a multiple Poisson model showing risk factors to include attained age, exposure to radiation to the ovaries in a dose-dependent manner, number and cumulative dose of alkylating agents, and a diagnosis of HL.[156] Green and colleagues found that male survivors were less likely to sire a pregnancy than siblings. Among survivors, the hazard ratio of siring a pregnancy was decreased by RT to the testes, higher cumulative alkylating agent dose, and treatment with cyclophosphamide or procarbazine.[157]

Studies of HL survivors treated in the more contemporary age of chemoradiotherapy are underway to see if reduction in anthracyclines, alkylating agents, and radiotherapy have resulted in fewer long-term adverse chronic health conditions.

Various pediatric cooperative groups have developed long-term follow-up guidelines, which provide a foundation for the type of follow-up care that should be delivered. However, the recommendations are not completely consistent with one another and recommendations are consensus-based, and thus, the optimal follow-up strategy is yet to be fully elucidated. Efforts are underway for international harmonization among large childhood cancer groups.[158–161,162–164,165–167]

CONCLUSIONS

Cure rates for HL are one of the highest in pediatric oncology, but the very therapies that have afforded such cure rates share the etiologic limelight for adverse long-term health outcomes. Ongoing clinical trials thus seek to balance efficacy with both short- and long-term toxicity. For a meaningful minority of patients with higher risk initial disease, refractory, and recurrent disease, the challenge remains increasing the cure rate and incorporating novel agents that may better target the underlying biology and pathophysiology. And last, additional study is required to understand the complex biology and epidemiology of HL better to understand better how they interface with one another, affect disease presentation, response to therapy, and long-term outcomes.

Key Summary Points

For initial diagnosis:

Work-up: History and exam; CT neck, chest, abdomen, pelvis, FDG-PET scan, Bone marrow; CBC/differential, metabolic panel, erythrocyte sedimentation rate, ferritin, bone marrow; excisional lymph node biopsy.

Initial treatment: Risk-based (Table 94.3); Enroll on open clinical trial when available.

For refractory or recurrent disease:

Work-up: As per initial diagnosis.

Treatment: Risk based (Table 94.4). If relapse is not low stage after low-density low-risk chemotherapy protocol without radiotherapy, consider stem cell transplant once response is evident (FDG-PET non-avid).

For follow-up:

Follow clinically with imaging studies for first year to18 months, then clinically follow for long-term toxicity using COG guidelines (www.survivorshipguidelines.org).

CHAPTER 95

PRACTICAL APPROACH TO EVALUATION OF MONOCLONAL GAMMOPATHIES

Francis K. Buadi, Joseph R. Mikhael, William G. Morice II

The real incidence of monoclonal gammopathy is unknown; however, it increases with age, with most cases being identified in the 7th or 8th decade of life.[1–3] The presence of a monoclonal protein is indicative of an underlying clonal plasma cell or B cell disorder. These disorders encompass a spectrum of disease entities ranging from clinically benign monoclonal gammopathy of undetermined significance (MGUS) to clinically significant diseases such as multiple myeloma, and also including Waldenström macroglobulinemia, chronic lymphocytic leukemia, and various neurologic and cutaneous diseases.[4–12] Among 43,000 monoclonal gammopathies evaluated at Mayo Clinic from 1960 to 2010 most had MGUS (57.5%), multiple myeloma (18%), or primary (AL) amyloidosis (9%) (Fig. 95.1). However, 4% of these cases were associated with other conditions, such as POEMS syndrome, cryoglobulinemia, Castleman's disease, and light chain deposition disease, which do require therapy and should not be missed during evaluation. A systematic approach to the patient with a monoclonal immunoglobulin (monoclonal protein) disorder is required, on the one hand to prevent unnecessary testing in the majority who will not need treatment for the underlying condition, and on the other hand to ensure that those with a clinically significant condition will be adequately diagnosed.

This chapter addresses the initial approach to an individual with a monoclonal protein or suspected immunoglobulin disorder. We review the various conditions to consider in a patient with a monoclonal protein, so as to help guide the evaluation. The basic principles on the use of the various tests used, their interpretation, and limitations are also reviewed. Subsequent chapters in this book will deal with the detailed evaluation of specific diseases associated with monoclonal gammopathy.

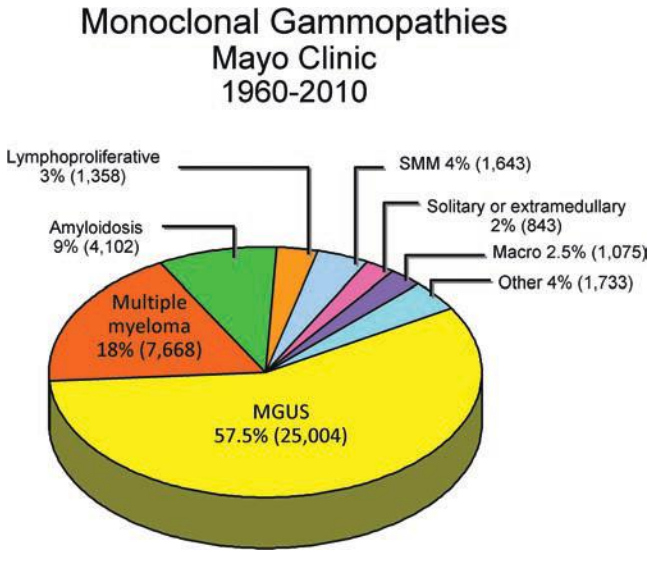

FIGURE 95.1. Distribution of monoclonal gammopathies seen at Mayo Clinic between 1960 and 2010. MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering multiple myeloma.

CLASSIFICATION OF MONOCLONAL IMMUNOGLOBULIN DISORDERS

A prior understanding of the various conditions associated with the production of monoclonal immunoglobulins (monoclonal protein) is essential in the evaluation of an individual with a monoclonal gammopathy. The clinical presentation may be due to the magnitude of the underlying tumor burden or the direct toxic effect of the monoclonal protein. However, a simple way of approaching the evaluation of these cases is to start with the type of monoclonal protein (Table 95.1). Although the various diseases can be broadly classified based on the type of monoclonal protein, there is overlap in the underlying conditions. For example, an IgM monoclonal protein is usually associated with lymphoproliferative diseases such as Waldenström macroglobulinemia and some lymphomas, but may also be associated with cases of IgM-associated multiple myeloma.[13]

Initial Evaluation

The usual test that will detect a monoclonal protein is not part of the typical healthy adult physical evaluation.[14] It is therefore usually detected during the evaluation of a clinical symptom or during further evaluation of an abnormal routine blood test. Abnormalities in routine clinical tests that suggest the possibility of a monoclonal protein disorder include rouleau formation in a peripheral blood smear, elevated total serum protein, proteinuria, anemia, renal dysfunction, or hypercalcemia. Clinical situations that may require evaluation for

TABLE 95.1

CLASSIFICATION OF MONOCLONAL PROTEINS

a monoclonal protein include back pain, osteoporosis disproportionate to age, pathologic fracture, osteolytic or sclerotic bone lesions, recurrent sinopulmonary infections, progressive peripheral neuropathy, infiltrative or restrictive cardiomyopathy, and Raynaud's phenomenon. It must, however, be noted that in these conditions a monoclonal protein may not always be detected by standard testing, and further evaluation may be needed to confirm or exclude an underlying plasma cell or lymphoproliferative disorder, particularly if the index of suspicion is high. Most patients with monoclonal protein are asymptomatic, especially those in whom a routine blood abnormality leads to further testing, resulting in the identification of a monoclonal protein. A simple algorithm taking into consideration the various tests available and clinical presentation is shown in Figure 95.2. Although there may be some overlap, following this algorithm should lead to the correct diagnosis in most cases.

Laboratory Evaluation

The following are important tests that will help in the evaluation of a patient with or suspected to have a monoclonal protein.

PROTEIN ELECTROPHORESIS

Serum and urine should both be evaluated for the presence of a monoclonal protein. High-resolution agarose gel electrophoresis or capillary zone electrophoresis is the preferred method for screening for a monoclonal protein.[15–19] These tests will separate serum or urine proteins into their various components in an electric field based primarily on their physical properties such as size and charge; the proteins are detected either by staining a solid matrix or by their electrical impedance as they exit the column. There are usually five components seen, albumin, α-1, and α-2, β-, and γ-globulin (Fig. 95.3).

Monoclonal proteins will usually migrate into the gamma regions; however, occasionally they may be seen in the β or α-2 region. Samples with a monoclonal protein usually will result in a spike in the gamma region (Fig. 95.4). This is referred to as the M-protein or M-spike with the "M" referring to monoclonal, not IgM. Further testing is then required to determine the type and quantity. All spikes should be evaluated, since in certain cases there may be two (biclonal gammopathy), or more, different monoclonal proteins in a single M-spike that should not be missed.[20–23] It must also be stressed that the gamma region contains all immunoglobulin isotypes (IgM, IgA, IgD, and IgE) and not only IgG. This same test can be used to determine the amount of monoclonal protein present using the densitometer tracing or peak size by capillary zone electrophoresis (Fig. 95.4). The measured M-protein by densitometry tracing is usually lower than the total involved immunoglobulin measured by nephelometry.[16] Protein electrophoresis occasionally

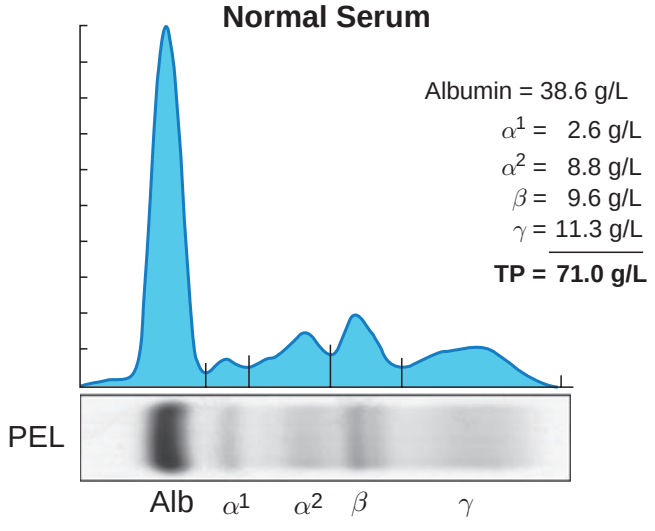

FIGURE 95.3. Images of a normal serum electrophoresis, showing the five protein components.

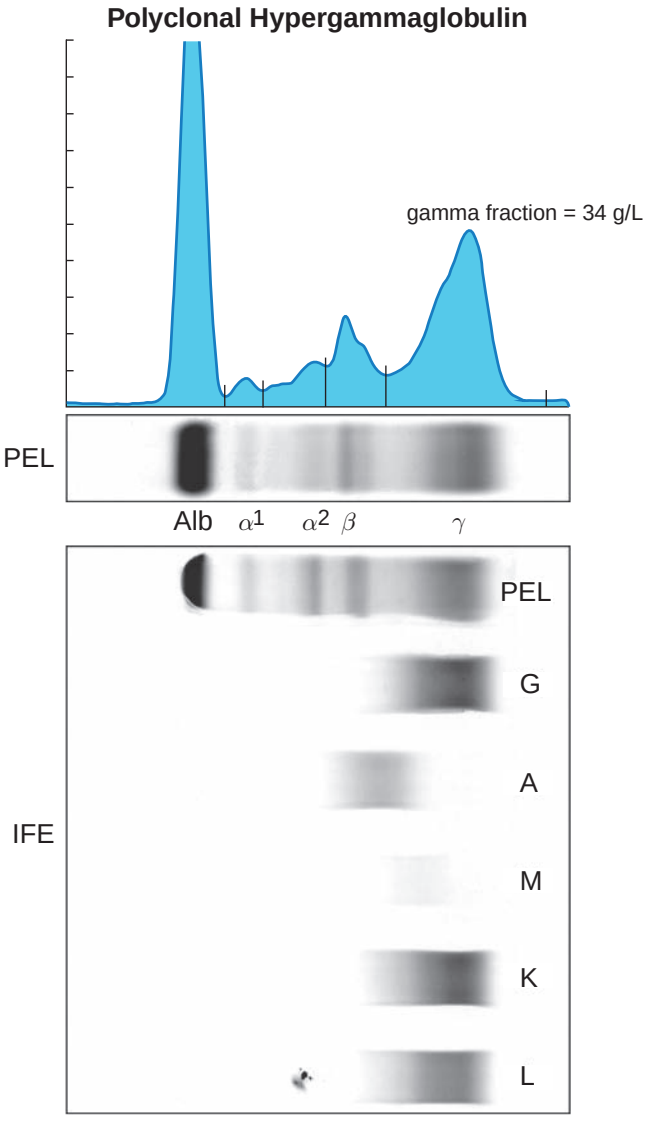

FIGURE 95.5. Images of a serum protein electrophoresis depicting a polyclonal gammopathy.

may fail to identify the presence of a monoclonal protein, especially in cases where there is only minimal production of the monoclonal protein, or minimal amounts of immunoglobulin free light chains.[24] Currently in such cases performing immunofixation despite a negative protein electrophoresis or using the serum free light chain analysis may be the only way to confirm the presence of an underlying clonal disorder, although tandem mass spectroscopy methods are currently being explored.[21,25,26] A monoclonal protein spike should not be confused with a polyclonal increase in immunoglobulin, which usually will be seen as a broad-based band in the gamma region and is not associated with a clonal cell disorder[27] (Fig. 95.5).

IDENTIFICATION OF THE TYPE AND QUANTITATION OF THE MONOCLONAL PROTEIN

The heavy and light chain isotypes of a monoclonal protein is usually determined by immunoelectrophoresis or immunofixation.[15,16,21] Immunoelectrophoresis, although less expensive, is infrequently used, as it is relatively insensitive. Immunofixation involves the application of anti-heavy and anti-light chain antibodies to the electrophoretic gel and has higher detection sensitivity. Immunofixation will identify both the heavy chain isotype (IgG, IgM, IgA, IgD, or IgE) and the light chain type (κ or λ) and should always be performed on all cases of protein electrophoresis with an M-spike. A case with an IgG heavy chain isotype and a κ-light chain will be reported as an IgG-κmonoclonal protein (Fig. 95.6). Most laboratories will initially only perform immunofixation for IgG, IgA, and IgM. Immunofixation for IgD and IgE must be performed if an M-spike is present and either initial immunofixation studies are negative or detect only a monoclonal light chain (Fig. 95.7). The isotype and quantity of the monoclonal protein is important for classification and prognosis. For example in MGUS, the risk of progression is lower in patients with IgG isotype and an M-spike less than 0.5 g/dl. The type of protein and quantity is also important for monitoring patients during therapy. Immunofixation should still be performed in cases where there is a strong suspicion of the presence of a clonal plasma cell or

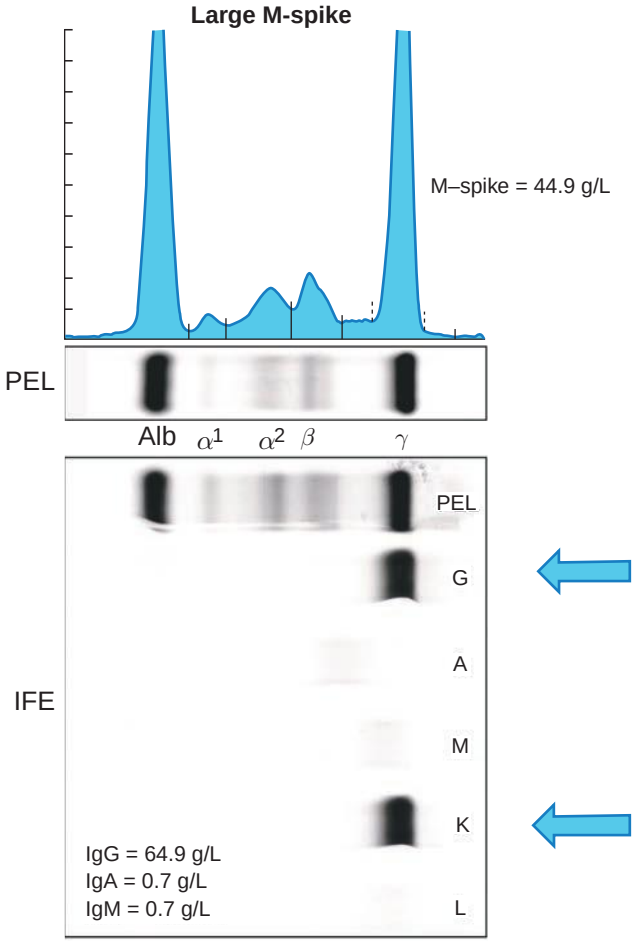

FIGURE 95.6. Protein electrophoresis and immunofixation studies characterize a monoclonal IgG-κ protein. The *arrows* indicate the lanes that show reactivity with the specific antibodies. The reactivity is consistent with the same migration shown in the extreme left column that shows the electrophoresis. Thus, in this assay the nature of the monoclonal protein seen in the electrophoresis is elucidated: isotype G and light chain-κ.

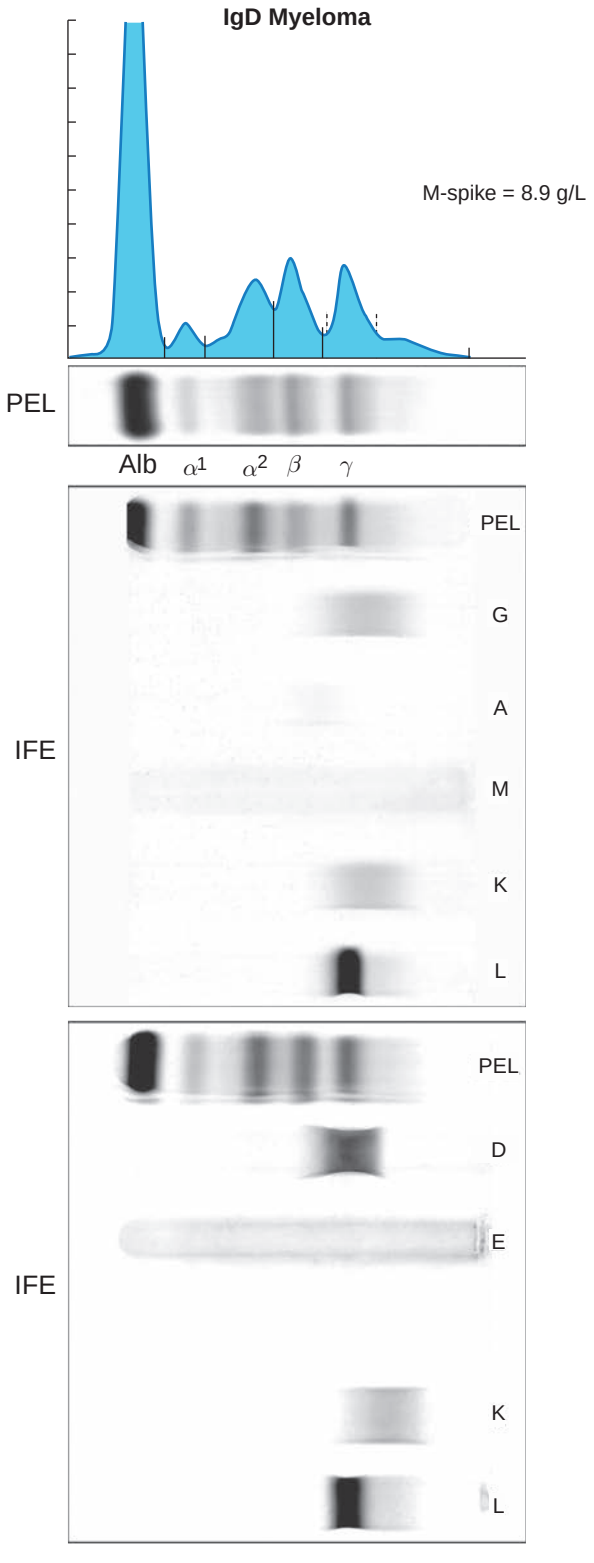

FIGURE 95.7. Images of a positive protein electrophoresis but initial negative immunofixation for IgG, IgA, or IgM isotype with further testing for IgD and IgE showing an IgD isotype with λ-light chain.

lymphoproliferative disorder, even if the protein electrophoresis is negative for an M-spike. Capillary zone electrophoresis with immunosubtraction is an automated system that is slightly more sensitive than high-resolution agarose gel electrophoresis and can be used in the identification, subtyping, and measurement of the M-protein.[17,19] This method is laborious and time consuming, however, making it less frequently used for typing of the monoclonal protein.

QUANTITATION OF IMMUNOGLOBULINS

Immunoglobulin (IgG, IgA, IgM) levels should always be measured at diagnosis and monitored regularly during therapy, especially the involved immunoglobulin. If immunofixation showed an IgD or IgE M-protein, then their levels should also be determined. In most clonal plasma cell disorders the levels of the uninvolved immunoglobulins are suppressed or reduced. Rate nephelometry is a reliable and rapid method for immunoglobulin quantification, although this method does not differentiate between monoclonal and polyclonal immunoglobulin.[28,29] Rate nephelometry also does not provide information on how much of the measure immunoglobulin is abnormal; therefore, in patients with normal total immunoglobulin it is not clinically helpful. This test does have value in clinical care however, as knowing the level in severely hypogammaglobulinemic states will help determine who should receive immunoglobulin replacement, especially those with recurrent sinopulmonary infections.

FREE LIGHT CHAIN ASSAY

A significant population of patients with clonal plasma disorders produces excess amounts of light chain but not a full immunoglobulin molecule: Bence Jones proteinemia.[30] Most of these patients will have a negative protein electrophoresis and immunofixation. In these patients the free light chain assay test may be the only way to detect the presence of a clonal plasma cell disorder.[24–26] Immunoglobulin free kappa (κ) and lambda (λ) light chains concentration in the serum is usually dependent on the rate of production from plasma cells and renal clearance. This results in a defined serum concentration and ratio. In clonal plasma cell disorders there is an excess production of only one of the light chain types, resulting in higher levels, with suppression of the uninvolved light chain, leading to an abnormal κ/λ ratio. The levels and ratio, however, may be affected by renal failure, since the light chains are cleared by the kidneys. This test has become very important in the evaluation and monitoring of patients with amyloidosis, since this is the major protein involved in AL-type amyloid deposits.[31]

URINE EVALUATION

In all patients with a serum M-protein or suspected to have a clonal plasma cell or lymphoplasmacytic disorder, a 24-hour urine collection should be examined for the presence of a monoclonal protein and 24-hour urine protein and monoclonal protein excretion. The excretion of immunoglobulin free light chain in the urine is referred to as Bence Jones proteinuria.[30] The pattern of protein excretion, whether the urine protein is solely albumin or Bence Jones protein, is of diagnostic importance. For example, nonselective proteinuria (albumin predominance) is associated with glomerular diseases such as AL amyloidosis caused by the presence of a monoclonal protein.[12,31]

Bone Marrow and Tissue Evaluation

Bone marrow aspiration and biopsy should be performed in all patients except in a selected group of completely asymptomatic patients with a very small monoclonal protein if a diagnosis of MGUS is favored.[32–34] Even in the latter setting, however, most hematologists will recommend this test, since apart from giving information on the type of clonal cell disorder, it also provides information on the extent of disease. For example, the presence of less than 10% marrow plasma cells distinguishes MGUS from smoldering multiple myeloma (SMM).[10]

Basic evaluation of the bone marrow sample should include extent of infiltration by the cells of interest, reported as a percentage of the total marrow nucleated cells and/or cellularity. Flow cytometric or immunophenotyping can confirm both the cell type (lymphoid vs. plasma cell) and clonality[35,36] (Fig. 95.8). Flow cytometry is particularly useful when following patients on therapy, as it is more sensitive in assessing the depth of response. Plasma cell DNA content can also be measured by flow cytometry, allowing measurement of ploidy status and proliferation rate, which, along with the proportion of normal plasma cells provides important prognostic information.[37] Plasma cell proliferation can also be measured by the labeling index (PCLI) which uses a BrdU pulse label and immunofluorescent detection.[38] However, it is not generally accessible and is not necessary in the majority of patients.

Metaphase cytogenetics and fluorescent in situ hybridization for specific gene targets should be obtained in a subset of cases, since these provide prognostic information in certain clonal cell disorders. For example, in multiple myeloma, cytogenetic abnormalities provide important prognostic information, and therefore this must be obtained in all suspected cases at the time of initial evaluation.[39–42] Gene expression profile analysis of the malignant plasma cells in multiple myeloma is of prognostic value and should be obtained if available.[43–45]

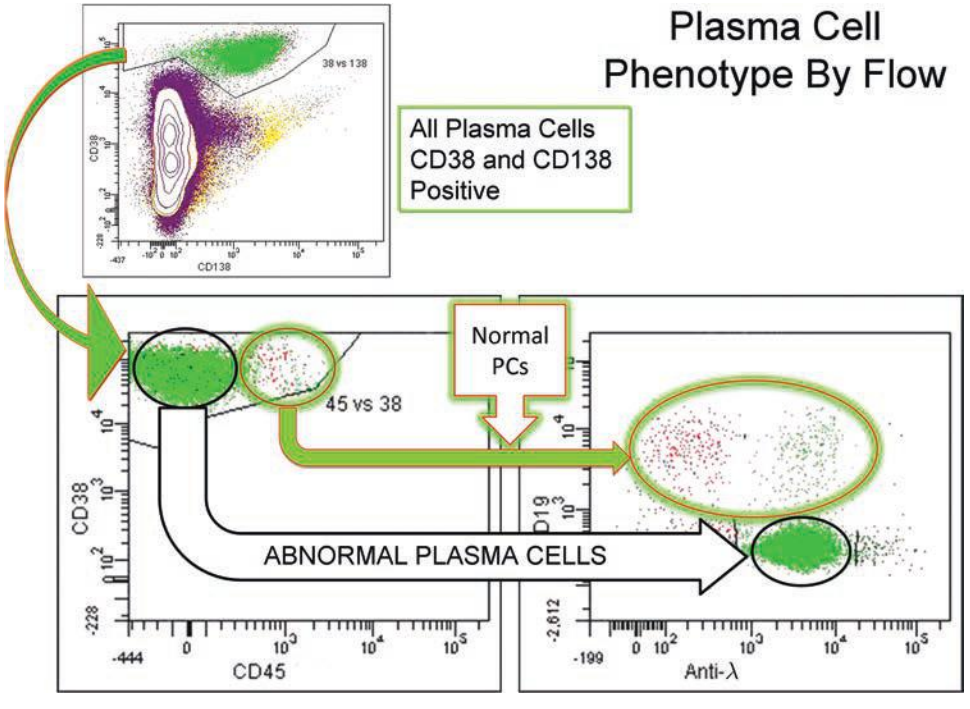

FIGURE 95.8. Identification of abnormal and normal plasma cells (PCs) by flow cytometry. All plasma cells are CD38 and CD138 positive. The abnormal plasma cells are CD19 and CD45 negative and λ-immunoglobulin light chain restricted.

CONGO RED STAIN

In certain cases, a Congo red stain of subcutaneous fat aspirate or a bone marrow biopsy will have to be performed, looking for amyloid deposition.[12,46,47] In about 70% of cases of AL amyloidosis Congo red staining of bone marrow or subcutaneous fat aspirate will be sufficient to make the diagnosis. The remaining cases will require biopsy of the involved organ. All patients with peripheral neuropathy, significant albuminuria, or infiltrative cardiomyopathy in the setting of a monoclonal protein should have this test done. It should also be considered in patients in whom there is a high clinical suspicion of amyloidosis. If this is positive, then liquid chromatography tandem mass spectometry of peptide extracts from the congophilic material should then be done for subtyping of the amyloid deposits.[48]

Imaging

The imaging required for the evaluation of a patient with monoclonal protein depends on the clinical syndrome and type of monoclonal protein. A metastatic skeletal survey should be performed in all patients with non-IgM monoclonal protein. In multiple myeloma this may show lytic bone lesions (Fig. 95.9). One should also look for vertebrae compression fractures, and osteoporosis or osteopenia. These radiologic studies should also be performed in IgM monoclonal gammopathies if there is a strong clinical suspicion of IgM myeloma. For all cases of suspect multiple myeloma, a skeletal survey is still considered the standard test for bone evaluation.[49–51] More sensitive modalities such as magnetic resonance imaging or PET-CT may provide further information.[52–55] Magnetic resonance imaging is particularly useful for the assessment of the extent and nature of soft tissue disease arising from bone lesions, especially those in the spine which may cause neurologic compromise. PET-CT is usually helpful in the evaluation of plasmacytomas and cases of nonsecretory multiple myeloma[56–58] (Fig. 95.10). In our experience, this modality has been helpful in the evaluation of patients with POEMS syndrome, by helping identify hypermetabolic osteosclerotic bone lesions. Computer tomography (CT) scanning of the chest, abdomen, and pelvis should be performed in cases of IgM gammopathy, since they are usually associated with lymphoproliferative disorders which may involve the lymph nodes, spleen, and mucosa-associated lymphoid tissues.

History and Physical Evaluation

A detailed history and physical examination should be obtained any time a monoclonal protein is identified. Certain signs and symptoms may help guide the evaluation and ultimately indicate the appropriate diagnosis. For instance, patients presenting with bone pain, pathologic fractures, weight loss, and symptoms of hypercalcemia or acute renal failure are more likely to have multiple myeloma.[9] Alternatively, those with night sweats, epistaxis,

FIGURE 95.9. Skeletal bone survey showing lytic lesions typically seen in multiple myeloma.

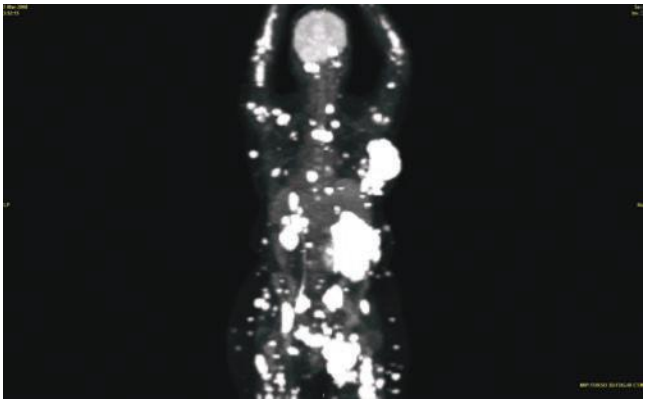

FIGURE 95.10. PET-CT scan showing multiple soft tissue plasmacytomas in a patient with negative marrow biopsy.

and lymphadenopathy are more likely to have lymphoproliferative disorders such as Waldenström macroglobulinemia, marginal zone lymphoma, or chronic lymphocytic leukemia/small lymphocytic lymphoma.[8,35,59–61]

Other less common conditions may also be revealed by patient assessment. A diagnosis of amyloidosis may be indicated by the presence of edema, shortness of breath, hepatomegaly, peripheral neuropathy (e.g., carpal tunnel syndrome), autonomic dysfunction, periorbital purpura, and macroglossia.[12,31,47] Skin rash, neuropathy, and Raynaud's phenomenon should prompt evaluation for cryoglobulinemia.[5,62] Those presenting with polyneuropathy, multiple endocrinopathy, skin lesions like glomeruloid hemangiomata, and organomegaly may have POEMS syndrome.[11] Importantly, one should never overlook the initial reason that led to the identification of the monoclonal protein. Most patients in whom a monoclonal protein is identified are asymptomatic. For these patients, the key to a correct diagnosis may be the reason for the initial testing for the monoclonal protein. In a case where a mildly elevated serum creatinine was the key factor, a nephrology evaluation with possible kidney biopsy may be the only way to diagnose immunoglobulin deposition disease of the kidney.[6,63,64]

Monoclonal gammopathies are common in the elderly, who are also at risk for other pathologic conditions and are usually on multiple medications with their side effects. Therefore it is necessary to always confirm that the identified abnormality is due to the clonal cell disorder or monoclonal protein rather than to another unrelated pathologic condition. For example, mild hypercalcemia in association with a monoclonal protein may be due to parathyroid disease or medication in a patient with benign MGUS rather than myeloma. Renal failure or proteinuria in a hypertensive or diabetic patient with monoclonal protein should be investigated thoroughly before attributing it to the monoclonal protein. Such cases may require a kidney biopsy.

Diagnostic Algorithm (Fig. 95.2)

In a patient suspected of having an underling gammopathy, one should first define the isotype and then quantity of the monoclonal protein. This will certainly help in identifying and defining the underlying clonal cell disorder. In the majority of cases, appropriate tissue biopsy and histopathologic evaluation should aid in providing a definitive diagnosis. Bone marrow biopsy is usually requisite. In certain situations, directed biopsy of a single bone lesion, lymph node, or soft tissue mass may also be needed. Tissue diagnosis can also be helpful in deciding therapeutic intervention; for example, the use of rituximab for the treatment of an IgM MGUS associated neuropathy can be indicated by finding an underlying CD20-positive lymphoproliferative disorder. Once the type of monoclonal protein and underlying clonal cell disorder has been established, the physician then needs to look into the patients' history, physical examination, and laboratory data to determine whether this clonal disorder is having any systematic effect. The typical issues are usually with the hematopoietic (anemia, thrombocytopenia, bulky lymphadenopathy), skeletal (lytic lesion, pathologic fracture, and sclerotic lesions), renal (cast nephropathy, immunoglobulin deposition disease, and nephrotic range proteinuria), nervous system (peripheral neuropathy, autonomic dysfunction), cardiovascular (restrictive cardiomyopathy), and/or the endocrine systems. There may be overlap of symptoms, but understanding the various syndromes is important in helping to arrive at the correct diagnosis.

Differential Diagnosis of Monoclonal Gammopathy (Table 95.2)

The majority of non-IgM monoclonal gammopathies are initially classified as MGUS.[10] In most MGUS patients the M-protein is a complete immunoglobulin molecule; however, some may have only light chain and therefore are classified as light chain MGUS.[2] MGUS patients do not have any symptoms or laboratory abnormalities attributable to the underlying clonal plasma cell disorder; specifically, they do not have anemia, hypercalcemia, renal insufficiency, or disease-associated bone disease. They should have less than 3 g/dl of monoclonal protein and less than 10% bone marrow plasma cell. Patients with similarly minimal clinical sequelae and an M-protein ≥ 3gm/dl or ≥ 10% clonal bone marrow plasma

cell are classified as having SMM.[65] Distinguishing between MGUS and SMM has prognostic significance and will determine frequency of follow-up. As bone marrow examination may be the only factor that will upgrade an MGUS to SMM, this must be strongly considered in the evaluation of all monoclonal gammopathies. Neither MGUS nor SMM require therapeutic intervention; patients with MGUS have a lower risk of progression to MM at about 1% per year, compared to 10% to 20% in patients with SMM. Closer follow-up is needed for SMM compared to MGUS.[10]

Patients with myeloma should meet the CRAB criteria, defined as hypercalcemia, renal insufficiency, anemia, or bone disease.[66] It is necessary to confirm that these complications are due to the underlying clonal plasma cell disorder. These patients do require therapy and should be under the care of a specialist with detailed knowledge of the management of multiple myeloma and associated complications. Solitary plasmacytomas should also be recognized, since these require only limited therapy.[56] These patients have a single bone or soft tissue mass, a negative bone marrow biopsy, and do not meet the CRAB criteria. Local therapy such as radiation, cryotherapy, or surgical excision is usually all that is required.[67] They do have a better prognosis.

A significant number of patients with monoclonal gammopathy develop complications as a result of the toxic effect of the monoclonal protein. In amyloidosis, misfolding of the monoclonal protein, usually the light chain component, results in the formation of insoluble amyloid deposits in major organs of the body.[12,31,47] This deposition results in structural and physiologic dysfunction of the affected organ. An amyloid diagnosis is easy to make when presenting with macroglossia in association with periorbital purpura.[68] Most, however, will present with symptoms secondary to the organ involvement, such as chest pain and shortness of breath due to restrictive cardiomyopathy in cardiac cases, and peripheral neuropathy and autonomic dysfunction in nervous system disease. Nonselective proteinuria with hypoalbuminemia is seen in kidney involvement. Hepatomegaly with elevated alkaline phosphates will be seen in those with liver disease, and those with gastrointestinal involvement will have constipation or diarrhea. Patients may present with multiple organ involvement, causing a protean constellation of findings; in such cases a strong suspicion of amyloidosis is required in order not to miss the diagnosis.

Nonamyloidotic immunoglobulin deposition diseases such as light chain deposition diseases are a group of conditions that should be considered during the evaluation of monoclonal gammopathy.[69] This involves the deposition of light chains in the kidney or heart. Renal involvement presenting with renal failure with some proteinuria is the most common.[64] Heart involvement, although not common, does occur, presenting with restrictive cardiomyopathy, and should be differentiated from amyloidosis.[70]

IgM monoclonal gammopathy is usually associated with an underlying B cell lymphoproliferative disorder, and true IgM myeloma is exceedingly rare.[13] A large percentage of these IgM monoclonal gammopathy patients will have an IgM MGUS or Waldenström macroglobulinemia.[59,71] The remainder often has a variety of other B cell lymphoproliferative diseases such as chronic lymphocytic leukemia, marginal zone lymphoma, and large cell lymphoma.[8] Those with Waldenström macroglobulinemia may present with cytopenias, hyperviscosity syndrome, epistaxis, lymphadenopathy, and splenomegaly.[35,61,72]

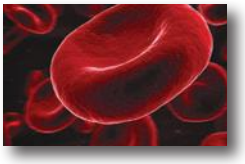
There are other rare monoclonal gammopathy associated conditions that should be considered during the evaluation of a monoclonal protein. The evaluation in these cases is usually dictated by the clinical presentation; for example, those with neuromuscular complications should be evaluated for conditions such as POEMS syndrome, the antimyelin associated glycoprotein–associated neuropathy, or sporadic late onset nemaline myopathy.[11,73,74] POEMS patients, in addition to the neuropathy, do have organomegaly (lymphadenopathy, splenomegaly, cardiomegaly, and hepatomegaly), multiple endocrine dysfunction, and skin changes (glomeruloid hemangiomata, hyperpigmentation). Almost all POEMS patients do have a λ-light chain restricted monoclonal protein, and it may be a non-IgM or IgM monoclonal protein. If a patient has a κ-light chain monoclonal protein, they most probably do not have POEMS syndrome.

Skin conditions such as scleromyxedema, necrobiotic xanthogranuloma, and cryoglobulinemia should be considered in the differential diagnosis when patients present with cutaneous lesions.[7,62,75–78]

Summary and Recommendations

The diagnostic approach to monoclonal gammopathy should be thorough and involve a detailed history, physical examination, appropriate laboratory testing, and imaging. This should distinguish benign from clinically relevant conditions that need immediate intervention. A good understanding of conditions associated with monoclonal gammopathy is essential. Testing and evaluation should include the following considerations.

- Serum and urine protein electrophoresis, followed by immunofixation will confirm the presence of the monoclonal protein, identify and classify the isotype, and provide an estimation of the amount. Immunoglobulin free light assay will help identify cases with only free light chain production, but negative protein electrophoresis.
- Immunoglobulin isotype quantification is helpful for monitoring.
- A bone marrow evaluation will determine the nature of the underlying B-lineage disorder (plasma cell or lymphoproliferative) and also the extent of marrow infiltration.
- Complete blood count analysis will identify cytopenias which may be due to bone marrow replacement or immune mediated causes.
- Comprehensive metabolic panel, looking at serum calcium, creatinine, bilirubin, lactate dehydrogenase, and liver transaminases is essential.
- Bone and soft tissue imaging, looking for bony lesion and soft tissue masses such as lymphadenopathy or plasmacytoma is also needed.
- A detailed history and physical evaluation should help direct further testing.



CHAPTER 96

MOLECULAR GENETIC ASPECTS OF PLASMA CELL DISORDERS

P. Leif Bergsagel, A. Keith Stewart, Stephen J. Russell, Rafael Fonseca

INTRODUCTION

Multiple myeloma (MM) is an age-dependent monoclonal tumor of bone marrow (BM) plasma cells (PCs), often with significant end organ damage that can include lytic bone lesions, anemia, loss of kidney function, immunodeficiency, and amyloid deposits in various tissues.[1] It has an estimated incidence of 21,700 in 2012, with 10,710 deaths in the United States.[2] Despite recent therapeutic advances, MM continues to be a mostly incurable disease but with a 5-year survival rate reported in the SEER database that has increased from 28% (1987 to 1989) to 43% (2002 to 2008).[3] In fact, a subset of younger patients initially treated in 1999 can be identified with a 10-year survival rate of 75%,[4] with presumably even better results possible for patients starting treatment today. The incidence is higher in blacks than whites, and in men than women (Fig. 96.1),[3] and it is evident from the SEER registry data that although the incidence of MM continues to rise with an annual percentage change of close to 1%, since 1995 the mortality rate has been decreasing at an even faster rate. MM cells are similar to postgerminal center (GC) long-lived PCs, characterized by strong BM dependence, extensive somatic hypermutation (SHM) of immunoglobulin (Ig) genes, and absence of IgM expression in all but 1% of tumors.[5] However, MM cells differ from healthy PCs because they retain the potential for a low rate of proliferation (1% to 3% of cycling cells). MM has served as a useful model for understanding the pathogenesis of lymphoid tumors because it is characterized by the presence of a premalignant precursor tumor and defined stages, with researchers able to isolate purified tumor cell populations at all stages.

MULTIPLE MYELOMA IS A PLASMA CELL TUMOR OF POSTGERMINAL CENTER B CELLS

Pre-GC B cells can generate short-lived PC that mostly remain in the primary lymphoid tissue (Fig. 96.2). Post-GC B cells can generate plasmablasts (PB) that have successfully completed multiple rounds of SHM and antigen selection, followed by IgH switch recombination, with both B cell–specific DNA modification processes having oncogenic potential.[6] These PB typically migrate to the BM, where stromal cells facilitate terminal differentiation into long-lived PC.[7] The surface immunophenotype of normal BM PCs is $CD38^{+}CD138^{+}$ $CD19^{+}CD45^{+}CD56^{-}$. Although monoclonal gammopathy of undetermined significance (MGUS), SMM, and MM tumor cells also are $CD38^{+}CD138^{+}$, 90% are $CD19^{-}$, 99% are $CD45^{-}$ or dim, and 70% are $CD56^{+}$.[8,9] The reason for this immunophenotypic difference is not known. Possibly there is a normal PC with an MM phenotype, but it is rare, and/or transient, and it has yet to be identified. Alternatively, the change in the phenotype may be a consequence of the transformation process.

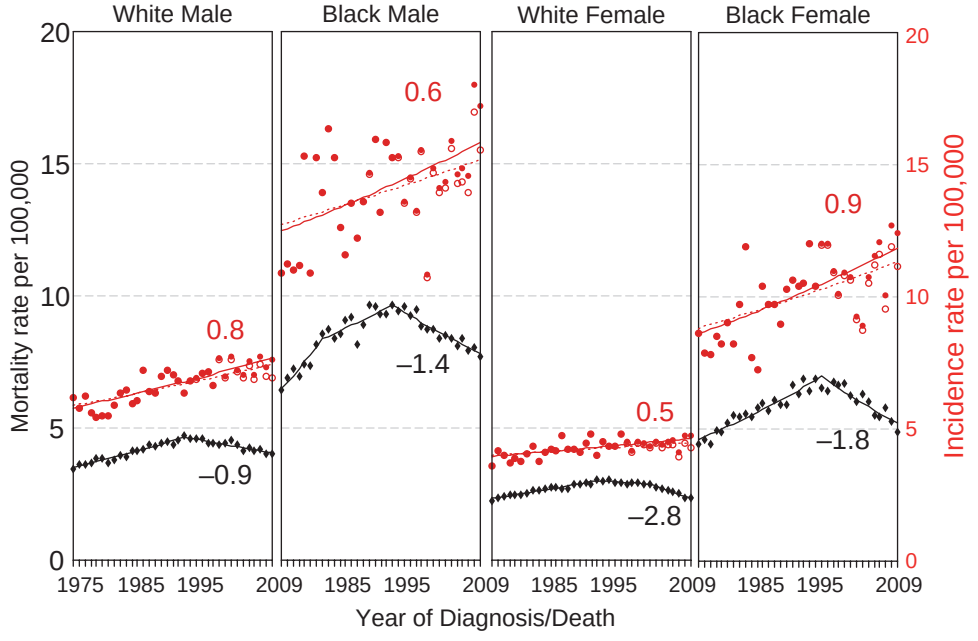


FIGURE 96.1. Differences in US incidence and mortality rates over time, by race and gender. Source is the SEER 9 areas and US mortality files. The most recent annual percentage change for each rate is indicated adjacent to the respective regression line.

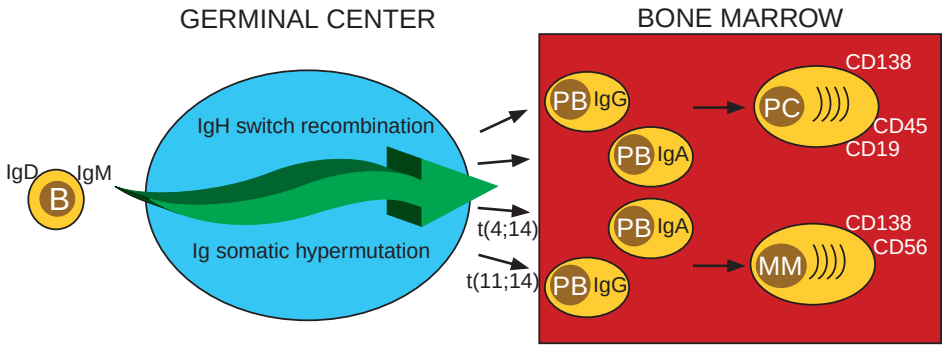

FIGURE 96.2. Normal and malignant plasma cell development. Pre-germinal center (GC) B cells expressing surface immunoglobulin can enter germinal centers where the immunoglobulin genes undergo repeated rounds of somatic hypermutation followed by IgH isotype switch recombination. In multiple myeloma (MM), IgH translocations occur as a result of errors in these two physiologic DNA modification processes (10% and 90%, respectively). Post-GC B cells can generate plasmablast that homes to the bone marrow where stromal cells facilitate differentiation into long-lived PC. Normal plasma cell (PC) express surface CD138, CD19, and CD45; whereas MM cells express CD138, only 10% express CD19, 99% are CD45$^-$ or dim, and 70% express CD56. Ig, immunoglobulin; PB, plasmablasts.

MULTIPLE MYELOMA IS ALMOST ALWAYS PRECEDED BY AN ASYMPTOMATIC MONOCLONAL GAMMOPATHY

An age-dependent premalignant tumor called monoclonal gammopathy of undetermined significance (MGUS)[10,11] is present in about 4% of individuals over the age of 50[12,13] and precedes almost every case of MM. A PC tumor must contain at least a billion cells to produce enough monoclonal Ig (M-Ig) or M-IgL (in the 15% of tumors that produce only IgL) to be detected by serum or urine electrophoresis or a serum–free IgL assay. It can be subclassified as lymphoid (15%) or PC (85%) MGUS, which can progress sporadically at average rates of 1% per year to chronic lymphocytic leukemia/lymphoma/lymphoplasmacytoma/Waldenstrom's macroglobulinemia and MM, respectively.[14] Lymphoid MGUS and PC MGUS can be distinguished by morphology, although clinically the distinction is primarily based on the type of M-Ig detected in serum or urine: mostly IgM for lymphoid MGUS and mostly non-IgM (including Ig light chain only) for PC MGUS. MGUS is distinguished from MM by having a M-Ig of <30 g/L, with no more than 10% of BM mononuclear cells being tumor cells, and no end organ damage or other symptoms. In primary amyloidosis (AL) there is a monoclonal gammopathy which is symptomatic because of pathologic deposits of intact or portions of M-Ig in various tissues.[15] Unfortunately, the pathologic deposits can lead to organ failure, so that the median survival of patients with AL is only 3 years, even with a very small number of premalignant tumor cells.[16] Progression of MGUS to smoldering MM and symptomatic MM is associated with an expanding BM tumor mass and increasingly severe organ impairment or symptoms.[1] Despite BM dependence, sometimes the tumor extends to extramedullary locations, such as spleen, liver, and extracellular spaces. *Extramedullary* MM (EMM) typically is a more aggressive tumor that sometimes is associated with secondary or primary *plasma cell leukemia* (PCL), depending on whether or not preceding intramedullary MM was recognized. Human MM cell lines (HMCLs), which provide a renewable repository of most oncogenic events involved in initiation and progression of the corresponding MM tumor, can sometimes be generated, but usually only from EMM tumors.[17,18]

A SELECTION FOR GENETIC MUTATIONS THAT ALLOW INDEPENDENCE FROM THE BONE MARROW MICROENVIRONMENT

In considering the diverse array of mutations in MM, it is helpful to place their pathways in the context of the biology of normal BM-localized PCs. MGUS and MM cells, similar to long-lived PC, are dependent on the BM microenvironment, which includes the extracellular matrix and many kinds of cells, e.g., stromal cells, osteoclasts, osteoblasts, immune cells (T lymphocytes, dendritic cells), other hematopoietic cells, and their precursors, vascular endothelial cells.[5,19,20] These cells mediate reciprocal positive and negative interactions by a variety of adhesion molecules, cytokines, and receptors. Additional stimuli such as hypoxia result in activation of HIF1-α and secretion of VEGF.[21] For MM, there are several biologic phenomena that are affected by these tumor–host interactions, including differentiation, and proliferation of tumor cells (most notably IL-6, IGF-1, APRIL); homing to BM; spread to secondary BM sites by the blood stream; generation of many paracrine factors that are involved in survival; angiogenesis; osteoclastogenesis; inhibition of osteogenesis; enhanced resistance to chemotherapeutic agents; humoral and cellular immunodeficiency; and anemia. Many of these tumor–host interactions (e.g., homing, differentiation, and survival) appear to be qualitatively similar for PC and MM tumor cells, whereas the altered composition of the BM microenvironment represents a pathologic response to the MGUS and MM tumor cells. Several therapies (IMiDs, proteasome inhibitors) might target not only the tumor cell but also its interaction with the BM microenvironment. Several of the secondary genetic events associated with the progression of MM discussed below constitutively activate the pathways implicated downstream of the interaction of the MM cell with the BM microenvironment.[22,23]

Seven Primary IgH Translocations Are an Early Oncogenic Event in Monoclonal Gammopathy of Undetermined Significance and Multiple Myeloma

Like other B cell tumors, translocations involving the IgH locus (14q32) or one of the IgL loci (κ, 2p12, orλ, 22q11) are common in MM. It seems likely that these events are mediated by errors in IgH switch recombination, or SHM, since the breakpoints are usually located near or within IgH switch regions, but sometimes near VDJ sequences.[24] Since there is no evidence that IgH switch recombination or SHM mechanisms are active in normal PC or PC tumors, it is presumed that these translocations usually represent primary—perhaps initiating—oncogenic events as normal B cells pass through GCs. The translocations result in dysregulated or increased expression of an oncogene that is positioned near one or more of the strong Ig enhancers. However, translocations involving an IgH switch region uniquely dissociate the intronic from one or both 3′ IgH enhancers, so that an oncogene might be juxtaposed to an IgH enhancer on either or both of the derivative chromosomes, as first demonstrated for FGFR3 on der(14) and

MMSET on der(4) in MM. Rarely, tumors can have translocations involving two of the primary translocation groups, suggesting that there can be some complementation.[18]

These IgH translocations are efficiently detected by fluorescent in situ hybridization analyses. Large studies from several groups show that the prevalence of IgH translocations increases with disease stage: about 50% in MGUS or SMM, 55% to 70% for intramedullary MM, 85% in PCL, and >90% in HMCL.[25,26] Limited studies indicate that IgL translocations are present in about 10% of MGUS/SMM tumors, and about 15% to 20% of intramedullary MM tumors and HMCL.[18] Translocations involving an IgK locus are rare, occurring in only 1% to 2% of MM tumors and HMCL.[18]

There are three recurrent primary IgH translocation groups, with the chromosomal sites, target oncogenes, and approximate prevalence in MM (~40% prevalence for all three groups) as follows: *CYCLIN D* (11q13-*CYCLIN D1*-15%; 12p13-*CYCLIN D2*- < 1%; 6p25-*CYCLIN D3*-2%) MAF (16q23-*MAF*-5%; 20q12-*MAFB*-2%; 8q24.3-*MAFA*-< 1%; MMSET/(FGFR3)-4p16-(*MMSET* in all but also *FGFR3* in 80% of these tumors)-15%.

Chromosome Content Is Associated with at Least Two Different Oncogenic Pathways

There is a consensus that chromosome content reflects at least two pathways of pathogenesis. Nearly half of MGUS and MM tumors are hyperdiploid (HRD), with 48 to 75 (mostly 49 to 56) chromosomes, usually with extra copies of three or more specific chromosomes (3,5,7,9,11,15,19,21). Nonhyperdiploid (NHRD) tumors have <48 and/or >75 chromosomes. Strikingly, HRD tumors rarely (~10%) have a primary IgH translocation, whereas NHRD tumors usually (~70%) have an IgH translocation.[27] Tumors with a t(11;14) may represent a distinct category of NHRD tumors as they often are diploid or pseudodiploid. Curiously, EMM tumors and HMCLs nearly always have a NHRD genotype, suggesting that HRD tumors are more stromal cell dependent than NHRD tumors. Although it has been proposed that NHRD and HRD tumors represent different pathways of pathogenesis, the timing, mechanism, and molecular consequences of hyperdiploidy is unknown. Interestingly, in patients with t(4;14) or t(14;16) or t(14;20) or del17p, the presence of one or more trisomies is associated with a substantially better prognosis than with the absence of trisomies. This suggests that the phenotype associated with trisomies may be dominant.[28]

Universal Cyclin D Dysregulation

Almost all cases of PC neoplasms starting from the MGUS stage express 1 or more of the CYCLIN D genes in an aberrant fashion, despite a low proliferation index.[29] Therefore, it has been proposed that dysregulation of a CYCLIN D gene provides a unifying, early oncogenic event in MGUS and MM. MGUS and MM appear closer to normal, nonproliferating PCs than to normal proliferating PB, for which 30% or more of the cells can be in S phase; yet the expression level of CYCLIN D1, CYCLIN D2, or CYCLIN D3 mRNA in MM and MGUS is distinctly higher than in normal PCs. This can be due to direct dysregulation in MM tumors with a CYCLIN D gene translocation or indirectly in tumors with a translocation of MAF, encoding a transcription factor that markedly upregulates CYCLIN D2. Although MMSET/FGFR3 tumors express moderately high levels of CYCLIN D2, the cause of increased CYCLIN D2 expression remains unknown. While normal BM PC express little or no detectable CYCLIN D1, the majority of HRD tumors express CYCLIN D1 biallelically, whereas most other tumors express increased levels of CYCLIN D2 compared to normal BM PC, both by unknown mechanisms. Only a few percent of MM tumors do not express increased levels of a CYCLIN D gene compared to normal PC, but many of these tumors appear to represent samples that are substantially contaminated by normal cells and another large fraction of these tumors often have inactivated RB1, the inhibitor downstream of CYCLIN D, eliminating the necessity of overexpressing a CYCLIN D gene.

Primary IgH Translocations

It is thought that CYCLIN D translocations only dysregulate expression of a CYCLIN D gene. By contrast, MAF translocations dysregulate expression of a MAF transcription factor that causes increased expression of many genes, including CYCLIN D2 and adhesion molecules that are thought to enhance the ability of the tumor cell to interact with the BM microenvironment.[29,30] The contributions of the two genes dysregulated by t(4;14) remain controversial. MMSET is a chromatin-remodeling factor that is overexpressed in all tumors with a t(4;14), whereas about 20% of tumors lack der(14) and FGFR3 expression. The rare acquisition of FGFR3 activating mutations during progression confirms a role for FGFR3 in MM pathogenesis. Although an activated mutant FGFR3 can be oncogenic, it recently was shown that wild-type FGFR3 (as is found in most t[4;14]) can contribute to B cell oncogenesis.[31] It remains to be determined if FGFR3 is critical early in pathogenesis but becomes dispensable during progression of t(4;14) MM. Preclinical studies suggest that tyrosine kinase inhibitors are active only against t(4;14) HMCL with activating mutations of FGFR3, whereas anti-FGFR3 monoclonal antibodies that inhibit FGFR3 signaling but also elicit antibody-dependent cell-mediated cytotoxicity are active against HMCLs expressing wild-type FGFR3.[32,33] Despite an apparently indispensable role in t(4;14) MM, it remains to be determined how MMSET, which sometimes has amino-terminal truncations caused by the translocation, contributes to MM pathogenesis. There are some clues. It is a histone methyltransferase for H3K36me2, and when overexpressed it results in a global increase in H3K36 methylation, and a decrease in H3K27 methylation, which might explain some of the many changes in gene expression associated with t(4;14) tumors.[29,34,35,36] In addition, it recently has been determined that MMSET has a role in DNA repair (Fig. 96.3). Following DNA damage *MMSET* is phosphorylated on Ser102 by *ATM* and is recruited to sites of double strand breaks (DSBs), where it results in methylation of H4K20, which is required for recruitment of p53 binding protein (*53BP1*). *53BP1* is required for p53 accumulation, G2/M checkpoint arrest, and the intra-S–phase checkpoint in response to ionizing radiation. Approximately half of the translocation breakpoints in t(4;14) MM result in a truncated *MMSET* that lacks Ser102 and cannot be recruited to DSBs, resulting in a failure to recruit *53BP1* and a loss of the normal DNA damage response pathway. It is not known whether this biologic difference results in a different clinical outcome for t(4;14) MM patients with a truncated versus full-length *MMSET*.[37] Importantly, loss of MMSET expression alters adhesion, suppresses growth, and results in apoptosis of HMCLs, suggesting that it is an attractive therapeutic target.[35]

Molecular Classification of Multiple Myeloma

The patterns of spiked expression of genes deregulated by primary *IGH@* translocations and the universal overexpression of *CCNDs* genes either by these translocations or other mechanisms led to the translocations and cyclin D (TC) classification that includes eight groups: those with primary translocations (designated 4p16, 11q13, 6p21, MAF), those that overexpressed *CCND1* and *CCND2* either alone or in combination (D1, D1 & D2, D2), and the rare cases that do not overexpress any CCND genes ("none") (Table 96.1).[29] Greater than 95% of the D1 group are HRD. In addition, most of the patients with HRD MM and trisomy 11 fall within the D1 and D1 & D2 groups, while those without trisomy 11 fall within the D2 group, although a majority of the D2 group are NHRD. This classification system therefore focuses on the different kinds of mechanisms that dysregulate a *CCND* gene as an early and unifying event in pathogenesis.

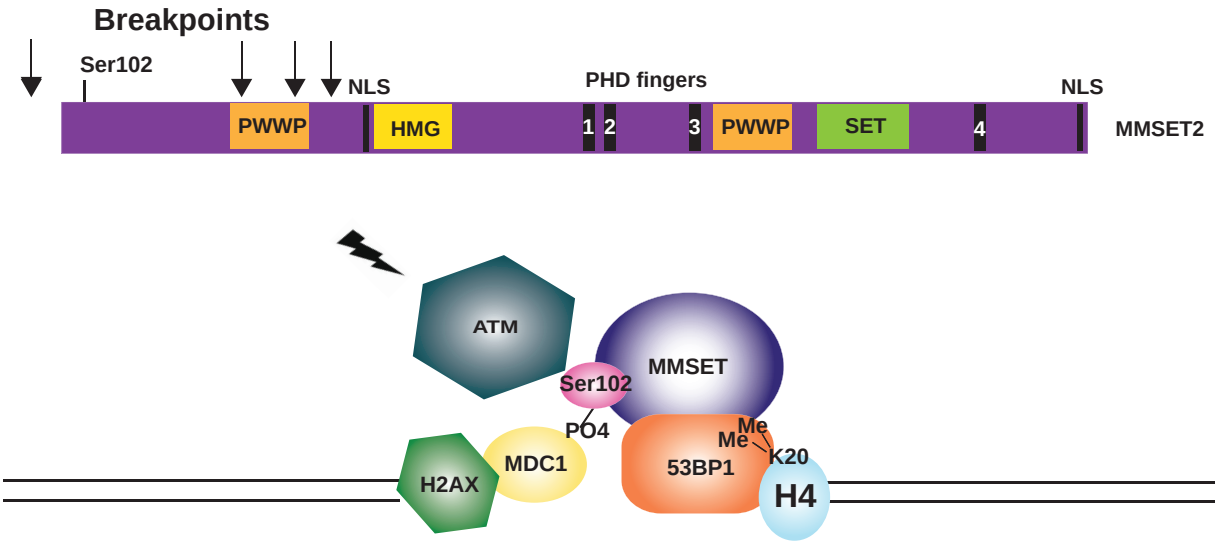

FIGURE 96.3. MMSET is involved in DNA repair. An ideogram of MMSET highlights the important functional domains of the protein, with *arrows* indicating the initiation of translation of the truncated forms, lacking Ser102, that result from translocation breakpoints in between the coding exons. Following DNA damage MMSET is phosphorylated on Ser102 by ATM and is recruited to sites of double strand breaks by MDC1, where it methylates H4K20. Dimethylation of H4K20 recruits p53-binding protein (53BP1), a key transducer of the DNA damage checkpoint signal.

An MM classification based on an unsupervised analysis of microarray gene expression profiling from the UAMS identified seven tumor groups characterized by the coexpression of unique gene clusters.[38] This classification was partially replicated in an independent unsupervised analysis of a combined HOVON-GMMG dataset that identified 10 tumor groups with considerable overlap with the UAMS groups.[39] Interestingly, these clusters also identify subgroups corresponding to the different primary translocations and hyperdiploidy. Importantly, however, they also highlight other important secondary events that can occur in each subtype of MM: proliferation (PR), expression of NF*k*B target genes (NF*k*B), cancer-testis antigens, and the phosphatase *PTP4A3/PRL3* (PRL3). The CD-1 and CD-2 groups represent subgroups of patients with t(11;14) and t(6;14), with the former characterized by arginosuccinate synthetase 1 expression, and the latter by expression of B cell antigens (CD20, VPREB, CD79A). Interestingly, they identify patients with markedly different clinical outcomes. Of all the molecular subgroups, CD-1 has the quickest onset and highest frequency of CR (90%), whereas CD-2 has the slowest onset and lowest frequency of CR (45%), when treated with Total Therapy 3. However, after the MF, the CD-1 has the shortest CR duration (77% at 2 years), whereas the CD-2 has the longest (100% at 2 years).[40]

Additional Oncogenic Events in Monoclonal Gammopathy of Undetermined Significance and Multiple Myeloma

MYC Dysregulation

There is increased expression of c-*MYC* in most newly diagnosed MM tumors compared to MGUS tumors.[41] Recently, it was shown that sporadic activation of a *MYC* transgene in GC B cells in an MGUS-prone mouse strain led to the universal development of MM tumors.[42,43] Hence, increased *MYC* expression seems to be responsible for progression from MGUS to MM. Complex translocations involving *MYC* (c-*MYC*>>N-*MYC*>L-*MYC*) appear to be secondary progression events that often do not involve Ig loci.[44] They are rare or absent in MGUS, but occur in 15% of newly diagnosed tumors, 50% of advanced tumors, and 90% of HMCLs.[18,45] A recent report suggests that a small molecule inhibitor of BRD4 can inhibit *MYC* RNA expression in MM, with therapeutic effect.[46]

TABLE 96.1

COMPARISON OF DIFFERENT MOLECULAR CLASSIFICATIONS IN MULTIPLE MYELOMA

Group	TC	Gene	%	CYCLIN D	UAMS	HOVON-GMMG
Cyclin D translocation	11q13	CCND1	15	CYCLIN D1	CD-1 CD-2	CD-1 CD-2
	12p13	CCND2	<1	CYCLIN D2		
	6p25	CCND3	2	CYCLIN D3		
MAF translocation	16q23	MAF	5	CYCLIN D2	MF	MF
	20q12	MAFB	2	CYCLIN D2		
	8q24	MAFA	<1	CYCLIN D2		
MMSET translocation	4p16	MMSET/FGFR3	15	CYCLIN D2	MS	MS
Hyperdiploid with trisomy 11	D1		33	CYCLIN D1	HY	HY CD-1 NFκB CTA PRL3
	D1 + D2		7	CYCLIN D1 & D2	PR	PR CTA
Hyperdiploid without trisomy 11 and others	D2		18	CYCLIN D2	LB	LB CTA PRL3
Other	None	RB1 biallelic deletion	2	No CYCLIN D	PR	PR CTA

Chromosome 13 Deletion

A recent study concludes that chromosome 13 deletion can be an early event in MGUS (e.g., in *MAF*, *MMSET* tumors) or a progression event (e.g., in t(11;14) tumors).[47] The pathogenic effect of this chromosome deletion is unknown, though it is possible that haploinsufficiency of *RB1* promotes tumorigenesis.[25] A recent genome-wide sequencing study identified mutations of DIS3, a gene of unknown function on 13q, in about 10% of MM. Although only very few mutations have been reported to date, it has been suggested that DIS3 mutations occur in parallel with deletions of RB1,[48] suggesting a possible dependence between these two events.

Activating Mutations of RAS and BRAF

The prevalence of activating *NRAS* or *KRAS* mutations is about 15% to 18% each in newly diagnosed and relapsed MM tumors,[25,49] but substantially higher in tumors that express CCND1 compared to tumors that express *CCND2*. For MGUS tumors, the prevalence of *NRAS* mutations is 7%, but *KRAS* mutations have not been described.[14] This is consistent with increasing evidence that *NRAS* and *KRAS* mutations have overlapping but nonidentical effects,[50] and also with the hypothesis that *KRAS* mutations provide a molecular mark of the transition of MGUS to MM.[51,52] MM tumors depend on the continued expression of activated but not wild-type *RAS*.[53] Recently, *BRAF* mutations were described in 4% of MM tumors, suggesting a possible role for BRAF inhibitors in these cases.[54]

Mutations that Activate the NFkB Pathway

Extrinsic ligands (APRIL and BAFF) produced by BM stromal cells provide critical survival signals to long-lived PCs by stimulating TACI, BCMA, and BAFF receptors to activate the NF*k*B pathways.[55] Most MGUS and MM tumors highly express NF*k*B target genes, suggesting a continued role of extrinsic signaling in PC tumors.[56,57] Activating mutations in positive regulators and inactivating mutations in negative regulators of the NFκB pathway have been identified in at least 20% of untreated MM tumors and ~50% of HMCLs, rendering the cells less dependent on ligand-mediated NF*k*B activation (Fig. 96.4).[54] Small molecules that inhibit extrinsic signaling (including TACI.Fc, IKKβ, and NIK [MAP3K14]) are being developed as potential therapeutic agents.[58,59] There also is some evidence suggesting that cells addicted to constitutive NF*k*B activation may be particularly sensitive to proteasome inhibition.[57]

Chromosome 17p Loss and Abnormalities of TP53

Deletions that include the *TP53* locus occur in ~10% of untreated MM tumors, and the prevalence increases with disease stage.[25,60] *TP53* mutations were present in 37% of untreated MM tumors with del17p, but not in patients without del17p.[61] It remains to be determined if the poor prognosis associated with monoallelic del17p but no *TP53* mutation is due to haploinsufficiency or to predisposition to complete inactivation of TP53 that is selected for with tumor progression. Recently, decreased expression of microRNAs miR-199, -192, and -215 in MM was reported to increase MDM2, an inhibitor of *TP53*.[62]

Gain of Chromosome 1q and Loss of Chromosome 1p

These genomic events frequently occur together in MM, and each is associated with a poor prognosis.[25,63] The relevant genes on 1q are unclear at this time. By contrast, there are potential targets on two regions of 1p that are associated with a poor prognosis: *CDKN2C* (p18INK4c) at 1p32.3, and *FAM46C* at 1p12.[64,65] Homozygous deletion of *CDKN2C*, which is present in about 30% of HMCL and about 5% of untreated MM tumors, is associated

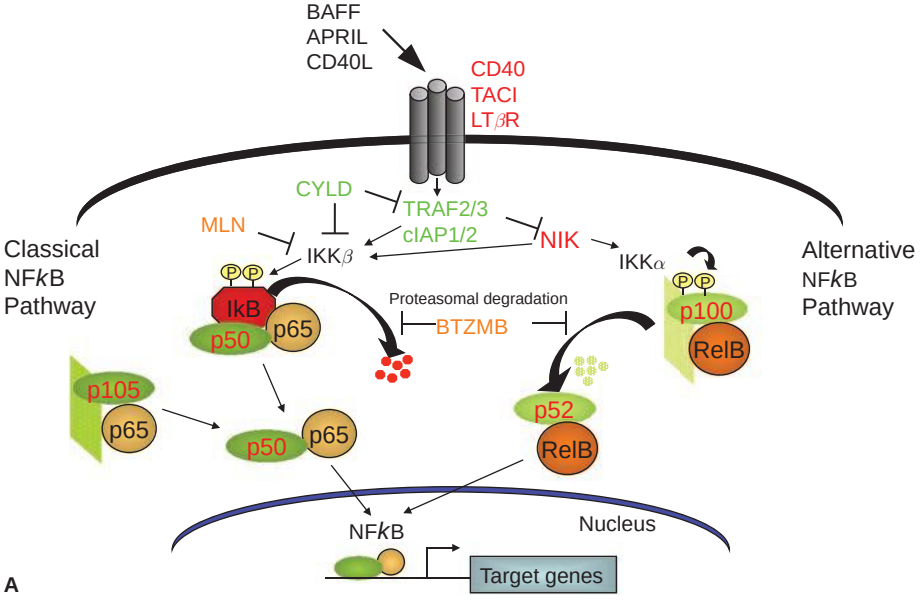

FIGURE 96.4. Role of NFκB pathway in normal plasma cell (PC), monoclonal gammopathy of undetermined significance (MGUS), and multiple myeloma (MM). **A:** Molecular components and processing events for the classical and alternative NF*k*B pathways are depicted, both of which result in the translocation of an active NF*k*B transcription factor into the nucleus. Both pathways can be activated by a variety of stimuli, including the interaction of external factors with PC receptors. Positive regulatory proteins (*red*) and negative regulatory proteins (*green*) are targets for mutations that constitutively activate NFκB during the progression of some MM tumors. Bortezomib (BTZMB) may act partially by inhibiting NFκB activity. **B:** Normal PC, as well as most MGUS and MM tumor cells, have a high NFκB index (NFκBi) as a result of bone marrow (BM) stromal cell ligands that stimulate their receptors. Tumors with NFκB mutations generate human MM cell line (HMCL) with a high NFκBi, whereas HMCL from tumors with other kinds of mutations has a low NFκBi. Potential therapeutic agents to block NFκB activation include BCMA-Fc, TACI-Fc, IKKβ inhibitors, and Bortezomib.

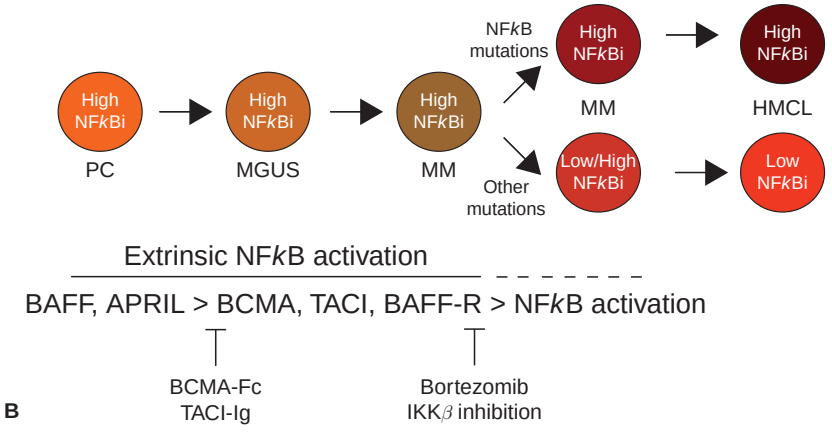

FIGURE 96.4. (continued)

with increased proliferation and a poor prognosis, whereas monoallelic deletion is not. Mutations of *FAM46C*—often with hemizygous deletion—were identified in 3.4% and 13% of MM tumors in two studies, and in 25% of 16 HMCL.[54,64]

Other Pathogenic Events

Secondary Ig translocations, including most IgK and IgL translocations and IgH translocations not involving one of the seven primary partners, can occur at all stages of disease, and with a similar frequency in HRD and NHRD tumors, but apart from MYC, few partner loci have been identified.[18] Other genomic rearrangements are frequent, but only a few specific target genes have been identified.[63,66,67] Changes in DNA methylation are frequent, with one study suggesting that a marked increase in hypomethylation is associated with the MGUS to MM transition,[68] whereas a second study suggests only a small increase in hypomethylation for MM compared to MGUS.[69] Mutations in seven genes regulating RNA metabolism, protein translation, and homeostasis were identified in 16 of 38 patients.[54] In addition to previous studies implicating roles for *MMSET* and *KDM6A* (UTX), genomic sequencing studies found that other histone-modifying enzymes are frequent targets of mutation, although the epigenetic consequences are unknown.[54] Similarly, changes in microRNA expression at different stages have been identified, but more extensive studies are needed.[62,70]

Intraclonal Tumor Heterogeneity Associated with High-risk Multiple Myeloma

Although the evidence is still emerging, it appears that many of the genetic events in MM are secondary and often present only in subclones of the tumor population.[48,67,71] Recently, a high level of intraclonal tumor heterogeneity has been described in some patients with high-risk MM[48,67,71] associated in one case with alternating clonal dominance under therapeutic selective pressure, observations with important clinical implications. The findings suggest a competition between subclones for limited resources and raise the possibility that early, suboptimal treatment may eradicate the "good" drug-sensitive clone, making room for the "bad" drug-resistant clone to expand. They support the use of aggressive multidrug combination approaches for high-risk disease with unstable genomes and clonal heterogeneity, and sequential one- or two-drug approaches for low-risk disease with stable genomes and lacking clonal heterogeneity.

CONCLUSION

Significant progress has been made in understanding the molecular pathogenesis and biology of MM (Fig. 96.5). Oncogenic pathways can be activated through cell intrinsic or extrinsic mechanisms. Similar to other cancers, MM is characterized by multistage accumulation of genetic abnormalities deregulating different pathways. Much of this knowledge is already being utilized for diagnosis, prognosis, and risk-stratification of patients. Importantly, from a clinical standpoint, this knowledge has led to development of novel therapeutic strategies, some of which are already in clinical use, and many others showing promise in preclinical and early clinical studies.

CHAPTER 97

MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE AND SMOLDERING MULTIPLE MYELOMA

S. Vincent Rajkumar, Robert A. Kyle, John A. Lust

INTRODUCTION

Nomenclature

Monoclonal gammopathy of undetermined significance (MGUS) is an asymptomatic, pre-malignant clonal plasma cell proliferative disorder.[1–4] It was initially referred to as *essential hyperglobulinemia* by Jan Waldenström, as well as several other terms such as benign, idiopathic, asymptomatic, nonmyelomatous, discrete, cryptogenic, and rudimentary monoclonal gammopathy; dysimmunoglobulinemia; lanthanic monoclonal gammopathy; idiopathic paraproteinemia; and asymptomatic paraimmunoglobulinemia.[5,6] However, because there is an indefinite risk of progression to multiple myeloma (MM) or related disorder such as Waldenström macroglobulinemia (WM) or amyloidosis (AL), the term MGUS is now the accepted nomenclature.[1,2,7,8] Smoldering multiple myeloma (SMM) is a clinically defined pre-malignant stage between MGUS and MM.[9,10] MGUS and SMM must be differentiated from MM, and from a number of related plasma cell disorders using the criteria listed on Table 97.1.[8,11]

Detection of Monoclonal Proteins

Immunoglobulins consist of two heavy polypeptide chains of the same class and subclass and two light polypeptide chains of the same type. The various types of immunoglobulins are designated by capital letters that correspond to the isotype of their heavy chains, which are designated by Greek letters: gamma (γ) constitutes immunoglobulin G (IgG), alpha (α) is found in IgA, mu (μ) is present in IgM, delta (δ) occurs in IgD, and IgE is characterized by epsilon (ε). IgG1, IgG2, IgG3, and IgG4 are the subclasses of IgG; the subclasses of IgA are IgA1 and IgA2. Kappa (κ) and lambda (λ) are the two types of light chains. An intact immunoglobulin consists of two heavy chains of the same class and two light chains of the same type. A monoclonal increase in immunoglobulins results from a clonal process such as MGUS or MM, and a polyclonal increase in immunoglobulins is caused by a reactive or inflammatory process. The monoclonal immunoglobulin secreted by clonal plasma cells in MGUS, SMM, MM, and related monoclonal gammopathies is referred to as a monoclonal protein or M protein.

Electrophoresis and Immunofixation

Monoclonal proteins are detected using agarose gel or capillary electrophoresis of the serum and urine.[12] An M-protein is usually visible as a localized band on protein electrophoresis, and as a tall narrow spike or peak in the β or γ region or, rarely, in the α2-globulin area of the densitometer tracing (Fig. 97.1A). A polyclonal increase in immunoglobulins produces a broad band or broad-based peak that migrates in the γ region. A suspected M protein on electrophoresis must be confirmed on immunofixation, which also determines the immunoglobulin heavy-chain class and its light chain type.[13] In addition, immunofixation is also done when MM, WM, AL (light chain) amyloidosis, or a related disorder is suspected, because small M proteins may not be detected with electrophoresis alone. Immunofixation is performed using commercial kits or systems such as Sebia, or Pentafix (Fig. 97.1B).

Quantitative Immunoglobulins

In patients with detectable M proteins, another assay that aids in monitoring is quantitation of immunoglobulins performed with a rate nephelometer. It can accurately measure 7S IgM, polymers of IgA, and aggregates of IgG. However, levels of IgM obtained by nephelometry may be 1,000 to 2,000 mg/dl higher than those expected on the basis of the serum protein electrophoretic tracing. The quantitative IgG and IgA levels may be increased similarly.[14]

Serum Free Light Chain Assay

The serum free light chain (FLC) assay (Freelite™, The Binding Site Limited, Birmingham, UK) is an automated nephelometric assay that measures free kappa (κ) and lambda (λ) light chains that are not bound to intact immunoglobulin.[15,16] The normal serum free-κ level is 3.3 to 19.4 mg/L and the normal free-λ level is 5.7 to 26.3 mg/L.[17] The normal ratio for FLC-κ/λ is 0.26 to 1.65. The normal reference range in the FLC assay reflects a higher serum level of free λ light chains than would be expected given the usual κ/λ ratio of 2 for intact immunoglobulins. This occurs because the renal excretion of free κ (which exists usually in a monomeric state) is faster than free λ (which is usually in a dimeric state).[15,16] Patients with a κ/λ FLC ratio <0.26 are considered to have a monoclonal λ free light chain and those with ratios >1.65 are defined as having a monoclonal κ free light chain. If the FLC ratio is >1.65, κ is referred to as the "involved" FLC and λ the "uninvolved" FLC, and vice versa if the ratio is less than 0.26.

The serum FLC assay can be used in place of urine protein electrophoresis and immunofixation in the initial screening algorithm for M proteins. In a study of 428 patients, Katzmann et al. found that urine studies can be eliminated by using the serum FLC assay in combination with the SPEP and immunofixation.[18] However, if a monoclonal plasma cell disorder is identified on screening, a 24-hour urine collection followed by electrophoresis and immunofixation should always be done to aid in the assessment of disease progression and response to therapy over time. In addition to its role as a substitute for urine studies in the screening of plasma cell disorders, the FLC assay is used to predict prognosis in MGUS, SMM, AL, and solitary plasmacytoma.[19–21] In addition, it is also used to monitor oligo-secretory MM, nonsecretory MM, light chain only form of MM, and AL amyloidosis.[16,22,23,24] In order to use the FLC assay to monitor disease progression, the baseline FLC ratio must be abnormal and the involved FLC level $\geq$100 mg/L.[24,25]

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Definition

MGUS is defined by the presence of a serum M protein <3 g/dl, bone marrow plasma cells $<10\%$, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).[26,27] In the case of IgM MGUS, there should be no evidence of

TABLE 97.1

DIAGNOSTIC CRITERIA FOR PLASMA CELL DISORDERS

Disorder	Disease Definition	References
Monoclonal gammopathy of undetermined significance (MGUS)	All three criteria must be met: • Serum monoclonal protein <3 g/dl • Clonal bone marrow plasma cells <10%, and • Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder; or in the case of IgM MGUS no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	(275)
Light chain MGUS	All criteria must be met: • Abnormal FLC ratio (<0.26 or >1.65) • Increased level of the appropriate involved light chain (increased κ FLC in patients with ratio >1.65 and increased λ FLC in patients with ratio <0.26) • No immunoglobulin heavy chain expression on immunofixation • Clonal bone marrow plasma cells <10%, and • Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder; or in the case of IgM MGUS no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	(4)
Smoldering multiple myeloma (also referred to as asymptomatic multiple myeloma)	Both criteria must be met: • Serum monoclonal protein (IgG or IgA) ≥3 g/dl and/or clonal bone marrow plasma cells 10-60%, and • Absence of end organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder	(275)

Multiple myeloma	All three criteria must be met except as noted:
	• Clonal bone marrow plasma cells ≥10%
	• Presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma), and
	• Either ≥60% clonal plasma cells in the marrow or evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically
	  • Hypercalcemia: Serum calcium ≥ 11.5 mg/dl or
	  • Renal insufficiency: Serum creatinine >1.73 mmol/L (or >2 mg/dl) or estimated creatinine clearance less than 40 ml/min
	  • Anemia: Normochromic, normocytic with a hemoglobin value of >2 g/dl below the lower limit of normal or a hemoglobin value <10 g/dl
	  • Bone lesions: Lytic lesions, severe osteopenia or pathologic fractures
		(276, 277)

IgM monoclonal gammopathy of undetermined significance (IgM MGUS)	All three criteria must be met: • Serum IgM monoclonal protein <3 g/dl • Bone marrow lymphoplasmacytic infiltration <10%, and • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	(75, 277–280)
Smoldering Waldenström macroglobulinemia (also referred to as indolent or asymptomatic Waldenström macroglobulinemia)	Both criteria must be met: • Serum IgM monoclonal protein ≥3 g/dl and/or bone marrow lymphoplasmacytic infiltration ≥10%, and • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	(75, 277–281)
Waldenström macroglobulinemia	All criteria must be met: • IgM monoclonal gammopathy (regardless of the size of the M protein), and • ≥10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM^+, $CD5^{+/-}$, $CD10^-$, $CD19^+$, $CD20^+$, $CD23^-$) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma. • Evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder.	(75, 277–280)
Solitary plasmacytoma	All four criteria must be met • Biopsy proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells • Normal bone marrow with no evidence of clonal plasma cells • Normal skeletal survey and MRI of spine and pelvis (except for the primary solitary lesion)	(81, 282)

	• Absence of end organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB) that can be attributed to a lympho-plasma cell proliferative disorder	
Systemic AL amyloidosis	All four criteria must be met: • Presence of an amyloid-related systemic syndrome (such as renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement) • Positive amyloid staining by Congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy) • Evidence that amyloid is light chain related established by direct examination of the amyloid (possibly using mass spectrometry (MS)-based proteomic analysis, or immunoelectron microscopy; note that immunohistochemistry results to type amyloid may be unreliable), and • Evidence of a monoclonal plasma cell proliferative disorder (serum or urine M protein, abnormal free light chain ratio, or clonal plasma cells in the bone marrow). **Note:** Approximately 2–3% of patients with AL amyloidosis will not meet the requirement for evidence of a monoclonal plasma cell disorder listed above; the diagnosis of AL amyloidosis must be made with caution in these patients.	(283)
POEMS syndrome	All four criteria must be met • Polyneuropathy • Monoclonal plasma cell proliferative disorder (almost always λ) • Any one of the following three other major criteria: 1. Sclerotic bone lesions 2. Castleman's disease 3. Elevated levels of vascular endothelial growth factor (VEGF)[a] • Any one of the following six minor criteria 1. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy) 2. Extravascular volume overload (edema, pleural effusion, or ascites) 3. Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, pancreatic)[b] 4. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails) 5. Papilledema 6. Thrombocytosis/polycythemia	(137,284)

FLC, free light chain.

Note: Not every patient meeting the above criteria will have POEMS syndrome; the features should have a temporal relationship to each other and no other attributable cause. Anemia and/or thrombocytopenia are distinctively unusual in this syndrome unless Castleman disease is present.

[a]The source data do not define an optimal cut-off value for considering elevated VEGF level as a major criterion. We suggest that VEGF measured in the serum or plasma should be at least three- to fourfold higher than the normal reference range for the laboratory that is doing the testing to be considered a major criterion

[b]In order to consider endocrinopathy as a minor criterion, an endocrine disorder other than diabetes or hypothyroidism is required inasmuch as these two disorders are common in the general population

Modified from Kyle RA, Rajkumar SV. Criteria for diagnosis, staging, risk stratification and response assessment of multiple myeloma. Leukemia 2009;23:3–9.

lymphadenopathy or organomegaly attributable to the clonal lymphoid/ plasma cell proliferative disorder. A new subtype of MGUS termed light chain MGUS is defined by the presence of an abnormal FLC ratio (<0.26 or >1.65), elevated level of involved FLC, no immunoglobulin heavy chain (IGH) expression on immunofixation, bone marrow plasma cells <10%, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).[4] A diagnosis of MGUS requires exclusion of plasma cell malignancies (MM, solitary plasmacytoma, and WM), monoclonal immunoglobulin deposition disorders (AL, light chain deposition disease), as well as SMM. In addition to these closely related disorders which are unique progression events, MGUS can be associated with a variety of malignant and nonmalignant disorders where the association between the monoclonal process and the associated disorder can vary from a coincidental finding to a direct paraprotein related syndrome.

Epidemiology

Prevalence

MGUS is the most common plasma cell proliferative disorder (Fig. 97.2). The prevalence of MGUS has been estimated in a large population-based study that included 21,463 of the 28,038 enumerated residents (77%) of Olmsted County, Minnesota, who were 50 years or older.[3] MGUS was identified in 694 (3.2%) of these subjects. Age-adjusted rates were greater in men than in women, 4.0% versus 2.7% ($P < 0.001$; Fig. 97.3). The prevalence of MGUS was 5.3% among persons 70 years or older and 7.5% among those 85 years or older. Several other studies have reported similar prevalence estimates (Table 97.2).[28] In addition, approximately 1% of the general population over the age of 50 have light chain MGUS.[4]

The incidence of M proteins is higher in blacks than in whites. In the study by Cohen et al., the prevalence of an M protein was 8.4% in 916 blacks and 3.6% in whites.[29] Landgren et al., in a study of 4 million African American and white males admitted to Veterans Affairs Hospitals, found that the prevalence of MGUS was 0.98% in African Americans and 0.4% in whites.[30] The age-adjusted prevalence ratio of MGUS in African Americans compared with whites was 3.0 (95% confidence interval, 2.7 to 3.3). The increase of MGUS in blacks may be related to genetic or environmental factors. A population-based study found that the increased risk of MGUS seen in African Americans was also seen in blacks in Ghana, suggesting that the racial disparity may be due more to genetic factors.[31] Furthermore, a study of women in the southern part of the United States found that the racial disparity between blacks and whites persisted even after adjusting for socioeconomic status, again suggesting that the differences were more likely genetic rather than environmental.[32]

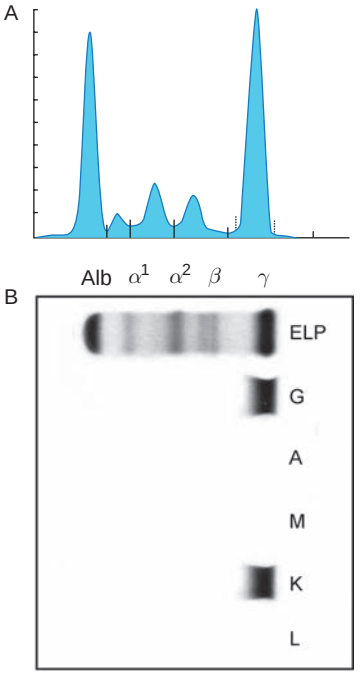

FIGURE 97.1. Monoclonal (M) protein on serum protein electrophoresis. Note tall, narrow-based peak of fast γ mobility **(A)**. Immunofixation of serum with antisera to immunoglobulin G (IgG), IgA, IgM, κ, and λ shows a localized band with IgG and κ, indicating an IgG κ monoclonal protein **(B)**.

One study found that only 2.7% of elderly Japanese patients had a monoclonal gammopathy.[33] A subsequent population-based study in Japan found that the risk of MGUS was lower compared with the white population of Olmsted County.[34]

Incidence

The annual incidence of MGUS in males is estimated to be 120/100,000 at age 50, and rises to 530/100,000 at age 90 years.[35] The rates for women are 60/100,000 at age 50, and 370/100,000 at age 90. The fact that the increased prevalence of MGUS with rising age is not just related to accumulation of new cases but due to an actual increase in incidence suggests that an age-related cumulative damage model is at play in the pathogenesis of MGUS.

Risk Factors

The incidence and prevalence of MGUS rises with age.[3,35] MGUS is also more common in males. Blacks have a higher risk of MGUS than whites as discussed above.[29–32,36] In addition to age, race, and gender, there are other risk factors that have been identified, both genetic and environmental. First-degree relatives of patients with MGUS and MM have a two- to threefold higher risk of MGUS compared to those with no known affected relatives.[37,38,39] Obesity and immunosuppression are also known risk factors for MGUS.[32,40,41]

Pathophysiology

MM is almost always preceded by the asymptomatic premalignant MGUS stage.[42,43] For the screening arm of the nationwide population-based prospective prostate, lung, colon, ovarian (PLCO) cancer screening trial, annual blood samples were collected on 77,469 healthy adults. From this cohort, a joint study by the National Cancer Institute and the Mayo Clinic identified 71 individuals who developed MM during the course of the study. Serial serum samples (up to 6) obtained 2.0 to 9.8 years prior to MM diagnosis were then studied. The study found that an asymptomatic MGUS phase always preceded MM and was found in 100% of cases 6 years prior to MM.[42]

The events responsible for malignant transformation of MGUS to MM or a related plasma cell proliferative disorder are unknown. Genetic changes, bone marrow angiogenesis, various cytokines related to MM bone disease, and infectious agents may play a role in the progression of MGUS to MM or a related disorder.[44,45] However, the specific role of these alterations is not well understood.

Initiation of the Clone

The precise sequence of events that leads to the initiation of the MGUS clone are not known. However, antigenic stimulation and/or immunosuppression are thought to be predisposing factors. Toll-like receptors (TLRs) are normally expressed by B lymphocytes, and are essential for these cells to recognize infectious agents and pathogen-associated molecular patterns (PAMP) which then initiate the host–defense response.[46–48] The aberrant expression of TLRs by plasma cells may be an initiating event that causes these cells to respond abnormally to TLR-specific ligands resulting in increased MM cell proliferation, survival, and resistance to apoptosis, mediated in part by autocrine interleukin-6 (IL-6) production.[46,47]

Immunosuppression may also contribute to the initiation of monoclonal gammopathies inhibiting tumor surveillance. Monoclonal proteins are known to arise in the context of immunosuppressive states such as bone marrow or stem cell transplantation (SCT), organ transplantation, and human immunodeficiency virus (HIV) infection.[40,41,49–51] Moreover, patients undergoing renal transplantation develop monoclonal proteins dependent on the level of immunosuppression to which they are subjected.[41]

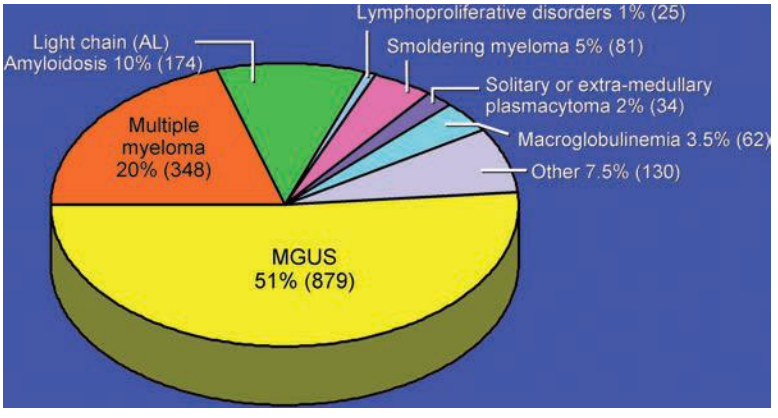

FIGURE 97.2. Distribution of 1,733 cases of monoclonal gammopathy seen at the Mayo Clinic in 2011. MGUS, monoclonal gammopathy of undetermined significance.

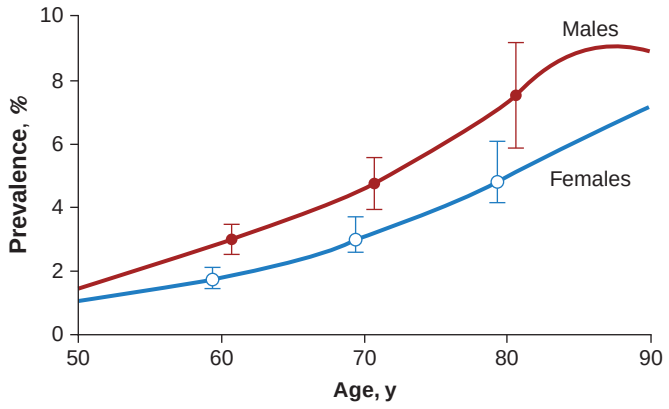

FIGURE 97.3. Prevalence of monoclonal gammopathy of undetermined significance, according to age. Of 21,463 residents 50 years of age or older, 694 had a monoclonal protein. The I bars represent 95% confidence interval. Years of age older than 90 have been condensed to 90 years of age (x-axis). (From Kyle RA, Therneau TM, Rajkumar SV, et al. Prevalence of monoclonal gammopathy of undetermined significance. N Engl J Med 2006;354:1362–1369. Used with permission.)

Cytogenetic Changes

Cytogenetic changes are common in MM and in MGUS. On the basis of fluorescence in situ hybridization studies, almost all patients with MM have either IGH translocations involving chromosome 14q32 or trisomies. These cytogenetic changes referred to as "primary cytogenetic abnormalities" are also are present in MGUS.[52] Thus, approximately 50% of patients with MGUS have primary translocations on chromosome 14q32 (IgH translocated MGUS/SMM).[52,53] The most common partner chromosome loci are 11q13, 4p16.3, 6p21, 16q23, and 20q11.[54,55,56] These translocations lead to the dysregulation of oncogenes such as *CCND1* (cyclin D1) (11q13), *FGFR3/WHSC1* (fibroblastic growth factor receptor 3/Wolf-Hirschhorn syndrome candidate; 4p16.3), *CCND3* (cyclin D3; 6p21), *MAF* (16q23), and *MAFB* (20q11). The dysregulation of these oncogenes is thought to be critical for the initiation of the MGUS clone rather than progression of MGUS to MM. Approximately 40% of patients (40%) with MGUS have trisomies of odd-numbered chromosomes leading to hyperdiploidy (IgH nontranslocated MGUS). In a small subset, there are likely both IgH translocations and trisomies, and in some neither abnormality can be detected.

Deletions of chromosome 13 have been found to have an adverse prognostic value in MM. However, this cytogenetic abnormality occurs early in the disease pathogenesis and present in the MGUS stage.[57,58] Although deletions of chromosome 13 confer an adverse effect on MM, there are no data that the rate of progression from MGUS to MM is accelerated because of this abnormality. *K*- and *N-RAS* mutations and deletion of 17p are uncommon in MGUS in contrast to MM.[59]

TABLE 97.2

PREVALENCE OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE (MGUS)

Study	Diagnostic Criteria	Number of MGUS Cases	Sample Size	Overall Prevalence (95% CI)
Aguzzi et al.[285]	M protein <30 g/L No evidence of B-cell lymphoproliferative disorder	1,015	35,005	2.9
Anagnostopoulos et al.[286]	M protein <30 g/L Bone marrow <10% No end organ damage	60	1,564	4.0
Axelsson et al.[6]	M protein <30 g/L Bone marrow smear No end organ damage	64	6,995	0.9

Angiogenesis

Bone marrow angiogenesis is increased in MM and has prognostic value.[60] In a study of 400 patients with a spectrum of plasma cell disorders, the median microvessel density (in vessels per high-power field) was 1.3 in the 42 normal controls, 1.7 in AL, 3 in MGUS, 4 in SMM, 11 in MM, and 20 in relapsed MM.[61] Thus bone marrow angiogenesis increases progressively from the pre-malignant MGUS stage to advanced MM. Using a chick embryo chorioallantoic membrane angiogenesis assay, Vacca et al. reported that 76% of MM bone marrow samples had increased angiogenic potential compared with 20% of MGUS samples.[62] Their findings suggest that increased angiogenesis may play a role in progression of MGUS to MM.

Cytokines

There is overexpression of CD126 (IL-6 receptor α-chain) in MGUS compared to normal plasma cells.[63,64] IL-6 is a major growth factor for plasma cells and may therefore play a role in the clonal proliferation of plasma cells in MGUS. Another cytokine that is of importance is IL-1β. IL-1β is produced by plasma cells in all patients with MM, but is undetectable in most patients with MGUS.[65] IL-1β has strong osteoclast-activating factor activity, increases the expression of adhesion molecules, and induces paracrine IL-6 production. This activity parallels the development of osteolytic bone lesions, homing of MM cells to bone marrow, and IL-6–induced cell growth.[66,67]

As the MGUS clone evolves with additional cytogenetic abnormalities and changes in the microenvironment, there is overexpression of receptor activator of nuclear factor-κB ligand (RANKL) by osteoblasts (and possible plasma cells) and macrophage inflammatory protein 1-α (MIP 1-α) by plasma cells.[68,69] Furthermore, there is a reduction in osteoprotegerin, the decoy receptor for RANKL. This leads to osteoclast activation and bone resorption. In addition, increased dickkopf 1 (DKK-1) expression by MM cells is felt to play a major role in simultaneous suppression of osteoblasts and new bone formation.[70] This combination of factors is thought to be critical for development of lytic bone lesions in MM.

Clinical Features

MGUS is an asymptomatic condition. It is typically detected as an incidental finding when electrophoresis and immunofixation of the serum and/or urine or the serum FLC assay are performed during the work-up of suspected MM or WM. Thus, MGUS is usually detected during the work-up of unexplained weakness or fatigue, increased erythrocyte sedimentation rate, anemia, unexplained back pain, osteoporosis, osteolytic lesions or fractures, hypercalcemia, proteinuria, renal insufficiency, or recurrent infections. MGUS is also detected during work-up of patients with symptoms suggestive of AL amyloidosis such as unexplained sensorimotor peripheral neuropathy, carpal tunnel syndrome, refractory congestive heart failure, nephrotic syndrome, orthostatic hypotension, malabsorption, weight loss, change in the tongue or voice, paresthesias, numbness, increased bruising, bleeding, and steatorrhea.

Most cases of MGUS remain undiagnosed due to the asymptomatic nature of the condition. At age 60, the proportion of prevalent cases that are clinically recognized is only 13%.[35] This rate rises to 33% at age 80. When MGUS is first diagnosed, it is estimated that the condition has already been present in an undiagnosed form for a median duration of over 10 years.[35] For example, it is estimated that 56% of women age 70 diagnosed with MGUS have had the condition for over 10 years, including 28% for over 20 years. Corresponding values for men are 55% and 31%, respectively.

TABLE 97.3

CLASSIFICATION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Type	Risk of Progression
Non-IgM MGUS[a]	1% per year risk of progression to multiple myeloma, AL amyloidosis, or related disorder
IgM MGUS[b]	1.5% per year risk of progression to Waldenström macroglobulinemia; rare patients can progress to IgM multiple myeloma
Light chain MGUS[c]	Risk of progression to light chain myeloma and AL amyloidosis. Rate of progression not defined.

IgM, immunoglobulin M; MGUS, monoclonal gammopathy of undetermined significance

[a]Almost all patients are IgG or IgA type. Occasional patients may have IgD or IgE monoclonal proteins.

[b]Note that conventionally IgM MGUS is considered a subtype of MGUS. Thus, when the term MGUS is used, in general, it includes IgM MGUS.

[c]Because light chain MGUS was only defined in 2010, studies pertaining to MGUS prior to that time do not include patients with this entity; unless otherwise specified studies since then may also not include patients with light chain MGUS.

From Rajkumar SV. Preventive strategies in monoclonal gammopathy of undetermined significance and smoldering multiple myeloma. Am J Hematol 2012;87:453–454.

There are three distinct categories of MGUS each with a different mode of progression: IgM MGUS, non-IgM MGUS, and light chain MGUS, each with a different mode and risk of progression (Table 97.3).[4,7,71]

Prognosis

Mayo Clinic Referral Population

The prognosis of MGUS was first established in a study of 241 patients seen at the Mayo Clinic from 1956 through 1970.[1] The actuarial rate of progression to MM or related disorder at 10 years was 17%; at 20 years, 34%; and at 25 years, 39% (Fig. 97.4).[72] Of the 64 patients with progression, 44 (69%) had MM.

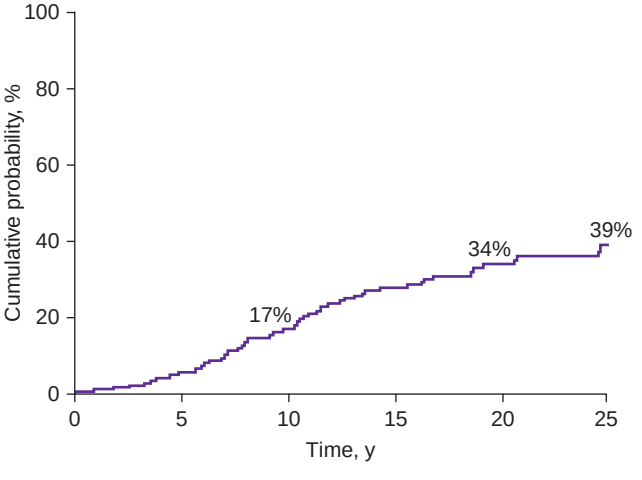

FIGURE 97.4. Actuarial analysis of incidence of multiple myeloma, macroglobulinemia, amyloidosis, or lymphoproliferative disease after recognition of monoclonal protein in 241 patients with monoclonal gammopathy of undetermined significance. (From Kyle RA, , Therneau TM, Rajkumar SV, Larson DR, Plevak MF, Melton LJ 3rd. Long-term follow-up of 241 patients with monoclonal gammopathy of undetermined significance: the original Mayo Clinic series 25 years later. Mayo Clin Proc 2004;79:859–866.)

Southeastern Minnesota Study

The risk of progression has also been estimated in a larger population-based study of 1,384 persons with MGUS who resided in the 11 counties of southeastern Minnesota, the risk of progression of MGUS to MM or related disorder was found to be 1% per year.[2] The median age at diagnosis of MGUS was 72 years. The M-protein level at diagnosis ranged from unmeasurable to 3.0 g/dl. On the basis of the heavy-chain type of immunoglobulins, 70% of the M proteins were IgG, 12% IgA, and 15% IgM. A biclonal gammopathy was found in 45 patients (3%). The light chain type was κ in 61% and λ in 39%. A reduction of uninvolved (normal or background) immunoglobulins was found in 38% of 840 patients in whom quantitation of immunoglobulins was determined. The 1,384 patients in this study were followed up for a total of 11,009 person-years (median, 15.4 years; range, 0 to 35 years). During follow-up, MM, primary AL, lymphoma with an IgM serum M protein, WM, plasmacytoma, or chronic lymphocytic leukemia developed in 115 patients (8%). The cumulative probability of progression to one of these disorders was 10% at 10 years, 21% at 20 years, and 26% at 25 years (Fig. 97.5). Patients were at risk for progression even after 25 years or more of stable MGUS. Although the risk of progression is 1% per year, it must be emphasized that this does not take into account other competing causes of death in elderly patients. After adjusting for competing causes of death, the true lifetime probability of progression of MGUS for the average patient is only approximately 10% (Fig. 97.6).

The number of patients with progression to a plasma cell disorder (115 patients) was 7.3 times the number expected on the basis of the incidence rates for those conditions in the general population (Table 97.4). The risk of MM developing was increased 25-fold; WM, 46-fold; and AL amyloidosis, 8.4-fold. The risk of development of lymphoma was only modestly increased at 2.4, but this risk was underestimated because only lymphomas associated with an IgM protein counted in the observed number, whereas the incidence rates for lymphomas associated with IgG, IgA, and IgM proteins were used to calculate the expected number. The risk of development of chronic lymphocytic leukemia was only slightly increased.

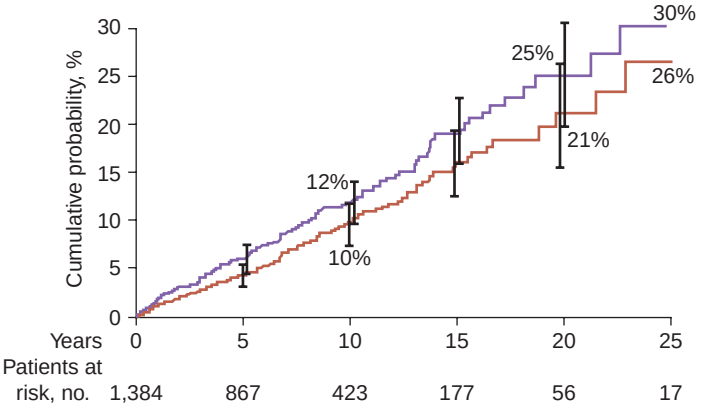

FIGURE 97.5. Probability of disease progression among 1,384 residents of southeastern Minnesota in whom monoclonal gammopathy of undetermined significance (MGUS) was diagnosed from 1960 through 1994. The top curve shows the probability of progression to a plasma cell cancer (115 patients) or of an increase in the monoclonal protein concentration to more than 3 g/dl or in the proportion of plasma cells in the bone marrow to more than 10% (32 patients). The bottom curve shows only the probability of progression of MGUS to multiple myeloma, IgM lymphoma, primary amyloidosis, macroglobulinemia, chronic lymphocytic leukemia, or plasmacytoma (115 patients). The error bars indicate 95% confidence intervals. (From Kyle RA, Therneau TM, Rajkumar SV, et al. A long-term study of prognosis of monoclonal gammopathy of undetermined significance. N Engl J Med 2002;346:564–569. Used with permission.)

The 75 patients in whom MM developed accounted for 65% of the 115 patients who had progression to a plasma cell disorder. The mode of development of MM among the patients with MGUS was variable. The M-protein level increased within 2 years of the recognition of MGUS in 11 patients, whereas the serum M-protein level was stable for more than 2 years and then increased within 2 years in 19 patients; in 9 others, the M-protein level increased gradually after having been stable for at least 2 years. In 9 patients, the M-protein level increased gradually during

follow-up until the diagnosis of symptomatic MM was made. In 10 patients, the serum M-protein level remained essentially stable; the diagnosis of MM was unequivocal in these 10 patients because of an increase in bone marrow plasma cells, development of lytic lesions, or occurrence of anemia, renal insufficiency, or an increased level of urine M protein. Seventeen patients had an insufficient number of serum M-protein measurements to determine the pattern of increase. In patients with WM, the M-protein level showed a gradual increase in 3, stable levels were followed by a sudden increase in 2, and data were insufficient in 2.

Spontaneous disappearance of M protein after the diagnosis of MGUS was rare.[2] The M protein disappeared without an apparent cause in 27 patients (2%), and only 6 of these 27 patients (0.4% of all patients) had a discrete spike on the densitometer tracing of the initial electrophoresis (median, 1.2 g/dl); the rest had small M proteins detected on immunofixation only.

Follow-up in Other Series

The risk of progression of MGUS has been estimated in several other studies, and the results mirror those seen in the Southeastern Minnesota study. For example, Baldini et al. noted that 6.8% of 335 patients with MGUS had progression during a median follow-up of 70 months.[73] In the Danish Cancer Registry, 64 new cases of malignancy (5 expected; relative risk, 12.9) were found among 1,229 patients with MGUS.[74]

Prognostic Factors

No findings at diagnosis of MGUS can reliably distinguish patients whose condition will remain stable indefinitely from those in whom MM or related malignancy develops. However, there are several known prognostic factors that assist in estimation of the risk of progression for appropriate counseling and management.

Size of M Protein

The size of the M protein at recognition of MGUS is one of the most important predictors for the risk of progression. In the study of 1,384 patients from Southeastern Minnesota, the risk of progression to MM or a related disorder 10 years after diagnosis of MGUS was 6% for patients with an initial M-protein level of 0.5 g/dl or less, 7% for 1 g/dl, 11% for 1.5 g/dl, 20% for 2 g/dl, 24% for 2.5 g/dl, and 34% for 3.0 g/dl.[2] Corresponding rates for progression at 20 years were 14%, 16%, 25%, 41%, 49%, and 64%, respectively. The risk of progression in a patient with an M-protein level of 1.5 g/dl was almost twofold greater than that in a patient with an M-protein level of 0.5 g/dl, and the risk of progression in a patient with an M-protein level of 2.5 g/dl was 4.6 times that of a patient with a 0.5-g/dl spike.

Type of M Protein

Patients with an IgM or IgA M protein have a higher risk of progression compared with those with an IgG M protein.[2] IgM MGUS is a unique subtype of MGUS in which patients are at risk of progression to WM rather than MM.[75] Due to a confusion in terminology, some patients with WM are referred to as having non-Hodgkin lymphoma or lymphoplasmacytic lymphoma (a term commonly used by pathologists to describe the bone marrow findings of patients with WM). Rarely do patients with IgM MGUS evolve into IgM MM.[71] Among 213 patients in the Southeastern Minnesota MGUS study, 23 developed "non-Hodgkin lymphoma" or WM, 3 developed chronic lymphocytic leukemia, and 3 developed AL amyloidosis.[75] The risk of progression was 1.5% per year. The risk of progression of light chain MGUS relative to IgA, IgG, or IgM MGUS is not known.

Bone Marrow Plasma Cells

Cesana et al. have found that patients with MGUS who have 5% to 9% bone marrow plasma cells have a higher risk of progression compared with those with <5% bone marrow plasma cells.[76] Of 1,104 patients with MGUS in this study, at a median follow-up of 65 months, 64 MGUS cases (5.8%) evolved to MM or related plasma cell disorder. Patients with greater than 5% marrow plasmacytosis had a significantly higher risk of progression compared to those with 5% or fewer plasma cells, 1.35 versus 0.64 per 100 person years, respectively, $P = 0.004$.

Abnormal Serum-Free Light Chain Ratio

An abnormal FLC ratio is an independent risk factor for progression of MGUS. In a study of 1,148 patients with MGUS, 379 (33%) had an abnormal FLC ratio.[19] The risk of progression in patients with an abnormal FLC ratio was significantly higher than that in patients with a normal ratio (hazard ratio 3.5; $P < 0.001$) and was independent of the size and type of serum M protein (Fig. 97.7). The production of excess monoclonal FLC in MGUS may be a biomarker for plasma cells bearing a higher degree of cytogenetic abnormalities thereby serving as a biomarker for a higher risk of progression.

Risk Stratification

A risk-stratification model can be used to predict risk of progression in MGUS, and is useful for management.[19] The model is based on the size and type of the M protein and the FLC ratio (Table 97.5). Patients with all three risk factors consisting of an abnormal serum FLC ratio, IgA or IgM MGUS, and an increased serum M-protein value (≥1.5 g/dl) have a risk of progression at 20 years of 58%, whereas the risk is 37% with any two risk factors present, 21% with one risk factor present, and 5% when none of the risk factors are present. When competing causes of death were

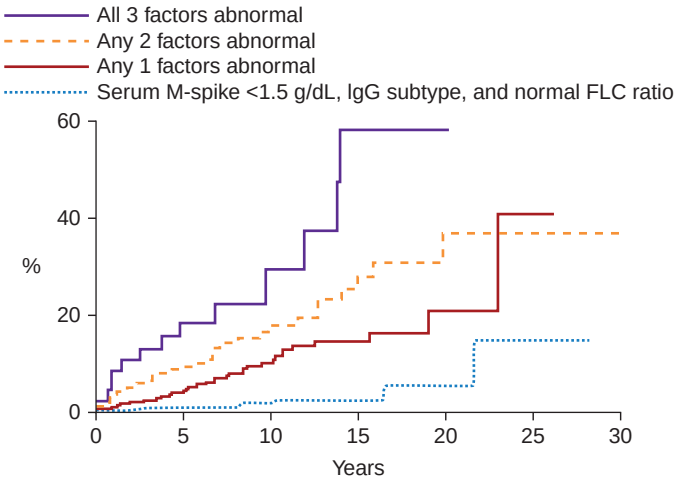

FIGURE 97.7. Risk of progression of monoclonal gammopathy of undetermined significance (MGUS) to myeloma or related disorder. The top curve illustrates the risk of progression with time in patients with three risk factors: abnormal serum $\kappa:\lambda$ free light chain (FLC) ratio (<0.26 or >1.65), a high serum monoclonal (M)-protein level (≥1.5 g/dl), and non-IgG MGUS. The second curve is the risk of progression in patients with any two of these risk factors. The third curve illustrates the risk of progression with one of these risk factors. The bottom curve is the risk of progression for patients with none of the risk factors. (From Rajkumar SV, Kyle RA, Therneau TM, et al. Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS) Blood 2005;106;812–817. © the American Society of Hematology.)

taken into account, the risk of progression in the low risk group is only 2% at 20 years.

Life Expectancy and Cause of Death

In the Mayo Clinic study of 241 patients with MGUS, survival was shorter compared with an age- and sex-adjusted 1980 U.S. population (13.7 vs. 15.7 years).[77] Similarly, in the population-based study of 1,384 patients with MGUS in Southeastern Minnesota, median survival was 8.1 years compared with the expected median of 11.8 years for Minnesota residents of matched age and sex ($P < 0.001$).[2] In the study by van de Poel et al.[78], the long-term survival of 334 patients with MGUS was slightly shorter than the expected survival of an age- and sex-adjusted population. However, it is not clear from these studies if there is an excess risk of death from MGUS once the deaths due to malignant progression are accounted for.

Management

The differentiation between MGUS and MM and other related disorders is based on the criteria listed on Table 97.1.[8] At the time of initial diagnosis all patients need a complete blood count (CBC), serum calcium, and serum creatinine, and a radiographic survey of the skeleton. A bone marrow aspiration and biopsy is also recommended for most patients, and cytogenetic studies should be done at baseline on the bone marrow sample. Although a bone marrow biopsy is required for the definition of MGUS, not all patients need to have such an examination if the clinical picture is otherwise consistent with MGUS, and the patient is low-risk by the risk-stratification model shown on Table 97.5.[19] If available, peripheral blood flow cytometry for circulating plasma cells should be done.

Once the diagnosis is made, the CBC, serum calcium, creatinine, and serum protein electrophoresis (and serum FLC if light chain MGUS) must be repeated in 6 months.[79] If stable, then in patients with low-risk MGUS, an assessment of the M protein level is needed only if symptoms worrisome for progression develop. This recommendation is based on the fact that the progression risk is very low in these patients, and that there are no data that monitoring can prevent complications in a timely manner.[80] In all other patients with MGUS, annual follow-up of the M protein is recommended lifelong.

No single factor can differentiate a patient with a benign monoclonal gammopathy from one in whom a malignant plasma cell disorder develops subsequently. However, the presence of a high plasma cell proliferative rate, circulating plasma cells or other concerning clinical or laboratory features in a patient with MGUS needs to be followed up frequently for other evidence of progression.

TABLE 97.5

RISK-STRATIFICATION MODEL TO PREDICT PROGRESSION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE TO MYELOMA OR RELATED DISORDERS

Risk Group	No. of Patients	Relative Risk	Absolute Risk of Progression at 20 Years (%)	Absolute Risk of Progression at 20 Years Accounting for Death as a Competing Risk (%)
Low risk (Serum M protein <1.5 g/dl, IgG subtype, normal FLC ratio (0.26–1.65)	449	1	5	2
Low-intermediate risk (Any 1 factor abnormal)	420	5.4	21	10
High-intermediate risk (Any 2 factors abnormal)	226	10.1	37	18
High risk (All 3 factors abnormal)	53	20.8	58	27

SMOLDERING MULTIPLE MYELOMA

Definition

SMM is defined by the presence of a serum M protein ≥3 g/dl and/or bone marrow plasma cells 10% to 60%, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (Table 97.1).[26,27]

Epidemiology

SMM accounts for approximately 15% of all cases of newly diagnosed MM.[81] In a study conducted at the M.D. Anderson Cancer Center, 95 (15%) of 638 patients with MM were considered to have asymptomatic MM.[82] Other investigators have found a higher proportion of patients with SMM, but the sample size in these studies is small.[83,84] The prevalence estimates for SMM are distorted because many reports include asymptomatic patients with lytic bone lesions on skeletal survey. Some exclude patients with bone lesions on skeletal survey but include patients who have lytic lesions on magnetic resonance imaging. Calculation of the true prevalence of SMM on the basis of strict criteria is not available.

Pathophysiology

SMM is not a unique biologic entity.[44,45] It is a heterogeneous entity created primarily for clinical purposes to identify a group of patients with asymptomatic plasma cell dyscrasia that have a much higher risk of progression than MGUS (10% per year) so that these patients can be monitored more closely.[10,44,85] From a biologic standpoint, SMM includes patients with pre-malignancy (biologic MGUS) and patients with early asymptomatic malignancy (MM).[45,86] Unfortunately, at present, histopathologic and other laboratory methods cannot distinguish SMM patients with pre-malignant MGUS from those who have early MM because there is no clear marker of malignancy that can distinguish a clonal pre-malignant plasma cell from a clonal malignant MM cell.

Clinical Features

As with MGUS, SMM is asymptomatic and is diagnosed during the routine work-up for a variety of symptoms and signs.[79,85] SMM should be differentiated from related plasma cell disorders using the criteria listed on Table 97.1.[8]

Prognosis

The risk of progression of SMM is much higher compared with MGUS, 10% per year compared with 1% per year. In a study of 276 patients with SMM, the risk of progression was 10% per year for the first 5 years, 5% per year for the next 3 years, and then 1% to 2% per year thereafter.[10] This pattern of progression in which there is a plateau after 10 years is consistent with the heterogeneous nature of SMM; in the first 10 years, the subset of patients with early MM declare themselves with symptomatic disease, and after 10 years, the remaining cohort of patients is identical to MGUS in biology and clinical behavior. A subset of patients can remain free of progression for several years.[9] Another study has reported a lower rate of progression of only 20% at 6 years.[76] However, the definition of SMM used in this study was different; it considered patients to have SMM only if they had no disease progression after 1 year of follow-up.

Prognostic Factors

The assessment of prognostic factors for SMM is hampered by varying diagnostic criteria used to define the cohort. Several studies also include patients with lytic lesions. Future studies of SMM need to use more uniformly accepted criteria so that results can be compared.

Extent of Bone Marrow Involvement

The natural history of SMM in the literature is based almost exclusively on data from patients with bone marrow plasma cells of less than 60%. In studies describing the diagnosis, natural history, and progression of SMM, no upper limit of bone marrow involvement was defined.[10] In a study of 276 patients with SMM only 6 of 276 patients (2%) had a bone marrow plasma cell percentage of ≥60%.[87] Four of these 6 patients progressed to symptomatic MM between 3 to 9 months following diagnosis of SMM. The median progression free survival was 7.7 months. In a separate cohort of 655 patients with SMM seen from1996 to 2010 at the Mayo Clinic, only 21 patients (3.2%) had a bone marrow plasma cell percentage of ≥60%. Ninety-five percent of patients with ≥60% bone marrow plasma cells progressed to MM within 2 years of diagnosis, with a median time to progression (TTP) of 7 months. Patients with SMM who have bone marrow involvement of 60% or greater almost invariably progress to MM within 2 years, and we now recommend that such patients be considered as MM regardless of the presence or absence of end organ damage and be initiated on therapy.[86,87] The prognostic value of levels of bone marrow involvement from 10% to 60% needs further study.

Circulating Plasma Cells

The ability of plasma cells to escape from the bone marrow microenvironment and circulate in the peripheral blood ("marrow emancipation") is a likely hallmark of aggressive disease as well as malignant transformation. Except for the small subset of solitary plasmacytoma, most MM patients present with lytic bone lesions in multiple bones, suggesting hematogenous dissemination once a malignant transformation has occurred. Patients with abnormal peripheral blood monoclonal plasma cell studies, defined as an increase in the number or proliferative rate of circulating plasma cells by immunofluorescent assays, are at higher risk for earlier progression to MM. In a study of 57 patients, Witzig et al. found that the median TTP was 9 months for those with abnormal circulating plasma cell values on a slide-based immunofluorescent assay versus 30 months for those with normal results ($P < 0.01$).[88] In a more recent study of 91 patients diagnosed with SMM at the Mayo Clinic, Bianchi et al. found that the level of circulating plasma cells could be used to identify patients with a high risk of progression to MM within the first 2 years.[89] Patients with a high level of circulating plasma cells on an immunofluorescent assay (absolute peripheral blood plasma cells $>5{,}000 \times 10^6$/L and/or >5% cytoplasmic immunoglobulin positive plasma cells per 100 peripheral blood mononuclear cells) were significantly more likely to progress to active disease within 2 years compared with patients without high circulating plasma cells, 71 versus 25%, respectively, $P = 0.001$. Corresponding rates for progression within 3 years were 86 versus 35%, respectively, $P < 0.001$. The slide-based immunofluorescent method is not widely available, and these results can be more practically applied by detecting and quantifying circulating plasma cells using a six-color flow cytometric assay. In the flow assay, circulating plasma cells can be detected with high sensitivity by counting 150,000 mononuclear cell events, and can be used to calculate the absolute number of blood plasma cells per μl in SMM patients.

Abnormalities on Magnetic Resonance Imaging

Patients who undergo magnetic resonance imaging often have abnormalities detected even when the skeletal survey shows no

lytic lesions.[81,90] Abnormal focal lesions on magnetic resonance imaging are associated with a shortened TTP in SMM.[91,92]

Serum Free Light Chain Assay

The serum FLC ratio can predict risk of progression in MGUS.[19] Similarly, among 116 patients with solitary plasmacytoma, an abnormal FLC ratio was associated with higher risk of progression to MM ($P = 0.039$).[21] In a study of 273 patients with SMM, an FLC ratio of ≤0.125 or ≥8 was an independent risk factor for progression (HR, 2.3; 95% CI, 1.6 to 3.2). Patients identified as high risk based on this assay had a 25% per year risk of progression in the first 2 years.[20]

Absence of Normal Plasma Cells on Multiparametric Flow Cytometry

Certain immunophenotypic markers distinguish MM cells from normal PCs with a high degree of accuracy.[93] A Spanish study defines abnormal (MM-type) plasma cell immunophenotype as lack of expression of CD19 and/or CD45, expression of CD56, or weak expression of CD38. In SMM, if >95% plasma cells in the bone marrow have an abnormal immunophenotype, there is a 17-fold increased risk of progression.[94] In other words, the presence of <5% normal bone marrow plasma cells in a patient with SMM is associated with a significantly higher risk of progression.

Cytogenetic Abnormalities

The prognostic value of cytogenetic abnormalities in SMM have not been fully evaluated. In general, the presence of *MYC* abnormalities, 17p deletion, and *RAS* mutations, particularly *K-RAS,* are markers of malignant transformation and are likely associated with higher risk of progression in SMM.[59]

Plasma Cell Proliferative Rate

A cardinal feature distinguishing MGUS from MM is the proliferative rate of the clonal plasma cell population. Indeed, using a slide-based immunofluorescent assay, there are preliminary data that high plasma cell labeling index (PCLI) values (≥1) identify patients with SMM who progress within 2 years with high specificity.[95] However, the PCLI method is subjective, and not widely available. A six-color flow cytometric assay, currently in clinical practice, offers greater sensitivity and reproducibility. Further studies are needed to investigate the flow cytometry-based proliferative rate as a biomarker that can distinguish SMM patients with malignant transformation from those who have MGUS.

Management

The current standard of care in SMM is close follow-up once every 3 to 6 months without chemotherapy.[79,85] Two trials done prior to the arrival of thalidomide, lenalidomide, and bortezomib found no significant improvement in OS in patients who received immediate treatment with melphalan plus prednisone compared with those who received treatment at progression for stage I or asymptomatic MM. Hjorth et al. randomly assigned 50 patients with asymptomatic stage I MM to observation versus chemotherapy with melphalan and prednisone.[96] No differences were observed in OS between the two groups. Grignani et al. reported similar survival time with immediate or deferred therapy in a series of 44 patients with asymptomatic MM.[97] However, these trials were underpowered, and more data are needed.[86] The recommendation to observe closely without treatment until progression is also based on the possible short-term and long-term side effects of therapy, and the fact that in some patients SMM may not progress for months to years.

TABLE 97.6

POTENTIAL BIOMARKERS FOR PREDICTING HIGH RISK OF PROGRESSION IN SMOLDERING MULTIPLE MYELOMA

High involved/uninvolved free light chain ratios (≥100)
High levels of circulating plasma cells
High bone marrow plasma cell proliferative rate
Abnormal plasma cell immunophenotype
Marked suppression of uninvolved immunoglobulins
Specific cytogenetic abnormalities
Abnormalities on magnetic resonance imaging studies
Rise in monoclonal protein or light chain levels over time

From Rajkumar SV. Preventive strategies in monoclonal gammopathy of undetermined significance and smoldering multiple myeloma. Am J Hematol 2012;87:453–454.

More recently, clinical trials have found that thalidomide may delay TTP, but there are long-term side effects associated with this treatment that make it unsuitable for intervention in an asymptomatic population.[98,99] In a randomized trial, Witzig et al. compared thalidomide plus zoledronic acid versus zoledronic acid alone in patients with SMM.[100] The TTP was superior for patients treated with thalidomide plus zoledronic acid ($n = 35$) compared with zoledronic acid alone ($n = 33$); median TTP 2.4 years (95% CI:1.4 to 3.6) versus 1.2 years (95% CI:0.7 to 2.5), respectively, $P = 0.02$. Lenalidomide plus dexamethasone has also shown promising activity in high-risk SMM. A recent randomized trial of lenalidomide plus dexamethasone in high-risk SMM is an excellent example of this strategy, in which the investigators demonstrated a significant prolongation of TTP, and preliminary evidence of a survival benefit.[101] An ECOG trial is comparing lenalidomide versus observation in this patient population. Other trials are exploring agents such as bisphosphonates, IL-1β inhibitors, clarithromycin, and dehydroepiandrosterone in an attempt to delay progression of SMM to symptomatic MM.[102]

In addition to clinical trials, efforts are also under way to identify biomarkers that can predict patients who will inevitably progress to symptomatic MM within 2 years with high (80% or greater) accuracy.[45,86] Many groups are actively working toward this goal, and several promising biomarkers have already been identified as candidates for further study (Table 97.6).[20,94] If such biomarkers are validated, patients with SMM who are considered as high risk (>80% progression risk within 2 years) may be candidates for initiation of therapy similar to MM.

VARIANTS OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Secondary Monoclonal Gammopathy of Undetermined Significance

During the course of MM, new M proteins of an isotype distinct from the original clone can arise, and are referred to as secondary MGUS. In a study of 1,942 patients with MM, 128 (6.6%) developed a secondary MGUS, at a median time of 12 months from the diagnosis of MM.[103] The median duration of secondary MGUS was 6 months. In 34 (27%) of the 128 patients with secondary MGUS, there were multiple secondary MGUSs of varying isotypes. Secondary MGUS was more common in patients who had undergone SCT compared to those who had not undergone such a procedure: 23% versus 2%, respectively, $P < 0.001$. Most secondary

MGUS M proteins were small, detectable by immunofixation only in 84 patients (66%). OS was significantly superior among patients who developed secondary MGUS compared with those who did not develop a secondary MGUS: 73 months versus 38 months, respectively, $P < 0.001$. Other studies on secondary MGUS have also found a survival benefit with secondary MGUS that appears in MM patients following SCT.[20,104,105] Among patients with secondary MGUS, there is a trend to better OS in those in whom the MGUS resolved compared to those with persistent MGUS.

Biclonal and Triclonal Gammopathy

Biclonal gammopathies are characterized by the presence of two different M proteins and occur in 3% to 6% of patients with monoclonal gammopathies. The two M proteins may be caused by the proliferation of two different clones of plasma cells, each producing an unrelated M protein, or by production of two M proteins by a single clone of plasma cells. In one study, biclonal gammopathy of undetermined significance was found in 37 of 57 patients with a biclonal gammopathy.[106] Riddell et al. reported that 2.5% of 1,135 patients with monoclonal gammopathy had biclonal gammopathy.[107] They postulated that in some patients complete class switching in a single plasma cell clone resulted in the production of two M proteins, but in others the M proteins arose from two separate plasma cell clones.

Triclonal gammopathy is rare. Most reported cases have been associated with immunodeficiency syndromes or lymphoproliferative disorders.[108–110]

Idiopathic Bence Jones Proteinuria (Benign Monoclonal Light Chain Proteinuria)

Idiopathic Bence Jones proteinuria represents a more advanced stage of light chain MGUS, in which there is excretion of monoclonal light chains in the urine without any evidence of end organ damage to suggest MM or related disorder.[111,112] It is best considered as representing light chain SMM.[7] In one study, two patients with stable serum M-protein levels excreted 0.8 g/d or more of Bence Jones protein for more than 17 years without disease progression.[111] In a separate study, seven patients with Bence Jones proteinuria (>1 g/24 hour) were described in whom there was no evidence of heavy chain expression in the serum or urine, and no evidence of MM or a related disorder.[113] During long-term follow-up, three of the seven patients developed MM, two others had an increase of their Bence Jones protein (BJP), and two remained stable during follow-up. One of the two patients who remained stable died of lung cancer after 10 years follow-up without change in the BJP, whereas the other patient died of a cardiac arrhythmia 36 years after diagnosis. An autopsy showed no evidence of MM or AL amyloidosis. The precise cut-off of urine M protein excretion that will distinguish LC-MGUS from idiopathic Bence Jones proteinuria remains unclear and is the subject of ongoing studies. Although idiopathic Bence Jones proteinuria may remain stable for years, as with MGUS or SMM, there is a continued risk of progression to MM or related disorder, and therefore patients must be followed up indefinitely.

IgD Monoclonal Gammopathy of Undetermined Significance

In most studies of MGUS, there are few if any patients with IgD MGUS making it hard to ascertain the natural history of this entity. In general, because IgD is not usually secreted, the presence of a serum IgD M protein almost always indicates MM, AL amyloidosis, or plasma cell leukemia. However, IgD MGUS has been reported occasionally. O'Connor et al. described a patient with an IgD λ protein level of 0.5 g/dl who was followed up for more than 6 years without evidence of progressive disease.[114] Similarly, an IgD λ MGUS patient has been reported from the Mayo Clinic who remained stable for more than 8 years without development of MM or related disorder.[115] The IgD λ protein in this patient has remained stable after 24 years follow-up.

ASSOCIATION OF MONOCLONAL GAMMOPATHY WITH OTHER DISEASES

Serum protein electrophoresis is commonly done in patients presenting with a wide variety of clinical symptoms. This results in the incidental diagnosis of MGUS in a wide variety of clinical settings. Inasmuch as MGUS is common in the general population, and because the prevalence increases with age, "associations" with various diseases can occur just coincidentally. Thus over the years, over a hundred different medical conditions have been reported to be associated with MGUS, and most such reported associations are not likely causally related. The only method to ascertain definitively true disease associations with MGUS that are etiologically related is to screen all persons in a geographic population for the presence or absence of MGUS, and then determine the diseases that are significantly associated in patients with and without MGUS. Only one such systematic study has been conducted so far. Bida and colleagues studied the association of MGUS with all diseases in a population-based cohort of 17,398 patients, all uniformly tested for the presence or absence of MGUS.[116] Among 17,398 persons, 605 MGUS cases and 16,793 negative controls were identified. The computerized Mayo Medical Index was used to obtain information on all diagnoses entered between January 1, 1975 and May 31, 2006 totaling 422,663 person-years of observations. The study encompassed all prior reported associations in detail, and also looked for new associations not hitherto described. Data were analyzed using stratified Poisson regression, adjusting for age, gender, and total person-years of observation. The study confirmed a significant association in 14 (18.7%) of 75 previously reported disease associations with MGUS, including vertebral and hip fractures and osteoporosis (Table 97.7). Several of these associations were known progression events of MGUS such as MM and Waldenström macroglobulinemia. A systematic analysis of all 16,062 diagnostic disease-codes found additional previously unreported associations, including hyperlipidemia, mycobacterium infection, and superficial thrombophlebitis.

Some commonly reported disease associations are briefly discussed below. In some of these cases, the association with MGUS is undoubtedly causal and has great clinical relevance such as MGUS-associated neuropathy, membranoproliferative glomerulonephritis (MPGN), and several dermatologic disorders. In others, the association is real, but carries limited clinical consequences such as M proteins that arise with immunosuppression. In others, such as the association with leukemia and other hematologic disorders, connective tissue disorders, neurologic disorders, and rheumatologic disorders it is impossible to determine whether the reported associations are coincidental, and they have limited clinical or etiologic significance. Most such associations are reported from studies in which not all patients were screened for the presence or absence of MGUS. Thus, the reported associations merely reflect the type of diseases and clinical settings in which a serum protein electrophoresis is ordered rather than a true association with the result of the test.

Monoclonal Gammopathy of Undetermined Significance Associated Neuropathy

MGUS-associated neuropathy is a well-described entity.[117,118] In a Mayo Clinic study of 279 patients with a sensorimotor peripheral

CI, confidence interval; CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; MGUS, monoclonal gammopathy of undetermined significance

[a]Rates age and sex adjusted

[b]Unadjusted P values.

From Bida JP, Kyle RA, Therneau TM, et al. Disease associations with monoclonal gammopathy of undetermined significance: a population-based study of 17,398 patients. Mayo Clin Proc 2009;84:685–693.

neuropathy of unknown cause, MGUS was found in 6%.[119] Other series have found similar rates.[120–122] In one study, neuropathy was found on testing in 2 of 34 patients with IgG (6%) MGUS, 2 of 14 with IgA MGUS (14%), and 8 of 26 with IgM MGUS (31%).[122] However, the neuropathy was not clinically apparent in approximately 50% of these patients.

In most cases, MGUS-related neuropathy is predominantly a demyelinating process with some features of axonal degeneration.[123] When patients classified as having chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) are studied, patients with an associated MGUS have a more indolent course, less severe motor symptoms and weakness, but more frequent sensory loss.[124] Occasionally a MGUS neuropathy can present with a predominant axonal pattern. This subtype is associated with mild, symmetric, slowly progressive, predominantly sensory neuropathy involving the lower extremities.[125] In a Mayo Clinic series, the size of the M spike was not associated with the severity of the neuropathy.[126]

The most common type of M protein in MGUS neuropathy is IgM. The clinical and electrodiagnostic manifestations resemble those of chronic inflammatory demyelinating polyneuropathy.[122,127] Motor involvement is less prominent than sensory involvement. Cranial nerve and autonomic functions are intact.[128] The course of the neuropathy is progressive in more than two-thirds of patients.[126] In approximately half of patients with an IgM monoclonal gammopathy and peripheral neuropathy, the M protein binds to myelin-associated glycoprotein (MAG).[129,130] The MAG-reactive polyneuropathies are characterized by a slowly progressive, mainly sensory neuropathy beginning in the distal extremities and extending proximally. In a Mayo Clinic study, the type and severity of neuropathy with anti-MAG were not greatly different from those without anti-MAG.[126] Discriminative and proprioceptive modalities are more severely involved than touch, pain, and temperature. The IgM protein may also bind to various other peripheral nerve components such as anti-GM-1 IgM antibodies, but the pathogenetic relationship needs further study.[131,132,133]

The relationship of IgG and IgA M proteins to peripheral neuropathy is less well documented.[118,134] IgG and IgA neuropathy may have more motor impairment and may have more features of axonal degeneration than IgM neuropathy.[122]

Differential Diagnosis

Inasmuch as 3% to 4% of the general population has an MGUS, in most patients the association of MGUS and neuropathy is likely coincidental. Therefore, the first step in a diagnostic evaluation should be to consider and exclude other causes of neuropathy. MGUS neuropathy is a diagnosis of exclusion, and there are no specific clinical or laboratory tests that are specific for the diagnosis. Intervention often involves administering anticancer therapy in patients without malignancy, therefore a diagnosis of MGUS neuropathy should not be made lightly. In the absence of other causes of neuropathy, the younger the patient, and the more severe the neuropathy, one should be more serious in considering MGUS as the cause of neuropathy and one that warrants intervention. The differential diagnosis of MGUS neuropathy should also consider other plasma cell disorders that are

associated with neuropathy, namely AL amyloidosis and POEMS syndrome.[135,136,137] In neuropathy related to AL amyloidosis both upper and lower extremities tend to be affected, whereas in MGUS neuropathy peripheral regions of the lower extremities are primarily affected. AL amyloidosis also has a greater tendency to be associated with autonomic features (postural hypotension, sphincter dysfunction, anhidrosis). In most cases, MGUS neuropathy tends to be primarily demyelinating, whereas neuropathy in AL amyloidosis is characterized by axonal degeneration. A diagnosis of AL amyloidosis is often suggested by the presence of other organ involvement, and requires demonstration of Congo red positive amyloid material on fat aspirate, or an affected organ. POEMS syndrome is associated with a predominantly motor chronic inflammatory demyelinating polyneuropathy, sclerotic bone lesions, and a varying number of associated abnormalities such as hepatomegaly, hyperpigmentation, hypertrichosis, gynecomastia, testicular atrophy, clubbing, polycythemia, thrombocytosis, and Castleman's disease. In POEMS syndrome, the neuropathy is often progressive and disabling. Although MGUS neuropathy is also demyelinating in most instances, it is typically more of a sensory neuropathy. MM and WM can also be associated with neuropathy, either directly due to the plasma cell disorder, or as a result of therapy. When related to the plasma cell disorder, the neuropathy in MM and macroglobulinemia is similar in pathogenesis to MGUS neuropathy; in contrast the pathogenesis of neuropathy in AL amyloidosis and POEMS syndrome is probably different mechanistically from MGUS neuropathy.

Treatment

The results of treatment of peripheral neuropathy and monoclonal gammopathy have been disappointing. A variety of interventions has been tried, but there are few good trials.[138] Most treatment recommendations are based on anecdotal experience. Intravenous immunoglobulin has been used, but the results have been disappointing.[139] However, intravenous immune globulin may be of benefit in patients with IgG MGUS related neuropathy, with 40% of patients showing improvement in one study.[140] Plasmapheresis has been of benefit in some patients.[141] In a double-blind controlled trial conducted at the Mayo Clinic, 39 patients with peripheral neuropathy and MGUS of the IgG, IgA, or IgM type were randomly assigned to undergo plasmapheresis or sham plasmapheresis.[142] Plasma exchange prevented worsening of or ameliorated the neuropathy. Patients with IgG or IgA gammopathy had a better response to plasma exchange than those with IgM gammopathy. In another study, 8 of 13 patients with a monoclonal gammopathy and peripheral neuropathy obtained benefit from plasma exchange.[143] Patients who do not respond to this program may be given rituximab when the M protein is of the IgM type or standard treatments used for MM such as lenalidomide and dexamethasone, or melphalan plus prednisone for IgG and IgA gammopathies.[144] In one study, 21 patients with IgM MGUS neuropathy treated with rituximab were compared with 13 untreated controls.[145] Rituximab treatment was associated with decreased IgM levels and improvement in strength. Two randomized trials have investigated the role of rituximab in IgM MGUS neuropathy.[146] In one trial, the authors randomized 26 patients with anti-MAG positive IgM MGUS to rituximab versus placebo.[147] An improvement in neuropathy was noted in approximately 25% of patients. In another randomized trial, 54 patients were studied, and a similar benefit was observed.[148] Additional studies, with placebo controls and blinded outcome measures, are warranted to further test the efficacy of rituximab treatment of IgM-associated polyneuropathies. In patients with IgM MGUS neuropathy refractory to rituximab, fludarabine or other treatments used for WM can be tried.[149,150,151]

Membranoproliferative Glomerulonephritis

A substantial proportion of cases with "idiopathic" immune-complex mediated MPGN are now felt to be related to MGUS.[152,153] In a study of 126 patients with MPGN conducted at the Mayo Clinic, 22% were associated with a monoclonal gammopathy.[152] Excluding other known causes such as hepatitis B and hepatitis C, approximately 40% of cases of idiopathic MPGN could be attributed to MGUS. MGUS-associated MPGN is characterized by subendothelial and mesangial deposition of immune complexes that show light chain restriction on immunofluorescent studies. The optimal treatment has not been well defined, but depending on the clinical symptoms, therapy targeted against the M protein is reasonable.[153] In a small subset of patients light chain restricted MPGN is seen on renal biopsy with no M protein in the serum or urine, and no clonal plasma cells in the bone marrow. The natural history of this subset is unclear.

Inasmuch as the kidney is often involved in plasma cell disorders such as light chain cast nephropathy, light chain deposition disease, and AL amyloidosis, renal involvement in patients with M proteins requires a careful evaluation and differential diagnosis. Besides MPGN and these known entities, other reported associations include rapidly progressive glomerulonephritis,[154] dense deposit disease,[155] and "idiopathic" focal and segmental glomerulosclerosis.[156]

Dermatologic Diseases

A variety of dermatologic diseases has been associated with MGUS.[157] Lichen myxedematosus (papular mucinosis, scleromyxedema) is a rare dermatologic condition frequently associated with an IgG λ monoclonal protein.[158] Scleredema (Buschke's disease) has been noted with an M protein, but the role of the M protein is unknown.[159] Other known associations include pyoderma gangrenosum,[160] diffuse plane xanthomatosis,[161–163] and subcorneal pustular dermatosis.[164,165] Necrobiotic xanthogranuloma, is frequently found with an IgG M protein,[166,167] and Schnitzler's syndrome is a rare disorder characterized by the presence of chronic urticaria and an IgM monoclonal gammopathy.[168–171]

Immunosuppression

M proteins arise in patients with immunosuppression. M proteins have been reported in patients with the acquired human immunodeficiency syndrome, but do not appear to have any prognostic significance.[172,173] M proteins have been detected in approximately 5% to 10% of patients following renal transplantation.[174,175,176] Others have reported rates as high as 30%.[177,178] In fact, in one study, the incidence was 10 times greater than that in a control group with chronic renal insufficiency who were receiving dialysis.[177] The presence of cytomegalovirus infection after renal transplantation in pediatric patients has been associated with an increased incidence of M proteins.[179] M proteins have also been reported in patients receiving other forms of organ transplantation. Approximately 25% of patients following heart transplantation,[180,181] and approximately 30% of patients following liver transplantation have been reported to develop M proteins.[182,183]

The effect of organ transplantation on patients with MGUS is unclear. In a report of five patients with MGUS undergoing transplantation, SMM developed in two and one had an increase in the serum M protein.[184] Amyloidosis developed 10 years after an IgG κ M protein was recognized after renal transplantation in another patient. In a more recent study, 3,518 patients who underwent renal transplantation at the Mayo Clinic were studied.[185] MGUS was identified in 42 patients: 23 prior to transplantation, and 19 after transplantation. Of the patients who had MGUS prior to

renal transplantation, 2 developed progression of the plasma cell disorder, both to SMM. None of the 19 patients who developed an MGUS after transplant progressed to MM or related disorder. Thus, progression of MGUS following renal transplantation is rare. A few patients in this study developed post-transplant lymphoproliferative disorder and the relationship of this entity with MGUS needs further study.

Leukemia and Other Hematologic Disorders

Mailankody and colleagues studied the risk of acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) in patients with MM and MGUS using population-based data from Sweden.[186] They identified 8,740 patients with MM and 5,652 patients with MGUS diagnosed between 1986 and 2005. They found a 11.5-fold increased risk of AML or MDS in patients with MM. But more strikingly, MGUS patients also had an 8-fold (95% CI 5.4 to 11.4) increased risk of AML/MDS compared with controls. The risk was confined to IgG/IgA MGUS, and the highest risk was seen in patients with an M protein of >1.5 g/dl. A subsequent study from the Mayo Clinic has also found an increased risk of acute leukemia and MDS in MGUS.[187] This study utilized data from the population-based cohort established in Olmsted County to estimate the prevalence of MGUS in the general population and therefore was not subject to detection or ascertainment bias.[3] MGUS patients had a significantly higher risk of developing acute leukemia (AML or acute lymphoblastic leukemia) or MDS compared with controls, risk ratio 2.20 (95% CI 1.23, 3.92), $P = 0.008$.[187] These findings suggest that there may be an inherent increased risk of acute leukemia and MDS in patients with plasma cell disorders that is independent of MM therapy.

An association between MGUS and chronic lymphocytic leukemia has been reported. In one study, 100 patients with chronic lymphocytic leukemia and an M protein in the serum or urine were described.[188] The M protein type was IgM in 38%, and IgG in 51%. No major differences were apparent in patients with chronic lymphocytic leukemia, whether they had an IgG or an IgM M protein. Monoclonal gammopathy also has been reported in hairy cell leukemia,[189] adult T-cell leukemia,[190] mycosis fungoides,[191] Sézary syndrome,[192] non-Hodgkin lymphoma,[193] Kaposi sarcoma,[194] and chronic myeloid leukemia,[195] but the significance of these associations is not known.

MGUS has been reported in patients with MDS,[196] and myeloproliferative disorders including chronic myeloid leukemia, myelofibrosis and polycythemia vera.[197–201] Duhrsen et al. found that the frequency of M proteins was 8.5% (16 of 188) among patients with idiopathic myelofibrosis, which suggests a possible true association.[201]

MGUS has also been linked to a variety of coagulation disorders. Cases of acquired von Willebrand's disease resulting from monoclonal gammopathy have also been described.[201–204] In several patients, a specific interaction between the M component and the antigenic portion of the factor VIII molecule was demonstrated.[205–209] In these patients, intravenous gamma globulin had a longer-lasting effect than did infusion of von Willebrand's factor concentrate.[210] In addition to acquired von Willebrand disease, a bleeding diathesis may also occur in MGUS from binding of an M protein to thrombin.[211] Thromboembolic disease has also been noted to be more frequent in patients with MGUS.[212] The mechanisms are unknown, but in rare instances the paraprotein in MGUS may have lupus anticoagulant activity.[213] An increased incidence of antiphospholipid antibodies has also been reported in patients with MGUS.[214]

Other rare associations that have been reported include Gaucher disease[215] and pernicious anemia,[216] as well as pure red cell aplasia caused by a block in the maturation of the erythroid burst forming unit (114) .[217,218]

Connective Tissue Disorders

Rheumatoid arthritis,[219] seronegative erosive arthritis,[220] systemic lupus erythematosus, and other connective tissue disorders have been reported with MGUS.[221–223] Polymyalgia rheumatica and polymyositis have also been reported with monoclonal gammopathy.[224–226]

Neurologic Disorders

Several instances of monoclonal gammopathy and amyotrophic lateral sclerosis have been reported, including one series of 120 patients with amyotrophic lateral sclerosis in whom 11 (9%) had an associated M protein.[227–229] However, a causal relationship has not been established. Other neurologic disorders that been reported in association with MGUS include myasthenia gravis,[230,231] ataxia-telangiectasia,[232,233] and nemaline myopathy.[234]

Miscellaneous Conditions

Systemic Capillary Leak Syndrome

Numerous other associations have been reported with MGUS. One important association is with angioneurotic edema and acquired deficiency of C1 esterase inhibitor.[235] In some instances, the M protein functions as an antibody that modifies the interaction between C1 inhibitor and its target protein.[236] The most important consequence is systemic capillary leak syndrome which can be life-threatening.[237] In a review of the literature, all 21 patients with a systemic capillary leak syndrome had a serum M protein (IgG κ in 12; IgG λ in 7; IgA in 1; IgG with an unspecified light chain in 1).[238] In another series of 25 patients with systemic capillary leak syndrome seen at the Mayo Clinic, the median age at diagnosis was 44 years.[239] The median time to diagnosis from symptom onset was approximately 1 year, but in 25% the time to diagnosis was longer than 4 years (interquartile range, 0.5 to 4.1 years). A monoclonal gammopathy, mostly IgG-κ type, was found in 19 patients (76%). The degree of albumin decrease during an attack was correlated with the development of rhabdomyolysis. Acute attacks are usually managed with fluids and supportive care. Long-term prophylactic therapy usually consists of theophylline (or aminophylline) along with terbutaline. A leukotriene inhibitor can be tried in patients refractory to theophylline or terbutaline.

Hepatitis C

Most cases of type II cryoglobulinemia are related to hepatitis C, and are associated with an IgM monoclonal protein.[240,241] The incidence of hepatitis C virus infection was 69% in 94 patients with mixed cryoglobulinemia and 14% in 107 patients without cryoglobulinemia[242]. In another series of 102 cases of MM, WM, or MGUS, hepatitis C virus infection was found in 16% of patients but in only 5% of controls.[243] An M protein was found in 11% of 239 hepatitis C virus-positive patients but in only 1% of 98 hepatitis C virus-negative patients. Thus, the prevalence of M proteins in patients with hepatitis C virus-related chronic liver diseases is high.[244]

Other Disorders

M proteins have been noted in numerous other disorders such as chronic active hepatitis, primary biliary cirrhosis, Henoch-Schönlein purpura, bacterial endocarditis, Hashimoto thyroiditis, idiopathic pulmonary fibrosis, pulmonary alveolar proteinosis, idiopathic pulmonary hemosiderosis, sarcoidosis, thymoma,

hereditary spherocytosis, Doyne macular heredodystrophy, and eosinophilic fibrohistiocytic lesions of the bone marrow, but these associations are likely coincidental.[116] M proteins have also been associated with corneal crystalline deposits and hyperlipoproteinemia, and the relationship of monoclonal gammopathy to these diseases is not clear.

M Proteins with Antibody Activity

M proteins may have autoantibody activity, and there have been numerous reported associations.[245,246] Of 612 patients in whom M proteins were studied for their antibody activity against actin, tubulin, thyroglobulin, myosin, myoglobin, fetuin, albumin, transferrin, and double-stranded DNA, 36 (5.9%) had antibody activity.[247] In some patients with MGUS, MM, or Waldenström macroglobulinemia, the M protein has exhibited unusual specificities to dextran,[248] antistreptolysin O,[249] antinuclear activity,[250] smooth muscle,[251] riboflavin,[252,253] thyroglobulin,[254] insulin,[255] double-stranded DNA,[256] apolipoprotein,[257] thyroxine,[258] cephalin,[259] lactate dehydrogenase,[260] anti-HIV,[261] and antibiotics.[262]

In one patient, xanthoderma–xanthotrichia (yellow discoloration of the skin and hair) was caused by an IgG λ protein with antiriboflavin antibody activity. Xanthoderma disappeared when the IgG level decreased to less than 2 g/dl after chemotherapy.[252] Another patient with similar clinical and laboratory features has been reported.[253]

DiMinno et al. described a patient with MM and a bleeding diathesis in whom an IgG1 κ protein reacted with platelet glycoprotein IIIa.[263] This produced a thrombasthenia-like state. An IgM κ M protein that agglutinated platelets and produced a pseudothrombocytopenia has been reported.[264]

The binding of calcium by M protein may produce hypercalcemia without symptomatic or pathologic consequences.[265,266] This situation must be recognized so that patients are not treated for hypercalcemia.[267] Copper-binding M protein has been found in two patients with MM.[268,269] Binding of an M protein with transferrin, producing a high serum iron level, has been reported.[270,271] Hilgard et al. described a patient with multiple thrombi from intravascular precipitation of an IgG λ monoclonal cryoglobulin with transferrin and fibrinogen.[272] Pettersson et al. described a patient with an IgG κ protein that bound phosphate, producing a spurious elevation of the serum phosphorus level.[273] Transient M proteins with antibody activity have also been recognized after infection in children. One report described a newborn with congenital toxoplasmosis who had an IgG λ protein.[274]

CHAPTER 98

MULTIPLE MYELOMA

Angela Dispenzieri, Martha Q. Lacy, Shaji Kumar

Multiple myeloma (MM) is a neoplastic plasma cell dyscrasia (PCD) characterized by a clinical pentad: (1) anemia, (2) a monoclonal protein in the serum or urine or both, (3) bone lesions and/or bone pain, (4) hypercalcemia, and (5) renal insufficiency. With the exception of monoclonal gammopathy of undetermined significance (MGUS), it is the most common PCD, with an incidence of about 4.5 per 100,000 per year in the United States. Solitary plasmacytoma and plasma cell leukemia (PCL) are recognized as separate entities and are much less prevalent. The underlying pathogenesis of the plasma cell malignancies is not well understood but is an area of active investigation. At present, according to the WHO (World Health Organization) classification system, there is only one category for MM.[1] Results of clinical trials are confounded by this underclassification. Emerging information about the genetic underpinning of the disease, however, will likely change this deficiency.

The interactions among the plasma cells, their antibody product, the local bone and bone marrow environment, and other organs are complex. There is no cure for MM, but there are many effective treatments that prolong and improve the quality of life in patients with the disease.

HISTORY

The Earliest Diagnoses and Diagnostic Methods

Samuel Solley reported the first well-documented case of MM (mollities ossium) in Sarah Newbury in 1844.[2,3] Several years later, William MacIntyre described and recorded the properties of the disease we now call MM in Thomas Alexander McBean.[4] Both Drs. MacIntyre and Bence Jones noted and described some of the peculiar urine properties of this same patient. On heating, the urine was found to be "abound in animal matter," which dissolved on the addition of nitric acid but reappeared after cooling. These urinary proteins became known as Bence Jones proteins.[5] MacIntyre and Dalrymple described the post-mortem examination of Mr. McBean's bones.[4] The former described the affected bones as softened and fragile, with their interiors replaced with a soft "gelatinform" blood-red substance. Dalrymple suggested that the disease began in the cancellous bone and extended through the periosteum. The nucleated cells, which formed the bulk of the gelatinous material, were heterogeneous in size and shape, but the majority were round to oval. Many of the larger and more irregular cells frequently contained two or three nuclei.[3] The term "multiple myeloma" was coined in 1873 by von Rustizky,[6] who independently described a similar patient to emphasize the multiple bone tumors that were present.

In 1889, Professor Otto Kahler[7] described a case involving a 46-year-old physician with MM and published a major review of the disease. He described the skeletal pain, albuminuria, pallor, anemia, a precipitable urinary protein, and the findings on necroscopy and linked these findings as part of a clinical syndrome that bears his name (MM has also been referred to as Kahler disease).

In 1898 Weber predicted the usefulness of Roentgen x-rays in establishing the diagnosis[3,8] and later postulated the Bence Jones protein was produced in the bone marrow.[9] Wright[10] emphasized that MM arose specifically from plasma cells of the marrow, Jacobson[11] recognized Bence Jones proteins in the bloodstream, and Walters[12] concluded that the Bence Jones protein was probably derived from blood proteins through the action of the abnormal cells in the bone marrow. The technique of bone marrow aspiration[13] facilitated the diagnosis of MM.

Serum electrophoresis, described by Tiselius in 1937,[14] made it possible to separate serum proteins. Longsworth et al.[15] applied electrophoresis to the study of MM and described the tall narrow-based "church spire" peak. The use of filter paper as a support for protein electrophoresis permitted the separation of protein into distinct zones that could be stained with various dyes.[16] Paper electrophoresis was supplanted by filter paper in 1957 and most recently by high-resolution electrophoresis on agarose gel. Immunoelectrophoresis[17] and immunofixation or direct immunoelectrophoresis[18] made it possible to detect small monoclonal light chains not recognizable by electrophoresis. The immunoglobulin free light chain assay has been added to the diagnostic armamentarium to detect circulating free light chains in the majority of patients previously designated nonsecretory.[19]

Kunkel[20] hypothesized that monoclonal proteins were the product of malignant plasma cells and were the equivalent of normal antibodies produced by normal plasma cells. Before 1960, the term "gamma globulin" was used for any protein that migrated in the gamma mobility region of the electrophoretic pattern; however, in 1959, Heremans[21] proposed the concept of a family of proteins with antibody activity. In 1961 in a Harvey Lecture,[22] Waldenström distinguished between monoclonal and polyclonal hypergammaglobulinemia.

In 1928, Geschickter and Copeland[23] reported on the largest case series of MM—13 cases—and reviewed the 412 cases reported in the literature since 1848. They documented a higher incidence in men than women and an overall survival (OS) of about 2 years. They emphasized six features: (1) involvement of the skeletal trunk, (2) pathologic rib fractures, (3) Bence Jones proteinuria in 65% of cases, (4) backache with early paraplegia, (5) anemia in 77% of cases, and (6) chronic renal disease. They did not note abnormalities of blood protein or an increased erythrocyte sedimentation rate.[3] In 1931, Magnus-Levy[24] described amyloidosis as a complication of MM. Salmon, Durie, and Smith developed methods to quantitate the total body burden of tumor cells[25] and to stage patients[26] in 1970 and 1975, respectively.

Prior to the discovery in 1950[27] of salutary effects of adrenocorticotropic hormones on MM (Fig. 98.1), medications used to that point included stibidine and urethane, neither of which had activity upon critical testing.[3] During that decade, it was recognized that the adrenocorticotropic hormones cortisone and prednisone were useful agents in patients with MM. Corticosteroids decreased bone pain, improved hypercalcemia, increased hemoglobin values, and decreased abnormal serum and urine globulin concentrations.[28] However, it was not until 1967 that high-dose corticosteroids were recognized as effective antineoplastic agents against MM.[29]

Blokhin et al.[30] reported benefits in 3 of 6 patients with MM who were treated with sarcolysin (a racemic mixture of the *d*- and *l*-isomers of phenylalanine mustard). Subsequently, the *d*- and *l*-isomers were tested separately, and the anti-MM activity was found to reside in the *l*-isomer, melphalan. Bergsagel et al.[31] reported significant improvement in 14 of 24 patients with MM with the use of melphalan; this activity was quickly substantiated by others.[32] Similar effectiveness was noted with cyclophosphamide.[33] Subsequently, interferon-α (IFN), doxorubicin, carmustine, thalidomide, bortezomib, lenalidomide, bendamustine, and carfilzomib[34–36,37,38,39] have each been reported to have activity as a single agent in MM.

INCIDENCE AND EPIDEMIOLOGY

As described in Chapter 97, recent evidence supports the theory that all MM arises from a preceding MGUS.[40] Increasingly it is becoming apparent that there is an increased risk of developing MM or MGUS among first-degree relatives of both MGUS and MM patients.[41,42] Whether this family linkage is due to either genetic susceptibility factors or shared environmental risk factors (or both) is yet to be determined.

Epidemiology of Myeloma

The 2012 annual estimate in the United States for new cases of MM is 21,700 and for deaths is 10,710.[43] SEER (Surveillance, Epidemiology, and End Results) data incidence age-adjusted rates from 1992 through 1998 show an overall incidence of 4.5 per 100,000 per year, with the incidence among whites being 4.2 per 100,000 per year and among blacks, 9.3 per 100,000 per year.[44] Male-to-female ratio is 1.3 to 1.[43] The median age at diagnosis of MM is 71 years. Since the turn of the century, 5-year survival rates in blacks and whites have equalized.[43] MM accounts for 1% of all malignancies and 10% of all hematologic malignancies in whites and 20% in African Americans.[44] International mortality data reveal that the highest rates of MM occur in Northern Europe, North America, Australia, and New Zealand and the lowest rates are in Japan, Yugoslavia, and Greece.[45] Geographic clusters[46] and familial clusters[47–52] of MM among first-degree relatives have been documented. Modest increases in MM rates were observed when incidence data from 1973 to 1992 were calculated in nine population-based cancer registries.[53] These increases are likely due to a heightened awareness of the disease.

Etiologic Factors

Radiation Exposure

Reports of increased MM incidence and mortality among Japanese atomic bomb survivors have suggested an association between ionizing radiation and MM. Initial evaluations of cancer incidence[54] and mortality[55] among Japanese atomic bomb survivors suggested an increased risk of MM with increasing radiation dose, an observation that was no longer seen with additional years of follow-up.[56] Subsequent data would suggest that the prevalence of MGUS is higher among those younger patients exposed to higher doses of radiation.[57]

An excess of MM deaths among American radiologists was reported in the 1960s.[58] MM risk was considered to be two times higher among radiologists exposed to low doses of radiation than among physicians not exposed to radiation.[59] However, among 27,000 Chinese diagnostic radiography workers, no excess incidence of MM was observed in a 30-year period.[60] An analysis of 115,000 workers from the combined roster of four different nuclear plants showed a positive association between MM and radiation exposure in older age groups.[61] No increases in MM incidence and mortality have been observed among British[62] or New Zealand[63] military men who participated in atmospheric nuclear weapons testing.

Diagnostic x-ray exposure has not been linked with the development of MM in most epidemiologic studies.[64–69] A large multicenter population-based case-control study showed no evidence of excess risk of MM among individuals who reported exposure for 10 or more diagnostic radiographs.[70] One study reported that the overall risk for MM was not high (RR, 1.14), but that there was evidence of increasing risk with exposure to increasing numbers of radiographic procedures.[71] Of historic interest is the finding of an association between MM and the use of Thorotrast.[65] Studies of the effects of therapeutic irradiation on MM risk have shown conflicting results, but a study of 180,000 women treated for cervical cancer demonstrated no overall excess risk of developing MM.[72] Similarly, a study of 14,000 patients suffering from ankylosing spondylitis and treated with radiation revealed no significant increase in the risk of developing MM.[73]

Workplace Exposures

Several epidemiologic studies have evaluated the risk of MM among agricultural workers, with positive associations reported by many[74–79] but not all of the studies.[80–82] Khuder and Mutgi[83] found a relative risk of 1.23 in a meta-analysis of several studies. Workers in various metal occupations and industries have been reported to have an increased MM risk.[84–86]

Benzene has been suggested as a possible etiologic agent for MM.[87–89] A comprehensive review of the published literature found no evidence of a link between benzene exposure and MM.[90] Subsequently, Sonoda and colleagues[91] conducted a meta-analysis of case-control studies and showed no excess risk for the development of MM. A meta-analysis by Wong and Raabe[92] of more than 350,000 petroleum workers similarly showed no increased risk.

Cigarette Smoking, Alcohol Consumption, and Diet

Multiple studies to date have found no etiologic role for cigarette smoking or alcohol consumption in the development of MM.[93–96] In contrast, Tavani et al.[97] suggested a dietary link for MM and found a higher risk among people consuming large quantities of liver (odds ratio [OR], 2.0) and butter (OR, 2.8), and a lower risk among people consuming large amounts of vegetables (OR, 0.4) No association of MM and consumption of coffee or red meat has been found.[97] Brown and colleagues[98] looked at diet and nutrition as risk factors for MM among blacks and whites in the United States. Only obesity was associated with increased risk, and obesity was more frequent in black than in white controls. Frequent consumption of cruciferous vegetables, fish, and vitamin C supplements was associated with decreased risk of MM. The authors concluded that the greater use of vitamin C supplements by whites and the higher frequency of obesity among blacks may explain part of the higher incidence of MM among blacks compared with whites in the United States.

Personal use of hair dyes was evaluated as a risk factor for MM,[99] including two prospective studies.[100,101] Thun et al.[100] found that women using permanent hair dyes are not generally at increased risk of fatal cancer. However, women with prolonged use of dark, particularly black, hair dyes may have increased risk

of fatal non-Hodgkin lymphoma and MM, but these women are a small fraction of hair dye users. A subsequent meta-analysis by Correa et al.[102] showed no increased risk.

Socioeconomic Status

Some investigators have reported that there is an inverse relationship between the risk of MM and socioeconomic status,[103] and that this inverse correlation may account for a substantial amount of the black and white differential of MM incidence.[104] Earlier studies did not show a link between socioeconomic status and MM.[105]

Chronic Antigenic Stimulation

Repeated or chronic antigenic stimulation of the immune system may lead to MM. Several case-controlled studies have suggested that MM risk is associated with past history of infections, inflammatory conditions, connective tissue disorders, autoimmune illnesses, and allergy-related disorders.[94,106,107] Patients with the human immunodeficiency virus may have an increased likelihood of developing MM.[108,109] In addition, MM and hepatitis C may be associated.[110–112] The finding of human herpes virus 8 has been suggested as a possible etiologic agent,[113] but this has not been confirmed.[114–117] Increased risk for MM has been observed in patients with rheumatoid arthritis.[51,118,119] Other studies of individuals with these conditions have shown no increased risk of MM.[120–123]

CLINICAL MANIFESTATIONS

The symptoms of MM may be nonspecific and include fatigue, bone pain, easy bruisability and bleeding, recurrent infections, manifestations of anemia, hypercalcemia, lytic bone lesions, hyperviscosity, thrombocytopenia, and hypogammaglobulinemia (Fig. 98.2). Weakness, infection, bleeding, and weight loss are reported in as many as 82%, 13%, 13%, and 24% of patients, respectively.[124–127] Hypercalcemia is present in 18% to 30% of patients.[124,125,126] One to two thirds of patients present with spontaneous bone pain.[124,125,126] "Tumor fever" is present in less than 1% of presenting patients.

Anemia

The most common clinical feature of MM is anemia. A hemoglobin concentration of less than 120 g/L occurs in 40% to 73% of patients at presentation[124,125,126] and contributes to the weakness and fatigue observed in as many as 82% of patients.[124,125,126]

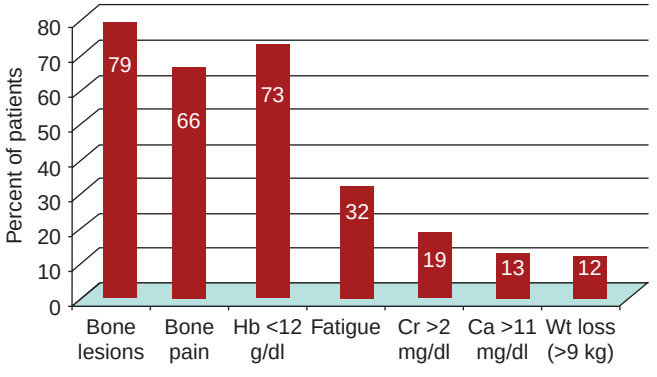

FIGURE 98.2. Signs and symptoms of 1,027 newly diagnosed myeloma patients seen at the Mayo Clinic from 1985 through 1998.

The anemia is normochromic, normocytic in most patients, but macrocytosis may be observed as well. When there are high concentrations of serum immunoglobulin, rouleau formation may be observed (Fig. 98.3A). The combination of anemia and hyperproteinemia leads to a marked increase of the erythrocyte sedimentation rate in more than 90% of cases.[128]

The anemia is related partially to direct infiltration and replacement of the bone marrow. Hemoglobin concentration is also correlated directly with the percentage of MM cells in S phase,[129] suggesting that the bone marrow cytokine milieu, permissive for MM cell proliferation, is not conducive to efficient erythropoiesis. Cytokines, like tumor necrosis factor-α and IL-1, may inhibit erythropoiesis.[130] Fas ligand-mediated erythroid apoptosis is also increased in patients with MM.[131] Finally, relative erythropoietin deficiency from MM-induced renal insufficiency also contributes to the observed anemia.

Monoclonal Proteins

The M protein (M component, myeloma protein, or M spike) is a hallmark of the disease; 97% of MM patients have either an intact immunoglobulin or a free light chain that can be detected by protein electrophoresis, immunoelectrophoresis, or immunofixation studies of the serum or urine (Fig. 98.3B,C).[124,126] Those cases without a detectable monoclonal protein have been referred to as nonsecretory MM, which had accounted for approximately 1% to 3% of MM cases. With the immunoglobulin free light chain assay, small free light chain monoclonal proteins heretofore not seen by aforementioned methods are seen in approximately two thirds of the cases that had been referred to as nonsecretory.[19]

Historically, monoclonal proteins have had a valuable role in the fields of immunology and molecular biology, for distinguishing MGUS from MM and for calculating MM tumor burden and kinetics.[25,132,133] Practically, both serum and urine M protein concentrations are used to stage MM patients and to document their response to treatment.

In a series of 1,027 newly diagnosed cases of MM, the immunoglobulin type was IgG, IgA, IgD, and free light chain only (Bence Jones MM) in 52%, 20%, 2%, and 16% of cases, respectively.[126] Fewer than 1% of MM cases are IgM; most IgM monoclonal proteins are associated with diagnoses of MGUS, lymphoma, Waldenström macroglobulinemia, or primary systemic amyloidosis.[134] A total of 93% of patients have a monoclonal protein detected in their serum. About 90% of MM patients have reduction in at least one of their uninvolved immunoglobulins.[134] About 70% have a monoclonal protein—or fragment thereof—detected in the urine.

Histopathology

The bone marrow microenvironment is hospitable to malignant plasma cells that circulate through the blood. There is a complex interaction among the malignant clone, its surrounding stromal cells, and the remaining immune cells. The morphologic and immunologic phenotypes of MM cells can vary, and they often resemble normal plasma cells. Plasma cells are at least two to three times the size of peripheral lymphocytes and are round to oval, with one or more eccentrically placed nuclei (Fig. 98.3D). The nucleus, which contains either diffuse or clumped chromatin, is displaced from the center by an abundance of rough-surfaced endoplasmic reticulum, the site of specialized immunoglobulin synthesis. Intranuclear and cytoplasmic inclusions are not uncommon.[135] There is a perinuclear clear zone that is the site of the Golgi apparatus, the machinery used for immunoglobulin packaging and glycosylation for secretion. Derangements of immunoglobulin secretion are responsible for an assortment of cytologic aberrations, including flaming cells, Mott cells, Russell bodies, and Gaucher-like cells. Flaming cells are plasma cells that have intensely eosinophilic cytoplasm with a magenta or

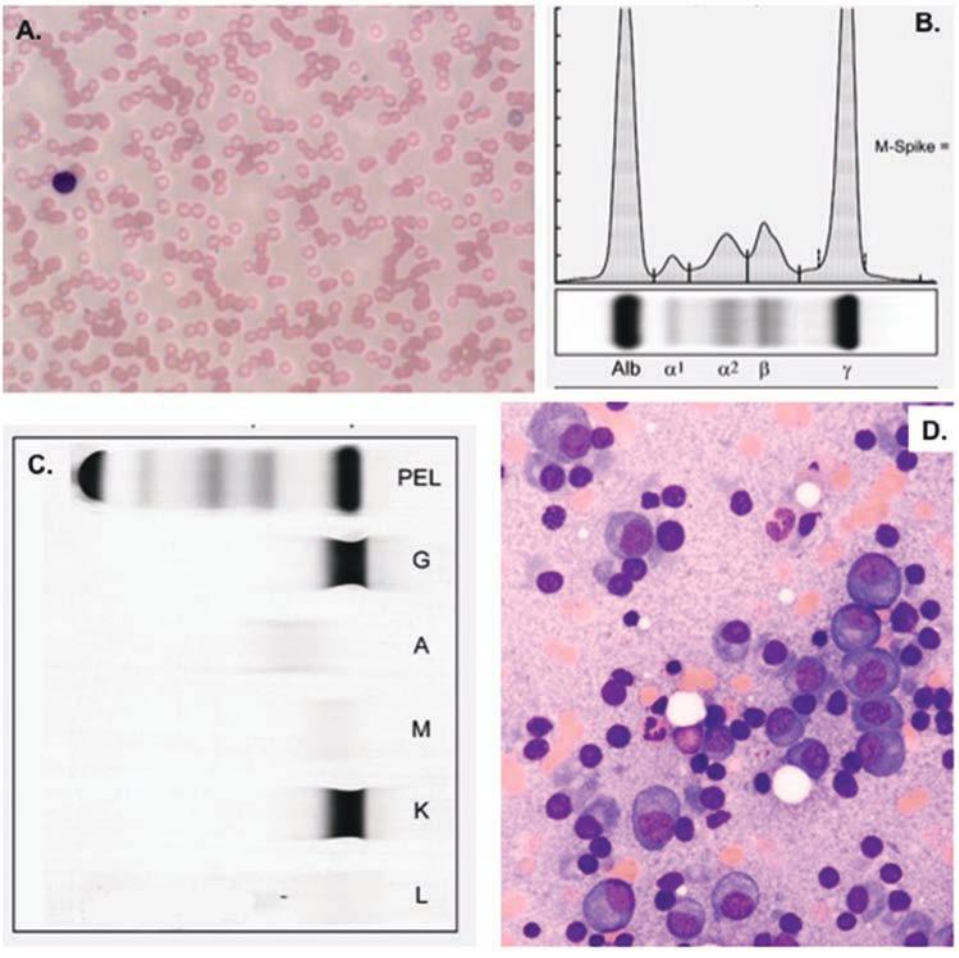

FIGURE 98.3. Laboratory findings in patients with multiple myeloma. A: Rouleaux. **B:** Serum protein electrophoresis, illustrating a 3-g/dl monoclonal protein spike. **C:** Immunofixation electrophoresis, illustrating a monoclonal IgG lambdam monoclonal protein. **D:** Bone marrow: myeloma cells on aspirate specimen.

carmine coloring of their margins, which is due to plugging of peripheral secretory channels by precipitated immunoglobulin or immunoglobulin fragments. These cells are most commonly seen in IgA MM. Thesaurocytes are large flaming cells with a pyknotic nucleus that is pushed to the side. Mott cells (grape cells or morula forms) are plasma cells filled with dense spherical immunoglobulin inclusions; these inclusions are colorless, pink, or blue. Other inclusions are Russell bodies and their intranuclear counterparts (intranuclear dense bodies); these appear cherry red and can be as large as several microns in diameter. Gaucher-like cells are not uncommon in MM infiltrates; these cells are macrophages laden with sphingolipids released by the dying plasma cells.[136] None of these interesting inclusions is specific for malignancy nor do they have prognostic value.

In MM, there is often discordance between the nucleus and cytoplasm, the former appearing immature and the latter highly differentiated. About 20% of MM cases have plasmablastic morphology: a diffuse chromatin pattern, nucleus greater than 10 microns or nucleolus greater than 2 microns, relatively less abundant cytoplasm, and a concentrically placed nucleus with little or no hof.[137,138] Both diffuse and nodular infiltration patterns can be observed, although the former is more common. A minority of patients have plasma cells that have a lymphoplasmacytic appearance. MM cells are commonly present in cords around bone marrow microvessels. There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating fraction of marrow plasma cells in patients with MM.[139,140] Mild marrow fibrosis may be observed in as many as 27% of cases; extensive fibrosis is rare.[141,142] Less than 1% of cases have an extensive idiopathic granulomatous reaction.[135]

The immunophenotype of MM cells is complex. In general, MM cells are CD45 negative and CD38 and CD138 positive.[143,144] However, there is increasing evidence that a subset of MM cells is CD45 positive,[144,145] with an increasing proportion of CD45 positive MM cells in less advanced disease.[146,147] CD19 and CD20 are earlier B-cell antigens that are variably expressed on MM cells; surface immunoglobulin is seen in up to one third of patients. CD56 is strongly positive in about 55% to 78% of MM cases.[144,148,149] CD56-negative MM cells tend to be present in more aggressive disease, such as end-stage MM or plasma cell leukemia.[149,150] Other surface antigens such as CD10 (CALLA), CD28, CD117 (c-KIT), CD13, CD33, and CD20 are present on a minority of patients' MM cells.[143–145,151,152] Co-stimulatory molecules involved in the activation of B- and T-lymphocytes (CD28 and CD40) are seen in 40% and 70% of patients, respectively.[153,154]

No individual bone marrow finding, however, is pathognomonic for a malignant plasma cell process; the bone marrow diagnosis of MM relies on percentage of clonal bone marrow plasma cells, with 10% accepted as a cutoff. The clinical diagnosis, of course, is made from a synthesis of bone marrow findings and other clinical features.

Bone Disease

Approximately one third to two thirds of patients present with bone pain.[124,125,126,127] There is an uncoupling of the balance between osteoclastic and osteoblastic activity. Even before the development of bone lesions, enhanced osteoblastic recruitment with an increased generation of new osteoclasts is observed in early MM.[155] Regardless of the initiating signal, whether IL-1β,

IL-6 and sIL-6R, tumor necrosis factor-α, MIP-1α, receptor activator of NF-kappaβ (RANK) ligand, or parathyroid hormone-related protein (PTHrP),[156] the eventual outcome is bone destruction.[157]

MM bone disease is a major source of morbidity and may present as an area of persistent pain or as a vague migratory bone pain, often in the lower back and pelvis. The type, location, and duration of the pain have no characteristic features. At times, pain and tenderness may be sudden in onset, especially when associated with a pathologic fracture, and are most commonly precipitated by movement. Persistent localized pain also may be associated with a pathologic fracture.

A myelomatous lesion may extend through the cortex of a vertebral body and cause either nerve root or spinal cord compression in less than 2% of patients.[125] Alternatively, the MM can disturb the mechanical integrity of a vertebral body, resulting in compression fracture with retropulsion of either plasmacytoma or bony fragments into the spinal canal, again causing neurologic deficit. Approximately 75% of patients have punched-out lytic lesions, osteoporosis, or fractures on conventional radiography (Fig. 98.4A,B). The vertebrae, skull, ribs, sternum, proximal humeri, and femora are involved most frequently.[124,126,127] A small subset of patients has de novo osteosclerotic lesions,[158] and in a few patients osteosclerosis is seen after therapy and may serve as a marker of healing.

Because myelomatous bone lesions are characteristically lytic, conventional radiography is superior to technetium-99m bone scanning.[159,160] About twice as many myelomatous bone lesions are detected by radiograph as by bone scan; an exception to this general finding is at the lumbar spine and the rib cage, where the two methods are equally reliable.[160] There have been reports supporting the use of technetium-99m sestamibi scans. These scans are almost as sensitive as plain radiographs for bone disease in untreated patients (i.e., patients with active disease).[161] They may be able to distinguish active myelomatous bone lesions from inactive lesions[161] and are quite sensitive for bone marrow involvement.[162–164] There is a high concordance between scintigraphic findings and clinical status in patients undergoing chemotherapy or autologous stem cell transplantation (ASCT).[165,166] 18-Fluorodeoxyglucose positron emission tomography (FDG–PET) also shows promise in the staging of MM, with sensitivity and specificity rates of 84% to 92% and 83% to 100%, respectively[167] (Fig. 98.4D,E).

Computed tomography and magnetic resonance imaging (MRI) are more sensitive than conventional radiography (Fig. 98.4C). Both reveal specific lesions in 40% of stage I MM patients.[168] The presence of lacunae larger than 5 mm with trabecular disruption on computed tomography appears to be sensitive and specific for MM. This information may be useful in distinguishing between senile and myelomatous osteoporosis and compression fractures.[169] Among asymptomatic MM patients with normal radiographs, 50% have tumor-related abnormalities on MRI of the lower spine.[170] In patients with Durie-Salmon stage I MM, MRI can distinguish patients at higher and lower risks of progression.[171] One third of patients with an apparently solitary plasmacytoma of bone have evidence of other plasma cell tumors on MRI.[172]

MRI is superior to radiographs for the detection of lesions in the pelvis and the spine, but overall it is inferior to radiographs for detecting bone involvement in MM (79% versus 87%, respectively).[173] On MRI, vertebral fractures due to spinal infiltration or osteoporosis are seen in 48% of patients with symptomatic MM, and spinal canal narrowing with impingement occurs in 20%.[170] Nanni et al.[174] compared MRI to FDG-PET/CT in 28 newly diagnosed myeloma patients. In 25% of patients FDG-PET/CT

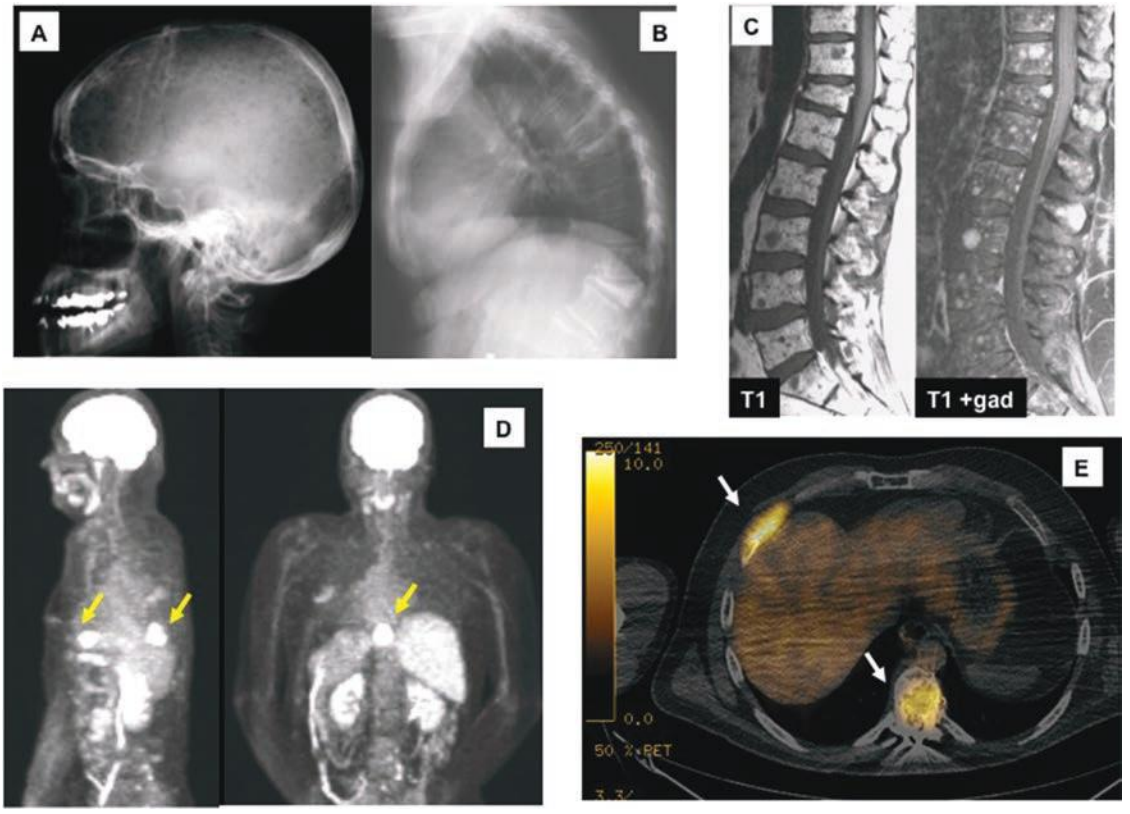

FIGURE 98.4. Myeloma bone disease. **A:** Plain radiograph of a skull with punched-out myeloma lesions. **B:** Plain radiograph of a compression fracture thoracic spine. **C:** Myelomatous marrow involvement of the lumbar spine by magnetic resonance imaging (MRI) with and without gadolinium. **D:** 18-Fluorodeoxyglucose positron emission tomography (FDG-PET), spine and rib involvement. **E:** Fusion image of CT/FDG-PET scan demonstrating lesion at rib and thoracic vertebra.

detected more lytic bone lesions, all of which were out of the field of view of MRI, and in 25% of patients MRI detected an infiltrative pattern in the spine that was not discerned on FDG-PET/CT. In subsequent studies, whole body MRI has been reported to have a higher sensitivity and specificity than FDG-PET/CT[175] and than multidetector-row computed tomography.[176] A major limitation, however, to MRI and PET/CT is that there are no uniformly accepted standard acquisition or interpretation protocols, limiting their generalizability. Detection of marrow infiltration on MRI does not translate into a deficit of cortical bone integrity. Also, given the expense of MRI, it cannot be recommended for routine clinical use in all patients.

Hypercalcemia

Hypercalcemia occurs in 18% to 30% of patients. About 13% have concentrations greater than 11 mg/dl. Rates of hypercalcemia at presentation have been decreasing in the last few decades, perhaps because of the earlier diagnosis of patients.[124,125,126,127] Hypercalcemic patients may complain of fatigue, constipation, nausea, or confusion. Calcium can precipitate in the kidneys and aggravate renal insufficiency. Inorganic phosphate is rarely decreased, except in cases of acquired Fanconi syndrome.[177]

Renal Insufficiency

Approximately 25% of MM patients have a serum creatinine value greater than 2 mg/dl at diagnosis. Another 25% have mildly elevated creatinine values.[124,125,126,127,178–181] Patients with Bence Jones or IgD MM have the highest rates of renal insufficiency.[179,181] Free light chain proteinuria is a risk factor for renal failure.[182] Contributing factors to the renal insufficiency associated with MM kidneys include hypercalcemia, dehydration, hyperuricemia, and the use of nephrotoxic drugs.[183] If the renal insufficiency reverses with therapy, as it does in more than half of cases,[183,184] survival is fourfold to sevenfold higher than in those in whom it does not.[178,185] Factors predicting for renal function recovery include a serum creatinine less than 4 mg/dl, serum calcium value greater than 11.5 mg/dl, proteinuria less than 1 g/24 h, and adequate rehydration.[178]

The pathologic lesion of MM kidney consists of monoclonal light chains in the tubules in the form of dense, often laminated, tubular casts. These casts contain albumin and Tamm-Horsfall protein. Light chains are normally filtered by the glomeruli and reabsorbed and catabolized in the nephron's proximal tubules. It is postulated that these systems become overwhelmed, and casts result. When other causes contributing to renal insufficiency are excluded, there is a good correlation between the extent of MM cast formation and the severity of renal insufficiency.[186,187] Tubular atrophy and degeneration correlate well with renal dysfunction.[188] The most common findings on autopsy include tubular atrophy and fibrosis (77%), tubular hyaline casts (62%), tubular epithelial giant cell reaction (48%), and nephrocalcinosis (42%). Evidence of acute and chronic pyelonephritis were observed in 20% and 23% of cases, respectively. Plasma cell infiltrates and amyloid may be observed in 10% and 5% of cases, respectively.[127] Rarely, MM may be associated with acquired Fanconi syndrome.[177,189]

An important feature of myeloma kidney is that it is primarily a tubular, rather than a glomerular, disease.[188] Glomerular function is preserved initially, and there is a predominance of immunoglobulin light chain protein in the urine instead of the nonspecific protein loss observed in glomerular disease. This feature helps predict the renal lesion: nonspecific protein loss (i.e., mostly albumin) is more compatible with primary systemic amyloidosis, light chain deposition disease of the kidney, or proteinuria unrelated to the PCD;[186] a free light chain predominance is consistent with myeloma kidney.

Infection

Patients with MM are at high risk for bacterial infections and for dying of overwhelming bacteremia. Overall, the incidence of infection is from 0.8 to 1.4 per patient-year.[190–192] During the first 2 months after initiating chemotherapy the infection incidence is as high as 4.68 infections per patient-year[192] but decreases to 0.44 to 0.49 per patient-year in those reaching a plateau phase.[191,192] Risk factors for infection are serum creatinine values greater than or equal to 2 mg/dl[190,192] and decreased levels of polyclonal serum immunoglobulins.[191,192] Since the 1960s, Gram-negative bacilli have become more common pathogens than *Streptococcus pneumoniae* in patients with MM.[193] At disease onset, infections with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are most common.[193] After diagnosis, the proportion of infections due to Gram-negative bacilli and *Staphyloccocus aureus* increases markedly, and are responsible for more than 90% of deaths from infection.[193]

Hemostasis in Multiple Myeloma

MM can be associated with hemostatic abnormalities, more often bleeding than thrombosis. Bleeding as a complication of MM may be present in as many as one third of patients[194] and is related to thrombocytopenia, uremia, hyperviscosity, and interference with the function of coagulation factors. Rarely, MM proteins may also interact with coagulation proteins.[192,193]

The association with thrombosis is less clear because of coexisting factors such as old age and immobility that confound the interpretation of available data, however, the risk of thrombosis may be increased in MM patients.[194,195] Individual cases of aberrance have been reported. Monoclonal proteins have been shown to be responsible for lupus anticoagulants,[196,197] acquired protein S deficiency,[198,199] acquired activated protein C resistance,[200] and inhibition of tissue plasminogen activator.[201]

Fewer than 7% of MM patients have a viscosity greater than 4.[124,126] Symptoms of hyperviscosity include bleeding (particularly of the oronasal areas), purpura, decrease in visual acuity, retinopathy, neurologic symptoms, dyspnea, expanded plasma volume, and congestive heart failure. Most patients become symptomatic when the serum viscosity is 6 or 7 centipoise (normal is less than or equal to 1.8 centipoise).

"Acute Terminal Phase of Plasma Cell Myeloma" and Cause of Death

Bergsagel and Pruzanski[202] described the "acute terminal phase" of patients with MM, which they observed in about one third of their preterminal patients. They defined the syndrome as rapidly progressive disease with an unexplained fever and pancytopenia and a hypercellular marrow. Extramedullary plasmacytomas are also not uncommon preterminally.[203] As the disease progresses, and at autopsy, cutaneous, visceral, and even meningeal involvement is possible.[203] Besides "progressive disease," the most frequent causes of death are infection in 24% to 52% and renal failure in about 20%.[127,183,202,203] Acute leukemia, myelodysplastic syndromes, and hemorrhage are the causes of death in a minority of patients.[127,202,203] In one autopsy series, 85% of patients had evidence of either bacterial or fungal infection, and myelomatous involvement was found in the spleen, liver, lymph nodes, and kidneys in 45%, 28%, 27%, and 10% of patients, respectively. Other less frequent areas of myelomatous involvement were the lung, pleura, adrenal glands, pancreas, and testis.[127]

DIAGNOSIS

The diagnosis of MM has not been subject to static norms. In 1973, the Chronic Leukemia–Myeloma Task Force[204] set forth guidelines for the diagnosis of MM (Table 98.1). These criteria,

TABLE 98.1

CRITERIA FOR DIAGNOSIS OF MGUS, SMM, AND MM

	Chronic Leukemia-Myeloma Task Force Definition of Multiple Myeloma (1973)[a]	Criteria for Diagnosis of MGUS, SMM, and MM, International Working Group (2003)[b]
Monoclonal Gammopathy of Undetermined Significance	Not described	- Serum monoclonal protein (<30 g/L) - Bone marrow <10% plasma cells - No evidence of other B-cell proliferative disorders - No related organ or tissue impairment[c,d]
Smoldering Myeloma (asymptomatic)	Not described	- No related organ or tissue impairment[c] - Serum monoclonal protein (≥30 g/L) *and/or* - Bone marrow clonal plasma cells ≥10%
Multiple Myeloma	If M protein present in serum or urine, one or more of the following must be present: - Marrow plasmacytosis >5% in absence of underlying reactive process - Tissue biopsy demonstrating replacement and distortion of normal tissue by plasma cells - >500 plasma cells/mm^3 in peripheral blood - Osteolytic lesion unexplained by other causes If no M protein in serum and urine, radiologic evidence of osteolytic lesions or palpable tumors and one or more of the following required: - Marrow plasmacytosis of >20% from two sites in absence of reactive process - Tissue biopsy demonstrating replacement and distortion of normal tissue by plasma cells	ACTIVE OR SYMPTOMATIC MM - Monoclonal protein present in serum and/or urine - Clonal bone marrow plasma cells or plasmacytoma - Related organ or tissue impairment[a]

MM, multiple myeloma; MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering MM.
[a]From Chronic Leukemia-Myeloma Task Force, National Cancer Institute,[204] shown for historical purposes.
[b]From Chronic Leukemia-Myeloma Task Force, current definitions.[205]
[c]The absence of CRAB (calcium elevation [> 1 mg/dl above upper limit of normal], renal dysfunction [creatinine >2 g/dl], anemia [hemoglobin 2 g/dl below lower limit of normal], bone lesions [lytic lesions or osteoporosis with compression fracture] attributable to the plasma cell disorder).
[d]The existence of immunoglobulin light chain amyloidosis or another paraneoplastic disorder attributable to the monoclonal gammopathy, like a peripheral neuropathy would be termed "monoclonal gammopathy associated with…"

which by today's standards are not stringent enough, have been replaced by a more modern definition.[205] In the last 3 decades, the terms and definitions of MGUS, smoldering MM, indolent MM, and symptomatic MM[124,206–208] have evolved and are now to be replaced by the following designations: MGUS, inactive (smoldering) MM, and active (or symptomatic) MM.[205]

Because MM includes a spectrum of biologic features, physicians should not feel compelled to start treatment as a result of a single threshold value. The diagnosis of active MM is not a straightforward pathologic one; rather, it is a clinical diagnosis that requires thoughtful synthesis of multiple variables. Patients with Durie-Salmon stage I disease, who also meet the criteria for smoldering or asymptomatic MM, should be managed expectantly. Median progression-free survival in asymptomatic stage I patients, observed without any therapy, is 12 to more than 48 months;[209–212] for similar stage II patients, progression-free survival is 12 months.[209] Until recently,[213] no survival advantage had been demonstrated by treating asymptomatic MM patients.[208,210,211,214]

SYSTEMIC THERAPY FOR MULTIPLE MYELOMA

Before starting therapy for MM, a distinction must be made between smoldering (asymptomatic) MM and active MM (Table 98.1). Approximately 20% of patients with MM are recognized by chance without significant symptoms; such patients can be carefully monitored without instituting therapy (see Chapter 97). Once the decision has been made to treat for symptomatic disease, a long-term plan for managing the disease should be formulated before instituting therapy. Because high-dose therapy with autologous hematopoietic stem cell transplantation (ASCT) has been accepted as an important treatment modality for patients younger than age 70, only a limited amount of alkylator-based therapy should used prior to the collection of hematopoietic stem cells in patients considered candidates for high-dose therapy.

Historically, the bifunctional alkylating agents, including melphalan and cyclophosphamide, had been the foundation of therapy for MM. MM cells tend to proliferate slowly, and alkylators, whose effectiveness does not rely heavily on cell division and DNA replication, are useful therapeutic agents. Prior to 1999, the bifunctional alkylators, nitrosoureas, doxorubicin, and glucocorticoids were the primary agents shown to have single-agent activity against MM in vivo.[215] These drugs along with vincristine, either singly or in combination, had been the mainstay of chemotherapy for MM from the early 1960s to the present (Fig. 98.1). Until recently, the higher response rates seen with regimens that combine multiple active agents as part of initial therapy, had not resulted in improved OS rates.[216] IFN-α had been incorporated into induction and maintenance protocols with minimal benefit.[34,217–219] Both autologous and allogeneic stem cell transplantation (AlloSCT) have become important therapeutic options since McElwain and Powles' description in 1983[220] of the benefit of dose intensification of melphalan in patients with MM. With the recognition of thalidomide's activity against MM in 1999[37] and the subsequent development of bortezomib,[38] lenalidomide,[39] and carfilzomib[221] there is hope that the next 4 decades of MM treatment will be even more promising than the last.

Before discussing induction, transplantation, maintenance, and salvage therapies, two general concepts are reviewed: interpretation of study response data and the efficacy of single

FIGURE 98.5. chemotherapeutic agents commonly used to treat MM. Figure 98.5 is one potential algorithm for treating patients with newly diagnosed MM.

Interpreting Study Response and Survival Data

Four points are emphasized regarding the interpretation and comparisons of the MM treatment literature. First, historically definitions of response have varied (Table 98.2). Second, definitions of evaluable patients may be different. Third, concurrent corticosteroid therapy, either as part of the regimen or for other indications, may confound interpretation of efficacy. Finally, patient population risk and prognosis may differ substantially. Lead-time bias and treatment of MGUS or smoldering MM can significantly distort survival figures, as can effective salvage regimens.

The measurement of MM disease burden is complex, and investigators have used different methods to define response (Table 98.2). The four most common response criteria that had been used until acceptance of the Uniform Response Criteria (URC) in 2006[222] were the Chronic Leukemia–Myeloma Task Force (CLMTF),[204] Southwest Oncology Group (SWOG),[223,224] Eastern Cooperative Oncology Group ECOG),[225] and Autologous Blood and Marrow Transplant Registry and the International Bone Marrow Transplant Registry (IBMTR/ABMTR).[226] Although all address calcium, bone changes, and bone marrow plasmacytosis, the main distinction among them is their consideration of the serum and urine M components. With the exception of the old SWOG criteria,[223,224] a partial response (PR) has been considered to be a 50% reduction in serum M component and a greater than 50% to 90% reduction in urine M component. Until about 1990, a SWOG objective response was defined as a 75% reduction in the *tumor mass index* (*NOT* serum M protein) and improvement was defined as a 50% to 74% reduction in the *tumor* mass index.[224] A subsequent iteration of the SWOG response criteria used the M component (rather than the tumor mass index) as the primary measurement of the plasma cell burden.

In the earliest literature, response included such factors as increasing hemoglobin concentration or performance status, or decreasing blood urea nitrogen levels. Neither the CLMTF or SWOG originally had a complete response (CR) category, because it was unusual for the M protein to disappear completely. It was not until the advent of high-dose melphalan that investigators[227,228] began to define a complete remission category. Earliest definitions of CR only included disappearance of M protein as determined by electrophoresis, which is less sensitive than immunoelectrophoresis or immunofixation. Subsequent definitions have required immunofixation negativity to qualify as complete remission.[226] The first iteration of an international consensus definition of MM response was the IBMTR/ABMTR response criteria.[226] After nearly 8 years of use, several deficiencies were noted, and the International Myeloma Working Group issued a new consensus definition called the International Uniform Response Criteria (URC) which includes the Intergroupe Français du Myélome (IFM) very good partial response category,[229] the ability to measure response using the serum immunoglobulin free light chain, and a new category of "stringent complete response," which requires documentation of the absence of clonality in the bone marrow and by including a normal serum immunoglobulin free light chain ratio in the definition.[222]

TABLE 98.2

RESPONSE CRITERIA

Response	Study	% BMPC	M protein		Duration, wk
			Serum	Urine	
Stringent CR (sCR)	IRC[222]	<5[a]	IF —[b]	IF —	0
Complete response	IRC[c]	≤5	IF —	IF —	6
	IBMTR[c,226]	<5	IF —	IF —	6
	SWOG[224]	<1[a]	IF —	IF —	8
	ECOG[225]	≤3	IF —	IF —	6
	CLMTF[204]	Not defined			—
Very good partial response	IRC		≥90% reduction	< 100 mg/24 hr	
Objective response	SWOG	—	↓ ≥ 75%[c]	↓ ≥ 90%	8
Partial Response	IRC[d]	—	↓ ≥ 50%	↓ ≥ 90%	6
	ECOG/IBMTR	—	↓ ≥ 50%	↓ ≥ 90%[e]	6
	SWOG ("Improvement")	—	↓ ≥ 50%[c]	↓ ≥ 75%	8
	CLMTF[f]	—	↓ ≥ 50%	↓ ≥ 50%	—
Minimal response	IBMTR	—	↓ ≥ 25%	↓ ≥ 50%	
Progression	IRC/IBMTR/SWOG	—	> 25%[g]	> 25%[h]	—
	ECOG	—	≥ 50%[i]	≥ 50%[h]	—

BMPC, bone marrow plasma cells; CLMTF, Chronic Leukemia-Myeloma Task Force; CR, complete response; ECOG, Eastern Cooperative Oncology Group; IBMTR, International Blood and Bone Marrow Transplant Registry; IF, immunofixation; IRC, International Response Consensus; IF, immunofixation; MR, minimum response; PR, partial response; SWOG, Southwest Oncology Group.
[a]Clonal plasma cells as measured by flow cytometry, immunohistochemistry, or immunofluorescence.
[b]Also requires normalization of serum immunoglobulin free light chain ratio.
[c]Change in synthetic index and not monoclonal protein concentration.
[d]Allows for immunoglobulin free light chain responses in patients whose serum and urine are not measurable.
[e]Or <200 mg/24 hours.
[f]Response also takes into account reduction in size of plasmacytomas, >2 g/dl Hb rise, weight gain, correction of calcium, renal function, albumin.
[g]Absolute increase must be at least 5 g/L.
[h]Absolute increase must be greater than 200 mg/24 hours.
[i]For ECOG, Absolute increase must be at least 20 g/L.

Efficacy of Single Chemotherapeutic Agents

Single agents are not commonly used as upfront therapy, but they are used in the relapsed setting, and understanding each drug's activity provides insight into how much they may be contributing to combination therapy.

Melphalan

Bergsagel et al.[31] demonstrated the benefit of melphalan in 14 of 24 patients with MM. Others (Table 98.3) have substantiated that melphalan as a single agent results in response rates of 20% to 34% and median OS duration of 15 to 27 months.[32,230–233] Since early reports by Blokhin et al.[30] and Bergsagel et al.,[31] various schedules of melphalan have been tried, including continuous daily dose, 6 to 10 mg/day for 2 to 3 weeks, followed by maintenance therapy of 0.01 to 0.03 mg/kg per day; intermittent total doses of 0.25 mg/day given for 4 days every 4 to 8 weeks; or 0.15 mg/kg per day for 7 days every 6 weeks.[232,234] Several studies suggest that the intermittent schedule is superior to continuous daily dosing.[232,234]

Cyclophosphamide

Korst et al. were the first to report on the activity of oral cyclophosphamide.[33] A partial response (50% M-protein reduction) was achieved by 24% of MM patients, and 48% had objective improvement. Median survival was 24.5 months in all 207 patients and 32 months in the group that received at least 2 months of cyclophosphamide therapy. The single-agent activity of cyclophosphamide (Table 98.3) has been demonstrated in a placebo-controlled trial,[231] in multiple studies of previously untreated patients,[235,236] and in those who relapsed or had refractory disease.[237]

Despite documented equivalency for low-dose oral regimens of cyclophosphamide and melphalan,[235] induction therapies of MP have historically been preferred over those of cyclophosphamide and prednisone. Cyclophosphamide has most commonly been used in multidrug combinations for induction, for therapy in relapse, and for stem cell mobilization rather than as a single agent for induction, as has melphalan. In newly diagnosed MM, oral daily dosing of cyclophosphamide (150 mg/d)[235,238,239] or intravenous doses of 600 mg/m2 every 3 weeks[236] with or without prednisone resulted in a response rate of approximately 25% and median survival of 24 months.

Glucocorticoids

In 1950, Thorn et al.[27] reported the first observations on the beneficial effects of adrenocorticotropic hormone in MM. Adams and Skoog[28] observed a marked decrease in the MM serum protein in 18 of 26 patients treated with corticosteroids. Surprisingly, Mass[240] failed to show a difference between the survival of 55 patients randomly assigned to prednisone therapy or placebo despite clinical improvement in the former group. Subsequently, high-dose corticosteroids have been shown to produce response rates of 40% to 50% in previously untreated patients, and 25%

[a]Difference is significant.
[b]Survival estimated from survival curves.
[c]Patients stratified for good and poor risk; median survival given as all patients (good risk, poor risk). Authors note that much quicker response observed with prednisone but worse survival with prednisone in poor-risk patients.

in refractory or relapsed patients;[29,241–247] median survival of responding patients is 16 to 22 months.[243–245] In reviewing their experience with single-agent dexamethasone and VAD, Alexanian et al.[244] noted that in patients with refractory disease, response rates with single-agent dexamethasone were comparable to those with VAD (27% vs. 32%). In contrast, in relapsed disease, response rates achieved with single-agent dexamethasone were inferior to those with VAD. These data were not randomized but rather serial observations. On occasion, patients who do not respond to high-dose dexamethasone can be salvaged with intermittent high-dose methylprednisolone.[245]

Despite their contribution to quicker and more abundant responses, there are conflicting data as to whether corticosteroids prolong survival.[230,232,248] As initial therapy for elderly patients, single-agent dexamethasone is responsible for both higher treatment-related morbidity and mortality as compared to melphalan-containing regimens.[249] The mechanism of action of this drug class is complex. Corticosteroids suppress the production of cytokines important in MM growth, such as IL-6 and IL-1β, and reduce nuclear factor κB activity, resulting in enhanced apoptosis.[250–253]

Vincristine

Although never evaluated as a single agent in newly diagnosed MM, vincristine has little activity as a single agent in refractory disease. There were 21 patients treated with a 0.5 mg bolus of vincristine followed by 0.25 to 0.5 mg/m2 per day as a continuous infusion over 5 days on a 3-week schedule. Two patients had transient responses (1.2 and 2.2 months).[254] Finally, the activity credited to vincristine as a maintenance therapy is also ambiguous. Although a superior survival (35 vs. 27 months, $P = 0.003$) was reported in patients treated with single-agent melphalan and maintained on bimonthly vincristine (1 mg/m2) and prednisone (0.6 mg/kg for 7 days), the benefit could easily be attributed to prednisone alone.[255]

Alexanian et al.[256,257] suggested that regimens which included vincristine resulted in better patient outcome than protocols not including this agent. The theory behind its posited utility was that after an initial kill of MM cells by alkylating agents, the subsequent increase in the mitotic index made MM cells more sensitive to vincristine.[258] Reports by Lee , Salmon, and Case have been cited as confirmatory evidence for activity of vincristine in MM.[259–261] However, several randomized controlled trials do not support this premise.[262–265] The most compelling of these is the MRC IV Trial in Myelomatosis, which randomized 530 newly diagnosed MM patients to monthly MP, with or without monthly vincristine. Median survival in both arms was 26 months.[264] Even though vincristine has not been shown to have significant single-agent in vivo activity or to improve OS,[254,264–266] it has been included in multiple therapeutic regimens.

Anthracyclines

Doxorubicin is the most commonly used anthracycline in the treatment of MM, but it has not been studied as a single agent in newly diagnosed MM patients. Its activity as a single agent in relapsed or refractory disease is modest, with response rates of about 10%.[35,267] The pegylated form has been used in a number of MM regimens since the 1990s.[268,269] A phase II trial of mitoxantrone as a single agent (12 mg/m2 every 3 weeks) yielded a partial response rate of 3% (1 of 35). An additional 4 patients showed clinical improvement lasting 4 to 7 months.[270] Idarubicin is another anthracycline that has been studied in MM. Response rates of 0% to 27% have been observed in relapsed and refractory patients with single-agent oral regimens (30 mg/week in three divided doses given 3 of 5 weeks or 40 mg/m2 every 3 weeks).[271,272]

Etoposide

In relapsed and refractory disease, single-agent etoposide (200 to 250 mg/m2 over 5 days) has minimal activity; in 85 patients the response rate was < 5%.[273] Barlogie et al.[274] treated 14 patients with 200 mg/m2 by continuous infusion, and 2 responded. In addition, there are two anecdotal reports of activity of low-dose (25 to 50 mg/day) oral etoposide.[275,276]

Nitrosoureas

The nitrosoureas have single-agent activity in MM. In a randomized trial of 361 previously untreated patients, objective response frequency with carmustine (BCNU; 40%) and lomustine (CCNU; 42%) was lower than that of melphalan (59%), although the survivals for all groups were not significantly different.[262]

Interferon

Despite the encouraging reports that daily human leukocyte IFN (3 to 9 MU/day) could induce responses in as many as 60% of MM patients[34,217] subsequent studies with recombinant IFN yielded rates of 10% to 20%.[219,277–280] Toxicity was not inconsequential.[280] In vitro activity had good predictive value for in vivo clinical response in 26 patients studied.[278] However, IFN has a stimulatory effect in about one third of MM samples tested in vitro.[278] This drug has been used most commonly in the maintenance setting as discussed below.

Bendamustine

Bendamustine is a multifunctional alkylating agent with a purine-like ring system and a novel mechanism of action. Bendamustine appears to be more efficient in inducing DNA double-strand breaks compared with other more commonly used alkylating agents such as cyclophosphamide or phenylalanine mustard.

In a phase I study of bendamustine, Knoop et al. enrolled 31 patients with MM that had progressed after high-dose chemotherapy. Bendamustine 100 mg/m^2 on days 1 and 2 per cycle was found to be the maximal tolerated dose. The overall response rate was 55% with a median progression-free survival of 26 (0 to 61) weeks. Toxicity was mild and mainly hematologic.[281,282] In this retrospective analysis of a single institution experience, 39 patients with relapsed or refractory MM received bendamustine as salvage therapy.[283] Bendamustine used at 80 to 150 mg on day 1 + 2 of a monthly cycle with or without steroids resulted in 3% VGPR, 33% PR, 18% MR, 26% SD, and 20% PD. The median EFSand OS were 7 and 17 months, respectively.

Thalidomide

Thalidomide is the first in the class of drugs called immune modulatory drugs (IMiDs). Recognition of the role of increased angiogenesis in the pathogenesis and progression of MM,[139] and evidence of thalidomide's antiangiogenic properties,[284,285] led to clinical trials in MM.[37,286] The observed responses in patients without high-grade angiogenesis suggest that thalidomide may act via other mechanisms as well.[287] In vitro data suggest that the drug and its metabolites may inhibit angiogenesis, but in addition may modulate adhesion molecules of MM cells and their surrounding stroma, modulate cytokines, and affect natural killer cells. There is evidence that thalidomide and its analogues induce apoptosis and G1 growth arrest in MM cells.[287]

The first report of the utility of thalidomide in patients with relapsed MM[37] who were treated with escalating doses of thalidomide was published in 1999. Patients were started on 200 mg each evening; the dose was escalated every 2 weeks, if tolerated, to a final maximal dose of 800 mg daily. A total of 25% of patients had at least a 50% reduction in their serum paraprotein. Preliminary evidence of response was apparent within 2 months in more than three quarters of the patients who did respond. Other investigators have confirmed a partial response rate of 25% to 58%, with an additional 6% to 26% achieving a minimal response, median response duration of 9 to 12 months, 2-year progression-free survival of 10% to 20%, and 2-year OS of 48%.[286,288–294,295,296] As a single agent in previously untreated patients, response rates of 25% may be achieved.[297–299] The role of dose intensity in thalidomide effectiveness is unclear.[293,300] In the original reports, the highest dose tolerated was administered.[37] In high-risk patients there was a suggestion that response rates were higher and survival longer in patients receiving high doses of thalidomide (greater than or equal to 600 mg/day).[301] However, in some patients, responses may be seen with doses as low as 50 to 100 mg/day.[300]

Toxicities associated with thalidomide include fetal malformations, constipation, weakness or fatigue, somnolence, skin problems, and sensory neuropathy in more than one third of patients. There is also an increased risk of thrombosis in patients treated with thalidomide, which appears to be exacerbated by the use of concurrent combination chemotherapy, with rates as high as 28%.[302,303,304] Other life-threatening complications have included Stevens–Johnson syndrome and hepatitis.[305,306]

Thalidomide received US Food and Drug Administration approval for use in conjunction with dexamethasone for newly diagnosed MM in 2006.

Lenalidomide (CC-5013; Revlimid™)

This drug is a small molecule derivative of thalidomide and a member of the immunomodulatory (IMiD) class. Lenalidomide is more potent than thalidomide in mediating direct cytokine-related and immunomodulatory effects against human MM cell lines and patient-derived cells in vitro. It induces apoptosis of MM cells; overcomes cytokine and bone marrow stromal cell-mediated drug resistance; has antiangiogenic effects; and stimulates host anti-MM T and natural killer cell immunity.[39,307] In the original phase I study, 30% of patients responded to the single-agent drug, with a median duration of response of 6 months.[39] At 50 mg per day the dose limiting toxicity was myelosuppression. In the randomized phase II trial, two schedules were evaluated: 25 mg daily and 15 mg twice daily. In both arms, drug was given only 21 out of 28 days. Overall approximately 17% of relapsed or refractory patients achieved a partial response, including a 4% complete response rate, with a median progression-free survival (PFS) of 4.6 months for the patients receiving once-daily dosing.[39,307] Aside from myelosuppression, other grade 3 to 4 toxicities included neuropathy and fatigue in 3% and 7% of patients. In the open label phase II tral, including 222 patients, there was 25% partial response rate, with a time to progression of 5.1 months.[308] newly diagnosed MM, single agent lenalidomide induces responses in fewer than one-third of patients.[309] The FDA approved the drug in combination with dexamethasone as second line therapy for patients with MM in 2006.

Pomalidomide (CC-4047; Actimid™)

Pomalidomide is another IMiD with activity[310] that is currently undergoing clinical trials in relapsed MM.[311,312] Preclinical studies have shown changes that suggest a significant immunomodulatory effect of the drug, with decrease in CD8+/CD45RA+ cells and CD4+/CD45RA+ initially following therapy, which was also accompanied by a corresponding increase in CD8+/CD45RO+ cells and CD4+/CD45RO+, suggesting a switch from naïve cells to activated effector T-cells.[310] It also has an effect on the inflammatory pathways via transcriptional inhibition of cyclooxygenase-2 (COX-2) production, which is associated with increased prostaglandins in human lipopolysaccharide (LPS)-stimulated monocytes.[313] In addition to the direct anti-MM activity and the immunomodulatory functions, pomalidomide also alters the tumor microenvironment. In vitro studies also have shown potent inhibitory effect on osteoclast differentiation as well as bone marrow angiogenesis.[314,315] A total of 54% of previously treated patients respond to the single-agent drug. Median PFS was 9 months. Additional studies have been done as are described in the section of relapsed/refractory disease. As of this writing, the drug is not available except in clinical trials.

Bortezomib (Velcade™, PS-341)

Bortezomib is the first drug in its class of proteasome inhibitors. It is a boronic acid dipeptide that reversibly and selectively inhibits the proteasome, an intracellular complex that degrades primarily ubiquitinated proteins. The proteasome has a key role in protein degradation, cell-cycle regulation, and gene expression. Tumor cells, including MM, are heavily dependent on proteasome-regulated proteins for their growth and interaction with stromal cells. Inhibition of the proteasome has emerged as an important antitumor target, and bortezomib has been shown in vitro and in vivo to cause growth arrest, to induce apoptosis, and to inhibit angiogenesis.

Of newly diagnosed MM patients, 38% to 48% will respond to single-agent bortezomib.[316–318] The addition of dexamethasone results in an overall response rate of 67% to 88%.[317,319] Single-agent response rates in relapsed/refractory MM range from 28% to 38% with a median duration of response of 8 months.[308,320–322] The most common adverse events associated with bortezomib are: gastrointestinal disturbances, fatigue, peripheral neuropathy, and myelosuppression. There were 75% of patients who had serious (grade 3 to 4) adverse events, the most common of which were thrombocytopenia, neutropenia, anemia, gastrointestinal disturbances, fatigue, and peripheral neuropathy (sensory, motor, and pain).[321,323] In a review of 256 patients treated on two phase II studies, over 80% of paitents had baseline peripheral neuropathy. Treatment-emergent neuropathy was reported in 35% of patients. Grade 1–2, 3, and 4 neuropathy occurred in 22%, 13%, and 0.4% of patients, respectively. Grade 3 neuropathy was more likely to occur in patients with a baseline neuropathy. A total of 71% of patients with neuropathy greater than or equal to grade 3 and/or requiring discontinuation who had resolution to baseline or improvement. Subcutaneous administration and/or weekly administration of bortezomib reduces the incidence of severe peripheral neuropathy by nearly 40%.[324]

The FDA approved bortezomib for patients with refractory MM in 2003, patients who failed one prior regimen in 2005, and as initial therapy in 2008. Because of toxicity, two important modifications to bortezomib administration have been made over the past decade. The first was introduction of weekly bortezomib rather than twice weekly followed by a 10-day rest; the second was the subcutaneous administration rather than the intravenous route of administration. This latter change was approved by the FDA in 2012 based on a randomized control trial that demonstrated comparable efficacy but significantly lower toxicity.[324] Overall response rate for both arms was 42% to 43%, but grade 3 or higher peripheral neuropathy was 6% versus 16% and any neuropathy was 38% versus 53%, favoring the subcutaneous administration.

Carfilzomib (PX-171, Kyprolis™)

Carfilzomib is a selective proteasome inhibitor that binds irreversibly to its target. It differs from bortezomib in that it does not contain a boronic acid residue, and irreversibly binds to the proteasome subunit. It was FDA approved for the indication of relapsed or refractory MM among patients who have had prior exposure to an IMiD and bortezomib. Two schedules had been tested in hematologic malignancies,[325,326] and best tolerance was seen with an IV infusion on days 1, 2, 8, 9, 15, and 16 every 28 days. In bortezomib-naïve patients,[221] reponse rates were seen in 25% of patients treated at the 20 mg/m^2 level and in 52% of patients treated with first cycle 20 mg/m^2, but subsequent cycles at 27 mg/m^2. An additional 17% and 12% of patients had a minimal response (i.e., a 25% reduction in their serum M-protein) in the 20 mg/m^2 cohort and the 20/27 mg/m^2 cohorts, respectively. Median duration of response is 13 months among patients achieving a a PR or better. The most common side effects of drug are fatigue, nausea, anemia, dyspnea, cough, and pyrexia occurring in 34% to 62% of patients. The most common grade 3 or higher AEs were hematologic (13% to 16%) and pneumonia (12%). Treatment-emergent peripheral neuropathy was rare with only 1 patient in 129 developing a grade 3 PN. Because fever, chills, shortness of breath, and/or rigors may occur during cycle 1 and sometimes cycle 2, dexamethasone 4 mg daily can be given before each dose in cycle 1 and before the first dose of the cycle 2 if dose escalation is planned.

Other Agents

Barlogie et al.[274] explored the utility of cisplatin therapy for patients with MM. A total of 14 patients were treated with 10 mg/m2 for 7 days by continuous infusion, and 2 responded. The drug has been incorporated into other regimens for relapsed disease[274,327,328] and induction therapy.[329]

Cytosine arabinoside,[330] tenoposide,[331] topotecan,[332] deoxycoformycin,[333,334] arsenic trioxide,[335,336] and paclitaxel[337,338] have been reported to produce response rates of 7%, 28%, 16%, 0% to 15%, 7.1%, and 15% to 29%, respectively. Topotecan induces significant toxicity including greater than or equal to grade 3 granulocytopenia and thrombocytopenia in 93% and 53% of patients, respectively.[332] Patients treated with paclitaxel were premedicated with 40 mg of dexamethasone every 21 days,[337,338] bringing into question whether the observed responses were attributable to dexamethasone or paclitaxel.

Agents that do not appear to have any activity in MM include drugs that are interesting from an historical perspective and drugs that have known activity in other diseases. Agents in the former category include diamidines, such as stilbamidine; 1-aminocyclopentanecarboxylic acid; amsacrine,[339,340] aclarubin,[341] chlorozotocin,[342] hexamethylmelamine[343] and azaserine.[32] Other agents without activity against MM include: methotrexate, 6-mercaptopurine, 6-thioguanine, 5-fluorouracil, fluorodeoxyuridine, hydroxyurea, mitomycin C,[32] vinblastine, vindesine,[243] carboplatin,[344] bleomycin,[267] ATRA (all *trans*-retinoic acid), fludarabine,[345] 2-chlorodeoxyadenosine,[346] flavopiridol,[347] and imatinib.[348] Although Durie et al.[349] reported a 57% response rate with clarithromycin, subsequent reports did not corroborate this response rate, and the activity observed in the original report was attributed to concurrent corticosteroid therapy.[350–352]

Combination Chemotherapy for Induction

Combining multiple active agents in an effort to achieve synergy is a logical corollary. The last 3 decades of the 20th century were spent combining alkylators, anthracyclines, corticosteroids, and IFN. Thirty years of study indicate that the higher response rates

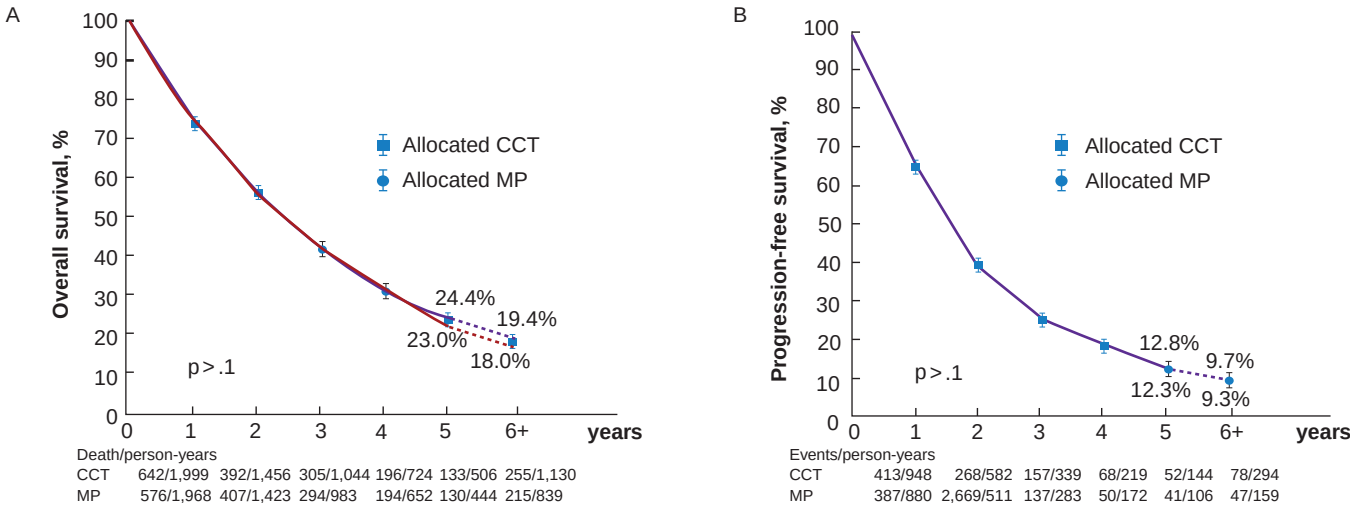

FIGURE 98.6. Melphalan and prednisone (MP) versus combined chemotherapy (CCT) as induction. Results from 6,633 patients from 27 randomized trials. A: Overall survival. **B:** Response duration. (From the Myeloma Trialists' Collaborative Group.[216] By permission of the American Society of Clinical Oncology.)

afforded by these combinations as initial therapy did not translate into longer OS rates than standard MP therapy[216] (Fig. 98.6), and the data are conflicting as to whether patients with more advanced disease benefited from combination alkylator chemotherapy.[210,216,233,258,353–355] Once IMiDs and proteasome inhibitors were shown to have activity, clinical investigators began using these drugs in combination. Table 98.4 serves as a reference for commonly cited regimens. For expediency, the section on induction regimens is separated into three larger categories: those commonly used in all types of MM patients, those specifically for transplant-ineligible patients, and those for transplant-eligible patients.

Clinical research in MM began to move at breakneck speed starting in the first decade of the 21st century. Because of the abundance of induction data and the absence of definitive "best options," the Mayo Clinic group has published a treatment algorithm for patients with newly diagnosed MM called mSMART.[357,358] This is an online algorithm that is updated as new data emerge (Fig. 98.5; http://www.msmart.org/index.html). As a general rule, patients who are being considered for stem cell collection and transplantation receive nonalkylator-containing induction regimens, or if alkylator-containing regimens are used, the number of cycles is restiricted to four prior to stem cell mobilization.

Commonly Used Regimens for Any Newly Diagnosed Multiple Myeloma Patient

Three of the most commonly used induction regimens in the United States—lenalidomide/dexamethasone (Rd), bortezomib/lenalidomide/dexamethasone (VRD), and cyclophosphamide/bortezomib/dexamethasone (CyBorD)—are regimens that can be used for patients regardless of their transplant eligibility. Surpisingly, these three regimens have the least published phase III data to support their use. The mSMART method of prioritizing their use is shown in Figure 98.5.[357,358] Table 98.5 also lists these regimens, as well as other phase II regimens of interest that are discussed later in this chapter.

Lenalidomide/Dexamethasone (Rd)

In previously untreated patients with active MM, the combination of lenalidomide and dexamethasone with or without clarithromycin yields overall response rates of 91% to 95%, with complete response/very good response rates of 32% to 38%.[359,360] Rajkumar et al.[359] treated 34 patients with lenalidomide 25 mg orally days 1 to 21 and dexamethasone 40 mg days 1 to 4, 9 to 12, and 17 to 20, both repeated every 28 days. Aspirin was given as DVT prophylaxis. The overall response rate was 91%, with 6% achieving complete response and 32% very good partial response. Grade 3 to 4 neutropenia occurred in 12% of patients. A total of 47% of patients experienced grade 3 or higher nonhematologic toxicity, most commonly fatigue (15%). The 2-year progression-free survival rates for patients proceeding to SCT and patients remaining on Rev-Dex were 83% and 59%, respectively; the OS rates were 92% and 90% at 2 years and 92% and 85% at 3 years, respectively. The 3-year OS rate for the whole cohort was 88%.[361]

Niesvizky et al.[360] treated 72 patients with clarithromycin, lenalidomide, and dexamethasone (BiRD). The rationale for the clarithromycin use is that it alters the hepatic metabolism of both drugs, resulting in higher effective doses. The lenalidomide schedule was as above, but dexamethasone was administered only once weekly. Clarithromycin was given 500 mg twice daily. Aspirin was given as DVT prophylaxis. The overall response rate was 90%, including 39% CR and 35% VGPR. Twenty patients went on to receive ASCT. Two-year EFS for the nontransplant group was 75%. The most common grade 3 or higher nonhematologic AEs were myopathy (11%) and thromboembolic events (12.5%). Grade 3 or higher hematologic toxicies were neutropenia in 19.4%, anemia in 13.8%, and thrombocytopenia in 22.2%.

A randomized controlled trial comparing lenalidomide with standard dexamethasone (12 days/month schedule)—RD—to lenalidomide with reduced intensity dexamethasone (weekly dexamethasone)—Rd.[362] After 4 months of therapy, 79% of the RD patients and 68% of the Rd patients had achieved a partial response or better; however, at 1 year, OS was superior in the Rd arm as compared to the RD arm (92% vs. 87%, $P = 0.0002$). Among those aged less than 65, the 1-year OS was 91% with RD and 98% with Rd; among those older than 65, the 1-year OS was 83% with RD and 94% with Rd. The trial was stopped due to this safety concern, and patients receiving high-intensity dexamethasone (RD) were crossed over to the low-intensity arm (Rd). Grade 3 to 4 AEs and early deaths were higher in the RD group (52% vs. 35%, $P = 0.0001$ and 5.4% vs. 0.5%, $P = 0.003$), respectively. The most common grade 3 or higher toxicities were DVT (26% vs. 12%, $P = 0.0003$), infections (16% vs. 9%, $P = 0.04$), and fatigue (15% vs. 9%, $P = 0.08$).

Because of the ease of administration and low early death rate, many consider Rd an excellent first-line therapeutic option. Others express concern that a 68% response rate and a VGPR or better rate of 40% is insufficient, and therefore favor the use of triplets, especially in younger patients. To date, there are no

[a]Repeated at 4-week intervals.

[b]Repeated at 6-week intervals.

[c]Repeated at 3-week intervals.

[d]Initial treatment strategy for VISTA trial was bortezomib 1.3 mg/m^2 on days 1, 4, 8, 11, 22, 25, 29, and 32, repeated every 6 weeks for four cycles, and then repeated every 5 weeks, with bortezomib schedule changing to weekly administration for 4 weeks followed by 1 week rest. Due to high rates of neuropathy, recommended modification is to start with weekly administration and 5-week cycles.[397]

[e]Repeated every 5 weeks.

[f] Dexamethasone 40 mg days 1–4, 9–12, 17–20 for cycle 1; then days 1, 8, 15, and 22.

completed randomized trials demonstrating survival advantage of any of the triplets over the Rd. Several clinical trials are ongoing that compare a triplet (MPT, VRD) to Rd. In the absence of prospective data, a retrospective comparison of three consecutive clinical trials [RD (lenalidomide-dexamethasone, $n = 34$), CLD (cyclophosphamide-lenalidomide- dexamethasone, $n = 53$), and CyBorD (cyclophosphamide/bortezomib/dexamethasone, $n = 63$)], has been reported.[363] Overall response rates were comparable at 94%, 85%, and 90%, but complete response/near complete response rates were highest in the CyBorD arm, 35%, 15%, and 41%, $P = 0.006$. Despite this difference, however, PFS and OS were no different among the groups. Respective median PFS rates were: 3.2, 2.3, and 2.7 years, $P = 0.11$, and respective 3-year OS rates were 88%, 79%, and 88%. Poor cytogenetic risk was not overcome by any of these regimens. A notable finding of this study was that 80% of patients were alive at 4 years.

Despite the concern of an increased rate of secondary malignancies when using lenalidomide as maintenance after ASCT and in conjunction with MP, the use of Rd appears to impart a lower rate of acute myeloid leukemia and myelodysplastic syndrome than MPT with respective rates of 0.15 per 100 person-years (95% CI 0.05 to 0.47) versus 1.04 per 100 person-years (95% CI 0.56 to 1.94),

respectively. Rates of other secondary primary malignancies were comparable in both arms and within the expected range for an elderly population.[364]

Cyclophosphamide, Bortezomib, and Dexamethasone (CyBorD or VCD)

The combination of cyclophosphamide, bortezomib, and dexamethasone (CyBorD or VCD) has been explored both in the relapsed setting and in patients with newly diagnosed MM. The first resport was that of a four 28-day cycles of bortezomib 1.3 mg/m^2 intravenously on days 1, 4, 8, and 11, cyclophosphamide 300 mg/m^2 orally on days 1, 8, 15, and 22, and dexamethasone 40 mg orally on days 1 to 4, 9 to 12, and 17 to 20 on a 28-day cycle for four cycles.[365] Among the 33 pateints enrolled, responses were rapid. The overall response rate was 88%, with 39% achieving complete/near complete response. Peripheral neuropathy rate was 66%, with 7% grade 3. A modified extension of that trial included another 30 patients to maximize dose delivery and reduce toxicity.[366] Patients received the same weekly cyclophosphamide schedule, but bortezomib was increased to 1.5 mg/m^2 IV on days 1, 8, 15, and 22 and dexamethasone was modified to 40 mg once weekly after cycle 2. Response rates were comparable and toxicity was less; grade 3/4 AEs dropped from 60% to 40% of patients, and no patient had grade 3 PN.

Bensinger reported results from a phase II study of two sequential three-drug combinations: three 21-day cycles of bortezomib, cyclophosphamide, and dexamethasone (VCD) followed by three 21-day cycles of bortezomib, thalidomide, and dexamethasone (VTD).[367] Among the 42 evaluable patients, overall response rate was 95%, including 19% stringent complete response (sCR). Adverse cyctogenetics did not appear to affect response. With a median follow-up of 21 months, 1-year EFS and are OS were 81% and 91%, respectively. The most common nonhematological grade 3/4 AE was periphaeral neuropathy, which occurred in 11% of patients. Four patients had cardiovascular events all during the VTD cycles.

A randomized phase II study comparing bortezomib, dexamethasone, cyclophosphamide, and lenalidomide (VDCR); bortezomib, dexamethasone, and lenalidomide (VRD); and two formulations of VCD in 140 previously untreated patients has

been reported.[368] A maximum of eight 21-day cycles followed by maintenance bortezomib (1.3 mg/m^2 every other week for 24 weeks) was administered. The bortezomib was administered as 1.3 mg/m^2 days 1, 4, 8, and 11 and the dexamethasone was administered as 40 mg days 1, 8, and 15 for all patients. The VRD patients received lenalidomide 25 mg days 1 to 14, whereas the VDCR patients received lenalidomide 15 mg days 1 to 14 and cyclophosphamide 500 mg/m^2 days 1 and 8. The VCD paitents received cyclophophamamide 500 mg/m^2 days 1 and 8, whereas, the VCD-mod patients received cyclophophamamide 500 mg/m^2 days 1, 8, and 15. Nearly all patients responded and the VGPR or better (CR) rates were 58% (25%), 51% (24%), 41% (22%), and 53% (47%) for patients on VDCR, VDR, VCD, and VCD-mod, respectively. The corresponding 1-year progression-free survival was 86%, 83%, 93%, and 100%. Grade 3 or higher AEs were seen in 76% to 88% of patients, with the highest rate of AE resulting in discontinuation in the VDCR arm. The highest rate of grade 3/4 hematologic AEs was in the VDCR and VCD arms. Grade 3/4 peripheral neuropathy rates ranged from 9% to 18%. The two regimens recommended by the authors were VCD-mod and VRD.

Kropff et al. reported phase I results of a variant of CyBorD. Thirty patients were treated with three 21-day cycles of bortezomib 1.3 mg/m^2 on days 1, 4, 8, 11 plus dexamethasone 40 mg on the day of bortezomib injection and the day after plus cyclophosphamide at 900, 1,200, or 1,500 mg/m^2 on day 1.[369] The maximum tolerated dose of cyclophosphamide was defined as 900 mg/m^2. Overall response rate across all levels was 77%, with a 10% CR rate.

Bortezomib, Lenalidomide, Dexamethasone (VRD)

Richardson and colleagues reported on 66 patients treated on a phase I/II study using the combination of bortezomib, lenalidomide, and dexamethasone for previously untreated MM patients.[370] Patients receved eight 3-week cycles and either proceeded to transplantation or maintenance. All patients responded, and 67% achieved a VGPR or better. A total of 42% proceeded to ASCT. With median follow-up of 21 months, estimated 18-month PFS and OS for the combination treatment with/without transplantation were 75% and 97%, respectively. Sensory neuropathy occurred in 80% of patients and 32% reported neuropathic pain (grade 2/3 in 14%). Grade 3 to 4 neutropenia and thrombocytopenia occurred in 9% and 6% of patients respectively.

Summary statement: Based on complete response rates, the triplets are superior. Based on toxicity, lenalidomide and dexamethasone are superior. There are no compelling OS data to support one option over another.

Transplant Ineligible Patients

Transplant Ineligible Patients: Phase III Trials of Induction Regimens Including IMiDs and/or Proteasome Inhibitors (Table 98.6)

The combination of melphalan and prednisone (MP) was the standard for all patients with MM for nearly 40 years. The combination of MP has been studied extensively.[223,230] Response rates are 40% to 60% and anticipated median survivals are 18 to 42 months.[210,216,223,230,232,236,257,263,264,354,371–386] Because of the variable gastrointestinal tract absorption of melphalan, intravenous regimens of 15 to 25 mg/m^2 every 4 weeks along with oral prednisone or dexamethasone have been tried and resulted in response rates of 50% to 82%.[386,387] An important phase III trial (IFM 95-01) directed at the elderly (age 65 to 75 years) was a four-arm study comparing MP to melphalan–dexamethasone (MD), dexamethasone, or dexamethasone–IFN.[249] A total of 488 patients was randomized, and follow-up was 83 months. Response rates were significantly higher among patients receiving MD, and PFS was significantly better among patients receiving melphalan (22 vs. 13 months), but there was no difference in OS among the four treatment groups. The median survival for the whole series was 35 months. The morbidity associated with dexamethasone-based regimens was significantly higher than with MP.

With the advent of ASCT, MP was relegated to those not eligible for ASCT. As drugs outside the alkylator, anthracycline, and corticosteroid classes began to show activity around 2000, combining these drugs with alkylator and prednisone became the obvious path for study.[388–395,396,397–400] Such regimens have become part of the standard for treating elderly patients with MM (Table 98.6) in addition to a few combinations that have not been directly compared to MP, but have shown promise in either phase II or III trials.[362,365,366,370] A major limitation of several of the trials that compare a doublet to a triplet is that it is often unclear what percentage of the doublet patients got access to the third drug at the time of relapse or progression.

There have been seven randomized controlled trials comparing MP to MP and a novel agent.[388–395,396] In terms of the six MPT studies, all have favored MPT with regard to higher CR rates. Four of six have been positive with regard to PFS, again in favor of three drugs over two drugs, but only three of six have been positive with regard to OS. An individual patient meta-analysis has recently been reported.[401] In aggregate, MPT was superior to MP in terms of overall response rate (59% vs 37%), median PFS (20 versus. 15 months), and median OS (39 vs. 33 months). Although this meta-analysis is an extraordinarily important study, there was no effort to examine what percentage of the relapsing MP patients received thalidomide as salvage. In a side meta-analysis examining serious adverse events of individual patient data of these same six trials,[402] a higher cumulative incidence of grade 3 to 4 nonhematologic (39% vs. 17%, HR 2.78, 95%CI 2.21 to 3.50) and hematologic (28% vs. 22%, HR 1.32, 95%CI 1.05 to 1.66) toxicities was documented with MPT. Nonhematologic toxicities were more likely to occur in patients with a baseline poorer performance status (HR 1.18, 95%CI 1.06 to 1.32). The specific serious adverse events that were more common in patients receiving MPT were peripheral neuropathy, neurologic other than peripheral neuropathy, thrombosis, and dermatologic toxicity. The experience of a nonhematologic grade 3 to 4 AE had a negative impact on both PFS (HR 1.24, 95%CI 1.07 to 1.45, $P = 0.006$) and OS (HR 1.23, 95%CI 1.03 to 1.47, $P = 0.006$).

The first positive MP versus MPT trial (Table 98.6) is the the IFM 99-06 study,[388] in which 447 patients were randomized to twelve 6-week cycles of either of MP (melphalan 0.25 mg/kg per day and prednisone 2 mg/kg/day days 1 to 4 every 6 weeks) or MPT (MP plus 200 to 400 mg of thalidomide daily) or to two sequential miniautologous peripheral blood stem cell transplants (MEL100). The thalidomide was not continued past the twelfth cycle of therapy. Higher response rates and longer PFS were seen with the MPT as compared to either the MP or MEL100 groups, with respective PFS times of 28, 18, and 19.0 months. With a median follow-up of 51 months, there was a significant survival advantage for the patients on the MPT arm, with respective OS times not reached at 52 months, 33 months, and 38 months.[388]

The IFM01-01[391] included 129 patients over the age of 75. They were randomized to twelve 6-week cycles of either of MP (melphalan 0.2 mg/kg per day and prednisone 2 mg/kg/day days 1 to 4 every 6 weeks) or MPT (MP plus 50 to 100 mg of thalidomide daily). With a median follow-up of 47.5 months, in the MPT arm both median OS (44 vs. 29 months, $P = 0.03$) and PFS (24 vs. 19 months, $P = 0.001$) were longer. Grade 2 to 4 peripheral neuropathy (20% vs. 5%, $P = 0.001$) and neutropenia (23% vs. 9%, $P = 0.003$) were more frequent in the MPT arm.

In the GIMEMA MP versus MPT trial, patients were randomized to either standard dose oral MP for 6 months or to MP for 6 months with concurrent thalidomide, which was continued indefinitely.[389,390] Overall response rates were significantly higher with the MPT than the MP as were the complete response rates and the median PFS rates (22 vs. 14 months, $P = 0.004$). In the initial

CR, complete response; MP, melphalan and prednisone; MPT, melphalan, prednisone, thalidomide; NA, not available; OS, overall survival; PFS/EFS, event-free survival or progression-free survival; VMP, bortezomib, melphalan and prednisone; VMPT, bortezomib, melphalan, prednisone and thalidomide.
[a]Third arm of this study which treated patients with two sequential miniautologous ASCTs is not included in this table.
[b]Thalidomide was continued as maintenance in MPT arm.
[c]Received thalidomide or bortezomib; number of patients in control arm receiving thalidomide as salvage not specified.
[d]Complete response + very good partial response.
[e]Secondary randomization to either VT or VP.

report, there was a trend toward an improved 3-year OS in favor of MPT, but a second report with 38 months follow-up showed no difference in OS. This trial addressed a maintenance question as much as an induction question.

In the Dutch–Belgium Hemato-Oncology Cooperative Group (HOVON) 49 trial, patients were randomized to either eight cycles of MP (melphalan 0.25 mg/kg per day and prednisone 2 mg/kg/day days 1 to 5 every 4 weeks) or MPT (MP plus 200 mg/day thalidomide). The median EFS was 9 months with MP and 13 months with MPT, and 2-year PFS was 33% versus 21%, $P < 0.05$. OS of those treated with MPT was also superior (40 vs. 31 months, $P < 0.05$). In a partner health-related quality-of-life study,[403] the higher frequency of adverse events associated with the MPT arm did not translate into a negative effect on the health-related quality of life. Only the score for paresthesia worsened in the MPT arm, but subscales rating emotional function and future perspectives favored the MPT arm.

In the Nordic study,[392] 357 patients were randomized to MP (4 days of melphalan 0.25 mg/kg per day and prednisone 100 mg/day every 6 weeks) or MPT (MP plus 200 to 400 mg/day thalidomide). Treatment was continued to plateau and the thalidomide was continued until relapse. Although there were superior CR and PR rates in the MPT arm, there was no difference in PFS or OS between the two groups. In fact, there was a higher mortality rate in the first 6 months among the MPT patients over age 75. In a partner health-related quality-of-life study, patients in the

MPT arm had higher rates of constipation and lower rates of diarrhea, physical function, and social function.

The final MP versus MPT study was conducted in Turkey where 114 patients were randomized to 12 months of MP (melphalan 9 mg/m^2/day and prednisone 60 mg/m^2/day for 4 days every 6 weeks) or MPT (MP plus thalidomide 100 mg/day continuously). Although response rates were higher in the MPT patients than the MP patients, PFS and OS did not differ.

CTDa (cyclophosphamide, thalidomide, and dexamethasone) is a variation on the theme of MPT. The MRC IX trial[399] randomized elderly patients to either MP or CTDa (Table 98.4) to maximum response, with a minimum of six cycles to a maximum of nine cycles (Table 98.6). There was a secondary randomization to thalidomide or no thalidomide maintenance.[404] Median follow-up is 44 months, and PFS was marginally better in the CTDa arm, but OS was not different between the two arms. Patients in the CTDa group had higher rates of sensory and motor neuropathy, thromboembolic events, constipation, infection, rash, and elevated alkaline phosphatase levels than did those in the MP group, but lower incidence of cytopenias.

The combination of thalidomide and dexamethasone (TD) has also been compared to MP.[405] In these 282 elderly patients although there were higher response rates using TD (68% vs. 52%, $P = 0.002$), there was also higher rates AEs: neuropathy (72% vs. 33%), psychological toxicity (36% vs. 18%, $P < 0.001$), constipation (33% vs. 13%, $P < 0.001$), and a trend toward more DVTs (10% vs. 4%). The only toxicity more commonly seen in the MP arm was myelosuppression. With a median follow-up of 28 months, there was no difference in PFS, but there was a trend toward shorter OS among TD-treated patients which was more notable in patients older than 75 years. MP has also been compared to the combination of melphalan, prednisone, and lenalidomide in a three-arm phase III trial[398]: MP versus MP with lenalidomide (MPR) versus MPR with lenalidomide maintenance (MPR-R). A total of 459 patients was randomized to either MP (nine 4-week cycles of melphalan 0.18 mg/kg/day and prednisone 2 mg/mg/kg/day days 1 to 4), MPR (nine 4-week cycles of MP plus lenalidomide 10 mg days 1 to 21), or nine cycles of MPR with indefinite lenalidomide maintenance (10 mg days 1 to 21 every 4 weeks). Overall response rates were lowest in the MP (50%) arm with progressively better rates for MPR (68%) and MPR-R (77%). With a median follow-up period of 30 months, however, neither PFS nor OS was better among patients treated with MPR as compared to MP. MPR-R patients had better PFS (31 months vs. 14 and 13 months) but not 3-year OS (70%) as compared to the other two groups (62% vs. 66%). Toxicity was substantially higher in the lenalidomide arms.

The VISTA trial[395] is the one large trial comparing MP to bortezomib and MP (VMP). Patients received nine 6-week cycles of either melphalan (at a dose of 9 mg/m^2) and prednisone (60 mg/m^2) on days 1 to 4, alone or in combination with bortezomib (1.3 mg/m^2) on days 1, 4, 8, 11, 22, 25, 29, and 32 during cycles 1 to 4 and on days 1, 8, 22, and 29 during cycles 5 to 9. All response and survival outcomes were superior with the VMP, most notably CR rates of 30% versus 4%. Median PFS was 24 months as compared to 17 months, and 3-year OS was 68% as compared to 54%.[396] Time to response was also quicker with VMP 1.4 months versus 4.2 months. Grade 3 to 4 adverse events, however, were more frequent in patients receiving VMP (46% vs. 36%). A total of 33% of patients discontinued bortezomib due to toxicity. Peripheral sensory neuropathy occurred in 44% of patients with grade 3 to 4 in 13%. Neuralgia was also reported in 36% of patients.

There are three phase III trials for the elderly that compare VMP to other regimens.[400,406] A major finding of two of these trials was the feasibility and efficacy of changing the bortezomib scheduled from days 1, 4, 8, 11 every 21 days to a once-weekly schedule. This alteration dramatically reduced rates of peripheral neuropathy.

With median follow-up of 32 months, the VMP vs. VTP trial was negative.[400] Response rates, PFS, and OS were comparable but grade 3 to 4 AEs were significantly higher in the VTP arm. More patients in the VTP arm discontinued therapy prematurely, and they had higher rates of cardiac events (8% vs. 0%) but lower rates of infection (1% vs. 7%). An analysis based on cytogenetic risk was done, comparing outcomes based on hyperdiploidy versus nonhyperdiploidy. The 3-year OS in the VMP-treated patients was no different based on cytogenetic risk category implying that this regimen may abrogate the risk of nonhyperdiploid cytogenetics; this difference was not observed in the VTP-treated patients. There was a secondary randomization in this trial to maintenance with either bortezomib and thalidomide (VT) or bortezomib with prednisone (VP).

Palumbo and colleagues randomized patients to receive either nine 5-week cycles of VMP (Table 98.6) or nine 5-week cycles of VMPT, which also added thalidomide 50 mg continuously, and continued with maintenance thalidomide along with alternate week bortezomib. Median follow-up at the time of the publication was 23 months. Response rates and PFS were higher in the four-drug combination with maintenance as compared to the three-drug with no maintenance, but OS was not different. Toxicity was significantly higher using the four-drug regimen: grade 3 to 4 neutropenia (38% vs. 28%; $P < 0.02$), cardiologic events (10% vs. 5%; $P < 0.04$), and thromboembolic events (5% vs. 2%, $P < 0.08$). The most important observation of this trial was that the bortezomib schedule could be changed from days 1, 4, 8, 11, 22, 25, 29, and 32 to days 1, 8, 15, and 22 without reducing efficacy (or actual dose of drug delivered) but significantly reducing adverse events. Severe sensory peripheral neuropathy was reduced from 16% to 3%.

The multicenter, phase IIIb UPFRONT study compares the efficacy and safety in newly diagnosed MM patients ineligible for HDT–SCT of three bortezomib-based induction regimens followed by weekly bortezomib maintenance: VcD (bortezomib–dexamethasone); VTD; and VMP.[406] Although this has only been presented in abstract and oral presentation, the findings are important. Despite the highest rates of VGPR or better in the VTD arm (51% vs. 37% and 40%), with a median follow-up of 26 months, there was no difference in PFS or OS among the groups, but the mean global health status score (QOL) worsened for all groups during induction. During maintenance, QOL trended back toward baseline for the VcD and the VMP arms, but remained much lower than baseline for the VTD cohort.

Two trials address the combination of thalidomide–dexamethasone (TD) versus dexamethasone alone.[407,408] The smaller trial is discussed in a later section and is reviewed in Table 98.7 inasmuch as the majority of patients proceeded to ASCT.[407] The larger trial is summarized in Table 98.6 and includes patients not destined for ASCT. In the TD arm, time to progression was significantly better (17.4 months, 95% CI: 8.1 months not reached versus 6.4 months, 95% CI: 5.6 to 7.4 months), but grade 3 to 4 adverse events were also higher: DVT/PE 15.4 versus 4.3%; cerebral ischemia 3.4% versus 1.3%; myocardial infarction 4.7% versus 1.3%, and peripheral neuropathy 3.8% versus 0.4%.[407]

In E4A03, the subset of patients aged 70 or older who were treated with lenalidomide with high-intensity dexamethasone (RD) or low-intensity dexamethasone (Rd) are considered.[362,409] Although in this trial there is no comparator to MP, it is still relevant because many judge it to be an effective and well-tolerated option for elderly patients. The major findings are shown in Table 98.6. Patients treated on the high-intensity dexamethasone arm had slightly higher response rates, comparable PFS, and inferior OS as compared the low-intensity dexamethasone arm. Rates of nonhematologic toxicity in the RD and Rd arms were 68% and 61%, respectively, with treatment-related deaths in 13% versus 4% of patients. The 2-year OS survival rate of 90% for patients treated with Rd in this randomized trial prompted a large trial

[a]Regimens listed as "induction" + "consolidation/maintenance."
[b]The basis of TT2 is a complex 6 or 7 drug induction followed by 2 autologous stem cell transplants, followed by 2 cycles of 5 drug consolidation, indefinite interferon maintenance, and 1 year of dexamethasone.
[c]Statistically significant difference between arms.
[d]Maintenance not included in response, although patients were randomized to thalidomide or prednisone.
[e]ASCT was not a predetermined part of these trials, so data include both patients who did and did not undergo ASCT.

comparing Rd to MPT, which has completed accrual (MM-020), but has not yet been reported.

Transplant-Ineligible Patients: Induction Chemotherapy for Patients Ineligible for ASCT Prior to the 21st Century

The 1970s and 1980s were a testing ground for various combinations of alkylators, corticosteroids, and doxorubicin. Melphalan-cyclophosphamide-prednisone,[256] carmustine-cyclophosphamide-prednisone,[371,372] melphalan-cyclophosphamide-carmustine-prednisone (MCBP),[256,353] and vincristine-melphalan-cyclophosphamide-prednisone (VMCP)[256] resulted in response rates of 47%, 37% to 50%, 49% to 68%, and 62%, respectively. Median survivals with these regimens were 25 to 36 months.[256,353,371,372] Lee and Case[260] introduced the five-drug regimen of vincristine-carmustine-melphalan-cyclophosphamide-prednisone (VBMCP or the M-2 regimen), which included the same four drugs as MCBP plus vincristine; dose intensities, however, were different in these two regimens. The response rate for VBMCP was about 85% in previously untreated patients with a median survival of 38 months.[260,410] The success of the VBMCP regimen supported the value of vincristine. However, the MRC IV trial, which randomized 530 previously untreated patients with MM to MP versus melphalan-vincristine-prednisone, revealed no difference in either response rate or OS between the two arms.[264] VMCP has not produced any response or survival advantage over MP.[383,411]

Although subsequent randomized trials have substantiated the superior response rates of VBMCP over standard MP,

they have not demonstrated superior survival.[263,376,385,412] In fact, the meta-analysis performed by the Myeloma Trialists' Collaborative Group[216] involving 6,633 patients in 27 randomized trials, revealed a superior response rate (60.2% vs. 53.2%, $P < 0.000001$, two-tailed) but no survival benefit for combination chemotherapy over standard MP (Fig. 98.6). A prior meta-analysis of 18 published trials (3,814 patients) also demonstrated no benefit for combination chemotherapy in terms of survival. There was a suggestion of a survival advantage in the subgroup of patients with more aggressive disease,[355] but this was not substantiated in the larger meta-analysis.[216]

The use of alkylator–doxorubicin-based combination chemotherapy was stimulated by a report on the benefits of a combination of doxorubicin and BCNU in patients who had become resistant to melphalan.[413] Regimens such as MAP (melphalan-doxorubicin-prednisone), CAP (cyclophosphamide-doxorubicin-prednisone), VCAP (vincristine and CAP), and VBAP (vincristine-BCNU-doxorubicin-prednisone) were tried; by SWOG response criteria, objective response rates were 41%, 46%, 64%, and 61%, respectively.[256,414] Median survival ranged from 30 to 32 months; subsequent analysis demonstrated a superior median survival for the VBAP arm of 37 months.[415] Enthusiasm for alternating VMCP and VBAP (or VCAP) was generated by the SWOG study of 237 patients randomized to MP or the above regimens.[380,381] Response rates and OS were superior in the alternating combination chemotherapy arms compared to the MP arm,[414,415] but the survival benefits of this initial study were not reproducible by others.[257,377,378,382,384,416,417] The V MRC myelomatosis trial randomized patients to ABCM (VBAP-VMCP without the vincristine or prednisone) or melphalan as a single agent on the basis of findings emanating from the IV MRC trial, which demonstrated a lack of benefit attributable to the addition of vincristine. Median survival in the ABCM group was superior to that of the melphalan-only arm (32 vs. 24 months, $P = 0.0003$).[233,266]

Combination Chemotherapy with Interferon-α for Induction

IFN and dexamethasone have been combined as an induction regimen in patients with newly diagnosed myeloma and a low tumor mass. A retrospective comparison showed that the response rate of this regimen (57%) was similar to the response rate (48%) previously observed with dexamethasone alone.[418] A randomized trial comparing MP, melphalan-dexamethasone, dexamethasone, and dexamethasone-IFN did not demonstrate any added benefit by incorporating IFN into the treatment regimen.[249] Ahre et al.[419] randomized 55 patients to MP or IFN (3 to 6 MU daily); response rates in the MP arm were significantly higher than in the IFN arm (44% vs. 14%, $P < 0.001$). These results spawned a multitude of trials adding IFN to MP[420–428] and numerous alkylator-corticosteroid combinations with or without anthracycline[422,429–438] as part of an induction regimen. Results have been mixed. Two meta-analyses have been performed in an attempt to reconcile these conflicting results.[439,440] The first, reported in 2000,[439] used published data and included 17 induction trials[420–428,430–435,437,438] with 2,333 evaluable patients;[439] the second, reported by The Myeloma Trialists' Collaborative Group in 2001,[440] used primary data from 12 induction trials[420–428,430,432–434,436–438,441] involving 2,469 patients.[440] Overall, the results were similar. In the first meta-analysis, the benefits attributable to the addition of IFN to the induction regimen included a 6.6% higher response rate ($P < 0.002$) and a 4.8-month and 3.1-month prolongation of relapse-free ($P < 0.01$) and OS ($P < 0.01$).[439] In the second meta-analysis, patients receiving IFN had a slightly better response rate (57.5% vs. 53.1%, $P = 0.01$) and PFS (30% vs. 25% at 3 years, $P < 0.0003$), with a superior median time to progression of about 6 months. The survival advantage of 2 months, however, was not significant ($P = 0.1$).[440] These meta-analyses suggest that incorporation of IFN into induction provides a modest prolongation of response and possibly of survival. Wisloff et al.[442] evaluated the quality of life of 583 patients randomized to either MP or MP plus IFN as induction. During the first year of treatment with IFN, the patients reported significantly more fever, chills, dry skin, fatigue, pain, nausea, vomiting, and appetite loss than the control patients. After the first year, however, the only symptom reported more often was dizziness. Although patients receiving IFN had a 5- to 6-month prolongation of the response and plateau phase, there was no late quality-of-life benefit observed to compensate for the early impairment. The authors questioned the clinical value of the plateau phase prolongation and reported that only 60% of patients continued to receive IFN after 24 months, suggesting that their data might underestimate the potential toxicity of the drug.

Transplant Eligible Patients

VAD-like regimens—incorporating different corticosteroids,[243,246,443] and C-VAMP (cyclophosphamide-vincristine-doxorubicin-methylprednisolone)[245] had commonly been used as induction therapy before stem cell collection and transplantation, but have been largely replaced by regimens incorporating IMiDs and/or proteasome inhibitors. These VAD-like regimens had initially been piloted with salutary effect in relapsed disease, and were subsequently applied in previously untreated patients with response rates of 50% to 84%.[444–453] Median survival for patients treated initially with VAD and no transplant was about 36 months.[454] The complete response rate of C-VAMP was higher than that of VAMP alone, but survival was not different.[447] Response rates of 80% have also been achieved using the CAD (cyclophosphamide-doxorubicin-dexamethasone) regimen.[455] The addition of etoposide to C-VAD appears to contribute only toxicity.[456]

By the late 1990s and early 2000s, single-agent high-dose dexamethasone was used by some experts in lieu of VAD for induction in those patients destined for stem cell collection based on a nearly comparable response rate of single-agent high-dose dexamethasone of 43%[242] and the advantage of an oral noninfusional therapy. This strategy was used successfully, resulting in adequate collections of peripheral blood stem cells without any apparent adverse effects on complete remission rates or progression-free survival in several single-arm studys.[457,458] With the advent of additional therapies, single-agent dexamethasone is no longer a standard induction option.

There is controversy about which induction is best for patients before stem cell collection and ASCT. In the absence of mature data, there are two philosophical camps. There are the proponents of "deepest response," who argue that using those multidrug regimens yielding highest CR rates is essential. These investigators point to the circular reasoning that those patients with the deepest response do best.[459] The counterargument posed by others is that until randomized controlled trials demonstrate a survival advantange or at least a PFS advantage with improved quality of life for one regimen over another, selection of a regimen that may give a higher CR rate but more toxicity and cost may not prove to be the most prudent course of action. Unfortunately, for the majority of regimens there are no completed prospective randomized trials to answer this question. Many of the trials discussed here suffer from a paucity of information about future access to the novel agent in the control arm, making it impossible to discern whether an advantage seen using a multiagent induction regimen lies in synergy of a particular combination or merely in access to yet another drug with activity against MM.

Transplant-Eligible Patients: Phase III Trials of Induction Regimens Including Immune Modulatory Drugs and/or Proteasome Inhibitors (Table 98.7)

Table 98.7 includes published phase III induction regimens that are part of an ASCT transplant treatment plan. Five of them include a mix of patients who are and are not destined for transplant,[362,407,460–462] five include include planned maintenance,[463–467,468] and three do not specify post-transplant

maintenance.[469–471] Further limitations of many of these trials are short follow-up and different maintenance arms, making it difficult to tease out benefit due to induction versus maintenanace. There is also a paucity of information about quality of life associated with these protocols. Patterns arise in terms of response and PFS: that is, addition of thalidomide is better than no addition, but addition of bortezomib is better yet. Despite these advantages in response rate and PFS, to date only one study has shown a better OS, the HOVON-65 trial. As more drugs are added, there is more toxicity, especially peripheral neuropathy.

The IFM 2005-1 randomized 482 patients to either four cycles of VAD or bortezomib dexamethasone (BD)[470] followed by DCEP (dexamethasone-cyclophosphamide-etoposide-cisplatin) for two cycles versus no DCEP. Patients were to have a single ASCT, and those without a VGPR or better were to receive a second ASCT. An undefined number of patients received maintenance lenalidomide as part of a different trial of lenalidomide versus placebo (IFM 2005-2 trial). Pretransplant CR, VGPR, and PR were superior with BD. By protocol, fewer patients who received BD were deemed candidates for second ASCT than patients who had VAD induction, but only 21% and 27%, respectively, actually received a second ASCT. The improvement in response in the BD arm persisted after transplant, but with a median follow-up of 32 months, there was no difference in PFS or OS. The incidence of grade 3 to 4 adverse events appeared similar between groups, but hematologic toxicity and deaths related to toxicity (0 vs. 7) were more frequent with VAD. In contrast, rates of grade 2 (20.5% vs. 10.5%) and grades 3 to 4 (9.2% vs. 2.5%) peripheral neuropathy during induction through first transplantation were significantly higher with BD.

Based on the promising phase II results using VTD in previously untreated myeloma,[472] the GIMEMA group randomly allocated 480 patients to either three 21-day cycles of thalidomide (100 mg daily for the first 14 days and 200 mg daily thereafter) plus dexamethasone (40 mg daily on 8 of the first 12 days), either alone or with bortezomib (1.3 mg/m(2) on days 1, 4, 8, and 11).[466] After double autologous stem-cell transplantation, patients received two 35-day cycles of their assigned drug regimen, VTD or TD, as consolidation therapy. All patients were subsequently maintained on dexamethasone 40 mg days 1 to 4 every 28 days. After induction therapy, higher rates of complete or near complete response were observed in the VTD arm as compared to TD (31% vs. 11%, $P < 0.0001$). These improved response rates persisted after first and second ASCT and after two cycles of consolidation. 3-year PFS was better in the VTD group (68% vs. 56%, $P = 0.006$), but with a median follow-up of 36 months, the estimated 3-year OS rates were no different. Grade 3 or 4 adverse events post induction were recorded in a significantly higher number of patients on VTD than in those on TD (56% vs. 33%, $P < 0.0001$), with a higher occurrence of grade 3 to 4 peripheral neuropathy in patients on VTD (10% vs. 2%, $P = 0.0004$).

The HOVON 50/GMMG-HD3-trial is a phase III study of 536 randomized patients up to 65 years[464] to either three cycles of TAD (thalidomide, 200 mg for HOVON and 400 mg for GMMG; adriamycin 9 mg/m^2, days 1 to 4; and dexamethasone 40 mg, days 1 to 4, 9 to 12, 17 to 21) or VAD. TAD resulted in more grade 2 to 4 AEs as compared with the VAD arm (31% vs. 21%, $P = 0.008$). The TAD had superior overall response rates pre- and post-ASCT, but with a median follow-up of 52 months, there was no significant difference in median OS (73 vs. 60 months, $P = 0.77$). Patients who had been randomized to the thalidomide arm had a markedly shorter survival post-relaspse.

In the MRC IX trial (transplant pathway), 1,111 paitents were randomized to either oral cyclophosphamide-thalidomide-dexamethasone (CTD) or to infusional cyclophosphamide, vincristine, doxorubicin, and dexamethasone (C-VAD).[465] As many as six cycles were given prior to ASCT. The post-induction overall response rate was significantly higher with CTD than C-VAD (82.5% vs. 71.2%, $P < 0.0001$, including superior complete response rates (13.0% vs. 8.1%, $P = 0.008$). This response advantage persisted post-autologous stem-cell transplantation (complete response, 50.0% vs. 37.2%, respectively; $P = 0.00052$). Patients had a secondary randomization to either maintenance thalidomide or prednisone. With a median follow-up of 47 months, there was no difference in either PFS or OS. FISH risk had no impact on outcome.

To date, the HOVON-65 trial is the only randomized trial incorporating novel therapies into induction that has shown an improvement in OS.[467] These results are confounded by the fact that these same patients had different maintenance regimens as well, making it difficult to know if the induction, the maintenance, or merely access to bortezomib was the value-added step, in terms of the OS benefit. This trial randomized 827 patients to 3 weeks of initial therapy with either VAD or bortezomib, doxorubicin, and dexamethasone (PAD), followed by one or two ASCT. Post-ASCT maintenance for the VAD group was thalidomide 50 mg daily and for the PAD group bortezomib 1.3 mg/m^2 once every 2 weeks. Maintenance was continued for 2 years. After completing induction therapy with PAD, 31% of patients had achieved a CR in contrast to 15% of VAD patients. This improved CR rate persisted even after one or two ASCT. PFS was superior in the PAD-bortezomib maintenance arm as compared to the VAD-thalidomide arm, 35 months versus 28 months. After a median follow-up of 66 months, OS was also better in the PAD arm, 5-year OS of 61% versus 55%, $P = 0.05$ when adjusted for risk factors (age, performance status, ISS, double ASCT, and FISH abnormalities) in the multivariate analysis. Of note, the hazard ratio for double ASCT was similar to that of being on the PAD-bortezomib arm. Peripheral neuropathy grades 2 to 4 were reported in 18% of VAD patients versus 40% of PAD patients, $P < 0.001$. The discontinue rate of thalidomide maintenance was higher than that of bortezomib maintenance (30% vs. 11%, $P < 0.001$). An important observation made in this trial is that the use of bortezomib both before and after ASCT appeared to attenuate the poor prognostic impact of deletion 17p.[473]

The Spanish Myeloma Group conducted a trial to compare VTD versus TD versus vincristine-BCNU-melphalan-cyclophosphamide-prednisone alternating with vincristine-BCNU-doxorubicin-dexamethasone plus bortezomib (VBMCP/VBAD/B) in patients aged 65 years or younger with MM destined for ASCT.[468] A total of patients was allocated. The CR rate was significantly higher with VTD than with TD (35% vs. 14%, $P = 0.001$) or with VBMCP/VBAD/B (35% vs. 21%, $P = 0.01$). The median PFS was significantly longer with VTD (56.2 vs. 28.2 vs. 35.5 months, $P = 0.01$). With a median follow-up of 35 months, the 4-year OS was 74% for VTD, 65% for TD, and 70% for VBMCP/VBAD/B, P = NS.

The IFM 2007-2 trial[471] was a randomized trial to compare bortezomib-dexamethasone (VD) as induction ASCT to a combination consisting of reduced doses of bortezomib and thalidomide plus dexamethasone (vtD), the latter of which was comprised of four 3-week cycles of IV bortezomib 1 mg/m^2/m^2 day 1, 4, 8, and 11 along with thalidomide 100 mg/day orally, and dexamethasone 40 mg days 1 to 4 (all cycles) and days 9 to 12 (cycles 1 and 2). In the case of less than PR after cycle 2, the dose of bortezomib was increased to 1.3 mg/m^2 and the dose of thalidomide to 200 mg/day. The VD patients received two drugs on the same schedule as vtD, but the dose of bortezomib was 1.3 mg. Patients receiving the three-drug regimen had similar overall response rates and CR rates, but VGPR or better occurred significantly more often in the vtD group. This same pattern was observed after a single ASCT. Of note, the number of stem cells collected was less in patients receiving the three-drug regimen. Subsequent post-ASCT consolidation and/or maintenance was at treating physician's discretion; more patients receiving VD received maintenance therapy. Despite these differences, there was no significant difference in PFS or OS with a median follow-up of 32 months. There were significantly

higher rates of peripheral neuropathy among patients on the VD arm: overall 70% versus 53%, $P = 0.01$ and grade 3 in 11% versus 3%, $P = 0.03$. The authors concluded that vtD, including reduced doses of bortezomib and thalidomide, yields higher VGPR rates compared with VD and can be considered a new effective triplet combination before HDT/ASCT.

E1A00,[407] E4A03,[362] and S0232[460] (Table 98.7) were conducted with response endpoints rather than PFS or OS. The two trials comparing variants of VAD using pegylated doxorubicin had response and toxicity as major endpoints.[461,462] E1A00 compared single-agent dexamethasone to thalidomide-dexamethasone (TD). Its premise was to validate whether the addition of thalidomide to dexamethasone increased response rates as reported in phase II studies. The overall response rate of TD was significantly higher than dexamethasone alone (63% vs. 41%); however, toxicity was greater using the combination with grade 4 to 5 toxicity being 45% vs. 21%, $P < 0.001$.[407] For nearly a decade TD was used as induction in the months before stem cell collection because of its high response rates and its ease of administration, but with the introduction of lenalidomide and bortezomib, the TD doublet is not commonly used in the United States as induction. The results of the two lenalidomide trials (E4A03[362] and S0232[460] have been discussed.

In an attempt to avoid the contiuous infusion required to administer VAD, the use of the pegylated liposomal doxorubicin has been explored in two randomized trials. Doxil-vincristine-dexmathasone (DVD)—using either standard high dose dexamethasone[462] or attenuated doses of dexamethasone [461]—was compared to VAD. Results were comparable between arms with regards to response rates, 42% in the attenuated dexamethasone trial[461] and 61% with the standard dose dexamethasone trial.[462] PFS and OS were comparable, but there was more alopecia, grade 3/4 neutropenia in the nonliposomal doxorubicin arms and more palmar-plantar erythrodysesthesia in liposomal doxorubicin arms.

Total Therapy Approach

Barlogie and colleagues have championed the "total therapy" (TT) approach since 1990.[329,463,474,475] The concept is to use all therapies with activity against malignant plasma cells as early as possible with prolonged treatment courses. Advances have come from this approach, especially the concept of tandem transplantation, but the major limitation of the total therapy studies is that they have not been compared to less aggressive strategies in a randomized fashion. With successive trials—total therapy 1 (TT1), total therapy 2 (TT2), and total therapy 3 (TT3)—there have been improvements in outcomes including complete response, PFS, and OS (Table 98.8).[329] Complete response rates have increased from 38% to 62% of patients and 5-year OS rates have increased from 57% to 73%. Although other investigators have not reported duration of complete response rates that approach those of TT3, since the beginning of the 21st century 5-year OS rates of 50% to 80% among transplant-eligible patients are increasingly common using less intensive treatment strategies.[363,476] Moreover, toxicity of the total therapy strategies is not inconsequential. For example in TT2 grade 3/4 adverse events include PN in 27%, thrombosis or embolism in 30%, bowel obstruction in 14%, and syncope in 12%.[463]

Other Induction Regimens of Interest

Table 98.5 includes a number of regimens that have reported in the up-front setting,[316–319,360,365–368,472,477,478,479,480,481,482–485] but no recommendation can be made regarding their use given the absence of randomized trials that may better define their role in patients with myeloma. Several have been discussed in previous sections.[365–368,472,480,481,486] All of the other regimens are novel triplets or quadruplets. Response rates are listed in Table 98.5, therefore much of the emphasis of this section focuses on toxicity.

Four phase II studies use either single-agent bortezomib or bortezomib in combination with dexamethasone. One study is notable because all patients on that study (E2A02) were high-risk as defined by B2M and/or cytogenetic abnormalities, and none of the pateints had early transplantation. Median PFS was 8 months and 2-year OS was 76%.[316]

Two regimens exclude corticosteroids, VT (bortezomib, and thalidomide),[478] and VDT (bortezomib, pegylated liposomal doxorubicin, and thalidomide).[482] The VT study treated 27 patients with bortezomib 1.3 mg/m^2 on days 1, 4, 8, and 11 every 21 days and thalidomide 150 mg/d for a maximum of eight cycles.[478]

TABLE 98.8

DCEP, dexamethasone, cyclophosphamide, etoposide, cisplatinin; DPACE, dexamethasone, cisplatinin, doxorubicin, cyclophosphamide, etoposide; IFN, interferon; VAD, vincristine, doxorubicin, dexamethasone; Thal, thalidomide; TT, total therapy; VTD-PACE, bortezomib, thalidomide, dexamethasone, cisplatinin, doxorubicin, cyclophosphamide, etoposide.
[a]Excluding interferon maintenance duration.

The overall response rate was 81.5% with 25.8% near complete response or greater. The most common grade 3 toxicities were peripheral neuropathy (22%), pneumonia (15%), fatigue (7%), and anemia (7%). No venous thromboembolic events were observed even in the absence of prophylactic anticoagulation. Forty-three newly diagnosed MM patients were enrolled onto the VDT study.[482] The overall response rate and complete response (CR) + near complete response (nCR) rate were 78% and 35%, respectively. Median time to progression was 29.5 months. Fatigue, rash, neuropathy, constipation, and infections were the most common side effects.[482]

Kumar et al. built on the Rd experience by adding cyclophosphamide.[487] A total of 85% of patients responded, and the toxicities were manageable with over 80% of planned doses delivered; 6 patients went off study for toxicity. The median PFS for the entire group was 28 months (95% CI: 22.7 to 32.6) and the OS at 2 years was 87% (95% CI: 78 to 96). Note that 14 patients with high-risk MM had similar PFS and OS as the standard-risk patients ($n = 39$).

Carfilzomib, lenalidomide, and dexamethasone[479] have been used in the up-front setting with excellent response rates.[479] The long-term utility of this regimen is not known, but in a phase I/II study in 53 patients with newly diagnosed MM the maximum tolerated dose was 28-day cycles of: carfilzomib 20/ 36 mg/m^2, days 1, 2, 8, 9, 15, 16, and 1, 2, 15, 16 after cycle 8; lenalidomide 25 mg/d, days 1 to 21; and weekly dexamethasone 40/20 mg cycles 1 to 4/5+. Most patients did not require dose modifications. Thirty-five patients underwent stem cell collection after cycle 4, and 7 proceeded to early transplant. After a median of 12 cycles (range, 1 to 25), 62% achieved at least near-complete response (CR) and 42% stringent CR. With median follow-up of 13 months, 24-month progression-free survival estimate was 92%. Grade 3/4 toxicities included hypophosphatemia (25%), hyperglycemia (23%), anemia (21%), thrombocytopenia (17%), and neutropenia (17%); peripheral neuropathy was limited to grade 1/2 (23%).

Lenalidomide, bortezomib, pegylated doxorubin, and dexamethasone (RVDD) were tested in a phase I/II trial including 72 pateints.[485] The MTD was 3-week cycles of lenalidomide 25 days 1 to 14, bortezomib 1.3 mg/m^2 on days 1, 4, 8, and 11, and pegylated doxorubin 30 mg/m^2 in day 4, and dexamethasone 20 mg days 1, 2, 4, 5, 8, 9, 11, and 12 (cycles 1 to 4, but 10 mg for cycles 5 to 8). The maximum number of treatment cycles was 8, and patients who did not go to ASCT were to receive maintenance that included lenalidomide, bortezomib, and dexamethasone indefinitely. The median treatment duration was 4.5 cycles and 15% of patients achieved stringent CR. Grade 3/4 AEs included neutropenia (19.4%), infections (14%), thrombocytopenia (11%), sensory peripheral neuropathy (6%), and thromboembolism in 3%. All grade fatigue, constipation, sensory neuropathy, and infection occurred in 83%, 69%, 65%, and 57%, respectively. The 18-month PFS for patients proceeding and not proceeding to ASCT was 93% and 64%, respectively. Although the decision of proceeding to ASCT was nonrandomized, there was a significant difference in PFS between the groups. With a median follow-up of 15 months, the 2-year OS for all patients was approximately 75%.

There are three phase II reports of adding thalidomide to pegylated doxorubicin, and dexamethasone with[488,489] or without vincristine.[490] Response rates were comparable. In the ThaDD trial which did not include vincristine, grade 3 to 4 infections and thromboembolic accidents were observed in 22% and 14% of patients, respectively.[490] In the DVd-T and T-DVD trials grade 3 to 4 toxicities included: neutropenia (14% to 15%), thrombosis (10% to 25%), pneumonia (12%), constipation (10%), rash (5% to 8%), and peripheral neuropathy (5% to 22%) . It is notable that although the ThaDD cohort[490] was older and received lower doses of the thalidomide and no vincristine, similar response rates and less toxicity were seen.

Hematopoietic Stem Cell Transplantation

Autologous Transplant

To overcome resistance of the myeloma cells to conventional-dose chemotherapy, McElwain and Powles[220] pioneered the use of high-dose melphalan to treat MM and plasma cell leukemia. The treatment was complicated by prolonged myelosuppression. Barlogie et al.[491] subsequently used a regimen combining high-dose melphalan with total body irradiation supported by autologous bone marrow transplantation in MM patients refractory to VAD. Ten years hence, Attal et al. published the first prospective randomized controlled trial demonstrating an improved OS for patients undergoing high-dose therapy with autologous stem cell support compared to conventional chemotherapy.[229]

Although high-dose therapy followed by ASCT is not curative, it improves event-free and OS in three[229,492,493] of the seven published randomized controlled trials addressing this issue,[494–497] Table 98.9. Three of the four "negative" studies are

CR/VGPR, complete response or very good partial response; ORR, any response greater than or equal to a partial response; OS, overall-survival; PFS, progression-free survival; SCT, patients known to receive an autologous hematopoietic stem cell transplant.
[a]Significant.
[b]Transplant arm is 2 low dose (melphalan 100 mg/m^2) autologous stem cell transplants.
[c]Often included in "double transplant" tables because both arms received melphalan 70 mg/m^2 × 2 without stem cell support as induction therapy.

largely "'early" versus "delayed" transplant trials, and the fourth "negative" study excludes from their randomization those patients who did not respond to induction therapy.[497] Response rates with ASCT are 75% to 90%, and complete response rates are 20% to 40%.[229,492–497]

In contrast to the experience with malignant lymphoma, stem cell transplantation appears to be useful for patients with primary resistant disease.[498–500] Patients with MM, in whom first-line therapy such as VAD fails, can be sensitive to high-dose chemotherapy with stem cell reconstitution. Alexanian et al.[498] reported a decrease of 75% in tumor burden in 56% of patients and a marked improvement in survival compared with matched historical controls. Kumar et al.[500] also looked at stem cell transplantation in primary refractory disease and found that although there was a lower complete response rate (20% vs. 35%) in the the primary refractory patients, the 1-year PFS was similar to that of patients with chemosensitive disease. The benefit of high-dose therapy is less clear among patients who fail induction with immunomodulatory agents. A more recent retrospective study from the Mayo Clinic[501] analyzed PFS and OS in patients who did not have a partial response (never responded or progressed during continuous therapy) after induction therapy with a regimen that included thalidomide or lenalidomide. Patients who did not achieve partial remission had a significantly shorter OS from ASCT (73.5 vs. 30.4 months) and a shorter PFS (22.1 vs. 13.1 months; $P < 0.001$).

As shown in Table 98.9, the Intergroupe Français du Myélome[229] published the first randomized trial comparing high-dose chemotherapy followed by autologous bone marrow transplantation with conventional chemotherapy (Fig. 98.7). A total of 200 patients with previously untreated MM were randomized to receive ASCT or combination chemotherapy (CCT). The 5-year EFS (28% vs. 10%) and OS rates (52% vs. 12%) were higher in the transplantation group. An updated analysis with a median follow-up of 7 years confirmed that high-dose chemotherapy improves EFS (median, 28 months vs. 18 months), as well as OS (median, 57 months vs. 44 months).[502]

The Medical Research Council VII trial was the second published study addressing the question of CCT versus ASCT.[492] This trial included 401 randomized patients. They found that the complete response rates (8% vs. 44%), the median EFS (19 vs. 31 months), and the OS (42 vs. 54 months) all significantly favored the ASCT arm, even though only 75% of the patients assigned transplant actually received it and 15% of patients in CCT arm received salvage ASCT.

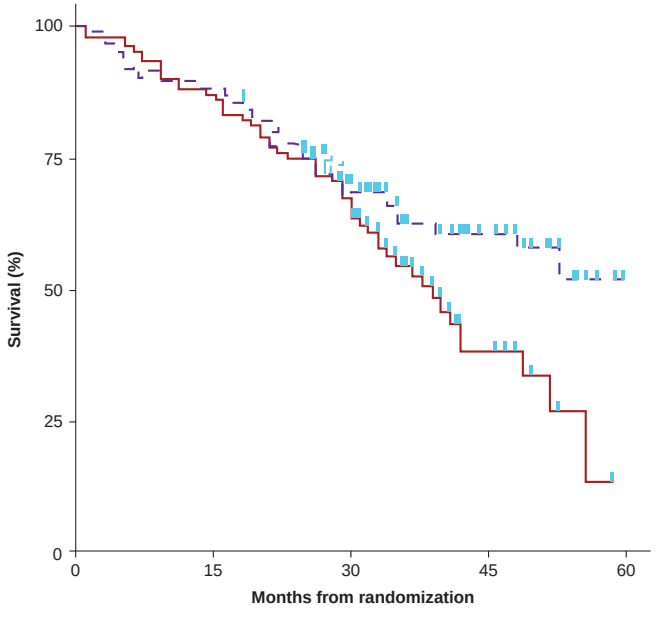

FIGURE 98.7. Conventional chemotherapy versus autologous hematopoietic stem cell transplantation, IFM 90 Trial. (With permission, Attal M, Harousseau JL, Stoppa AM, et al. A prospective, randomized trial of autologous bone marrow transplantation and chemotherapy in multiple myeloma. Intergroupe Francais du Myelome. N Engl J Med 1996;335:91–97. Copyright © 1996 Massachusetts Medical Society. All rights reserved.)

Three trials address the "early" versus "delayed" transplant strategy.[494–496] The first is the MAG90 trial in which Fermand et al. demonstrate that among the 185 patients randomized to either early or late ASCT, the OS in both groups was 64 months and the percentage of the respective groups actually receiving a ASCT was 98% and 78%, respectively.[495] This trial was important because it gave patients and physicians license to time their transplant either up-front or delayed. Most chose to transplant early because the time without systemic therapy (TWiST) was longer in the early than the delayed ASCT group, potentially providing better quality of life for the early transplant group. The MAG91 trial[494] randomized 190 patients under the age of 56 to CCT or HSCT, but this trial ended up being another early versus late transplant trial. Only patients 55 to 65 years of age were included. EFS (19 vs. 25 months), but not OS (47.6 vs. 47.8 months) was better in the ASCT arm. Despite the 120-month follow-up, the OS statistics are confounded by the fact that only 75% of the "ASCT" arm received ASCT, and that 22% of the "CCT" received an HSCT. The intergroup trial (S9321) randomized 510 patients 70 or younger to CCT or ASCT.[496] With a 76-month follow-up, 7-year OS was no different between the arms, but again only 82% of the "ASCT" group received an ASCT and 34% of the "CCT" group received an ASCT. What is quite striking in this study is the fact that at 7 years after a myeloma diagnosis, 38% of patients were still alive.

Of note, there are no prospective randomized clinical trials addressing the "early versus late" question in the context of up-front IMiDs and proteasome inhibitors. One retrospective study tried to address this question and found that in ASCT-eligible patients who received IMiDs as initial therapy followed by early stem cell mobilization, delayed ASCT results in similar OS compared with early ASCT. It was noteworthy that an excellent 4-year survival rate of >80% was observed among ASCT-eligible patients who received initial therapy with lenalidomide and dexamethasone regardless of the timing of ASCT.[476]

The Spanish Cooperative Group prospective trial is dissimiliar from the other randomized trials in that only those patients responding to therapy were randomized. At enrollment, 216 patients were treated initially with four cycles of VBMCP and VBAD (vincristine, carmustine, doxorubicin, and dexamethasone),[497] and only 164 were randomized to receive eight additional courses of chemotherapy versus ASCT. There was no difference between the groups with respect to complete response rate, overall response rate, PFS, or OS. These data are discordant from the other ASCT trials, but can be interpreted in two possible ways: one, patients who achieve response with alkylator-based induction do not require consolidation with ASCT; or two, with longer follow-up and more events (i.e., deaths), an OS difference will be seen.

The MMSG97 trial was unique in that it randomized patients aged 50 to 70 years of age to either MP or two half-dose melphalan transplants.[493] Patients receiving MP had significantly worse outcomes. A significant difference between two low-dose ASCT and MP was not seen in the IFM 999-06 trial.[249]

The Hovon-24 trial is commonly grouped in the "single versus double" transplant category, although it is actually an "intensified chemotherpy without transplant" versus "intensified chemotherpy followed by high dose chemotherapy and a single ASCT."[503] There was a significantly higher complete response rate and EFS in the more intensive treatment arm. The differences in EFS, PFS, and TTP were not seen until 4-year follow-up had been reached. The authors reported that the lack of difference in OS was likely due to a "high proportion" of patients from the control arm receiving ASCT at first relapse.

It should be noted that all randomized studies of ASCT were designed and implemented before the availability of thalidomide, lenalidomide, and bortezomib. Therefore the role of transplant may evolve in the future. Studies are ongoing to evaluate whether prolonged treatment with bortezomib, lenalidomide, and dexamethasone (VRD) followed by lenalidomide maintenance is superior to induction chemotherapy followed by ASCT.

Single versus Double Transplantation

As the evidence was mounting that one course of dose-intensifed chemotherapy with ASCT was superior to conventional chemotherapy, investigators began experimenting with applying two consecutive ASCT. The concept of double or tandem transplant was promulgated by Dr. Barlogie and colleagues at the University of Arkansas.[329,504,505,506] These investigators reported high complete response rates and survival.[329,504,505,506] In the first report of "Total Therapy 1" which included 231 patients with newly diagnosed myeloma, the OS with this approach was 68 months.[329]

The largest and most mature randomized trial comparing single transplant to double ASCT was the IFM 94 study (Table 98.10). They found no difference in EFS or OS between double and single ASCTs after 2 years of follow-up[484]; however, by 4 years and beyond, an OS benefit was detected.[481] Although the response rate was not significantly different between the two groups (complete response and very good partial response, 42% in the single-transplant arm vs. 50% in the double-transplant group, $P = .15$), both EFS (25 vs. 30 months) and OS (48 vs. 58 months) were improved in the double-ASCT arm. The respective 7-year OS (21% vs. 42%) and EFS rates (10% vs. 20%) also significantly favored the double-ASCT group (Fig. 98.8 REALLY 98.8).[507] In this trial, four factors were associated with a longer survival: low β_2-microglobulin levels at diagnosis ($P < 0.01$), young age ($P < 0.05$), low lactate dehydrogenase (LDH) at diagnosis ($P < 0.01$), and the treatment arm to which the patient was assigned ($P < 0.05$). When the authors did an unplanned subgroup analysis, they found that patients who benefited most from the tandem ASCT were those who did not achieve a very good partial response or better after their first ASCT. Cavo et al.[482] have made similar observations based on preliminary data, including the benefit of a second ASCT being limited to those patients who do not achieve a very good partial response or better after their first ASCT. Most patients under the age of 65 years should have enough stem cells collected for at least two transplants.

A meta-analyisis was done comparing single ASCT to tandem ASCT for patients with MM.[508] Included were 1,803 patients enrolled in six randomized controlled trials. Patients treated with tandem ASCT did not have a better OS or EFS than patients treated with a single ASCT. Some of this difference may be in part related to patients receiving a second ASCT at relapse. Table 98.11 illustrates post-second ASCT performed in the salvage setting; patients can enjoy median OS rates ranging from 19 to 53 months.[509,510,511,512,513,514,515,523,524] Factors affecting OS included time to progression after first ASCT, number of prior lines of therapy, and chemosensitivity at time of second ASCT.

Hematopoietic Stem Cell Collection

Autologous peripheral blood stem cell transplantation has replaced autologous bone marrow transplantation because engraftment is more rapid and there is less contamination with myeloma cells.[525–527] Hematopoietic stem cells should be collected before the patient is exposed to alkylating agents[528,529] because prolonged melphalan exposure leads to an impaired harvest of peripheral blood stem cells when stem cells are mobilized with chemotherapy plus growth factors[530] or growth factors alone.[531] Data also suggest lenalidomide exposure may have adverse effects on the ability to collect stem cells.[532] This appears to be related to the duration of lenalidomide therapy as well as the age of the patient. For this reason, early mobilization of stem cells, preferably within the first four cycles of initial therapy, is now recommended.[533] Stem cell mobilization for myeloma patients is primarily performed using filgrastim granulocyte-colony stimulating factor alone or after cyclophosphamide chemotherapy. The target CD34 + cell dose to be collected as well as the number of apheresis performed varies by center, but a minimum of 2 million CD34 + cells/kg has been traditionally used for the support of one cycle of high-dose therapy.[534] In the setting of ASCT, CD34 + cell doses of >3 million/kg have been associated with better outcomes, primarily due to faster hematologic recovery and lower incidence of infectious and bleeding complications.[535,536] The use of plerixafor in conjunction with filgrastim has enhanced the ability to mobilize successfully the majority of patients undergoing ASCT. Plerixafor is a novel stem cell mobilizing agent. It is a bicyclam molecule that inhibits the SDF-1 alpha/CXCR4 binding that occurs between CD34 + stem cells and the marrow stroma. The inhibition of this interaction results in the release of CD34 + stem cells into the bloodstream facilitating their collection through apheresis methods.[537]

Historically, all peripheral blood cell products have been shown to be contaminated with malignant cells.[538,539] Purging marrow with cyclophosphamide derivatives[540] or with monoclonal antibodies[541–543] is feasible although associated with prolonged myelosuppression after transplantation. $CD34^+$ selection of peripheral blood progenitor cells provided effective hematopoietic support in a group of 55 patients with advanced MM after myeloablative chemotherapy.[544] However, two phase III randomized trials have shown no clinical benefit to using $CD34^+$ selected autologous peripheral blood stem cells.[545,546] Moreover, the risk of infection was higher in the CD34 selected group.[546]

Autologous Hematopoietic Stem Cell Transplantation in Special Populations

The mortality rate from ASCT is currently less than 5%. Age older than 65 years alone is not a contraindication for transplantation, although there are no randomized data proving or disproving its utility in this age group. Such patients are candidates for transplantation if they have good functional status and limited comorbidities.[547,548] Patients with renal failure, including dialysis patients can successfully undergo ASCT with melphalan 140 mg/m^2, with similar response rates and PFS, and a proportion will even have reversal of their renal failure. Treatment-related morbidity is higher,[549] and their OS is inferior to their dialysis-independent counterparts.[550,551]

Conditioning Therapy and Stem Cell Transplantation

In an effort to improve ASCT, various preparative regimens have been used. There has been only one prospective randomized controlled trial comparing conditioning regimens in patients with myeloma.[554] Moreau et al.[554] randomized 282 patients to receive either melphalan (140 mg/m2) plus total body irradiation or melphalan alone (200 mg/m2). There was no difference in response rates or EFS. Survival at 45 months favored the melphalan alone arm (65.8% vs. 45.5%, $P = 0.05$). Toxicity with melphalan alone was significantly less. Most investigators have now discontinued the use of total body irradiation and give only melphalan (200 mg/m2) as the preparative regimen.

Other regimens including various combinations of melphalan, busulfan, cyclophosphamide, idarubicin, etoposide, and/or thiotepa have been used,[555–560] without any evidence of superiority of these regimens over melphalan 200 mg/m2 and several with significantly more toxicity[556,560] and morbidity.[555] Innovative trials supplementing melphalan with skeletal targeted radiation (samarium 153-ethylenediaminetetramethylene phosphonate[561] and holmium 166 to 1,4,7,10-tetraazocyclodo-decane-1,4,7,10-tetramethylenephosphonic acid[562]) have been reported. Others have been studying bortezomib as a chemosensitizer for the melphalan.[563–565]

[a]TTP after initial ASCT affected OS.
[b]Number of lines of therapy affected OS.
[c]VGPR or CR after salvage affected OS.
[d]Included allogeneic transplant patients.

Desikan et al. retrospectively compared the impact of different conditioning regimens used for the second ASCT.[566] Outcomes of patients treated with melphalan 200 mg/m^2 were better than those conditioned with melphalan 200 mg/m^2 plus cyclophosphamide 120 mg/m^2, and melphalan 140 mg/m^2 plus total body irradiation (1,125 cGy).

Allogeneic Stem Cell Transplantation

AlloSCT includes both myeloablative and nonmyeloablative or "reduced intensity conditioning" (RIC) transplants. AlloSCT is appealing in theory because it avoids infusion of stem cells contaminated with myeloma cells and because there can be a beneficial graft versus myeloma effect.[547] Complete response rates of 22% to 67%, including molecular remissions in about one third,[495,548,549] can be achieved. Prolonged PFS is observed in approximately one quarter to one third of patients[471,495,550] (Table 98.12). The high treatment-related mortality (10% to 63%) and significant toxicity from graft-versus-host disease have limited the role of this procedure in the treatment of myeloma.[495,551,554]

Myeloablative Allogeneic Stem Cell Transplantation

There are no prospective randomized controlled trials that examine the role of myeloablative AlloSCT in myeloma. The US intergroup trial S9321[496] attempted to answer this question. Newly diagnosed patients with MM were treated with four cycles of VAD. Patients were randomly assigned to either high-dose therapy with melphalan (MEL) plus total body irradiation (TBI) or to standard dose therapy with VBMCP. Patients who were ≤55 years of age with an HLA-compatible sibling donor were offered the option of allogeneic transplantation with MEL 140 mg/m^2 plus TBI. However, this arm was closed when an excessive first-year treatment-related mortality rate of 53% was observed after enrollment of 36 eligible patients.With 7 years of follow-up the OS of the conventional chemotherapy, autologous and allogeneic transplant groups were identical at 39%. It was intriguing that that AlloSCT group showed a survival plateau whereas the other two groups did not, suggesting long-term benefit.

There have been seven case-control or cohort-control studies comparing autologous to AlloSCTs (Table 98.12).[558–564] The largest of these was by Bjorkstrand et al.[558] In their retrospective analysis of data compiled by the European Blood and Marrow Transplantation Group, there was inferior OS for myeloma patients treated with AlloSCTs compared to case-matched controls treated with ASCT (18 vs. 36 months).[558] The six smaller studies, which had relatively short follow-up, showed mixed results with regard to PFS and OS; transplant-related mortality, however, was consistently higher in the allogeneic groups (19% to 25%). Only one report favored allogeneic transplantation.[564] However, patients in the AlloSCT group were better-prognosis patients; they were significantly younger and less likely to have IgA myeloma. Although not reaching statistical significance, there were more ASCT patients having their transplant as salvage (37% vs. 23%). In addition, cyclophosphamide and TBI were used to condition both the ASCT and AlloSCT patients. With follow-up times for the two groups of 24 and 43 months, respectively, the 1-year OS was 86 and 64%, and the 4-year OS was 50% and 64%.

Reduced Intensity Conditioning Allogeneic Stem Cell Transplantation (Table 98.13)

Another strategy is to use ASCT to cytoreduce the myeloma followed by a reduced intensity conditioning alloSCT (allo-RIC). After two large series reported encouraging results,[567,568] four prospective trials have looked at this approach (Table 98.13). Only one of the five trials noted improved OS in patients undergoing tandem auto/allo transplants. Graft-versus-myeloma effect appears to be tightly linked to graft-versus-host disease (Fig. 98.9),[569] which has the potential to significantly affect quality of life.

Bruno and colleagues[570,571] enrolled 162 consecutive patients with newly diagnosed myeloma who were ≤65 years of age. All patients were initially treated with VAD, followed by high-dose melphalan and ASCT. Patients without an HLA-identical sibling received a second ASCT. Patients with an HLA-identical sibling then received nonmyeloablative TBI and stem cells from the sibling. The median OS was longer in the 80 patients with HLA-identical siblings than in the 82 patients without HLA-identical siblings (80 months vs. 54 months, $P = 0.01$).

The IFM enrolled 503 patients with high-risk MM (beta2-microglobulin level greater than 3 mg/L and chromosome 13 deletion at diagnosis) in two clinical trials.[572] In both protocols, the induction regimen consisted of VAD followed by first ASCT prepared by melphalan 200 mg/m^2. Patients with an HLA-identical sibling donor were subsequently treated with allo-RIC (IFM99-03 trial), and patients without an HLA-identical sibling donor were randomly assigned to undergo second ASCT prepared by melphalan 220 mg/m^2 and 160 mg dexamethasone with or without anti-IL-6 monoclonal antibody (IFM99-04 protocol). There were 284 patients enrolled in the IFM99-03 trial and 219 in the IFM99-04 trial. There were no differences in OS or EFS.

The PETHEMA group enrolled 110 patients with MM who had failed to achieve at least near-complete remission (nCR) after a first ASCT.[573] They received a second ASCT (85 patients) or a allo-RIC (25 patients), depending on the availability of an HLA-identical sibling donor. Those who received the allo-RIC had higher rates of complete remission (40% vs. 11%, $P = 0.001$) but no difference in EFS and OS. They noted a 66% incidence of chronic GVHD. The European Bone Marrow Transplant (EBMT), MM subcommittee

Outcomes for reduced-intensity allogeneic transplantation for multiple myeloma: an analysis of prognostic factors from the Chronic Leukaemia Working Party of the EBMT. Blood 2005;105:4532–4539. Copyright © the American Society of Hematology.)

enrolled 357 patients up to age 69. Patients with an HLA-identical sibling were allocated to the ASCT- allo-RIC arm and the remaining to a tandem ASCT arm. Complete response rates were higher in the ASCT- allo-RIC group as was PFS, but there was no difference in OS with a median follow-up of 61 months. Only 41% of patients in the tandem ASCT arm actually got a second ASCT whereas 85% of patients in the ASCT-allo-RIC group received their second transplant.

The Blood Marrow Transplant Clinical Trials Network (BMT CTN) enrolled 710 patients[574] and biologically randomized them to tandem ASCT or ASCT- allo-RIC. They, too, noted no difference in OS or PFS.

Given the toxicity of this approach—rates of chronic graft-versus-host disease of 50%—and the lack of suitable donors, allogeneic transplant, whether myeloablative or RIC, should be considered experimental in patients with myeloma.

Donor Lymphocyte Infusions

A graft-versus-myeloma effect has been noted after the administration of donor peripheral blood mononuclear cells for relapse after allogeneic transplantation.[575,576] DLI has been used in two ways in myeloma patients. Initially, it was used to treat relapsed or residual disease after full myeloablative AlloSCT.[575,576] Subsequently, it was used to re-introduce T-cells into a patient who had received an allogeneic T-cell depleted graft.[577,578] Most recently, it has been implemented in the context of allo-RIC programs to treat mixed chimerism, as well as for the older inductions.[579–581] In the largest DLI series for relapsed MM (n = 54), 52% of patients responded (35% with a partial response and 17% with a complete response). The majority of patients received some chemotherapy before DLI. PFS and OS were 19 and 23 months, respectively. Rates of overall acute GVHD and of grade III–IV acute GVHD were 57% and 20%, respectively. Rates of overall chronic GVHD and of extensive GVHD were 47% and 30%, respectively. Acute and chronic graft-versus-host disease following DLI were the strongest predictors for response.[582]

Maintenance Therapy

Strategies for maintenance therapy can be divided into two broad categories: continued induction therapy ad infinitum, and addition of a novel therapy after induction therapy. The former strategy was prevalent until recognition of the risk of developing alkylator-induced myelodysplastic syndromes and leukemia.[583–585,586,587,588] The latter strategy has predominantly applied immune modulators, including prednisone, IFN, cellular therapies, thalidomide, lenalidomide, and, most recently, bortezomib. To date, the benefit with these aforementioned strategies has been marginal at best, but for several of the agents, more study is required. The role of maintenance thalidomide, lenalidomide, and bortezomib are currently areas of both study and controversy as discussed below. No benefit has been observed with maintenance levamisole,[257,381] azathioprine,[589] or bacillus Calmette–Guérin (BCG).[414]

Maintenance Thalidomide

In terms of randomized controlled trials evaluating the role of thalidomide maintenance as compared to placebo or prednisone, there have been seven performed in the post-ASCT setting[404,463,464,574,590–592] and another three in the setting of low-dose alkylator-based therapy[390,392,393,404] (Table 98.14). In toto in all of the post-ASCT trials there was a PFS benefit among patients receiving maintenance thalidomide, but there was an OS benefit in only two of these trials.[590,591] Quality of life was significantly worse among patients receiving thalidomide in the NCIC CTG-MY.10 trial.[592]

Among the four nontransplant trials,[390,392,393,404] there was improvement in PFS in three of the trials, but an OS benefit in only one.[393] Three of these four nontransplant trials not only tested the value of maintenance thalidomide, but also used it as part of an induction triplet of MPT.[390,392,393] Due to this design limitation, it is impossible to state whether the induction component or the maintenance component contributed to any differences in outcomes. The MRC IX trial,[404] which compared attenuated CTD to MP, had a double randomization, so the effect of induction versus maintenance could be more easily separated. Although there was a modest improvement in PFS in this study (11 vs. 9 months), there was no difference in OS between the maintained and the nonmaintained groups.

Maintenance Lenalidomide (Table 98.14)

There are three randomized controlled trials evaluating lenalidomide maintaince (Table 98.14). The most experience, however, with lenalidomide maintenance is the continuous use of lenalidomide plus dexamethasone as the primary induction therapy without early transplant. All published studies evaluating this up-front combination have continued drug until ASCT or progression, and there are currently no studies that challenge this practice. The MM-020 trial, which has completed accrual, will in part address this question.

The use of the drug as maintenance after alkylator-based therapy has been addressed in three randomized controlled trials.[398,593,594] The first of these is the MM-015, which randomized patients among three arms: MP, MPR, and MPR with lenalidomide maintenance.[398] PFS was superior in the maintenance arm, but so far there is no difference in OS. The authors note that the greatest benefit was observed in those patients aged 65 to 75 years. Slightly more than twice as many secondary malignancies were seen in the lenalidomide maintenance arm.

The next two randomized controlled trials addressing lenalidomide maintenance are after ASCT. Both show improved PFS and a higher rate of secondary malignancies with maintenance lenalidomide,[593,594] but only the CALGB 100404 trial had a better OS (3-year OS 88 vs. 80 months, P = 0.03).[594] However, this OS advantage did not persist when the arms were stratified for beta-2 microglobulin and prior thalidomide use. A limitation to the CALGB 100404 trial is that in December 2009 (enrollment was April 2005 to July 2009), the study-drug assignments were unblinded when a planned interim analysis revealed a superior PFS in the lenalidomide arm. Patients who had been on placebo were encouraged to cross over to the lenalidomide. In contrast, in the IFM 2005-02 study,[593] the 4-year OS was 73% for the maintenance group and 75% for the placebo group. The duration of maintenance in this study was limited to 2 years once their data safety monitoring board noted a higher cumulative incidence of secondary malignancies in the lenalidomide arm. At last follow-up the incidence of second primary cancers was 3.1 per 100 patient-years for the lenalidomide arm as compared to the 1.2 per 100 patient-years for the placebo arm, P = 0.002. Another difference between the IFM 2005-02 study and the CALGB 100404 study is that all patients received two cycles of lenalidomide upon post-ASCT registration prior to getting either placebo or lenalidomide.[593] At this time no definitive recommendation regarding lenalidomide maintenance can be made.

Maintenance Strategies Incorporating Bortezomib

There are four randomized clinical trials that incorporate bortezomib into a maintenance strategy.[397,400,467,468] Due to the complexity of these trials, however, it is difficult to isolate the actual clinical benefit of the bortezomib maintenance. The first of the two ASCT trials was the HOVON-65/GMMG-HD4 trial,[467] which randomized patients to either PAD induction followed by one or two ASCT followed by maintenance bortezomib every other week for 2 years versus VAD induction followed by one or two ASCT followed by thalidomide maintenance for 2 years. Although OS was superior (5-year OS 61% vs. 55%) in the bortezomib containing arm, it is impossible to isolate the

effect of induction versus maintenance. Moreover, there was no information regarding the availability of salvage bortezomib in the VAD plus thalidomide arm. The other post-ASCT trial is the PETHEMA/GEM05MEN0S65 trial,[468] which is a complicated study of 387 patients who were randomized to one of three induction regimens followed by an ASCT followed by a secondary randomization to bortezomib (1.3 mg/m^2 days 1, 4, 8, and 11 every 3 months) plus thalidomide (100 mg/day), to single-agent thalidomide, or to thrice weekly IFN. PFS was superior with the VT as compared to the T or the IFN, but with 24 months follow-up there was no difference in OS.

The other two bortezomib maintenance trials were among elderly patients, who did not undergo ASCT. The first is the PETHEMA/GEM trial,[400] which randomized newly diagnosed elderly patients to eitherVMP or VTP with a secondary randomization to either VT or VP. After a median follow-up of 22 months from second randomization, PFS from this timepoint was 32 months for patients receiving VT and 24 months for those receiving VP (HR 1.4, 95% CI 0.8 to 2.1; $P = 0.1$). No difference in OS was observed. In the Italian study comparing VMP with no maintenance to VMPT plus VT maintenance,[397] PFS was superior with the four-drug combination with two-drug maintenance compared to the three-drug regimen without maintenance (32 months vs. 24 months), but there was no difference in OS. Based on these data, no recommendation regarding the utility of bortezomib maintenance can be provided.

Maintenance with Alkylators, Steroids, or Interferon

Through the 1970s and 1980s, several randomized studies established that alkylator-based maintenance therapy does not produce a survival benefit.[210,236,264,266,376,411,589,595,596] In general, patients not receiving maintenance had similar to slightly shorter remission duration than those receiving maintenance[210,376,411,589,596,597] but had higher rates of second remission.[596,597] Induction was commonly discontinued after plateau was reached (no change in M protein of more than 25% for 4 to 6 months).[210,264,598] With alkylator-based therapy, the ability to achieve a plateau is as important, if not more important, than the degree of response achieved.[210,598–601,604] No benefit has been documented for treatment beyond 12 months,[376] although it has been suggested—but not validated—that prolonged primary

chemotherapy may be beneficial in patients achieving less than a partial response, that is, a minimal response or stable disease.[605] Patients who relapse off alkylator-based chemotherapy have response rates of 25% to 80% with resumption of the original regimen.[210,414,596,597] In a study of 115 newly diagnosed patients treated with VBMCP for about 1 year, an initial response rate of 82% was achieved, with a median duration of response of 22 months. After a first relapse, 26 of 38 patients (68%) responded again and had a median duration of response of 11 months. After a second relapse, 7 of 16 patients (44%) responded, with a duration of response of 3.5 months.[606]

There are four studies that address the utility of corticosteroids as maintenance therapy. None justify a recommendation of prednisone as a standard maintenance regimen for all patients.

SWOG 9210 compared prednisone 10 mg every other day to prednisone 50 mg every other day in patients who had responded to 6 to 12 months of a VAD-based program, that is, a corticosteroid-intensive program. Median PFS for the higher-dose prednisone arm was 14 months compared to 5 months for the lower dose ($P = 0.003$). OS also was marginally better at 37 and 26 months ($P = 0.05$).[607] An earlier randomized study, which compared dexamethasone maintenance (20 mg/m2 orally daily for 4 days repeated monthly) to IFN maintenance after induction with melphalan and dexamethasone, demonstrated equivalence to inferiority of dexamethasone compared with IFN.[608] The CALGB 7,461 study addressed this issue less directly. Patients were treated initially with alkylator therapy and were randomized to observation or vincristine and prednisone as maintenance. OS and response rates were significantly longer and higher in the vincristine–prednisone maintenance group who had received up-front melphalan (median, 35.3 months vs. 27.0 months; $P = 0.003$) but not in patients who had received up-front BCNU or CCNU.[255] Finally, SWOG 8624, which evaluated the influence of corticosteroid dose intensity on response and survival, indirectly provided data on corticosteroid maintenance. Higher objective response and median OS (40 months vs. 31 months, $P = 0.02$) were observed in patients who received prolonged administration of glucocorticoids (prednisone 50 mg every other day) between chemotherapy courses.[454]

IFN has been studied both after conventional chemotherapy and after ASCT. The initial positive findings by Mandelli et al.[609] in 1990 demonstrated a superior disease-free and OS in chemotherapy-responsive patients randomized to maintenance IFN, but it took meta-analyses to clarify divergent results observed in over 1,500 patients in 13 maintenance trials.[439,440] With IFN there was a 4.4-month prolongation of relapse-free survival ($P < 0.01$) and a 7.0 month increase in OS ($P < 0.01$).[439] There are fewer data available examining the utility of IFN after ASCT.[610,611] The use of IFN in this setting cannot be recommended outside of clinical trials.

Management of Relapsed or Refractory Disease

The advances in the initial therapy of MM during the past decade has led to more effective control of the disease early in its course and has significantly improved the OS of these patients. However, the disease remains incurable with the current approaches and eventually relapses after the initial therapy. The combination of improved OS and the inability to eliminate the disease has lead to an increased number of patients living with the disease, making the management of relapsed disease an important component of the care of the myeloma patient.

At the same time, the increasing number of initial treatment approaches employed for myeloma has led to a significant heterogeneity among patients with relapsed MM. This combined with the underlying biologic heterogeneity intrinsic to the disease has precluded development of uniform approaches to management of relapsed disease. Recent studies using advanced genomic analyses have clearly shown that significant clonal evolution as well as clonal selection occurs as the disease suffers multiple relapses over time.

Definitions

Attempts have been made to standardize the definitions for relapsed and refractory disease. In general, relapses can be classified as biochemical relapses where the increase in the monoclonal protein component, bone marrow plasmacytosis, or size of plasmacytoma(s) meet the definitions of relapse as per the International Myeloma Working Group Uniform Response Criteria.[222] However, a significant proportion of patients who meet these criteria do not require therapy right away, a concept similar to how we manage early-stage asymptomatic myeloma. However, patients can have clinical evidence of progression, that may or may not satisfy the biochemical criteria, but clearly require therapeutic intervention. These typically include development of one or more components of the CRAB criteria that is used at the time of diagnosis. Several additional qualifying criteria need to be included in defining the patient with relapsed disease. This is not only important from a clinical trial perspective, allowing us to better compare results across different trials, but also helps us in deciding the future course of therapy. The most important aspect is the differentiation between relapses occurring on therapy and off therapy, with the former often having a poorer prognosis. An accepted definition for refractory disease, currently used in most of the clinical trials, is relapse occurring while on a particular therapy or relapse within 60 days of stopping the therapy. A subset of these patients may have never responded to the initial therapy or may have progressed within 60 days of stopping the intial therapy, a group referred to as having primary refractory disease.[612] These definitions should be further qualified by the class of agents or the treatment modality to which the patient is refractory.

Prognostic Factors in Relapsed Disease

Many of the prognostic factors that are relevant at the time of initial diagnosis continue to be important at the time of relapse. These include the International Staging System, the plasma cell proliferation rate, serum LDH, performance status, refractory status with respect to various drugs, cytogenetics and/or FISH findings, and the presence of circulating cells or extramedullary disease. Two key factors that become evident at the time of relapse are particularly relevant to the prognosis of patients with relapsed disease. The duration of response to the initial therapy is one of the most important prognostic factors at the time of relapse. Patients with short lasting responses to initial therapy or are primary refractory to the newer drugs have very poor OS. In fact, in a retrospective study the OS from relapse among a cohort of patients relapsing within 12 months of an ASCT was less than a year. Similar findings have been seen in nontransplant therapy settings as well. The second critical factor is the acquisition of new genetic abnormalities with disease evolution. The two most common abnormalities seen with increasing frequency among relapsed disease are loss of the *TP53* gene and chromosome 1 abnormalities, both of which portend a poor outcome.

Treatment of Relapsed Disease: General Approach

Before the era of high-dose chemotherapy with stem cell support, IMiDs, and proteosome inhibitors, treatment guidelines were more straightforward. If the relapse had occurred during an unmaintained remission, resumption of the patient's original therapy was a good rule.[597] If relapse occured after unmaintained remission, 50% to 60% of patients responded to repeat treatment[414,596,597,613] and median survival was about 10 months.[597,617] The current landscape, however, is more complicated. New combinations incorporating the new and the old agents are being tested worldwide,

leaving clinicians with an assortment of options but little guidance on how to proceed. There are a few guidelines that can be kept in mind while deciding the management approach to relapsed disease in any given patient. Regimens that have been effective previously, and to which the patient is not refractory can and should be considered again. Combinations of two drugs, where the individual drugs have not been very effective may be able to capitalize on the synergy and produce meaningful responses. Given the clonal slection processes that occur in the myeloma cells as shown through elegant genomic studies,[618] drugs that have previously become ineffective can be of benefit later on, alone or as part of combinations. Although deep responses typically translate into prolonged disease control, minor responses can be quite meaningful in those patient populations from the point of clinical benefit. Therapeutic selection should take into account residual toxicities from earlier therapies in order not to exacerbate the ongoing symptoms and must be tailored to the patient's performance status. Care should be taken in terms of the use of drugs with cumulative toxicity, particularly hematological toxicity, that will preclude subsequent use of some of the newer drugs.

Until MM is a curable disease in all patients, clinical trials will play a critical role in the treatment of these patients. They will assist in defining a better classification system for relapsed disease, clarify which treatments offer the most value, and bring new effective agents into standard clinical practice. The subject of chemotherapy for relapsed or refractory disease is divided into six sections: IMiD-based therapies, proteasome inhibitor-based therapies, IMiD-proteasome inhibitor combinations, emerging new agents and finally older therapies that incorporate alkylators or anthracyclines. Many of the newer regimens have been utilized in the setting of newly diagnosed disease and have been described in that section.

Immune Modulatory Drugs–Based Therapy for Relapsed or Refractory Disease

Thalidomide (Table 98.15). Single-agent thalidomide can induce a response in 25% to 58% of relapsed/refractory patients,[286,288–295] and higher response rates of 41% to 55%[624–627] when combined with dexamethasone.[299,625] Thalidomide doses have ranged between 100 and 400 mg per day in the different regimens, without any clear dose–response effect. In addition to corticosteroids thalidomide has been combined with a variety of different drugs, both old and new. Investigators have combined thalidomide with alkylators either with[628–633] or without corticosteroids[634,635] achieving overall response rates as high as 79%, including complete response rates as high as 26%. These have included combinations of thalidomide with melphalan, cyclophosphamide or bendamustine, with addition of dexamethasone or prednisone. DT-PACE is a combination of five drugs including thalidomide (Table 98.4) and is an integral part of "Total Therapy" programs piloted by Dr. Barlogie and colleagues at University of Arkansas.

Lenalidomide (Table 98.16). As a single agent approximately 18% to 25% of relapsed or refractory patients have achieved a partial response, and the median duration of response for responding patients is 20 months.[307] In the randomized phase II trial of lenalidomide, the addition of dexamethasone (40 mg days 1 to 4 and 15 to 18) to patients not responding to 2 months of lenalidomide resulted in partial response rates in an additional 22% of patients.[307] The combination of lenalidomide and dexamethasone has been studied in two large phase III trials.[636,647] The results of both were comparable with 59% of patients responding to the combination, including a 14% complete response rate. This was significantly better than what was observed with single-agent dexamethasone (PR 22.5% and CR 2%). In addition, both time to progression (11 to 13 months vs. approximately 5 months) and OS (not reached vs. 24 months) were superior in the lenalidomide/dexamethasone arm. The benefit with lenalidomide was independent of prior exposure to thalidomide.[648] A significant number of patients who initially had a PR improved the response to a CR or VGPR with continued treatment, especially among those obtaining a PR within the first four cycles.[649] As with other therapies, patients who achieved a CR/VGPR as their best response had significantly longer median response duration, time-

to-progression, and OS compared with those with only a partial response.[649] Continuation of lenalidomide treatment until disease progression in patients achieving a PR was associated with a significant survival advantage.[650]

As with thalidomide, lenalidomide has been combined with alkylators (melphalan, cyclophosphamide, or bendamustine) as well as anthracyclines. The results with these combinations are summarized in Table 98.17.[651,652]

Pomalidomide. Pomalidomide (CC-4047) is another thalidomide-based immunomodulatory drug that is currently undergoing clinical trials in relapsed myeloma.[311,312] The initial trials with pomalidomide were done several years ago, when the phase I trials established the maximum tolerated dose of pomalidomide as 2 mg daily or 5 mg on alternate days.[310,653] These studies used pomalidomide as monotherapy and have shown an excellent activity with an overall response rate of 52%.[653] In the initial phase II trial from Mayo Clinic, pomalidomide 2 mg daily in combination with dexamethasone 40 mg weekly were given to a cohort of 60 patients with relapsed myeloma, who had two to three prior regimens.[654] A total of 38 patients (63%) achieved confirmed response including CR in 3 patients (5%), VGPR in 17 patients (28%), and PR in 18 patients (30%). Responses were seen irrespective of their prior drug exposures, with 40% of lenalidomide-refractory patients, 37% of thalidomide-refractory patients, and 60% of bortezomib-refractory patients achieving a response. Subsequent cohorts of patients were enrolled studying different doses and schedules in different groups with respect to their refractoriness to bortezominb or lenalidomide.[655,656]

The optimal dose and schedule for pomalidomide remains an issue of debate. The studies done so far have examined either 2 mg or 4 mg, and given either continuously or for 3 out of every 4 weeks. Richardson and colleagues in a phase I/II dose escalation study showed that 4 mg pomalidomide daily given for 3 of 4 weeks is the MTD for that particular schedule.[657] The IFM group performed a randomized phase II trial looking at two dosing schedules, 21/28 days or 28/28 days with pomalidomide administered at 4 mg daily with weekly dexamethasone. The overall response rate and the duration of response were comparable with the two strategies as was the overall toxicity.[658]

Proteasome Inhibitor-based Therapies for Relapsed or Refractory Disease

Bortezomib (Table 98.17). Single-agent response rates in relapsed/refractory myeloma range from 28% to 38% with a median duration of response of 8 months.[308,320–322] In a phase III study, Richardson et al. randomly assigned 669 patients with relapsed myeloma to receive either an intravenous bortezomib or high-dose dexamethasone.[321] The overall response rate was significantly higher with bortezomib (38%) compared with dexamethasone (18%) and the median times to progression in the bortezomib and dexamethasone groups were 6.2 months and 3.5 months, respectively. Although the original studies using this drug included only eight cycles of therapy, 63 patients were treated on an extension study without significantly more serious adverse events than were seen on the parent studies of eight cycles alone.[659]

As with the IMiDs, the initial trials of bortezomib were followed by a series of trials examining various combinations including alkylator drugs and doxorubicin.[660,661–663] One of the most commonly used and effective combinations has been that of cyclophosphamide added to bortezomib and dexamethasone.[664–666] In an international phase III study, 646 patients were randomly assigned to receive either intravenous bortezomib with or without PLD.[660] The overall response rate was similar between bortezomib (41%) and PLD + bortezomib (44%). Median time to progression was increased from 6.5 months to 9.3 months with the combination and the 15-month survival rate for the combination was 76% compared with 65% for bortezomib alone.

Carfilzomib. Carfilzomib is a next-generation, selective proteasome inhibitor that has been approved for treatment of relapsed MM.[221,667,672] In an open-label, single-arm phase II study (PX-171-003-A1), patients received single-agent carfilzomib 20 mg/m^2 intravenously twice weekly for 3 of 4 weeks in cycle 1, followed by 27 mg/m^2 at the same schedule.[672] Among the enrolled patients, 95% were refractory to their last therapy and 80% were refractory or intolerant to both bortezomib and lenalidomide. Overall response rate was 24% with a median duration of response of 7.8 months and OS of 15.6 months. Common toxicities encountered were fatigue, anemia, nausea, and thrombocytopenia. Neutropenia was limited to grades 1 and 2, occurring in 10% to 15% of the patients.

In another phase II trial, 35 patients with relapsed and/or refractory MM who have received at least one bortezomib-based regimen, received carfilzomib 20 mg/m^2 in a twice-weekly, consecutive-day dosing schedule.[667] The best overall response rate was 17.1% and the clinical benefit response rate (ORR + Minor response) was 31.4%. The median duration of response was ~10 months and the median time to progression was 4.6 months. In a similar phase II study, 129 bortezomib-naïve patients with relapsed refractory MM received intravenous carfilzomib either at 20 mg/m^2 for all treatment cycles, or 20 mg/m^2 for cycle 1 and then 27 mg/m^2 for all subsequent cycles.[221] The overall response rate was 42.4% in the former group and 52.2% in the latter. The clinical benefit response (overall response rate + minimal response) was 59.3% and 64.2%; the median duration of response was 13.1 months and not reached, and median time to progression was 8.3 months and not reached, respectively. Several combinations of carfilzomib along with the older and new agents are ongoing, and will lead to more treatment options for patients with relapsed disease.

Immune Modulatory Drugs-Proteasome Inhibitor Combinations (Table 98.18)

Some of the most effective regimens reported to date in the therapy of relapsed disease and also with newly diagnosed disease, are combinations involving bortezomib with thalidomide or lenalidomide. The results of these clinical studies are summarized in Table 98.18. Bortezomib has been combined with the DTPACE regimen previously described; the resultant VDTPACE regimen is the standard initial therapy in the "Total Therapy" protocols used at the University of Arkansas.

Other Novel Agents for Relapsed or Refractory Disease

Several new classes of drugs are being tested in clinical trials that are at different stages of development. Several promising drugs are already in phase III testing including pomalidomide and carfilzomib, both of which were discussed previously.

Histone Deacetylase Inhibitors. Acetylation and deacetylation of histone proteins play an important role in the regulation of gene expression. Deacetylated histones by binding tightly to the DNA limit access to transcription factors, leading to inhibition of transcription. Acetylation on the other hand, neutralizes the charge of histones and opens up the DNA conformation, allowing expression of the corresponding genes. The opposing activities of two sets of

enzymes, histone acetyltransferase (HAT) and HDAC, control the acetylation status, with normal cells existing in a state of balance. Existing evidence suggests that aberrant recruitment of HDAC may play a role in the changes in gene expression in cancer cells. HDAC inhibitors are thought to affect multiple pathways in MM reversing the abnormalities of cell apoptosis and cell cycle, potentially sensitizing MM cells to apoptosis.[673,674] Several HDAC inhibitors have been studied in the context of myeloma, including suberoylanilide hydroxamic acid (SAHA; vorinostat),[675] ITF2357,[676] LBH589 (panobinostat),[677] and romidepsin.[678] Results thus far suggest modest single-agent activity in patients with MM.[674]

A phase I trial studied escalating doses of oral vorinostat 200, 250, or 300 mg twice daily for 5 days every week or 200, 300, or 400 mg twice daily for 2 of 3 weeks in patients with relapsed/refractory MM.[679] There were 13 patients enrolled and MTD was not reached. Drug-related adverse experiences included fatigue, anorexia, dehydration, diarrhea, and nausea. Of 10 evaluable patients, 1 had a minimal response and 9 had stable disease.

Romidepsin is an intravenously administered HDAC inhibitor that was studied in a phase II trial, patients with MM who were refractory to standard therapy were treated with romidepsin (13 mg/m^2) given as a 4-hour intravenous infusion on days 1, 8, and 15 every 4 weeks.[678] No objective responses were seen among the 123 patients treated.

Significant single-agent activity has been less than convincing, however, combinations with bortezomib or lenalidomide appeared to hold promise based on the initial trials. A phase I trial evaluated escalating doses of bortezomib (1 to 1.3 mg/m^2 on days 1, 4, 8, and 11 and vorinostat at 100 to 500 mg orally daily for 8 days of each 21-day cycle).[680] Among the 23 patients enrolled, overall response rate was 42%, including three partial responses among 9 bortezomib refractory patients. The most common toxicities were myelosuppression, fatigue, and diarrhea. In another phase I trial, patients with relapsed or refractory MM were randomized to oral vorinostat (200 mg twice daily or 400 mg once daily for 14 days) in combination with bortezomib (0.7 or 0.9 mg/m^2 on days 4, 8, 11, and 15 or 0.9, 1.1, or 1.3 mg/m^2 on days 1, 4, 8, and 11).[681] The best responses observed in the 33 evaluable patients included PR (36.4%), MR (18.2%), and SD (39.4%). Based on the initial results, a large phase III trial was performed comparing vorinostat with or without bortezomib. Overall, 636 patients were randomized to bortezomib in combination with vorinostat or placebo. Although the overall response rate was significantly higher with the vorinostat combination (56% vs. 41%), the PFS was only marginally improved (7.6 vs. 6.8 months) and no difference was seen in OS. Over a third of the patients had serious adverse events, with hematological and gastrointestinal toxicity and fatigue being the most common.[682]

The combination of panobinostat and bortezomib also has been explored in early stage trials. In a phase Ib trial, San Miguel et al. observed with 14 partial response or better (50%) among 28 evaluable patients, including 4 with complete response (CR).[683] Common adverse events included hematologic toxicity, diarrhea, fever, nausea, fatigue, and asthenia. In another trial, panobinostat was combined with melphalan, prednisone, and thalidomide, with some activity, but was accompanied by significant hematological toxicity.[684] A large phase III trial is currently evaluating the combination of panobinostat and bortezomib in patients with relapsed MM.

Harrison et al. studied the combination of romidepsin with bortezomib, identifying bortezomib 1.3 mg/m^2 on days 1, 4, 8, and 11, dexamethasone 20 mg (days 1, 2, 4, 5, 8, 9, 11, and 12), and romidepsin 10 mg/m^2 (days 1, 8, and 15) every 28 days as the MTD.[685] Thrombocytopenia was the most common hematologic toxicity and peripheral neuropathy occurred in 76% of patients. The overall response rate was 60% including 52% PR and 8% CR. The median TTP was 7.2 months, and the median OS was $>$ 36 months. This regimen shows activity with manageable toxicity and warrants further evaluation.

Heat Shock Protein 90 Inhibitors. Heat shock protein 90 (Hsp90) is a molecular chaperone that is induced in response to cellular stress and leads to stabilization of various client proteins involved in cell cycle control and apoptotic signaling. Hsp90 inhibitors have been shown to decrease MM proliferation, and sensitize MM cells to other anticancer agents.[686] Several hsp90 inhibitors have been evaluated in early-stage clinical trials.

Tanespimycin was one of the early hsp90 inhibitors to be tested in myeloma. In a phase I dose-escalation study, tanespimycin (150 to 525 mg/m^2) was given on days 1, 4, 8, and 11 of each 3-week cycle in patients with relapsed/refractory MM.[687] One patient (3%) achieved an MR, and 52% had SD with a median PFS of 2.1 months. Common adverse events included diarrhea, back pain, fatigue, and nausea, anemia, and thrombocytopenia.

Preclinical studies suggested potent synergy when hsp90 inhibitors were combined with bortezomib, paving the way for combination clinical trials. In a multicenter phase I/II trial tanespimycin (100 to 340 mg/m^2) was combined with bortezomib (0.7 to 1.3 mg/m^2) given on days 1, 4, 8, and 11 of a 3-week cycle.[688] The highest tested dose of tanespimycin at 340 mg/m^2 and bortezomib at 1.3 mg/m^2 was considered the phase II dose. The combination was well tolerated and among 67 efficacy-evaluable patients, there were 2 (3%) CR, 8 (12%) PR, and 8 (12%) minimal responses.

Signal Transduction Inhibitors. Various signal transduction pathways have been considered critical for the survival and proliferation of myeloma cells. Among these the PI3K-Akt pathway has been most studied from a therapeutic standpoint. Perifosine is the best-studied Akt inhibitor in the setting of myeloma.[689] In a phase II trial of perifosine, alone or with dexamethasone, the best response to single agent among 48 enrolled patients was an MR in 1 patient and stable disease in 22 patients (46%).[690] Addition of dexamethasone in 37 patients with disease progression led to a partial response in 13%. Most common adverse events included nausea, vomiting, diarrhea, fatigue, increased creatinine, and anemia. Subsequent trials have examined the combination of perifosine with lenalidomide or bortezomib with modest evidence of activity.[690,691]

The mTOR kinase, downstream in the PI3K/Akt pathway has been another target explored in myeloma. Both CCI779 and RAD001 have been studied in phase II trials in patients with relapsed disease with very little clinically relevant antimyeloma activity. Ghobrial et al. studied intravenous temsirolimus given at 15 or 25 mg with bortezomib at 1.3 or 1.6 mg/m^2 once a week enrolling 20 patients into the phase I study and 43 into phase II. The MTD was determined to be 1.6 mg/m^2 bortezomib on days 1, 8, 15, and 22 in combination with 25 mg temsirolimus on days 1, 8, 15, 22, and 29, given every 35 days. In the phase II study, the proportion of patients with a partial response or better was 33%. The most common treatment-related grade 3 to 4 adverse events were thrombocytopenia, hematologic disorders, and diarrhea.

Monoclonal Antibodies. Monoclonal antibody therapy has seen resounding success in B-cell malignancies, but has had minimal success with plasma cell disorders. Elotuzumab is a humanized monoclonal IgG1 antibody targeting human CS1, a cell surface glycoprotein. CS1 is highly and uniformly expressed on MM (MM) cells, with limited expression on natural killer (NK) cells and CD8 + cells and little to no expression in normal tissues. In a phase I study, escalating doses of elotuzumab (2.5, 5, 10, and 20 mg/kg IV) were administered on days 1 and 11 in combination with bortezomib (1.3 mg/m^2 IV) administered on days 1, 4, 8, and 11 of a 21-day cycle.[691] Dexamethasone 20 mg PO was added for patients with disease progression The MTD was not reached and the most frequent grade 3/4 side effects were lymphopenia, fatigue, thrombocytopenia, neutropenia, hyperglycemia, peripheral neuropathy, pneumonia, and anemia. A partial response or better was observed in 13/27 (48%) evaluable patients, including 7% CR and 41% PR. Another study examined the drug in combination with lenalidomide, using escalating doses of elotuzumab with

the standard lenalidomide dose.[692] No DLTs were observed at the maximum dose tested (20 mg/kg). A partial response or better was seen in 82% (23/28) of treated patients and 96% (21/22) of lenalidomide-naïve patients. Richardson et al. studied two doses of elotuzumab in combination with lenalidomide and dexamethasone in a randomized phase II trial: patients received elotuzumab 10 or 20 mg/kg IV (days 1, 8, 15, and 22 every 28 days in the first two cycles and days 1 and 15 of subsequent cycles), lenalidomide 25 mg PO (days 1 to 21) and dexamethasone 40 mg PO weekly.[693] Among 63 enrolled patients, 81% had a PR including 37% with VGPR. The overall response rates were 90% in the 10 mg/kg group (n = 31) and 72% in the 20 mg/kg group (n = 32). Median time to response was 30 days (range, 21 to 100). The most common toxicities were hematologic and infusion reactions.

The inflammatory cytokine interleukin (IL)-6 is a survival factor for malignant plasma cells. CNTO328 is a novel human–mouse chimeric monoclonal antibody targeting IL-6 that has inhibitory effect on tumor burden and potentiates bortezomib-mediated apoptosis. Initial studies support the feasibility of combining the antibody with bortezomib in patients with relapsed myeloma.[694]

Several other drugs have been tried with very modest activity. IFN has been shown to modulate the multidrug resistance phenotype and to re-induce chemosensitivity in patients with chemoresistant MM. In one study, nonresponding patients received the same chemotherapy to which they were resistant, preceded by a 5-day course of IFN. An objective response was achieved in 4 of 14 patients (28.6%).[695] Several investigators have combined IFN with dexamethasone[454,696] or methylprednisolone[697] as therapy for patients with relapsed or refractory disease. With response rates of 29% to 66%[696,697] it is difficult to isolate the corticosteroid and IFN effects. There is no clear evidence that the response rate or the survival time improved compared with similar treatments without IFN.[698]

Because patients with MM refractory to alkylating agents frequently express P-glycoprotein, which is associated with the multidrug resistance phenotype, cyclosporine, a multidrug resistance reversal agent, has been combined with VAD in patients with refractory or progressive disease. No benefit was observed.[699,700] As a result of the findings of a phase I/II trial in patients with myeloma,[701] PSC 833, a multidrug resistance glycoprotein modulator, was incorporated into a small phase III study of VAD versus VAD and PSC 833 in the relapsed/refractory setting.[702] There was no difference in response rate, PFS, or OS in PSC 833 arm, although there was more toxicity.

The human anti-CD20 antibody has demonstrated some effect in patients with myeloma. About 20% of patients with myeloma have CD20 expression on their plasma cells. In one study 1 of 19 patients had a partial response to therapy; an additional 5 had stable disease.[703]

Alkylator-based Regimens for Relapsed or Refractory Disease (Table 98.19)

There is cross-resistance among the alkylators, but it is not absolute and may be circumvented by increasing dose intensity. Without extreme dose intensification, 5% to 20% of patients with melphalan-resistant disease respond to cyclophosphamide or BCNU as single agents or in combination with prednisone.[617,704–709] Response rates as high as 30% to 38% can be obtained if prednisone is administered with the cyclophosphamide.[710–712] Higher doses of cyclophosphamide (e.g., 600 mg/m2 intravenously for 4 consecutive days) result in response rates of 29% to 43%.[237,713] Both response duration and OS tend to be short, approximately 3 and 9 months, respectively.[237,713] Consolidating the chemotherapy into a 1-day schedule rather than a 4-day schedule does not improve response rate but does increase the toxicity.[714] Similarly, administration of 3.6 g/m2 over 2 days with prednisone appears to produce comparable responses.[715]

Dose intensification of melphalan can also be quite effective and is the basis for high-dose therapy with stem cell support.[220] Selby et al.[227] reported that 66% of patients with resistant disease treated with 140 mg/m^2 without stem cell support responded, but median response duration was 6 months, with all patients relapsing within a year. Median times to leukocyte and platelet recovery were 42 and 37 days, respectively, and the regimen-related toxicity was 13%. Doses of 50 to 70 mg/m2 resulted in a 50% response rate and leukocyte and platelet recovery time of 20 and 16 days, respectively.[716,717] Further reducing the intensity to 30 mg/m^2 every 2 months resulted in response rates of 38% and progression-free survival of 10 months.[718]

VBMCP (the M-2 regimen) or MOCCA provided responses in 20% to 30% of refractory patients[375,719,720] with a median survival of about 11 months.[720] Combinations of cisplatin with BCNU, cyclophosphamide, and prednisone have produced response in heavily pretreated patients;[328] however, the addition of cisplatin and bleomycin to VBAP did not appear to produce better outcomes than standard VBAP.[274,327,328] The addition of etoposide to high-dose cyclophosphamide and granuocyte-macrophage

conlon-stimulating factor resulted in a response rate of 42%, but with significant myelosuppression.[721]

Bendamustine with or without corticosteroids can produce responses in approximate 55% of relapsed patients. Among patients relapsing after transplant PFS was 26 weeks (0 to 61). In another study among relapsed refractory patients, the median EFS and OS were 7 and 17 months, respectively.

Anthracycline-based Regimens for Relapsed or Refractory Disease (Table 98.19)

Various permutations of doxorubicin-containing chemotherapy regimens—doxorubicin and cyclophosphamide (AC);[413] doxorubicin, BCNU, cyclophosphamide, and prednisone (ABC-P);[722] CAP;[723] VCAP;[414] VBAP;[724,725] and BAP[723]—have been tried in patients with relapsed and refractory disease, resulting in response rates of 7% to 28%.[414,722–724] Response duration and survival tend to be short: less than 6 and 12 months, respectively. Responding patients tend to live 7 to 10 or even 22 months longer than nonresponders.[723–725] Patients who have relapsed disease, rather than resistant or refractory disease, have higher response rates (i.e., close to 30%). Augmenting these combinations with high-dose corticosteroids has been tried with some benefit,[243,246,443] yielding response rates of 47% to 59%, but with a high rate of infection. Concurrent IFN[435,698] adds nothing to response rate or OS. In single-arm studies, there does not appear to be any advantage to the addition of cyclophosphamide to VAD, VAMP, or vincristine, epirubicin, and dexamethasone (VED).[242,246,451,726,737]

After studying high-dose cytosine arabinoside, cisplatin, and etoposide as single agents, Barlogie et al.[329] did preliminary studies of DAP (dexamethasone, cytosine arabinoside, and cisplatin) and later EDAP (etoposide and DAP). In patients with refractory disease, response rates with these treatments were 7%, 14%, 17%, 0%, and 40%, respectively. Median survival in patients treated with EDAP was 4.5 months. This regimen is myelosuppressive, with more than half of treated patients requiring platelet transfusions and 80% requiring hospitalization for neutropenic fever. In the first month, treatment-related mortality was 15%. In the complex Total Therapy 2 program wherein this regimen was used as part of induction, the respective incremental objective and complete response rates went from 55% and 9% to 65% and 15% after EDAP treatment.[329]

RADIATION THERAPY

As early as the mid-1920s there was recognition that external beam radiation therapy could promote immediate relief of pain, healing of pathologic fractures, and resolution of extramedullary plasmacytomas.[23,738,739] Until the 1950s, radiation therapy was the only effective treatment available for the management of plasma cell tumors. With the advent of systemic chemotherapy, indications for irradiation were primarily palliation of bone pain and solitary plasmacytomas. Concern for maintaining bone marrow reserve also constrains the use of radiation in patients with MM. Sykes et al.[730,731] showed that radiation has long-term effects on the bone marrow; the majority of patients receiving concentrated local doses of 3,500 cGy or more showed persistent localized marrow aplasia. One must administer enough radiation to provide palliation, without jeopardizing opportunities for further systemic therapy. In a retrospective review, Norin[732] has found that objective improvement was lacking when the tumor dose was below a cumulative dose (single-dose equivalent) of 1,000 cGy. For palliation, the recommendation is, therefore, a cumulative dose of 1,500 cGy, corresponding to a tumor dose of 3,400 cGy in 10 to 15 fractions.[732,733] Leigh et al.[734] recommended a total cumulative dose of 1,000 cGy in these same patients. There is controversy as to whether the duration of response correlates with the radiation dose in myeloma patients.[734,735]

In contrast, the conventional wisdom has been that patients with solitary plasmacytoma of bone should receive higher doses in an attempt at cure. Although the optimal dose has not been established by randomized controlled trials, 4,000 to 5,000 cGy encompassing all disease with a margin of normal tissue is recommended by most experts.[736–738] A recent study of 203 patients with solitary plasmacytoma of bone has brought this principle into question.[739] These authors found that therapeutic doses above 3,000 cGy had no bearing on local control.

Radiation can often spare patients from undergoing surgery.[740] In a recent retrospective analysis of 35 cases of patients with cervical lesions and spinal instability, it was found that 19 of the 20 patients experienced resolution of pain, 15 of whom received radiation alone. Of the 10 patients with sufficient follow-up data, none showed clinical progression of instability.

The first report of using whole body irradiation to treat myeloma was by Medinger and Craver[741] in 1942. Partial or complete relief of pain was noted in the majority of patients. Once effective systemic chemotherapy came into wide use, this approach became less popular until 1971 when Bergsagel[742] postulated that sequential hemibody radiation could be a means of debulking tumor. He suggested that if a dose of approximately 725 cGy were given to the upper half of the body and 1,000 cGy to the lower half, a theoretical 3-log kill could be achieved and survival prolonged. After a series of retrospective studies[743–751] and a randomized study[417,752] evaluating its role in the earlier phases of myeloma, hemibody irradiation has once again fallen out of favor. In patients who have end-stage disease, with poor pain control, this treatment may still be important.

The majority of series involving hemibody or sequential hemibody radiation are retrospective and include patients who were either resistant to or relapsing from alkylator-based therapy. Significant relief of bone pain occurred in 80% to 90% of patients[743–751] and the median duration of survival was 5 to 11 months[733,745] Objective biochemical response occurred in 25% to 50% of patients.[745,746,753] Pain relief typically occurred 1 to 2 days after institution of therapy, with a maximal response in 1 to 2 weeks.[743] The most common side effects were moderate myelosuppression, pneumonitis, nausea, vomiting, diarrhea, and stomatitis.[733,743] If an oral lead shield was not used, mucositis also occurred.[733] Nadirs occurred within 3 weeks[745] and white cell count and platelet count recovery occurred by about 6 weeks.[733,745] Decrements in pulmonary function occurred in about half the treated patients.[733] The most serious complication was radiation-induced pneumonitis, which was seen in 14% of patients.[745] The option of sequential half-body radiation therapy must be balanced against unpredictable and varying degrees of pancytopenia and alternative treatment options.[753]

Bergsagel's postulate[742] and preliminary data from several small studies[744,749,750] led two cooperative group studies (SWOG 8229 and CALGB 8003) to incorporate systemic radiation therapy as consolidation therapy.[417,752] Neither study demonstrated a meaningful advantage to patients receiving adjuvant hemibody radiation,[417,752] and hemibody radiation is used only for pain palliation in end-stage chemotherapy-refractory myeloma patients.

PROGNOSIS AND PATHOGENESIS

Prognosis and pathogenenesis are covered together because in many instances there is an intimate relationship between them. To date no single molecular defect can account for the pathogenesis of MM, although by using single nucleotide polymorphisms and gene expression profiling, several candidate genes have been identified as being different between MGUS and MM.[754,755] It is not clear if a single critical genetic change in the clonal plasma cell of MGUS results in the "switch" to the malignant state of myeloma or if it represents the cumulative effect of

a series of changes, which may be different in different patients. Malignant plasma cells are long-lived cells, typically with low proliferative rates.[137,756] A post-germinal cell origin is indicated by their somatically hypermutated, rearranged immunoglobulin genes.[757] A multitude of abnormalities has been identified in signaling pathways, apoptotic mechanisms, the bone marrow microenvironment, and the cell cycle. Factors including the level of gene expression, protein expression, and phosphorylation status of cell cycle molecules may all be relevant for the propagation of the malignant plasma cells. Extracellular signaling alterations include changes in stromal cell, osteoblast, osteoclast, vessel endothelial cell, and immune cell interactions. These changes may in turn result in activation, adhesion, and cytokine production that fuel myeloma cell proliferation and survival (Fig. 98.10).

Prognosis and Staging

Survival of MM patients varies from months to more than a decade.[599,758] There are no precise methods of identifying the subset of newly diagnosed patients who are best served by standard intensity therapies, by maintenance therapies, by novel therapies, or by more intensive regimens such as hematopoietic stem cell transplantation. Prognostic factors are needed for patient counseling, therapeutic decision making, and clinical trial stratification. Given the disease heterogeneity and differing outocmes, it is important to understand the prognostic factors and develop adequate risk stratification systems in order to compare different group of patients from different studies or clinical trials. However, prognostication is a dynamic process changing within a given patient during the disease course as dictated by the response to therapies and acquisition of new genetic changes. It is also constantly changing for the disease as a whole with incorporation of newer therapeutic startegies for the disease.

Staging is one form of prognostic modeling. The Durie-Salmon system (Table 98.20), which until the present had been the most widely accepted MM staging system, separates patients predominantly by tumor burden and renal function.[26] As the biology of myeloma is better understood, novel markers reflecting myeloma cell kinetics, signaling, genetic aberrations, and apoptosis have eclipsed the prognostic significance of tumor burden as a predictor of survival.[415,759–765] At the time of its inception, the Durie-Salmon staging system was an elegant system that incorporated information about immunoglobulin production and half-life, hemoglobin, calcium, creatinine, and extent of bone disease to derive mathematically the total myeloma cell burden.[26] Quantification of bone lesions used in this staging system, however, is not always reliable as a prognostic factor[762] in that patients classified as stage III solely on the basis of bone lesion criteria do not have a poorer prognosis.

Other variables, including patient age, performance status, serum albumin, immunoglobulin isotype, and bone marrow plasma cell infiltration, have long been recognized to predict survival,[766–769] and subsequent models have incorporated these factors[236,599,765,770] whereas others have shown the prognostic value of serum β2M, C-reactive protein, lactate dehydrogenase, elevations in serum immunoglobulin free light chains, presence and quantity of circulating plasma cells, bone marrow plasma cell proliferative rate, plasmablastic morphology, bone marrow angiogenesis, and chromosomal abnormalities.[137–139,415,759–761,763–765,770–773,774,775–787] Most recently, MRI and PET-CT imaging has been shown to have some prognostic importance.[788–792] More esoteric prognostic factors include: decreased staining of bone marrow plasma cells for acid phosphatase,[793] increased circulating plasma cells as measured by the peripheral blood labeling index,[794] apoptotic index,[795] increased sIL-6R,[761,796] serum neopterin,[378] α1-antitrypsin,[797] C-terminal telopeptide of Type I collagen,[798,799] serum bone sialoprotein,[800] B12 binding protein,[801] soluble CD56,[802] soluble Fc receptor (CD16),[803] soluble syndecan or CD138,[804] and serum IL-6 levels.[797,805,806]

A staging system's relevance is based not only on its ability to predict outcome, but also on its at availability and cost.[807] An international consensus panel addressed this issue and developed the International Staging System (ISS) for MM (Table 98.21); it incorporates serum albumin levels and beta-2 microglobulin.[08] Although this staging system is inexpensive and readily available, it does not get to the heart of myeloma cell biology as do genetic changes, as discussed below. However, it does rely heavily on β2M concentration, which is the strongest and most reliable prognostic factor for MM that is routinely available.

Stage II	Not Stage I or III	45
Stage III	β_2M ≥ 5.5 mg/L	29

β2M, beta-$_2$ microglbouli.

β2M concentration is influenced by both tumor burden and renal function. Elevated β2M values predict early death.[229,760,763,809–814] Formulas to correct the β2M concentrations for the effects of renal insufficiency have not improved its predictive value,[815] and the β2M value is still prognostic in myeloma patients with normal renal function.[759] As discussed below, investigators have tried to enhance the performance of the ISS by adding other soluble markers or genetic risk features. An example is combining abnormal FLC ratio with the ISS risk factors to create four prognostic groups with median survival times of 51, 39, 30, and 22 months, respectively.[776]

Cytogenetics, Fluorescence In Situ Hybridization, and Other Genetic Abnormalities

The first cytogenetic abnormalities in myeloma were documented nearly 30 years ago (Fig. 98.11). In the past decade it has become increasingly apparent that cytogenetic testing is an integral element of establishing prognosis and a treatment plan for all newly diagnosed myeloma patients. Nearly all myeloma patients have abnormal chromosomes by fluorescence in situ hybridization (FISH), including deletions, aneuploidy, and translocations[816,817,818] (Fig. 98.12A,B), although abnormal karyotypes are seen in only 18% to 30% of cases. This apparent discrepancy is explained by the generally low proliferative rate of myeloma cells and the requirement of obtaining plasma cells (and not just the rapidly dividing normal myeloid precursors) in metaphase to generate conventional cytogenetics.[819–821] Therefore, any abnormality in conventional cytogenetics identifies a group with a higher proliferative rate[822] and poorer prognosis. There is an excellent correlation between abnormal conventional cytogenetics and a high plasma cell proliferative rate.[823,824] With interphase FISH, several chromosomal abnormalities, such as immunoglobulin heavy chain translocations and deletion of chromosome 13, are observed at equal frequencies among the spectrum of plasma cell proliferative disorders from MGUS to MM to PCL.[825,826]

Monoallelic loss of chromosome 13 (del 13) or its long arm (del 13q), when determined by metaphase cytogenetics, is a powerful adverse prognostic factor in patients treated with standard chemotherapy[764,827,828] or with high-dose chemotherapy and hematopoietic stem cell transplantation.[329,506,778,829,830] Approximately 50% of newly diagnosed MM patients have del 13 or del 13q by FISH.[824,826,831] Our group has shown that del 13q is associated with specific biologic features, including a higher frequency of λ-type MM, slight female predominance, higher PCLI, and a higher frequency of a serum M component of less than 10 g/L.[827] Patients with the deletion by FISH have a worse OS with standard chemotherapy,[764,824,827] high-dose therapy,[831,832] and IFN treatment.[827] The absence of abnormalities of chromosome 13 and 11 by conventional cytogenetics is associated with longer complete response duration, EFS, and OS in patients treated with high-dose therapy.[329] The prognostic significance of del 13q by FISH is less than that for del 13 by conventional cytogenetics, because the latter test incorporates both the chromosomal abnormality and a high rate of plasma cell proliferation, whereas the former captures only the chromosomal abnormality.

Hypodiploid myeloma has a worse prognosis than diploid or hyperdiploid myeloma. This has been demonstrated by flow cytometric methods[828,833,834] and metaphase cytogenetics.[830,835,836,837,838] Controversy exists about whether the deletion 13q adds any additional prognostic information to a hypodiploid karyotype.[835,838,839]

Up to 50% of patients with MM have translocations involving the heavy chain gene on chromosome 14.[818] These translocations include illegitimate switch recombinations of the variable regions of the immunoglobulin heavy chain gene at 14q32. Partners of the translocations into the IgH switch region on chromosome 14 include chromosomes 11, 4, 6, and 16.[840] The most common translocation in MM is t(11;14)(q13;q32),[820,839] which increases expression of cyclin D1,[841] a protein involved in cell cycle progression. The prevalence of t(11;14)(q13;q32) is 20% in MM.[820,839,842] Previous publications had suggested that this translocation was associated with an adverse outcome in MM,[764,778] but more recent data refute this hypothesis.[842] The t(6;14)(p21;q32) is also associated with a neutral prognosis.[843] The t(4;14)(p16.3;q32) is present in 15% of MM patients.[844–848] This translocation results in the up-regulation of fibroblast growth factor receptor 3 (FGFR3) and in the hybrid transcript *IgH/MMSET*.[844,845] This abnormality had been thought to be as bad as deletion 17p, but there are emerging data that long-term bortezomib use can abrogate some of this poor prognosis. The t(14;16)(q32;q23) is also seen in a

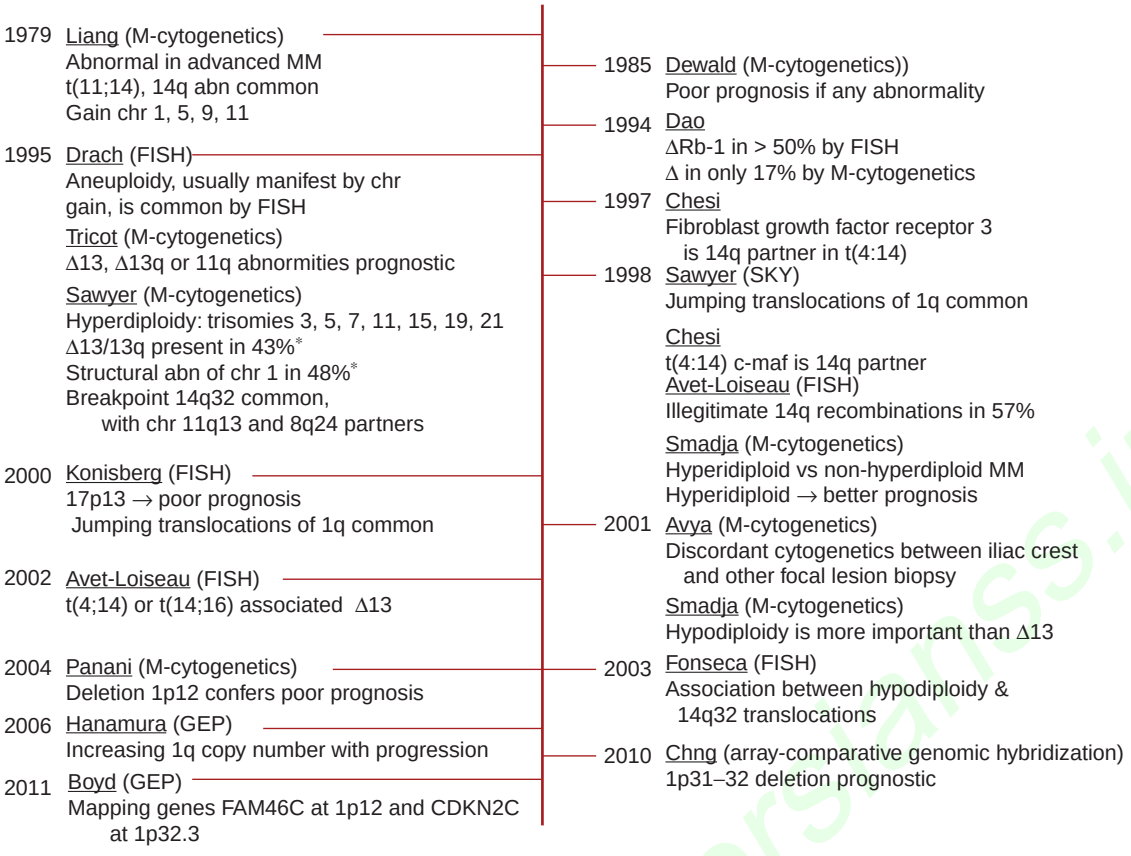

FIGURE 98.11. History of cytogenetic discovery in multiple myeloma.

small subset (~5%) of patients with MM.[839,845] Both convey a very poor prognosis, although a recent French study has questioned the poor prognostic value of t(14;16).[849] In one study there was a tight association of del 13 abnormalities and high β2M values with the unfavorable t(4;14) and t(14;16) abnormalities,[831] suggesting that the poor prognosis associated with del 13 may be because of other nonrandom, associated chromosomal abnormalities.

Trisomy is common by FISH and most often includes chromosomes 3, 6, 9, 11, and 15.[850] In another study trisomy of 3, 7, and 11 accounted for over 50% of the hyperdiploid cases.[851] Trisomies of chromosomes 6, 9, and 17 were associated with prolonged survival.[852] Recently it has been shown that presence of trisomies is associated with better outcomes even among patients with high-risk cytogenetic markers such as t(4;14), t(14;16) and 17p deletion (Fig. 98.12C).[818]

Deletion of the *TP53* gene locus as a result of monosomy 17 or deletion of 17p is seen in 10% of patients at diagnosis and is associated with very short median OS.[818,853,854,855] In contrast, inactivating mutation of *TP53*, locus 17p13, is rare in freshly explanted myeloma cells but is common in human myeloma cell lines and in patients with a terminal phase of myeloma.[856] Such mutations have been observed in ~5% of cases of early MM versus 20% to 40% of cases of PCL.[857–859,860]

Another set of new cytogenetic prognostic markers are abnormalities involving chromosome 1,[861–864,865] either gain of 1q21 or loss of 1p21, and have been associated with poor outcome.[861,862] Abnormalities of both the short and long arms of chromosome 1 have been noted since the first cytogenetic studies of myeloma.[819,866] Hanamura et al. demonstrated that the frequency of 1q21 amplications increases from monoclonal gammopathy of undetermined significance (0%), to overt MM (43%), and finally to relapse (72%). In a prospective clinical trial of high-dose therapy (HOVON 24), abnormalities of chromosome 1p and 1q were found in 19 (36% of patients with an abnormal karyotype) and 21 patients (40%).[862] There was a strong association between chromosome 1p and/or 1q abnormalities and deletion of chromosome 13 or 13q. Patients with 1p/q abnormalities had a significantly shorter OS than patients with normal karyotypes. Amplifications of 1q21 are concurrent with dysregulated expression of c-MAF, MMSET/FGFR3, or deletion 13.[867] Candidate genes for the molecular mechanism of prognosis imparted by the 1q21 amplification include *CKS1B*, *BCL-9*, or *RAB25*, but this has not been confirmed by others.[755]

Mutations of *RAS* have been noted in 30% to 50% of MM patients, with increasing prevalence in the advanced stages of the disease[868,869] and in patients who have shorter survival.[870] Mutations of *RAS* were first observed in fulminant disease,[856] but have also been observed in 27% to 39% of newly diagnosed cases.[868,870] Patients with *RAS* mutations had a median survival of 2.1 years versus 4 years for patients with wildtype *RAS*.[870]

Both metaphase cytogenetic and FISH testing each have their own advantages and disadvantages. The added value of metaphase cytogenetics is the additional negative prognostic information provided by the ability to generate a plasma cell karyotype, that is, capture proliferation in addition to information about ploidy status and specific structural abnormalities. The disadvantage is that certain interstitial abnormalities and translocations may be missed. In contrast, a standard myeloma FISH panel will contain probes for the common translocations and structural abnormalities and will detect them regardless of the proliferative rate of the plasma cells. FISH, however, provides no information on the proliferative index of the myeloma cells. Ideally, both metaphase cytogenetics and FISH should be done for all newly diagnosed patients, but if the cost is prohibitive, the test that is more readily available should be performed.

Boyd and colleagues combined FISH results with ISS among 1,069 patients with newly presenting myeloma treated in the MRC IX trial.[871] FISH lesions associated with short progression-free

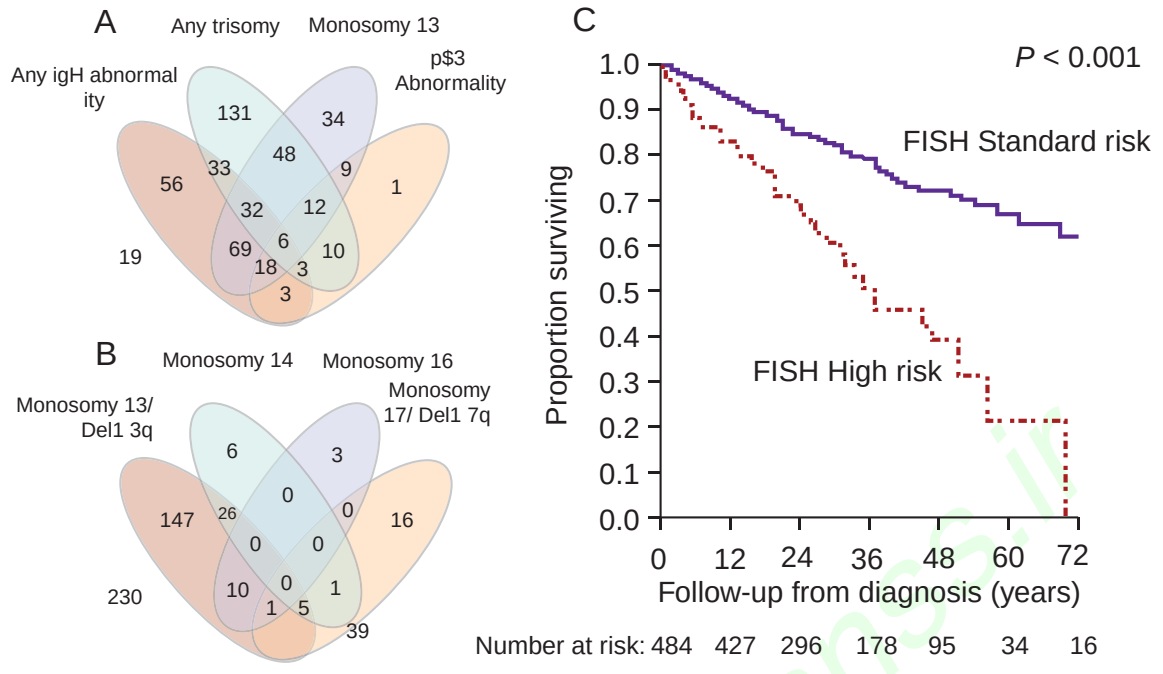

FIGURE 98.12. The relationship between genetic abnormalities among patients with multiple myeloma. A: Venn diagram demonstrating the overlapping nature between the common abnormalities seen with FISH in patients with newly diagnosed multiple myeloma. The actual number of patients with different abnormalities is presented from among 484 patients. The remaining 19 patients either had a normal FISH ($n = 15$) or another abnormality ($n = 4$). **B:** Distribution of various monosomies/deletions and their overlap. **C:** Modification of genetic risk system, using a hierarchical approach. High-risk includes deletion 17p, t(14;16), t(14;20), but with this new system, patients were reclassified into a new high-risk group, moving those patients previously classified as high-risk but with a trisomy into the standard-risk group. The survival of patients reclassified as high-risk ($n = 66$; 14%) was 3 years compared with not reached for the standard-risk group ($P < 0.001$). (From Kumar S et al. Blood 2012;119:2100–2105. and OS in multivariate analysis were + 1q21, del(17p13), t(4;14), t(14;16), and t(14;20). They defined a favorable risk group by the absence of any of these genetic lesions, an intermediate group with one lesion and a high-risk group defined by the co-segregation of >1 lesion. This genetic grouping was then combined with ISS to identify an high-risk group defined by ISS II or III and >1 adverse FISH finding. This high-risk group constituted 14% of patients and was associated with a median OS of 19.4 months.

Gene Expression Profiling

Many hematological malignancies have witnessed the development of prognostically relevant disease subclassification through microarray profiling. MM is no exception, and considerable progress has been made to predict accurately individual patients' clinical course and survival outcomes using a molecular classification. Zhan and colleagues have comprehensively studied the gene expression on purified plasma cells of 414 NDMM patients who underwent HDT with tandem transplants.[872] They introduced seven molecular subtypes of MM: PR(proliferation), LB(low bone disease), MS(*MMSET*), HY (hyperdiploid), CD-1(*CCND1*), CD-2 (*CCND3*), and MF (*MAF/MAFB*). HY, CD1, CD2, and LB comprised the low-risk group with 3-year actuarial probabilities of 81% to 88%. The two high-risk groups, MS and PR, did not achieve a therapeutic benefit on Total Therapy 2.[872] The same group of investigators identified 70 genes linked to shortened survival, with 30% of 51 overexpressed and 50% of 19 underexpressed genes mapping to chromosome 1, in a cohort of 532 newly diagnosed patients who received tandem transplants. This model was supplanted by an extremely powerful 17-gene prognostic model to detect the high-risk disease. In addition, this model could successfully prognosticate the patients with relapsed disease on either single-agent bortezomib, or high-dose dexamethasone (APEX phase III trial).[873] It has been validated using the Mayo Clinic dataset of 71 NDMM patients treated with HDT, but practical impediments remain in the routine clinical utilization of this model. The GEP70 signature has also been validated in the nontransplant setting among a group of patients with newly diagnosed MM receiving initial therapy with lenalidomide and dexamethasone.[874]

Zhan et al.[754,875] have studied the gene expression of 74 myeloma patients by using high-density oligonucleotide microarrays interrogating about 6,800 genes. On hierarchical clustering analysis, four distinct subgroups of myeloma (MM1, MM2, MM3, and MM4) were identified. The expression pattern of MM1 was similar to normal PCs and MGUS, whereas MM4 was similar to MM cell lines. Clinical variables linked to poor prognosis, including abnormal karyotype and high serum β2M levels, were most prevalent in MM4. Overexpression of genes involved in DNA metabolism and cell cycle control were observed in MM4.

Several risk stratification systems have been proposed on the basis of GEP results in addition to the ones from the University of Arkansas, including those from the French and Dutch groups.[876] These studies have helped us develop insights into the disease biology. However, the minimal overlap between different signatures raises questions as to the independence of these signatures from the type of therapy utilized as well as the potential influence of the sample prepration on the results and the ability to apply the method uniformly in a real-life clinical setting. Waheed et al. studied 612 patients in the context of the three Total Therapy regimens, showing an independent prognostic value for ISS and cytogenetic abnormalities even when the GEP-based risk stratification and presence *of TP53* deletion were incorporated.[877]

Routine incorporation of fluorescence in situ hybridization (FISH) as part of the initial work-up of MM has significantly improved our understanding of the disease biology, and a better appreciation of the genetic heterogeneity that underlies this disease.[818,878,879] The majority of the FISH-detected abnormalities are seen at the time of diagnosis, and the prevalence of some of the abnormalities increases with time as patients suffer multiple disease relapses. More recently, application of advanced genomic technologies such as whole genome sequencing has given a different perspective of the genetic chaos that exists in this disease. Chapman et al. performed massively parallel sequencing of 38 tumor genomes and compared them with matched normal DNAs. The pattern of mutations suggested the presence of several new and unexpected oncogenic mechanisms including mutation of genes involved in protein translation in nearly half of the patients, genes involved in histone methylation, and genes involved in blood coagulation. In addition, mutations were observed in 11 members of the NF-kappaB pathway, a pathway that has already been the focus of several studies in myeloma. Activating mutations of the kinase BRAF were observed in 4% of patients, suggesting the evaluation of BRAF inhibitors in MM clinical trials. Additional studies are ongoing, and will help us further delineate the genetic evolution in myeloma. Keats et al., in a recent study, showed that tumors can follow several evolutionary paths over a patient's disease course.[618] With the use of serial genomic analysis of samples collected at different points during the disease course of 28 patients with MM, they showed that the genomes of standard-risk patients show few changes over time, whereas those of cytogenetically high-risk patients show significantly more changes over time. The results indicated that the pattern of genetic evolution over time can follow either a quiescent pathway with few changes, incremental changes with addition of new abnormalities over time (clonal evolution), or consist of a mixture of clones that wax and wane over time based on treatment selection pressure (clonal selection).

Plasma Cell Proliferative Rate

That the rate of clonal plasma cell expansion determines the disease outcome has been known for a long time, and several methodologies have been used to assess the degree of proliferation. One such test, the plasma cell labeling index (PCLI), is a slide-based method that measures the percentage of bone marrow myeloma cells in the S-phase of the cell cycle[137] which is a powerful prognostic factor in MM.[759,760,765,880] An increased PCLI predicts a short remission and survival but does not predict response to therapy. All large studies published to date have confirmed the independent prognostic value of the PCLI for survival after treatment with conventional chemotherapy[759,761,781,881] or high-dose therapy.[811] A recent study highlighted the prognostic relevance of PCLI in the patients treated with immunomodulatory agents, thalidomide and lenalidomide, with high PCLI (≥1) at the time of initiation of therapy predicting a poorer progression-free survival. However, lenalidomide appears to negate the adverse impact of high PCLI on OS, an effect not seen in the thalidomide arm. Undoubtedly, a longer follow-up of patients is required to determine the true impact of the PCLI in patients on lenalidomide therapy.[882]

Determination of S phase by flow cytometry using a DNA/CD38 double-staining technique is also possible.[765,883,884] A high proportion of PCs in S phase (>3%) indicated poorer prognosis. A poor correlation between the slide and flow cytometric LI assays has been demonstrated by the Australian Group who questioned the sensitivity and accuracy of the less objective slide-based PCLI requiring manual enumeration of the plasma cells. In the flow cytometric analysis, the PCLI of primitive plasma cells (CD38++/CD45+) was higher than that of mature myeloma cells (CD38++/CD45–), and correlated better with the disease status (mean PCLI of 9.2% in the progressive disease and 2.2% in the plateau, $P = <0.001$).

Ki-67 protein is a marker for proliferation that is expressed by all the cells in the "growth fraction" of the tumor, including the cells in the late G1, S, G2, and mitotic phases of the cell cycle. The Ki-67 proliferative index represents the fraction of myeloma cells expressing Ki-67 antigen as detected by a monoclonal antibody. A higher index indicates poorer prognosis, and a cut-off of 8% could categorize newly diagnosed MM patients into two groups with a difference in survival OS ($P < 0.07$).[885–887]

Immunophenotype of Myeloma Cells

As discussed previously, the phenotype of malignant plasma cells is diverse[143–145,148,149,151,152] and potentially dynamic.[888,889] Investigators have demonstrated that surface expression of CD45, CD56, and CD117 portends a better prognosis,[145,147] whereas, expression of CD28, CD44, a worse prognosis.[145,890] Patients with the t(11;14) translocation are more likely to have surface expression of CD56, and CD117. Patients with nonhyperdiploid myeloma have an increased expression of both CD20 and CD28 in the absence of reactivity for CD56 and CD117, all poor prognostic findings.[145] Over the course of the last few decades, a continuous effort to identify diagnosis-, prognosis-, and therapy-related immunophenotypic markers has been instrumental in the recognition of the correlations between certain cellular antigens and the different phenotypic entities of MM. The extramedullary extension of the neoplastic plasma cells has been associated with a reduced expression or total absence (as in de novo or secondary plasma cell leukemia) of the adhesion molecule, CD56,[148] and up-regulation of CD44 on the plasma cells. CD28 (a T-cell marker) expression correlates with disease progression, and is universally expressed in the human myeloma cell lines.[148,891] Its association with t(14;16) and del(17p) is notable. The absence of CD45 and CD27 portends a worse outcome. In a multivariate analysis of 95 newly diagnosed MM patients who underwent HDT, the lack of CD45 expression was the only significant variable that affected the outcome (median OS.of 42 months for CD45- versus not reached at 4 years for CD45 + MM, $P = 0.004$).[146] A small subset of CD45 + plasma cells constitutes the proliferative compartment of the bone marrow, and the expression of this antigen is required for IL-6 signaling, but prevents insulin growth factor 1(IGF-1)-mediated AKT pathway activation. Furthermore, a lower degree of angiogenesis, likely due to reduced vascular endothelial growth factor production, was observed with CD45 + expression. CD27 expression is associated with a better OS (92% at 3 years for CD27 + MM versus 50% in CD27- MM.[892]

CD221 (IGF-1 receptor) overexpression is linked with t(4;14) or t (14;16) whereas CD20 expression is tightly associated with the more favorable t(11;14) and small lymphoplasmacytic morphology. Aberrant CD117 (c-KIT) expression is predominant in the MGUS and indolent phases, and infrequent (8%) in the relapsed cases.[893] It is associated with a superior outcome (3-year OS, 93% for CD117 + versus 64% for CD117- MM; $P = 0.05$). CD200 is a membrane glycoprotein that imparts an immunoregulatory signal through CD200R, leading to the suppression of T-cell–mediated immune responses. Using Affymetrix microarrays, Moreaux et al. quantified the expression of the CD200 gene in myeloma cells of 112 patients with newly diagnosed MM.[894] The CD200 gene expression was either absent or present in 22% and 78% of MMCs, respectively. Patients with low/absent CD200 had an increased EFS compared with the remaining patients in the context of high-dose therapy and stem cell transplantation.

The value of immunophenotyping newly diagnosed MM by multiparametric flow cytometry was clearly established by the Spanish group in a recent prospective analysis of 685 patients treated with HDT (GEM 2000 protocol).[895] A prognostic model, risk-stratifying the newly diagnosed MM patients into three

categories, the poor risk (CD28 +/CD117–; 23%), the intermediate risk (CD28–/CD117– or CD28+/CD117+; 56%) and the good risk (CD28–/CD117+, 21%) with OS 45 months, 68 months and not reached, respectively, was promulgated by this group. The HDT followed by ASCT was not beneficial in approximately one quarter of those patients, that is, the high risk group.[895]

Magnetic Resonance Imaging

The superiority of the more sensitive tests, such as whole body/spinal MRI and PET, over conventional radiography is being exploited to prognosticate patients with MM accurately.[788] One of the key features of the DS stage I patients is the absence of skeletal involvement detected radiographically. However, 29% to 50% of DS stage I patients demonstrate infiltration of the marrow by MRI. The extent of the BM infiltration influences survival and can be adequately estimated by MRI. Various MRI patterns of the BM infiltration—normal, focal, diffuse, and variegated—have been used to predict the OS (56, 51, 24, and 52 months, respectively). Within each ISS I and II stage, the concomitant detection of diffuse BM infiltration by MRI can segregate the patients into two groups with statistically different survival outcomes suggesting enhancement of the prognostic value of ISS with this test. This finding is similar to the previously described observation noted with the incorporation of PCLI to the ISS. Dynamic contrast enhanced (DCE)-MRI has been shown to correlate with the degree of tumor infiltration in the bone marrow as well as the degree of vascularity or angiognesis in the marrow.[789,790]

Positron Emission Tomography

The avidity of metabolically active myeloma cells for 18F fluorodeoxyglucose, a radiolabeled glucose analogue, may not be helpful only in making a diagnosis, but it may also be prognostic. Zamagni et al. prospectively studied the prognostic value of PET/CT at diagnosis, after thalidomide–dexamethasone induction therapy and double autotransplantation in 192 newly diagnosed MM patients.[791] Presence at baseline of at least 3 focal lesions, a SUV $>$ 4.2, and presence of extramedullary disease adversely affected 4-year estimates of progression-free survival. In addition, SUV $>$ 4.2 and EMD were predictive of a shorter OS. In a multivariate analysis, both EMD and SUV $>$ 4.2 at baseline and persistence of FDG uptake after ASCT were independent prognostic factors for a shorter PFS.

The use of PET scan and MRI overcomes the limitation of conventional radiography in prognosticating patients by the DS-staging, and a DS-plus staging system that incorporates the findings of PET/MRI to the original DS staging system has been proposed for predicting OS. PET scan can detect both medullary and extramedullary lesions simultaneously, and can potentially upstage the patients due to its greater sensitivity (85%) and specificity (92%).[792] A drawback of the PET scan is its inability to detect very small lesions (<1cm). Radiation-induced inflammatory changes can lead to false-positive PET which should therefore only be performed at the time of diagnosis, or at least 2 months after the therapy.[792]

Renal Failure

Renal failure has been shown to portend a poor outcome in patients with MM. In a study from[184] the Nordic myeloma group, renal failure, defined as plasma creatinine $>$ 130 micromol/l, was observed in 29% of the cases at the time of diagnosis. During the first year after diagnosis 58% achieved normalization of p-creatinine, and this was achieved mainly during the first 3 months. Patients who needed dialysis had a poor prognosis, with a median survival of 3.5 months. A 12-month landmark analysis showed that reversibility of renal failure was a more important prognostic factor than response to chemotherapy.

Prior to the 21st century, of those patients with MM and severe renal failure who survived the first 2 months on dialysis, only 40% would have an objective response to chemotherapy and a median survival of almost 2 years;[896] however, these statistics have changed with highly effective regimens including bortezomib with hematologic response rates of more than 70%[897] and renal improvements in 82% of patients with renal impairment.[898,899] In a study of 39 patients with biopsy-proven myeloma kidney with a median estimated glomerular filtration rate of 9 m/min/1.73 m^2, the relationship between renal recovery and serum immunoglobulin free light chain (FLC) reduction was linear. Achieving at least a 60% reduction in FLC by 21 days was associated with recovery of renal function for 80% of the population.[900]

Pathogenesis of Mutliple Myeloma

There is a synergistic pathologic relationship between myeloma cells and the cells comprising the bone marrow microenvironment or stroma, including fibroblasts, endothelial cells, osteoblasts, and osteoclasts. The stromal cells of the marrow of myeloma patients produce high levels of interleukin-6 (IL-6) in vitro.[901] The IL-6 serves as a growth and survival factor for benign and malignant plasma cells, which produce IL-1β,[902,903] VEGF, and macrophage inflammatory protein-1α (MIP-1α).[904,905] In turn, IL-1β and MIP-1α regulate and activate osteoclasts.[902,906,907]

Bone Marrow Microenvironment

A cell adhesion molecule belonging to the immunoglobulin superfamily, CD56 (N-CAM), is strongly expressed in most plasma cells of myeloma patients[908] and is believed to play a role in myeloma homing and cell adhesion to the marrow. Increased levels of the adhesion molecules lymphocyte function-associated antigen (LFA)-3,[150] LFA-1 (CD11a),[909] and very late antigen-4 (VLA-4) are expressed on the myeloma cells in the majority of patients. VLA-4 may act to bind myeloma cells to fibronectin in bone marrow,[910] which under appropriate conditions can significantly increase IL-6 production by stroma.[911] Cell–cell contact between marrow stromal cells and myeloma cells via VCAM-1 and $\alpha 4\beta 1$-integrin enhances production of osteoclast-stimulating activity.[912] Hyaluronan, a glycosaminoglycan component of the bone marrow extracellular matrix, appears to be a survival and proliferation factor for myeloma cells.[913] Notch receptors are expressed in early hematopoietic stem cells and Notch ligands are expressed on BMSCs. Myeloma cells expressing Notch receptors are activated by the BMSC Notch ligand, protecting the myeloma cells from drug-induced apoptosis. In addition, this interaction also activates Notch signaling in BMSCs, leading to secretion of IL-6, VEGF, and IGF-1.[914] Cell-adhesion–mediated drug resistance (CAM-DR) is a well-recognized entity.[915] Another signaling pathway that has been implicated in myeloma pathogenesis is the Hedgehog (Hh) signaling pathway. Hedgehog (Hh) signaling is a highly conserved pathway that plays an important role in development in both vertebrates and invertebrates.[916] Hh ligands secreted by the stromal cells, namely Indian (Ihh), sonic (Shh), and desert (Dhh) bind to their receptor, patched (PTCH) on tumor cells. This binding alleviates the inhibition of PTCH on its downstream target, smoothed (Smo), thereby activating it. This activation leads to activation of the transcription factor involved in glioma formation (Gli) which promotes the transcription of its target genes leading to tumor development and progression.[917] In the myeloma setting it has been found that the Hh pathway is essential for maintaining a subset of tumor-causing stem cells.

The endothelial microvascular environment has also been shown to be important in MM biology.[139] There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating (S phase) fraction of marrow plasma cells in patients with MM and in those with

MGUS.[139,918,919–923] VEGF plays an important role in angiogenesis by acting as a potent inducer of vascular permeability as well as serving as a specific endothelial cell mitogen. Plasma cells in the bone marrow from MM patients express VEGF,[924,925] which can thereby interact with the Flt-1 and KDR high-affinity VEGF receptors highly expressed on bone marrow myeloid and monocytic cells surrounding the tumor.[918]

Investigators are beginning to understand the complex interactions among osteoclasts, osteoblasts, and myeloma cells. Receptor activator of NF/B (RANK), which is found on osteoclasts, interacts with RANK ligand (RANKL) found on osteoblasts and bone marrow stromal cells. These interactions contribute to bone destruction.[926] Myeloma cells also prevent differentiation of osteoblasts through secretion of the Wnt-signal antagonist DKK1.[927] It has been shown that MM cell-derived DKK1, a soluble inhibitor of canonical Wnt signaling, disrupt Wnt3a-regulated OPG and RANKL expression in osteoblasts. This suggests that DKK1 may play a key role in the development of MM-associated bone lesions by directly interrupting Wnt-regulated differentiation of osteoblasts and indirectly increasing osteoclastogenesis via a DKK1-mediated increase in RANKL-to-OPG ratios.[928] MIP-1a is produced by myeloma cells and it serves as an inducer of osteoclast formation.[929] In turn, osteoclasts produce a number of factors that stimulate myeloma cells, including IL-6.[156]

In addition to these cells, other cells that are part of the immune system also play a significant role in the myeloma pathophysiology. It has been shown that bone marrow macrophages, in particular tumor-associated macrophages, were protectors of myeloma cells.[930] The protective effect was dependent on direct contact between macrophages and myeloma cells. Macrophages protected both myeloma cell lines and primary myeloma cells from spontaneous and chemotherapy drug-induced apoptosis by attenuating the activation and cleavage of caspase-dependent apoptotic signaling. Using both in vitro and in vivo MM xenograft models, Chauhan et al. showed that plasmacytoid dendritic cells (pDCs) in the bone marrow (BM) microenvironment both mediate immune deficiency characteristic of MM and promote MM cell growth, survival, and drug resistance.[931]

Cytokines and Cell Signaling

The search for a growth factor for myeloma cells culminated in the identification of IL-6, formerly known as B-cell growth factor or hybridoma growth factor.[932] IL-6 is among the most important proliferation and survival factors in myeloma.[933] Predominantly produced by bone marrow stromal cells—macrophages, fibroblasts, endothelial cells, osteoblasts, osteoclasts, and monocytes (Fig. 98.10) [934]—it serves as a growth factor and as an antiapoptotic factor.[935–938] IL-6 exerts its cellular effects through gp130, which can activate two pathways: the JAK-STAT pathway[939] and the Ras-MAP kinase pathway.[940] Through the former pathway, which includes JAK-2 and STAT3, the antiapoptotic proteins MCL-1[939] and BCL-X_L[941] are up-regulated; through the latter pathway, transcription factors such as ELK-1, AP-1, and NF-IL-6[939] are up-regulated. NF-κB[942] and IL-6[943,944] may also mediate the observed increase in the antiapoptotic proteins BCL-2,[945,946] MCL-1,[943] and BCL-X_L.[943,944,947,948] The overall effect of these pathways is prevention of apoptosis and enhancement of MM proliferation. In addition, the constitutive activation of STAT3 may also be important in the pathogenesis of MM, independent of IL-6.[949] Moreover, CD40 activation of myeloma cells can alter the cell surface phenotype, triggering autocrine IL-6 secretion regulating the myeloma cell cycle in a p53-dependent fashion.[950]

Other cytokines and growth factors produced by myeloma and stromal cells that maintain myeloma growth[951] include IL-1β,[952,953,954] VEGF, insulinlike growth factor (IGF),[955–960] hepatocyte growth factor (HGF),[961] and tumor necrosis factor-α.[962,963] Aberrant expression of IL-1β may be a critical step in the transition of MGUS to MM.[902,954] IL-1β up-regulates production of IL-6, changes expression of cell adhesion molecules, and has been shown to have osteoclast-activating factor activity. Although IL-1β does not stimulate myeloma cell proliferation directly, by virtue of its effect on stromal cells in the marrow it induces production of IL-6[903] and IL-8.[964] Myeloma cells are capable of expressing and secreting VEGF and responding to the cytokine in an autocrine fashion.[904,905] Moreover, stromal and microvascular endothelial cell exposure to VEGF induces an increase in IL-6 secretion,[904] which then further stimulates myeloma cells. The precise role basic fibroblast growth factor (bFGF), another potent angiogenic factor, plays in the growth of myeloma cells is under active investigation.[965] Higher bFGF levels have been found in more advanced stages of MM.[965] IGF, which is believed to signal through the phosphatidylinositol-3′-kinase (PI-3K) pathway,[955] is capable of directly stimulating myeloma cell growth and enhancing myeloma cell responsiveness to IL-6 through mitogen-activated protein kinase[958] and also inhibiting apoptosis by increasing expression of BAD.[955]

Cell Cycle

Regulatory signals underlying proliferation of myeloma cells include increased cyclin D1 expression, hypermethylation of the cyclin-dependent kinase (CDK) pathway regulatory gene p16,[966] mutations of the *RAS* oncogene,[868,870] loss of *TP*53,[868,870] and overexpression of *MYC* in progressive disease.[967] Approximately one third of myeloma patients have up-regulation of cyclin D1 by immunohistochemistry; the plasma cells of these same patients tend to have higher proliferative rates.[968] The t(11;14)(q13;q32) translocation, which juxtaposes the immunoglobulin heavy chain promoter and the cyclin D1 gene, is seen in approximately 25% of MM patients.[778,841,969–971] Bergsagel et al. has postulated that activation of one of the three cyclin D genes is an initiating event in myeloma.[972]

Both p15 and p16 are important cell cycle inhibitors that suppress cell proliferation through inhibition of CDK4 or CDK6 or both, thereby preventing the phosphorylation of the retinoblastoma gene (*RB*). Although large deletions of p15 and p16 are rare in myeloma (0% to 12% of cases),[973–975] selective methylation of these genes, a form of transcriptional inactivation, occurs in as many as 67% and 75% of cases, respectively.[976–978] Most data suggest that methylation of p16 or p15 is associated with disease progression.[979]

K- and N-*RAS* mutations have been described in 25% to 100% of newly diagnosed MM patients,[862,870,980] depending on the technique used for detection. A *TP*53 tumor suppressor gene deletion is present in plasma cells from nearly 10% of patients with newly diagnosed myeloma[818,981] and mutations are even less common.[857,858,859,860] The MYC protein and *MYC* RNA are overexpressed in about 25% of MM patients.[982,983] Rearrangements of the *MYC* gene are present in about 15% of patients with MM or primary PCL.[984] Dysregulation of *MYC* appears to be caused principally by complex genomic rearrangements that occur during late stages of MM progression.[967]

SPECIAL CASES OF MYELOMA

Nonsecretory Multiple Myeloma

Nonsecretory MM accounts for 1% to 5% of myeloma cases.[124,985–989] With more sensitive testing such as immunofixation[990] and free light chain assays,[19] a majority of these "nonsecretory" patients are found to be low secretors or oligosecretory. More than 85% of cases have a cytoplasmic monoclonal protein; in the remainder, no monoclonal protein can be detected in the cytoplasm.[988,989,991] Individuals in this latter group are referred to as "nonproducers."

From a clinical standpoint, both are termed "nonsecretory." Median survival of these patients is at least as good as for those with secretory myeloma.[985,987,988] Response is difficult to document, but with the new serum assays, quantitation of free light chains is possible in about two thirds of these patients.[19]

Immunoglobulin D and E Multiple Myeloma

IgD myeloma accounts for about 2% of all cases of MM.[992] The presence of a monoclonal IgD in the serum usually indicates MM, but three cases of IgD MGUS have been documented.[986] Patients with IgD MM generally present with a small band or no evident M spike on serum protein electrophoresis. Their clinical presentation is similar to that of patients with Bence Jones MM (light chain MM) in that both have a higher incidence of renal insufficiency and coincident amyloidosis as well as a higher degree of proteinuria than in IgG or IgA MM.[992] IgD MM patients, however, appear to have a higher frequency of monoclonal lambda light chain than kappa light chains.[992] With an incidence of 19% to 27%, extramedullary involvement is more prevalent in patients with IgD MM.[993–995] Survival of patients diagnosed after 1980 is comparable to patients with non-IgD MM.[986,996]

IgE myeloma is a rare form of MM. A disproportionate number of cases are PCL, although the sample size is small, with only about 40 cases of IgE myeloma reported in the literature.[997,998]

Plasma Cell Leukemia

PCL is a rare form of PCD. Between 2% and 4%[850,999,1000] of malignant PCD cases are PCL. By definition, there are more than 20% plasma cells in the peripheral blood with an absolute plasma cell count of more than 2×10^9/L. Some authors accept the diagnosis with only one of these criteria.[986] The presentation may be primary, de novo, or secondary, evolving from an existing case of myeloma as part of the terminal phase of the disease. About 60% to 70% of cases are primary.[999]

PCL plasma cells more frequently express the CD20 antigen[850] than those of MM (50% vs. 17%), and they often lack CD56 antigen,[148,850] which is present on the majority of MM cells.[850] CD56 is considered important in anchoring plasma cells to bone marrow stroma and is associated with a poor prognosis.[149,150] CD28 is more frequently expressed on malignant plasma cells in secondary than in primary PCL, which is consistent with an observation made in MM, i.e., that acquisition of the CD28 antigen on plasma cells appears to correlate with an increased proliferative rate and disease progression.[891]

PCL plasma cells have higher proliferative rates[850] and more complex karyotypes than myeloma plasma cells.[1000] By comparative genomic hybridization and by FISH techniques, losses on 13q[1001,1002] and monosomy 13[850] exist in more than 80% of PCL patients.[1001,1002] Losses on chromosome 16 also occur in about 80% of cases.[1002] Gains in 1q are present in about half of the patients by FISH,[850] but in all by comparative genomic hybridization.[1002] In addition, PCL patients have unique losses of 2q and 6p.[1002] Overexpression of PRAD1/cyclin D1 and t(11;14) is commonly observed in PCL.[1003]

The clinical presentation of primary PCL is more aggressive than that of MM, with a higher presenting tumor burden and higher frequencies of extramedullary involvement, anemia, thrombocytopenia, hypercalcemia, renal impairment,[850,999,1000,1004] increased levels of serum lactate dehydrogenase and β2M, and plasma cell proliferative activity.[850] The incidence of lytic bone lesions is slightly lower than that usually observed in MM.[850,1005]

Although the clinical and laboratory features of primary and secondary PCL are similar,[1005,1006] the response to therapy and OS in primary and secondary PCL go from poor to worse.[999,1000,1004,1005] Higher response rates can be achieved with multiagent chemotherapy rather than single alkylator programs (47% to 66% vs. 8% to 13%).[850,999,1000,1005] Regimens such as VMCP/VBAP, VAD, and combination cyclophosphamide and etoposide have resulted in median survivals of 18 to 20 months compared with 2 to 6 months when single-agent therapy is used.[850,999,1000,1005] When thalidomide and dexamethasone are used, responses are possible.[1007,1008] There are anecdotal reports of activity of bortezomib in these patients.[1009,1010,1011] Some patients derive excellent responses and 2- to 3-year disease-free survivals after ASCT.[1012–1016] Saccaro et al.[1017] reported on the cumulative outcomes of the literature of PCL patients undergoing hematopoietic stem cell transplantion. Median survival post autologous ASCT was 36 months, whereas it was only 12 months after allogenic ASCT. Registry studies have shown that overall survival with primary PCL approaches that of multiple myeloma, and up-front ASCT appears to outperform AlloSCT even when reduced intensity protocols are used.[1018]

Response and survival rates with secondary PCL remain low.[1005,1006] See the recent review of PCL.[1019]

Osteosclerotic Myeloma (POEMS Syndrome)

Osteosclerotic myeloma is a rare variant of myeloma (≤3.3% of cases).[1020] There is a straight osteosclerotic variant that is similar to MM in that anemia, significant bone marrow plasmacytosis, hypercalcemia, and renal insufficiency occur.[158] Survival in these patients is comparable to that of classic MM patients. There is, however, a more interesting form, which is known as Crow-Fukase syndrome, PEP (PCD, endocrinopathy, polyneuropathy) syndrome, Takatsuki syndrome, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes).[1021–1024] This variant is discussed in Chapter 101.

TREATMENT OF COMPLICATIONS AND SUPPORTIVE CARE

Complications Specific to Novel Therapies

Thrombosis is an important complication in patients undergoing treatment with IMiDs. As a single agent, there does not appear to be any heightened risk; however, concomitant chemotherapy,[389] especially anthracyclines,[1025,1026],high-dose corticosteroids,[359,407,1027] and erythropoietin[1028] appears to increase the risk of thrombosis to as high 58%. A phase III trial[1029] compared aspirin (100 mg/day), low-dose warfarin (1.25 mg/day), and enoxaparin (40 mg/day) in 667 patients with previously untreated myeloma receiving a thalidomide-based regimen. The primary endpoint was a composite that included serious thromboembolic events, acute cardiovascular events, or sudden deaths during the first 6 months of treatment. The most frequent complications were thromboembolic events that occurred in 5.9% in the aspirin group, 8.2% in the warfarin group and 3.2% in the LMWH group. Symptomatic pulmonary embolism episodes occurred only in the aspirin and warfarin groups. The absolute differences for serious thromboembolic events were +2.7% ($P = 0.173$) between aspirin and LMWH groups and +5.0% ($P = 0.024$) between warfarin and LMWH groups. These results did not reach a statistical significance. The same group conducted a prospective trial comparing aspirin (ASA) to low molecular weight heparin (LMWH) in 342 newly diagnosed patients[1030] who were treated with lenalidomide and dexamethasone or MPR. Patients were randomly assigned to receive ASA 100 mg/d ($n = 176$) or LMWH enoxaparin 40 mg/d ($n = 166$). The incidence of VTE was 2.27% in the ASA group and 1.20% in the LMWH group, a difference that was not significant. Based on this, ASA can be an effective and less-expensive alternative to LMWH thromboprophylaxis. Of note, however, patients considered high risk for VTE were excluded from both these studies. Those patients with advanced age, inherited thrombophilic

abnormalities, recent surgery, or a history of VTE should be considered for full-dose anticoagulation.

Pharmacologic Therapy of Myeloma Bone Disease

Myeloma bone disease is a significant contributor to morbidity, and there is expanding information about the relationships between bone turnover and plasma cell growth and survival.[157,926,1031–1033] A randomized trial has demonstrated that treating with bisphosphonates not only helps prevent secondary bony events in patients with existing bone lesions, but that the use of monthly zolendronic acid as compared to clodronate increases median OS of ALL patients (whether they have bone lesions or not) by 6 months.[1034] Bisphosphonates inhibit dissolution of the hydroxyapatite crystals and down-regulate the major osteoclast functions. After internalization, the nitrogen-containing bisphosphonates interfere with the biosynthetic mevalonate pathway by inhibiting farenesyl diphosphonate synthase with resultant inability of osteoclasts to form the ruffled borders of their membrane needed to activate bone resorption.

The first study showing a reduction of almost 50% of secondary skeletal events among myeloma patients who received monthly intravenous administration of pamidronate was published in 1996.[1035] At 12 months, there were fewer skeletal-related events in the pamidronate group than in placebo-treated patients (28% vs. 44%; $P < 0.001$).[1035,1036] With longer follow-up of 21 months, the difference between groups persisted but narrowed slightly to 28% in the pamidronate group versus 51% in the placebo group ($P < 0.015$).[1037] This prospective study subsequently led the FDA to approve the use of the drug in this setting. Equivalency of pamidronate and zoledronic acid has been demonstrated in two randomized clinical trials, a randomized phase II[1037] and a randomized phase III.[1038] In the phase III trial, patients with MM or breast cancer, who had lytic disease, were treated with zolendronic acid (4 or 8 mg per dose) or pamidronate (90 mg) every 3 to 4 weeks. The infusion time for zoledronic acid was increased from 5 minutes to 15 minutes during the trial due to an increase in creatinine occurring more frequently among patients receiving the rapid infusion. Renal problems continued to occur more often among patients randomized 8 mg zoledronic acid and their dose was subsequently reduced to 4 mg. The sample size was based on showing noninferiority of zoledronic acid to pamidronate, and of 1,648 patients who were enrolled 510 had MM and the remainder had metastatic breast cancer. The portion of patients with any SRE after 13 months did not differ among the three treatments and did not differ between the breast cancer and MM patients. In February 2002, the FDA approved an expanded indication for zoledronic acid for the treatment of patients with bone metastases that included its use in MM.

Despite the fact that the longest follow-up of patients in these studies was 24 months, the recommendation by the American Society of Clinical Oncology was to continue these agents indefinitely at monthly intervals.[1039] The rationale for practice was not data driven, but based on several theoretical benefits. The first was that patients have continued bone disease throughout the course of their disease. The second was predicated on the in vitro and in vivo (murine) data that bisphosphonates exert antitumor activity.[1031]

In the short-term, the drugs were well tolerated, with occasional episodes of mild pyrexia, renal function impairment, myalgias, and hypocalcemia. However, by 2003, avascular osteonecrosis of the jaw (ONJ) has been described as a new complication associated with their use.[1040,1041–1043,1044,1045,1046–1050] Bisphosphonate-associated ONJ has been described in various malignancies including MM, breast cancer, and prostate cancer. A management algorithm for ONJ has recently been published.[1051] It has been seen in both the mandible and the maxilla but is more frequent in the former. The etiology of ONJ is unclear, but is likely multifactorial in origin. Although most patients who develop ONJ have had recent dental or oral surgical procedures (70%), the remainder develop spontaneous ONJ.[1045] Proposed mechanisms include that inhibition of osteoclast activity reduces bone turnover and remodeling and that bisphosphonates prevent release of bone-specific factors that promote bone formation.[1052] In addition, bisphosphonates, particularly zoledronic acid, may have antiangiogenic effects which has been implicated in the development of ONJ. Finally, healing of an open bony oral wound may be challenged by bacterial insult from oral microflora.

The true incidence of this complication is hard to estimate, but is somewhere aroung 6.8% to 9.9%.[1047,1048] Risk factors for ONJ are longer duration of treatment, zolendronic acid (as compared to pamidronate). In one study,[1047] patients who developed ONJ received a median number of 35 infusions (range, 13 to 68) compared to 15 infusions (range, 6 to 74) for patients with no ONJ. The optimal dosing schedule and duration of therapy has not been adequately defined by randomized clinical trials. One retrospective study suggested quarterly infusions of zoledronic acid are as effective as monthly infusions with less risk of ONJ.[1053]

Most would agree that 1 to 2 years of IV bisphonate is standard after a dental check-up. The role of these drugs after this timepoint is uncertain. Many opt to reduce the frequency of administration after 2 years, especially if disease is in remission. Once on these drugs, invasive dental procedures should be limited if possible. Other drugs such as bone seeking radionuclides[561,1054,1055] and inhibitors of the receptor activator of nuclear factor κB (RANK) signaling known as osteoprotegerin[1056] are being tested. Denosumab (a fully human monoclonal nati-receptor activator of nuclear factor kappa-B ligand antibody) was compared to zolendronic acid for delaying or preventing skeletal-related events.[1057] Denosumab was noninferior to zolendronic acid in delaying a first skeletal event. Hypocalcemia was more commonly seen in the denosumab-treated paitents.

The standard method of following patients is with periodic (every 6 to 12 months) skeletal radiographs; the use of more sophisticated imaging modalities has been described in a previous section. Cross-linked N-telopeptides of Type I collagen, which can be measured in the serum or urine, appear to be a sensitive indicator of bone turnover,[799,1058] and urinary levels show a strong positive correlation with the dynamic histomorphometric indices of bone resorption.[1059] Serum levels of bone metabolism markers including osteocalcin, MIP-1α, RANKL, and osteopetegrin have been studied and shown to be aberrently expressed in patients with active myeloma.[157]

Nonpharmacologic Treatment of Myeloma Bone Disease

When a lytic bone lesion is present, significant risk factors for fracture of a long bone include increased pain with use, and the involvement of more than the diameter of the bone. These lesions should be treated prophylactically with surgery if they are situated in weight-bearing bones.[1060] Endosteal resorption of one half the cortical width of the femur weakens the bone by 70%. Surgical treatment should be considered for these lesions as well.[1061] Once a bone has fractured, healing can occur especially if proper internal fixation is performed and if patients have an anticipated survival of >6 months. Much of the data regarding malignant bone disease are derived from patients with carcinoma rather than MM. In patients with carcinoma metastatic to bone, modest post-operative radiation doses (≤3,000 cGy) as adjuvant therapy are associated with better healing,[1062] but the role of adjuvant radiation therapy in MM patients is less clear. MM is often chemotherapy sensitive; adjuvant systemic chemotherapy in MM patients may be more appropriate than adjuvant radiation therapy. In general, radiation therapy should be used for pain

relief in chemotherapy-refractory disease, because it relieves pain in 80% to 90% of patients with bony metastases,[1063] long-term in 55% to 70%.[1064]

Percutaneous vertebroplasty is occasionally an option for patients with vertebral body compression fracture. Pain relief is generally apparent within 1 to 2 days after injection and persists for at least several months up to several years.[1065] Complications are relatively rare, although some studies reported a high incidence of clinically insignificant leakage of bone cement into the paravertebral tissues. Compression of spinal nerve roots or neuralgia due to the leakage of polymer and pulmonary embolism have also been reported. Percutaneous kyphoplasty is also an option.[1066] There is one published trial in patients with MM that randomized patients in an unblended fashion to kyphoplasty or nonsurgical management.[1067] At 1 month, the back specific disability score was significantly better in the kyphoplasty group. Inasmuch as patients in the control group had the option of crossing over to the kyphoplasty arm, there are no long-term data on outcomes.

Spinal Cord Compression

In a paper published in 1979, it was estimated that nearly 10% of patients with myeloma either present with spinal cord compression or that it develops during the course of the disease;[1068] with higher awareness of myeloma and better imaging technology, the incidence is likely lower now. Cord compression, however, remains an important and emergent subject. The usual standard treatment is high-dose corticosteroids and radiation therapy.[1069–1072] On rare occasions, surgical decompression may be considered. Because most myelomatous lesions arise from the vertebral body, an anterior surgical approach is generally used, which may contribute additional morbidity. One small randomized trial addressing the question of radiation versus laminectomy and radiation, showed no benefit attributable to laminectomy;[1070] similarly, a larger retrospective series found no benefit.[1069] If the deficit is due to compression by the plasma cell tumor (rather than a bone fragment retropulsed by a pathologic compression fracture), outcomes with radiation therapy are probably equal (or superior) to surgical intervention in a radiosensitive tumor such as myeloma.[1069,1070]

High-dose corticosteroids may provide immediate pain relief and improvement in neurologic function.[1071,1072] The optimal corticosteroid dose has not been established, but common dose schedules for metastatic disease include dexamethasone in an initial bolus of 10 mg intravenously or 100 mg intravenously followed by 4 mg orally 4 times daily;[1073] or a 100-mg intravenous bolus followed by 96 mg in four divided doses for 3 days followed by tapering doses.[1071,1072]

Hypercalcemia

Patients with MM are at risk of severe hypercalcemia that can precipitate acute renal failure, hypertension, nausea, vomiting, pancreatitis, cardiac arrhythmia, coma, and death. The extracellular volume depletion associated with hypercalcemia should be corrected by vigorous hydration[745,1074] followed by an antiresorptive agent such as intravenous bisphosphonate. Serum calcium values usually decline rapidly, reaching the normal range within 2 to 3 days in more than 80% of cases. It occasionally goes below normal at the nadir. Corticosteroids can also reduce serum calcium concentration in about 60% of patients with hypercalcemia.[1075]

Gallium nitrate, mithramycin, and calcitonin are interesting from an historical perspective. Since the advent of bisphosphonates, they are not often used. Gallium nitrate therapy had been shown to be superior to maximally approved doses of calcitonin for acute control of cancer-related hypercalcemia.[1076]

Hematologic Complications Including Anemia, Secondary Leukemia, Hyperviscosity, and Cryoglobulinemia

Anemia

The anemia of MM can result from many factors. When the anemia is due solely to myelomatous bone marrow infiltration, chemotherapy remedies the problem. Other patients have a relative erythropoietin deficiency related to renal injury due to the myeloma or to age-related changes. In these patients, as in any patient with renal insufficiency, modest doses of recombinant erythropoietin are effective. For patients with chemotherapy-induced anemia, recombinant erythropoietin may be effective at higher doses (150 to 300 IU/kg thrice weekly or 40,000 units weekly). Two placebo-controlled trials in myeloma patients demonstrate significantly improved hemoglobin levels and a reduced number of red cell transfusions in patients receiving erythropoietin.[1077,1078] Erythropoetin increases the risk of thrombotic events.

Secondary Myelodysplasia and Acute Leukemia

The most ominous cause of anemia in the setting of previously treated MM is a secondary myelodysplastic syndrome or acute leukemia. Kyle et al.[583] were among the first to recognize that cytotoxic agents can induce myelodysplasia and acute myeloid leukemia.[583–585,586] The risk of a secondary myelodysplastic syndrome or acute leukemia is approximately 3% at 5 years and 10% at 8 to 9 years,[1079,1080] with estimates as high as 25% at 10 years,[1081] with multiple other estimates somewhere in between.[385,587,588] Some authors have suggested that higher cumulative doses of melphalan are implicated as a risk for acute leukemia.[1079] Others have shown no difference in incidence based on the number of courses of chemotherapy or the cumulative melphalan dose between the patients who did and did not develop acute leukemia.[1080] In a Finnish study, the mean number of chemotherapy cycles was 19.7 and 18.5 in patients with and without secondary leukemia; mean cumulative melphalan doses were 1,440 and 1,400 mg, respectively.[1080] Although cyclophosphamide has been shown to be leukemogenic, data suggest that it is less so than melphalan.[1079,1082,1083] After secondary leukemia is diagnosed, median survival tends to be short, about 2 months.[1080]

The occurrence of concurrent acute leukemia in MM suggests that there may be a proclivity for acute leukemia to develop in patients with myeloma.[1084,1085] After stem cell transplantation for myeloma, the risk of myelodysplastic syndrome appears to be related to prior chemotherapy rather than to the transplant itself, at least in one retrospective series.[1086]

Cryoglobulinemia and Hyperviscosity

Approximately 5% of myeloma gammaglobulins exhibit reversible precipitation in the cold, so-called cryoglobulins, forming either a flocculent precipitate or a gel-like coagulum when the serum is cooled.[1087] Plasmapheresis relieves the symptoms of hyperviscosity, but the benefit of this treatment in the absence of concurrent chemotherapy is short lived.[1088]

Renal Failure

Normal creatinine values are present in approximately 50% of MM patients at diagnosis,[124,125,126,127,178–181] and only 15% to 25% have a creatinine value above 2 mg/dl.[126,184] Patients in whom the renal failure is reversed have a better OS than those without improvement.[182,185] Factors that increase renal tubular cast formation include dehydration, infection, and hypercalcemia. There is some controversy around best management of patients with renal failure in terms of plasmapheresis and the relative

importance of alkylizing urine, but there are four points that are incontrovertible: (1) achieve a deep hematologic response as soon as possible, (2) avoid nephrotoxic drugs, (3) correct hypercalcemia, and (4) correct dehydration (maintaining a 24-hour fluid intake of at least 3 liters can improve renal function).[182]

In terms of best chemotherapeutic regimens to achieve rapid hematologic response, several have already been discussed. A bortezomib-based regimen such as CyBorD, VTD, or PAD is often favored in the setting of renal failure. In a recent trial in which patients were randomized to VAD or PAD followed by ASCT, the subset of patients presenting with creatinine above 2 mg/dl and who were randomized to PAD had a markedly improved median survival as compared to the VAD patients (54 months vs. 21 months, $P < 0.001$). Because light chains with the lowest isoelectric points tend to be more nephrotoxic in animal models, avoidance of a low or acidic urinary pH is recommended. Oral or intravenous bicarbonate is useful in the setting of acute renal failure.[1089] The MRC third myelomatosis trial randomized MM patients with significant renal failure to oral sodium bicarbonate to neutralize urine pH (or not), and there was a trend toward better survival in the bicarbonate recipients.[182]

The use of plasmapheresis in the setting of renal failure remains controversial. There are three randomized trials addressing this question, with conflicting results. One small randomized study of patients with active myeloma and progressive renal failure suggested benefit in a subset of patients.[1090] There were 21 patients randomized to either forced diuresis and chemotherapy (10 patients) or forced diuresis, chemotherapy, and plasmapheresis (11 patients). There was a trend toward better outcome in the plasmapheresis group, but the difference was not statistically significant. It is unclear whether the lack of significance is due to the small sample size, or to an equivalence of the two therapeutic strategies. The study did demonstrate that the severity of myeloma cast formation directly correlated with lack of improvement regardless of treatment strategy.

Another randomized study in myeloma patients with severe renal compromise compared plasma exchange (and hemodialysis when needed) with peritoneal dialysis.[1091] All patients received chemotherapy and corticosteroids. Of the 29 patients in the study, 24 received dialysis and 5 maintained serum creatinine concentrations of greater than 5 mg/dl without dialysis. Of the 15 patients in the plasmapheresis ± hemodialysis group 13 recovered renal function, reaching serum creatinine values of less than or equal to 2.5 mg/dl in most cases, whereas only 2 patients in the peritoneal dialysis group had enough improvement to stop dialysis. The 1-year survival rates were 66% and 28%, respectively ($P < 0.01$). The study's design was flawed in that one group received peritoneal dialysis and the other hemodialysis; the question about the role of plasmapheresis is not adequately settled.

The largest and most recent trial was a negative study.[1092] A total of 104 patients with newly diagnosed myeloma and a creatinine of 2.3 mg/dl were randomized to conventional chemotherapy with or without five to seven sessions of plasma exchange over 10 days. The primary outcome was a composite measure of death, dialysis dependence, or glomerular filtration rate of less than 30 ml/min/1.73 m^2. At 6 months the endpoint was reached in 58% of the plasma exchange group and 69% of the control group. At 6 months, 7 of the 39 control patients (18%) and 5 of 58 plasma exchange patients (9%) were on dialysis. At 6 months, 33% of each group had died. Criticisms of this study included the patient selection, including the absence of renal biopsy, the use of relatively ineffective conventional chemotherapy, and small sample size. Patients were eligible if the serum creatinine level was 2.3 mg/dl with an increase greater than 0.6 mg/dl in the preceding 2 weeks despite correction of hypercalcemia, hypovolemia, and metabolic acidosis. This would imply that institution of plasma exchange was delayed and that there could have been underlying pathologic renal lesions other than cast nephropathy, which would not be responsive to plasma exchange. More than twice as many patients on the plasma exchange group had MP as in the control group, which could have confounded the results because both overall response rates are lower and time to response is longer with MP than with VAD.

Infection Management

Infections are a major cause of morbidity in myeloma patients.[1093,1094] Pneumonias and urinary tract infections caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli* are most frequent.[193,1095–1097] The susceptibility to infection varies with the phase of illness.[192,1098] In one prospective study, the overall serious infection rate was 0.92 infections per patient-year and was four times higher during periods of active disease (1.90) than in plateau phase myeloma (0.49).[191] In a retrospective study evaluating the sequential incidence of infection, the first 2 months of initial chemotherapy emerged as a particularly high-risk period, with nearly half of the patients experiencing at least one clinically significant infection.[192] Infections late in the course of MM may be an inevitable result of long-standing immunosuppression and overwhelming tumor burden. Prevention of infection is a critical goal for improving survival.

Prevention of infections by use of vaccines is an attractive strategy. Unfortunately, responses to vaccines are poor among myeloma patients.[198,1099–1101] Patients with MM were investigated to assess whether immunologic risk factors predisposing to serious infection could be identified.[191] Specific antibody titers to pneumococcal capsular polysaccharides and tetanus and diphtheria toxoids were significantly reduced compared with the control population. Low antipneumococcal and anti-*Escherichia coli* titers correlated with risk of serious infection. In addition, among 41 immunized patients, responses to pneumococcus vaccine and tetanus and diphtheria toxoids were poor. IgG subclass levels were significantly reduced, and a poor IgG response to pneumococcus vaccine immunization was associated with an increased risk of septicemia. The predominant site of infection was the respiratory tract. Decreased concentrations of the uninvolved immunoglobulins were significantly associated with at least one serious infection.[191]

The two most common prevention strategies consist of prophylaxis with antibiotics[1102] or intravenous immunoglobulin (IVIg).[1102] A randomized, placebo-controlled trial of trimethoprim-sulfamethoxazole (TMP-SMX) demonstrated a significant decrease in severe infections among newly diagnosed myeloma patients randomized to TMP-SMX compared with controls.[1103] A larger follow-up trial, however, failed to show a benefit from prophylactic antibiotics.[1104] In that study 212 untreated, symptomatic myeloma patients who were on chemotherapy were randomized to receive ciprofloxacin ($n = 69$), trimethoprim-sulfamethoxasole ($n = 76$), or observation ($n = 67$) for the first 2 months of treatment. The use of prophylactic antibiotics did not decrease the incidence of infection.

A randomized, double-blind placebo-controlled trial demonstrated that IVIg significantly reduced the number of infections in high-risk patients with plateau phase MM.[1102] Eighty-two such patients received either IVIg (0.4 g/kg per month) or an equal volume of placebo for 1 year. There were no episodes of septicemia or pneumonia in patients receiving IVIg compared with 10 in placebo patients ($P = 0.002$). There were 38 serious infections in 470 patient-months for the placebo group, compared with 19 in 449 patient-months for the IVIg group ($P = 0.019$). A poor antibody response to pneumococcal vaccination (less than twofold increase) identified patients who had maximum benefit from IVIg. However, IVIg is expensive and inconvenient and can be associated with toxicity. Therefore, use of this agent is recommended only for patients with a significant history of severe infections.

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM is made from a constellation of findings, including anemia, monoclonal proteins, bone lesions, renal complications, hypercalcemia, and bone marrow plasmacytosis. Often the diagnosis is straightforward, but other disease entities associated with hypergammaglobulinemia or monoclonal bone marrow plasma cells must also be considered. These include reactive plasmacytosis, MGUS, primary systemic amyloidosis, Waldenström macroglobulinemia, light chain deposition disease, acquired Fanconi syndrome, solitary plasmacytoma, osteosclerotic myeloma or POEMS syndrome, and PCL.

Reactive plasmacytosis and polyclonal hypergammaglobulinemia must be distinguished from a clonal process. Patients with liver disease, chronic infections including human immunodeficiency virus, connective tissue diseases, other lymphoproliferative disorders, and carcinoma can have increased bone marrow plasmacytosis (polyclonal) and hypergammaglobulinemia (polyclonal).[22,123] These conditions should not be confused with MM or MGUS, which are clonal processes.

MGUS patients do not have bone marrow suppression, lytic bone lesions, hypercalcemia, renal failure, or susceptibility to infection. Standard clinical features do not accurately predict which patients will remain stable, and in approximately 1% per year MM develops.[133] The clinical distinction between MGUS and asymptomatic MM is derived from an arbitrary definition (Table 98.1), although the underlying biologic conditions may prove to be different.

The greatest challenges in differentiating MGUS (or asymptomatic MM) from MM occur in patients who have MGUS and (1) senile osteoporosis, (2) renal insufficiency from another cause, or (3) hypercalcemia due to hyperparathyroidism. Approximately 50% of women older than age 60 years have osteoporosis, and a fraction of these have vertebral compression fractures. Computed tomographic scan of the spine may help distinguish between senile osteoporosis and myelomatous bone disease. Similarly, renal insufficiency due to long-standing diabetes, hypertension, or nonsteroidal drug use is not uncommon. In such cases, a patient may still have MGUS (or smoldering MM) and "end-organ damage." The key is whether the damage is attributable to the plasmaproliferative disorder or another cause. In some instances, renal biopsy may be required to clarify this issue.

Immunoglobulin light chain amyloidosis (AL amyloidosis) is a rare disorder that is characterized by the deposition of amyloid fibrils and is discussed in Chapter 99. The diagnosis should be suspected when a patient with a monoclonal protein in the serum or urine presents with nephrotic-range proteinuria (primarily albumin) with or without renal insufficiency, cardiomyopathy, hepatomegaly, or peripheral neuropathy. A histologic diagnosis is made by demonstrating the amyloid fibrils: green birefringence under polarized light by using a Congo red stain, or 8- to 10-nm nonbranching fibrils by electron microscopy.

The nonamyloidogenic light chain deposition diseases (LCDDs) are due to pathologic protein deposition in various tissues and organs. Unlike the light chain deposits observed in patients with primary systemic amyloidosis, these infiltrates are not congophilic by light microscopy, and nonbranching fibrils are not observed by electron microscopy. Instead, amorphous nodular deposits are seen. LCDD may occur with or without co-existent MM. Renal involvement is most common, followed by cardiac and hepatic deposits. Clinically, LCDD can be differentiated from MM and primary systemic amyloidosis by the following findings. As in primary systemic amyloidosis, early in the disease course the light chain deposits have a predilection for the renal glomeruli rather than the tubules. This results in nonselective proteinuria, that is, a predominance of albuminuria, which is not usual in MM. It is impossible without tissue biopsy to distinguish clinically the cardiomyopathy and hepatopathy from primary systemic amyloidosis. In LCDD, the underlying clone is more commonly monoclonal κ rather than λ. The prognosis of patients who have this disorder depends on whether there is underlying MM. In one retrospective study of 19 patients with LCDD, 5-year actuarial patient survival and survival free of end-stage renal disease were 70% and 37%, respectively.[1105]

Fanconi syndrome is a rare complication of PCDs characterized by diffuse failure in reabsorption at the level of the proximal renal tubule and resulting in glycosuria, generalized aminoaciduria, and hypophosphatemia.[189] Fanconi first described the syndrome in children. Subsequently, acquired forms were described in adults. Acquired Fanconi syndrome is usually associated with MGUS. Overt hematologic malignancies may occur, such as MM, Waldenström macroglobulinemia, or other lymphoproliferative disorders. The prognosis is good in the absence of overt malignant disease. Clinical manifestations include slowly progressive renal failure and bone pain due to osteomalacia. The diagnosis of Fanconi syndrome can be made when a patient with a monoclonal plasma cell disorder presents with aminoaciduria, phosphaturia, and glycosuria. Electrolyte abnormalities typically include hypokalemia, hypophosphatemia, and hypouricemia. Bence Jones proteinuria is usually present and is almost always of the κ type. Rare patients have been reported with Fanconi syndrome associated with λ Bence Jones proteinuria. Treatment consists of supplementation with phosphorus, calcium, and vitamin D. Chemotherapy may benefit patients with rapidly progressive renal failure or symptomatic malignancy.

Waldenström macroglobulinemia should not be confused with IgM myeloma, which comprises only about 1% of myeloma cases.[126] Patients with Waldenström macroglobulinemia may have anemia, hyperviscosity, B symptoms, bleeding, and neurologic symptoms. Significant lymphadenopathy or splenomegaly may also be present. Lytic bone disease is markedly uncommon; if present, consider whether the patient has IgM myeloma. In Waldenström macroglobulinemia, bone marrow biopsy typically reveals infiltration with clonal lymphoplasmacytic cells (CD20 positive). The natural history and treatment options for Waldenström macroglobulinemia are different from those of MM[1106] (Chapter 100).

Solitary plasmacytoma of bone is a rare form of plasmaproliferative disease. Its true incidence has not been described, but it accounts for about 2% to 5% of malignant plasma cell dyscrasias treated at large referral centers.[208,1107,1108] In most series, the definition has required the following characteristics: (1) histologic proof that the solitary lesion is a plasmacytoma; (2) no other bone lesions on metastatic bone survey; (3) less than 5% plasma cells from a random bone marrow biopsy site; and (4) the absence of anemia, hypercalcemia, or renal insufficiency that had no attributable cause. Some definitions allow for <10% bone marrow plasma cells[736] and others have restricted the quantity of the serum or urine M spike. Others have excluded patients who developed disseminated myeloma within a year after diagnosis of the solitary plasmacytoma.[1109] The International Myeloma Working Group has adopted the above definition, but adds that if done, MRI should not demonstrate any other areas of marrow involvement.[205]

There is a clear male preponderance, and the median age is 55 years.[740,1109–1111] Plasmacytomas most commonly arise from the axial skeleton, particularly the vertebral bodies. Pain is the usual presentation. Spinal cord or nerve root compression may also be present. If the patient also has evidence of a peripheral neuropathy, and especially if the bone lesion is sclerotic, one should consider the diagnosis of POEMS syndrome (Chapter 101). Monoclonal proteins are present in about 50% of patients.[736,1109]

Careful staging should be done in all patients, including a complete blood cell count, protein electrophoresis and immunofixation of the serum and urine, serum immunoglobulin free light

chains, a complete radiographic skeletal survey, and random bone marrow aspiration and biopsy. At a minimum, immunohistochemical stains should be done on the bone marrow to identify a clone apart from the solitary plasmacytoma. MRI of the entire spine and pelvis should also be done to determine whether the lesion is solitary. Using MRI, Moulopoulos et al.[172] found unexpected bone marrow involvement in 4 of 12 patients with apparently solitary plasmacytomas of bone. FDG-PET may should also provide useful information.

From an historical perspective, solitary plasmacytomas of bone were treated surgically with or without adjuvant radiation.[1112] Present day, single modality, definitive radiation therapy is the treatment of choice. Although the optimal dose has not been established by randomized controlled trials, 4,000 to 5,000 cGy encompassing all disease with a margin of normal tissue is recommended by most experts on the basis of retrospective local relapse rate data.[736–738,1113] This principle, however, has been challenged by recent data which show no difference in local control as long as the therapeutic dose is over 3,000 cGy.[739]

Median 10-year disease-free survival is about 25% to 40%.[736,1114] Median time to failure, that is, local relapse, appearance of another plasmacytoma, or disseminated myeloma, is about 2 years,[736,739,1114] but these figures are contaminated by inadequate staging of patients. In a retrospective study at a major academic institution, fewer than 5% of patients referred for a diagnosis of solitary plasmacytoma of bone had adequate baseline staging.[1115] The majority of patients with a solitary "plasmacytoma of bone" had a low burden of clonal plasma cells in their marrow. Because these patients are typically not offered immediate chemotherapy, a novel term was used to label these patients, "plasmacytoma plus." The 21-month disease-free survival of patients that did not satisfy criteria for "plasmacytoma plus" was 100%.

Risk factors for evolution to myeloma include absence of a monoclonal protein at presentation (nonsecretory disease), depression of immunoglobulin values at presentation, persistence of the monoclonal protein after treatment,[1114] abnormal immunoglobulin free light chain ratio at presentation,[1116] tumor size of more than 5 cm, and a nonvertebral presentation.[739] The persistence of a monoclonal protein after radiation therapy does not guarantee relapse,[208,736] even after more than 10 years of follow-up.[1114] In rare instances, the maximum reduction of myeloma protein may take several years after completion of the radiation therapy.[208,736] Median survival for all patients presenting with solitary plasmacytoma of bone—based on data from patients staged before routine use of MRI and bone marrow clonality studies—was approximately 10 years.[736,739,1108,1114,1115] For those who progressed to myeloma, the median survival was 44 months after the start of chemotherapy.[208] Adjuvant chemotherapy has not been shown to produce a survival advantage and carries the risk of treatment-related myelodysplastic syndromes or acute leukemia; it cannot be recommended.

Solitary extramedullary plasmacytomas represent about 3% of all plasma cell neoplasms.[1118] They most commonly affect men in their early 60s and occur in the upper respiratory tract (paranasal sinuses, nose, nasopharynx, and tonsils). They also occur in lymph nodes, lung, thyroid, gastrointestinal tract, liver, spleen, pancreas, testes, breast, or skin.[1119] Amyloid involvement of the plasmacytoma occurs on occasion. Although extramedullary plasmacytomas are not common in newly diagnosed MM, classic myeloma must be excluded by thorough staging. A monoclonal protein in the serum and urine, lytic bone lesions, anemia, renal insufficiency, and hypercalcemia should be excluded. Histologically, an extramedullary plasmacytoma should be differentiated from reactive plasmacytosis, plasma cell granuloma, poorly differentiated neoplasms, and immunoblastic lymphoma. Some extramedullary plasmacytomas may represent marginal zone B-cell lymphomas that have undergone plasmacytic differentiation.[1120] Dimopoulos et al.[1118] compiled 128 extramedullary plasmacytoma patients from eight published series[1108,1119,1121,1122–1126] and summarized their clinical course. The local failure rate was 7%, multifocal extramedullary relapse occurred in 13%, and classic myeloma developed in 15%. Local radiation therapy is the treatment of choice and adjuvant chemotherapy is not recommended. The 10-year disease-free survival is 70% to 80%. Ozsahin et al.[1116] compiled 52 pateints through a Rare Cancer Network study. Their findings were similar with a 5-year progression rate of about 25% and a 5-year survival approaching 90%.

CHAPTER 99

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS (PRIMARY AMYLOIDOSIS)

Morie A. Gertz, Martha Q. Lacy, Angela Dispenzieri, Steven R. Zeldenrust

HISTORY

> The term lardaceous change has … come more into use chiefly through the instrumentality of the Vienna School…. The term, lardaceous changes … has but very little to do with these tumours, and rather refers to things, upon which the old writers … who were better connoisseurs in bacon than our friends in Vienna, would hardly have bestowed such a name…. The appearance of such organs … are said to look like bacon, bears … a much greater resemblance to wax, and I have therefore now for a long time … made use of the term waxy change…. These structures … by the simple action of iodine … assume just as blue a colour as vegetable starch….[1]

Schleiden, a German botanist, first used the term *amyloid* in 1838 to describe a normal constituent of plants.[2–4] In 1858, Virchow, head of a pathology department in Berlin, gave a lecture entitled "Amyloid Degeneration" and described amyloid deposits that stained blue with iodine and sulfuric acid, similar to the chemical reaction markers of starch. Virchow concluded that the substance was composed of starch[5] and used the word *amyloid* to describe it.[6] During the lecture, Virchow also criticized his chief competitor in Vienna, Rokitansky, who believed that amyloid was a lardlike substance—perhaps because amyloid deposits were white and glistening—found in patients with syphilis, tuberculosis, or malaria.[7] In 1859, Friedreich, Nikolau, and Kekule recognized that the waxy spleen described by Virchow did not contain any starchlike substances and that the deposits probably were derived from modified proteins.[8] Kekule was famous in his own right at the time for describing the structure of benzene from his dream of a serpent biting its own tail. In addition, Friedreich gave the first description of a form of ataxia that now bears his name.[9,10]

Budd analyzed the liver of a patient with amyloidosis and found that it was not lardaceous[11]; he also wrote original descriptions of rickets and scurvy.[12] Probably the first reported case of primary amyloidosis (AL; described as "idiopathic" at the time) was identified by Wilks, who detailed a 52-year-old patient with lardaceous change unrelated to an obvious cause.[13–15] Wilks was the first physician to use bromide in the treatment of epilepsy and wrote an original description of myasthenia gravis.

The amino acid composition of amyloid deposits was first described by Schmiedeberg in 1920.[16] Amyloid proteins strongly resembled serum globulin and therefore were neither fat nor carbohydrate. The first use of Congo red as the specific stain for detection of amyloid was reported in 1922 by Bennhold.[17] In 1927, Divry and Florkin[18] reported green birefringence under polarized light when amyloid-laden material from the brain of a patient with Alzheimer disease was stained with Congo red. However, the association between the neurodegeneration of Alzheimer disease and amyloid was forgotten for nearly 50 years. Magnus-Levy[19] postulated that Bence Jones proteins were a precursor of the amyloid substance and noted a relationship among amyloid deposits, Bence Jones proteins, and multiple myeloma.

The finding that amyloid proteins consisted of fibrils was credited to Cohen and Calkins in 1959.[5] They determined that all forms of amyloid were nonbranching and fibrillar. The fibril length varied, but the width was 9.5 nm. Apitz[20] claimed that amyloid in the tissues was analogous to the excretion of immunoglobulin (Ig) light-chain proteins by the kidneys; he coined the term *paraprotein* to describe monoclonal immunoglobulins. Isobe and Osserman[21] reported in 1974 that Bence Jones proteins had a direct role in the pathogenesis of AL. Physiologically normal proteins primarily have an α-helix configuration. In 1968, Eanes and Glenner[22] reported that they used x-ray diffraction to determine that amyloid proteins formed an alternate configuration of β-pleated sheets, similar to the configuration of silk proteins.[23]

As with silk, amyloid proteins are highly resistant to solvents, and this resistance is a feature of the purification process. Amyloid-laden tissue is homogenized repeatedly in saline and centrifuged. The supernatant, which contains soluble components, is discarded, and the residual pelletized material contains amyloid proteins. After the pellet is resuspended in distilled water, a relatively pure preparation of amyloid fibrils is obtained. Pras et al.[24] first described the purification of amyloid in 1968. Levin et al.[25] were the first to sequence amyloid protein, and they designated it as *amyloid A*. Benditt et al.[26,27] independently sequenced amyloid A at the same time. The first sequence of an immunoglobulin light-chain form of amyloid was reported in 1970 by Glenner et al.[28] and was recognized as an N-terminal fragment of the immunoglobulin light chain.[28,29,30,31,32]

CLASSIFICATION

The diagnosis of amyloidosis requires biopsy tissue specimens with deposits that are positively stained by Congo red.[33] With hematoxylin and eosin staining, amyloid deposits resemble hyalin. Deposits are always extracellular and appear amorphous. Apple-green birefringence is seen when Congo-red–stained material is viewed under polarized light.[34] The Congo red stain can be technically difficult to use and can form precipitates, yielding false-positive results.[35] Pathologists need to perform diagnostic assays regularly to be experts in the interpretation of stains. All forms of amyloid have a fibrillar appearance when viewed with electron microscopy, and the fibrils are rigid and nonbranching. However, not all fibrils identified with electron microscopy are amyloid proteins.[36–38] Such findings are strongly suggestive of amyloidosis, but in the absence of a positive result on Congo red stain and apple-green birefringence, the diagnosis remains unconfirmed.

Studies of recombinant-derived variable region fragments of immunoglobulins have shown a relationship between thermodynamic instability and fibrillogenic potential. Structural parameters and overall thermodynamic stability contribute to the fibril-forming propensity.[39] Human monoclonal immunoglobulin light chains can be converted to amyloid fibrils in vitro by digestion with pepsin.[30] Synthetically, amyloid fibrils can be produced by breaking the disulfide bonds of intact immunoglobulins. In the past, all forms of amyloid were thought to be derived from misfolded fragments of immunoglobulin light chains, but heavy-chain fragments have also been shown to produce amyloid (designated as *AH*).[40]

The classification scheme of amyloidosis has undergone revision as understanding of the pathophysiology of the disease has improved. In the 19th century, involvement of the liver, spleen, and kidneys was incorrectly thought to represent secondary amyloidosis (AA); amyloid that involved the heart, tongue, and peripheral nerves was classified as *AL* or *idiopathic amyloidosis*. Later, amyloidosis was classified by the site of first deposition and was referred to as *pericollagenous* or *perireticular amyloidosis*.[41,42] Familial amyloidosis (AF) was recognized generally by the

presentation of progressive painful peripheral neuropathy with an autosomal dominant inheritance pattern.[43,44] Families with inherited renal amyloidosis were also described.[45,46] Mutations in transthyretin (TTR), apolipoprotein A1, fibrinogen A-α chain, lysozyme, leukocyte chemotactic factor 2 (LECT2),[47] and apolipoprotein A2 are associated with hereditary amyloidosis. TTR amyloidosis is the most common form of AF, and it is associated with peripheral neuropathy.[48]

In the 19th century, when tuberculosis, leprosy, syphilis, and chronic infections were prevalent, patients with these infections often had concomitant AA. However, in the postantibiotic era, chronic inflammatory polyarthritis (e.g., ankylosing spondylitis, juvenile rheumatoid arthritis) is more commonly associated with AA. Crohn disease and chronic osteomyelitis have also been associated with a small number of AA patients in the Western hemisphere.[49] Hereditary periodic fever syndromes, such as familial Mediterranean fever (FMF; the most common entity of this disorder), hyperimmunoglobulinemia-D syndrome, and tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS), are characterized by recurrent fever and inflammation, and reactive amyloidosis is a complication of these hereditary periodic fevers. The causative genes of these syndromes have been identified. Anticytokine-based therapies are a new treatment option for these inflammatory conditions, and they potentially may prevent amyloidosis.[50] Etanercept, adalimumab, and infliximab have all been reported to be effective for patients with AA.

One hundred years ago, the term *primary amyloidosis* referred to idiopathic amyloidosis and included all cases that were neither familial nor secondary; cases of unrecognized AF and AA for which a cause could not be established were mistakenly classified as AL. Currently, AL refers only to systemic or localized amyloidosis that is immunoglobulin light chain derived. A clonal plasma cell disorder exists for all patients with systemic AL, and the disease spectrum ranges from a barely detectable plasma cell clone to overt multiple myeloma.[51] A classification of the various forms of amyloidosis is shown in Table 99.1.

In AL, the tertiary structure and amino acid sequence of immunoglobulin light chains are abnormal.[52,53] For patients with AL, three fourths of immunoglobulin light chains are of the λ type. In contrast, for patients with multiple myeloma and monoclonal gammopathy of undetermined significance, two thirds of the light chains are of the κ type (Fig. 99.1).[49] The implication is that λ immunoglobulin light chains have a greater tendency to form a β-pleated sheet. AL-associated immunoglobulins generally tend to have more β-pleated sheet proteins than α-helical proteins.

Certain immunoglobulins have "amyloidogenic" properties. No renal dysfunction is seen after mice are injected with purified immunoglobulin light chains derived from the urine of patients with multiple myeloma who do not have amyloidosis.[54] However, deposits of human AL develop in the kidneys of mice after injection of light chains purified from the urine of patients with AL.

Amyloid-associated germline gene usage has been determined.[55] The λ6 subgroup of immunoglobulin light chains is always associated with amyloid proteins, which suggests that unique amino acid sequences may result in formation of amyloidogenic proteins.[56] The λ3 family appears most frequently in amyloidosis and polyclonal states. Two germline genes that belong to the λ3 and λ6 families encode 42% of λ variable regions. The gene segment *3r* accounts for 22% of λ variable regions and is newly associated with the disease; gene segment *6a* accounts for 20%. These gene segments have a strong association with amyloidosis; they are represented in less than 11% of polyclonal conditions (Table 99.2). Overuse of *3r* and *6a* likely accounts for the λ light-chain overrepresentation that is typical of amyloidosis. Germline gene usage may also influence the organ tropism of AL.[57] Patients with clones derived from the *6a* germline gene are more likely to present with dominant renal involvement. Those with clones from *1c*, *2a2*, and *3r* are more likely to present with cardiac and multiorgan disease.[58]

The distinction between AL and amyloidosis associated with multiple myeloma is somewhat arbitrary (considerable overlap exists between them). However, a patient with amyloidosis and symptomatic multiple myeloma (e.g., widespread lytic bone disease, rib fractures, and lumbar spine compression fractures) is uncommon.[59] Renal insufficiency in amyloidosis is almost never a consequence of the formation of light-chain cast nephropathy, as is the case in multiple myeloma. For patients with amyloidosis, renal failure is attributable to tubular atrophy, a

TABLE 99.1

NOMENCLATURE OF AMYLOIDOSIS

Protein	Precursor	Clinical
AL or AH	Immunoglobulin (light or heavy chain)	Primary or localized amyloidosis; associated with myeloma or macroglobulinemia
AA	SAA	Secondary or familial Mediterranean fever; familial periodic fever syndromes associated with mutated tumor necrosis factor receptor
ATTR (form of AF)	Transthyretin	Familial and senile amyloidosis
Fibrinogen A-α chain (form of AF)	Fibrinogen	Familial renal amyloidosis (Ostertag amyloidosis)
Aβ_2M	β_2-Microglobulin	Dialysis-associated carpal tunnel syndrome
Aβ	AβPP	Alzheimer disease
Apo1, Apo2 (form of AF)	Apolipoprotein	Renal, nephrotic syndrome
Lysozyme (form of AF)	Lysozyme	Renal, hepatic rupture
LECT2 (form of AF)	Leucocyte chemotactic factor 2	Renal autosomal dominant inheritance

AA, secondary amyloid; Aβ, amyloid β; Aβ_2M, amyloid β_2-microglobulin; AβPP, amyloid β protein precursor; AF, inherited amyloid proteins; AH, immunoglobulin heavy-chain amyloid; AL, primary amyloid; Apo1, apolipoprotein A1 amyloid; Apo2, apolipoprotein A2 amyloid; ATTR, amyloid transthyretin; LECT, leucocyte chemotactic factor; SAA, serum amyloid A.

consequence of long-term albuminuria.[60,61] Often, the distinction between multiple myeloma–associated amyloidosis and AL is made on the basis of the percentage of plasma cells in the bone marrow.[62] For patients with AL, serial bone marrow biopsies performed over several years do not show a progressive increase in the plasma cell percentage. In amyloidosis, the process is clonal but typically is not proliferative, and the unrestrained growth associated with malignancy is absent. If it is not present at diagnosis, multiple myeloma does not develop subsequently in patients with AL who present with 10% to 30% bone marrow plasma cells; multiple myeloma develops in fewer than 0.5% of patients with amyloidosis.[51] We have established an arbitrary threshold of 30% plasma cells to fulfill the criteria of multiple myeloma–associated amyloidosis if no other clinical features of multiple myeloma are present. For patients who have greater than 30% plasma cells in the bone marrow, the clinical course is dominated by AL and not by myeloma bone disease or myeloma-induced anemia.

The incidence of AL is eight per million per year and has been stable for more than 50 years.[63] Multiple myeloma is five times more prevalent than amyloidosis.[64] Amyloidosis is uncommon; its incidence is similar to that of Hodgkin lymphoma (nodular sclerosing variant), chronic granulocytic leukemia (Philadelphia-chromosome–positive), and polycythemia rubra vera.[65–67] Bone marrow plasma cells from AL patients typically show chromosomal abnormalities.[68] Trisomies of chromosomes 7, 9, 11, 15, and 18 are seen in 42%, 52%, 47%, 39%, and 33% of patients with amyloidosis, respectively. Fifty-four percent of male patients and 13% of female patients have trisomy X, and 72% have deletions in chromosome 18. The finding of aneuploidy in monoclonal plasma cells is indicative of their neoplastic nature, despite the fact that these plasma cells are nonproliferative and are present in small numbers (median, 5% plasma cells).[69] An early pathogenetic event in the development of multiple myeloma is translocation at the immunoglobulin heavy-chain locus (band 14q32).[70,71] A total of 16 of 29 patients with AL (55%) showed translocations at the immunoglobulin heavy-chain locus. An additional 17% showed a pattern compatible with a possible IgH translocation.[72] Overall, an IgH translocation was seen in 21 of 29 patients by using fluorescent in situ hybridization analysis. Of the 21 patients, 16 had t(11;14)(q13;q32) translocations. For 15 of the 16 patients, cyclin D1 overexpression accounted for 76% of all IgH translocations.

SYMPTOMS AND SIGNS

Weight loss, paresthesia, edema, dyspnea, and fatigue are the most common symptoms of AL (Fig. 99.2).[73] These nonspecific complaints provide little help to a clinician evaluating patients. Patients with extreme weight loss frequently undergo evaluation for an occult malignancy. The fatigue, usually caused by early cardiac involvement with AL, generally is not associated with overt congestive heart failure and easily may be diagnosed incorrectly as stress-related or functional fatigue.[74] We have seen many patients undergo coronary angiography because of fatigue and breathlessness, only to have the evaluation end when angiogram findings are normal.[75]

Light-headedness occurs frequently in amyloidosis, but this is a common and nonspecific complaint in the primary care setting. In AL, the cause of light-headedness is multifaceted.[76] Patients with nephrotic syndrome have dizziness because of hypoalbuminemia and marked intravascular volume contraction, which leads to orthostatic hypotension.[77] Patients with cardiac AL have a low end-diastolic volume (because of restriction to filling during diastole)[78] and low cardiac output, but a normal ejection fraction is maintained until late in the course of the disease. The echocardiographic finding of a normal ejection fraction may be highly misleading and may hinder recognition of cardiac involvement in AL. Patients may have orthostatic hypotension as a consequence of autonomic neuropathy. Syncope is not unusual.[79,80]

The physical findings of amyloidosis are specific and diagnostic; however, they are present in only 15% of patients and may easily be overlooked. Amyloid purpura is seen in only one of every six patients with AL (Fig. 99.3).[81] Purpura may be periorbital but also may occur in the face, webbing of the neck, and upper chest. Purpura on the arms is not characteristic of AL, but petechial lesions on the eyelids should not be overlooked. The liver is palpable 5 cm below the right costal margin in only 10% of patients. Splenomegaly, if present, is usually of modest degree. Overall, any degree of hepatomegaly is present in one fifth of patients.[82]

Macroglossia is the most specific finding of AL (Fig. 99.4). In our experience, enlargement of the tongue is never found in AF, AA, or senile systemic amyloidosis.[83] Tongue enlargement is seen in 1 of 11 patients with AL and may be overlooked easily unless the physician knows to look for dental indentations on the underside of the tongue. However, presentation with fatigue, edema, breathlessness, or paresthesias would not immediately lead the physician to examine the patient's tongue. Tongue enlargement is almost always accompanied by concomitant enlargement of the submandibular salivary glands,[84] but salivary gland involvement should not be

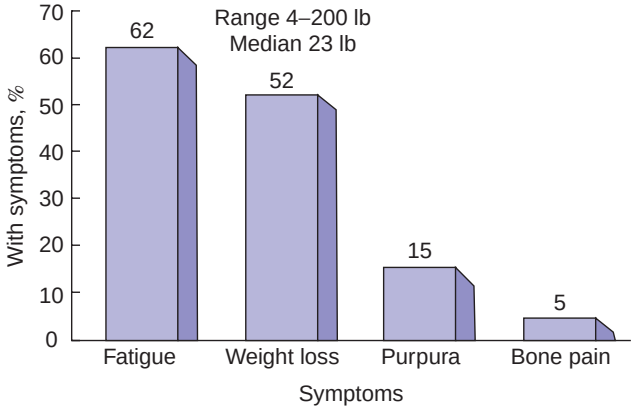

FIGURE 99.2. Prevalence of symptoms for patients with primary amyloidosis evaluated 1 month before or after diagnosis at Mayo Clinic, 1981–1992. (From Kyle RA, Gertz MA. Primary systemic amyloidosis. Clinical and laboratory features in 474 cases. Semin Hematol 1995;32:45–59. Used with permission.)

FIGURE 99.3. Classic truncal purpura in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211–1233. Used with permission.)

misinterpreted as submandibular lymphadenopathy. Major and minor salivary gland involvement may result in sicca syndrome.[85]

Vascular involvement without visceral organ dysfunction produces occlusion and ischemic symptoms, such as jaw claudication, when the temporal arteries are involved[86]; calf and limb claudication may occur when the microvasculature that supplies the extremities is involved.[87] Monoclonal protein in the serum may increase the sedimentation rate, and it is not unusual for amyloidosis and jaw claudication to be misdiagnosed as polymyalgia rheumatica.[88] Amyloid deposits may be found if a temporal artery biopsy is performed, but Congo red staining typically is not performed on such specimens.[87,89] The shoulder-pad sign is a consequence of periarticular infiltration with amyloid and may produce pseudohypertrophy. Although the musculature of the shoulder and hip girdle is enlarged, patients present with diffuse muscular weakness[90,91] and may have muscular atrophy because of chronic vascular occlusion.

DIAGNOSIS OF AMYLOIDOSIS

When should a clinician initiate a diagnostic algorithm to confirm the presence of AL? The symptoms and physical findings of AL generally are nonspecific and unhelpful to the clinician. Nevertheless,

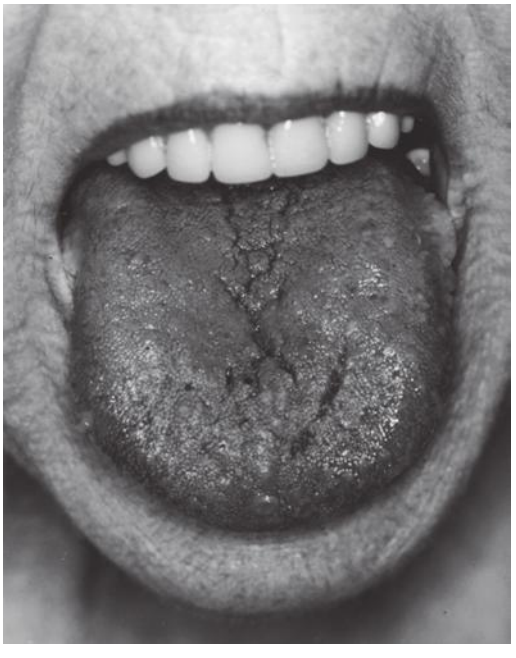

FIGURE 99.4. Tongue enlargement in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211–1233. Used with permission.)

TABLE 99.3

Carpal tunnel syndrome	21
Neuropathy	17
Orthostatic hypotension	12

eight critical clinical syndromes commonly associated with amyloidosis should trigger screening: (1) gastrointestinal tract symptoms of pseudo-obstruction or steatorrhea, (2) tongue enlargement, (3) carpal tunnel syndrome, (4) hepatomegaly, (5) peripheral neuropathy, (6) nephrotic-range proteinuria, (7) infiltrative cardiomyopathy with restrictive hemodynamics, and (8) atypical multiple myeloma. The diagnosis of AL must be considered when any one of these syndromes is seen (Table 99.3). AL also must be considered for any patient for whom the diagnosis of multiple myeloma is being considered and who has associated, unexplained weight loss or fatigue or a percentage of plasma cells in the bone marrow that does not meet the criteria for multiple myeloma.

A clonal population of plasma cells is observed in AL patients, even when the marrow percentage is less than 2%.[92] The insoluble, fibrillar β-pleated sheets of amyloid proteins are derived from the monoclonal immunoglobulin light chains produced by a clonal population of plasma cells. For any patient with a compatible clinical syndrome that includes monoclonal gammopathy, tests to confirm the diagnosis of AL should be pursued aggressively. Important screening tests for a patient with cardiomyopathy, neuropathy, hepatomegaly, or proteinuria are immunofixation of the serum and of the urine[93] and immunoglobulin free light-chain measurement.[94] The urine must be evaluated because serum assays may fail to detect monoclonal light chains (Fig. 99.5). Serum electrophoresis tests are inadequate because the light chains in AL are frequently present only in trace amounts and they do not produce a spike on an electrophoretic pattern. Monoclonal protein in the urine frequently is difficult to detect because most patients have proteinuria to the extent that small amounts of light chains are obscured (Fig. 99.6). If amyloidosis is being considered in the differential diagnosis, immunofixation of serum or urine (or both) is essential. The immunoglobulin free light-chain assay is tenfold more sensitive than serum immunofixation for the detection of serum light chains.[95] If all three tests are negative, systemic AL is not present.

For patients with a suggestive clinical syndrome, immunofixation is a good noninvasive screening test. For patients with light-chain levels in the serum or urine that are below the threshold of detection by immunofixation,[96] the bone marrow often shows a clonal population of plasma cells when examined by flow cytometry, immunofluorescence, or immunohistochemistry.[97,98] Such patients frequently have abnormal κ-to-λ ratios of free light chains. In patients with confirmed AL who did not have detectable levels of monoclonal protein in the serum or urine, 94% had a clonal population of plasma cells in the bone marrow when a slide-based immunofluorescence test was used to detect expression of clonal cytoplasmic immunoglobulin. If the patient does not have monoclonal protein in the serum or urine, has a normal free light-chain ratio, and has no detection of clonal population of plasma cells in the bone marrow, the diagnosis of systemic AL is very unlikely. If amyloidosis is present, it likely is not immunoglobulin light-chain derived, and further evaluation for familial, secondary, or localized amyloidosis should be performed.

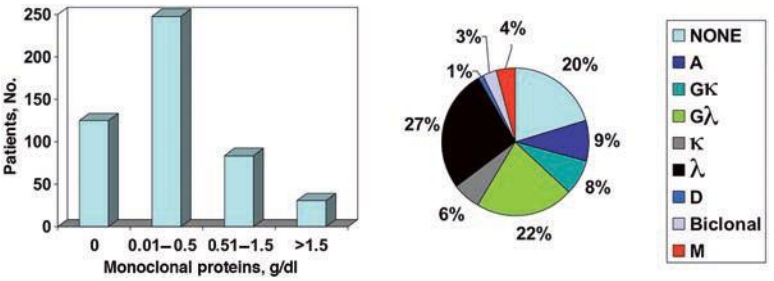

FIGURE 99.5. Serum monoclonal protein levels from patients with primary amyloidosis ($N = 488$). Inset, immunofixation results.

Our ability to recognize AL has been improved by the nephelometric assay for free light chains in the serum; the assay detects free immunoglobulin light chains that are not associated with an intact immunoglobulin molecule.[99,100] For 100 consecutive AL patients tested with the nephelometric assay, the assay sensitivity was 90% for patients with confirmed AL-κ, and similar sensitivity was noted for patients with confirmed AL-λ. For patients with detectable urinary light chains (but no detectable monoclonal protein in the serum with immunofixation assays), the nephelometric light-chain assay detected free light chains in the serum of 85% of patients with AL-κ and 80% of patients with AL-λ. For patients with AL who had no monoclonal protein detected in the serum or urine with immunofixation assays, the nephelometric light-chain assay identified free κ light chains for 86% of patients with AL-κ and free λ light chains for 30% of patients with AL-λ. The free light-chain serum assay is convenient and adds an important diagnostic tool for classifying and monitoring AL patients.

All forms of amyloid deposits contain the amyloid P component, a pentagonal glycoprotein that may represent as much as 10% of the amyloid fibril by weight. It is structurally similar to C-reactive protein and has been identified in all vertebrates. However, it does not function as an acute-phase reactant in humans because the concentration in plasma is relatively stable.[101] Amyloid P component maintains a dynamic circulating equilibrium between the serum and amyloid deposits. Because serum amyloid P (SAP) exchanges readily with the amyloid P component of amyloid fibrils, binding and release of SAP from amyloid deposits may be observed with an ^{123}I-labeled SAP scan.[102,103] In addition, the clearance rate of radiolabeled P components (^{125}I-labeled SAP) from the plasma may be used to assess the total-body burden of amyloid and to evaluate the effect of therapy.[104] Patients with large burdens of amyloid have rapid clearance, which is associated with shorter survival, but those with trace amounts of systemic amyloid deposits have plasma clearance rates similar to those of healthy individuals. Healthy adults have 50 to 100 mg of amyloid P component in the extravascular and intravascular compartments, whereas patients with amyloidosis may have up to 20,000 mg. Antibodies to P component have been used as therapy against amyloidosis.[105]

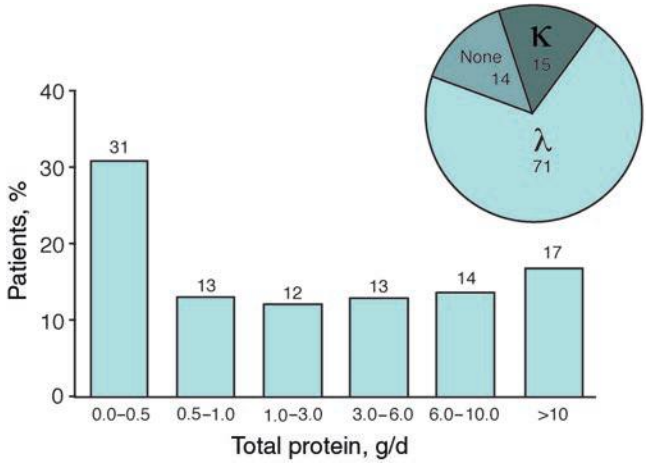

FIGURE 99.6. Total protein excreted in the urine of patients with primary amyloidosis (24-hour period). Inset, identification of immunoglobulin light chains, %. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002:445–463. Used with permission.)

The P component scan may be performed serially to determine whether patients have increasing rates of amyloid deposition. However, the technique does not determine whether the amyloidosis is AL, AF, AA, or localized. Cardiac amyloid deposits are not detected through the use of SAP scans,[106] but uptake of ^{123}I-labeled amyloid P component is seen in the spleen, liver, and kidneys in 87%, 60%, and 25% of patients, respectively. Imaging does not consistently show deposits in the carpal tunnel, kidneys, and gastrointestinal tract. The correlation is poor between imaging and the extent of organ dysfunction assessed clinically. The diagnostic sensitivity of SAP scintigraphy for systemic AA, AL, and amyloid TTR origin amyloidosis is 90%, 90%, and 48%, respectively; specificity is 93%. Splenic amyloid is observed in 80% of AL patients, even though it rarely is detected clinically. Bone marrow uptake is specific for AL in 21% of patients. More widespread organ involvement is identified with a scan than with a clinical examination.[107] Amyloid is distributed heterogeneously within individual organs. Presently iodine-labeled SAP scanning was not available in the United States.

The diagnosis of amyloidosis must always be confirmed by tissue biopsy.[108] For patients who have neuropathy, nephrotic syndrome, cardiac failure, or hepatomegaly, the diagnosis could be established by direct biopsy of the involved organs,[108] but an invasive visceral biopsy usually is not required to confirm AL. Because amyloid deposits typically are widespread at diagnosis and have involved the vasculature extensively,[109] biopsy procedures that are less invasive, lower risk, and lower cost may be used to establish the diagnosis.

For a patient with a syndrome consistent with AL and confirmed presence of monoclonal protein, we begin the diagnostic evaluation with a subcutaneous fat aspirate and bone marrow biopsy.[110] The subcutaneous fat aspirate is a 75%-sensitive, risk-free procedure that is performed by registered nurses.[111] Results are available within 24 hours (Fig. 99.7). Amyloid deposits are seen in half of the bone marrow biopsy specimens of patients with AL and generally are identified in blood vessels.[112] To exclude the diagnosis of multiple myeloma, a bone marrow biopsy is justified for any patient who has monoclonal immunoglobulin light chains. Knowledge of the percentage of bone marrow plasma cells is important prognostically.[113] Table 99.4 shows the findings of bone marrow biopsies and fat aspirations of patients with AL. With Congo red studies of fat and bone marrow, the diagnosis is established in 87% of patients. For the other 13%, the diagnosis may be established by a biopsy of the affected organ.

Less invasive biopsy procedures may be used to establish a diagnosis of AL. Xerostomia in amyloidosis is attributable to salivary gland infiltration, and lip biopsy findings have high sensitivity (up to 87%).[114,115] Subcutaneous blood vessels may be accessed through a skin biopsy and may show AL deposits.[116,117] Amyloid deposits regularly were confirmed by rectal biopsy in the

+, tissue positive for amyloid deposits; –, tissue negative for amyloid deposits.
Modified from Gertz MA, Lacy MQ, Lust JA, et al. Prospective randomized trial of melphalan and prednisone versus vincristine, carmustine, melphalan, cyclophosphamide, and prednisone in the treatment of primary systemic amyloidosis. J Clin Oncol 1999;17:262–267. Used with permission.

1970s and 1980s.[118] Rectal biopsy is an outpatient procedure, although occasionally it results in bleeding. Endoscopic biopsy specimens frequently are inadequate because submucosa is essential for specimen adequacy.

All patients who have nephrotic syndrome should undergo screening with immunofixation assays of serum and urine and free light-chain assays. Among 110 patients with AL, the sensitivity of the free light-chain assay was 92%, but in combination with serum and urine immunofixation assay findings, the sensitivity increased to 99.1%.[119] If either assay finding is positive, a fat aspiration is performed, which eliminates the need for a diagnostic renal biopsy for 70% of patients. The net result is reduced expense and reduced risk of bleeding and hospitalization.

Congo red may precipitate in tissue, and the resultant overstaining, particularly in subcutaneous fat, may produce a false-positive result.[120] Skin and subcutaneous fat have a high content of elastin and collagen; both bind Congo red and may also be interpreted as a false-positive result.[121] Rectal biopsy specimens containing amyloid may be misinterpreted as collagenous colitis if stained only with hematoxylin and eosin.[122] To recognize amyloid in the myocardium, our cardiac pathologists prefer to use sulfated Alcian blue stain.[123] The Peripheral Nerve Laboratory at Mayo Clinic stains sural nerve biopsy specimens with crystal violet during screening and confirms the diagnosis subsequently with Congo red.[124]

DIFFERENTIATING AMYLOIDOSIS FROM OTHER FORMS OF AMYLOIDOSIS

It is important that the diagnosis of amyloidosis be confirmed as AL, AF, or AA because therapy for the three syndromes differs.[125,126] Localized amyloidosis,[127] AF,[128] AA,[129] and senile systemic forms of amyloidosis[130] are not associated with a plasma cell dyscrasia. Except for the rare case of a patient who has one of these forms of amyloidosis and an incidental monoclonal gammopathy of undetermined significance, only AL patients have monoclonal light chains in the serum and urine or clonal plasma cells in the marrow. Patients with localized amyloidosis may present with hematuria,[131] respiratory difficulties,[132] and visual disturbances[133]; such symptoms may easily be confused with those of systemic amyloidosis. The localized amyloidosis syndrome, which usually involves the skin, tracheobronchial tree, or urogenital tract, never becomes systemic. The fibrils of localized amyloidosis may be immunoglobulin light-chain derived,[134] but clonal plasma cells are not seen in the bone marrow.

The site of amyloid deposition provides an important clue for recognizing localized amyloidosis. The most frequent sites of localized amyloid deposits are the respiratory tract, genitourinary tract, and skin.[126,135] Pulmonary amyloid may be subdivided into nodular, tracheobronchial, or diffuse interstitial deposits. Only the last type of deposit is a manifestation of systemic AL.[136] The diagnosis of tracheobronchial amyloidosis is made by bronchoscopy during evaluation of a patient with obstruction, cough, dyspnea, wheezing, or hemoptysis. The usual treatment is resection of the tissue with an yttrium–aluminum–garnet laser.[137] Tracheobronchial amyloid deposits are derived from immunoglobulin light chains.[138] Nodular amyloidosis presents as a solitary pulmonary nodule or multiple nodules, and the nodules do not indicate systemic AL.[139] Nodules are not calcified, and they often require resection to exclude a diagnosis of malignancy. The AL diagnosis is established during a thoracotomy or a video-assisted thoracoscopic surgical procedure. Amyloid can involve the vocal cords and false vocal cords and cause traction on the structures, leading to hoarseness. This form of laryngeal amyloidosis is always localized.[140]

Obstructive ureterovesicular amyloidosis is always localized. Patients present with hematuria and have a prebiopsy diagnosis of cancer. Amyloid deposits are found when cystoscopic biopsies are performed. Eighty-five percent of patients with this type of amyloidosis present with hematuria. Patients may undergo partial cystectomy, fulguration, or transurethral resection.[141] Dimethyl sulfoxide (DMSO) instillation in the bladder has been reported to reduce these deposits.[142] Colchicine has also been reported to be beneficial. Amyloid involving the renal pelvis or ureter is a localized amyloid syndrome.[143,144] These patients present with colic because of obstruction or hematuria, and deposits are found during surgery. Nephrectomy is commonly performed because the ureteral mass preoperatively is thought to represent a transitional cell malignancy, but the recognition of amyloidosis avoids nephrectomy. Patients may present with dysuria and hematuria when amyloidosis involves the urethra.[145] The preoperative diagnosis is usually a urethral malignancy. Resection is the treatment of choice.

Three forms of cutaneous amyloidosis are recognized. The lichen and macular forms are localized,[146] innocuous conditions that usually are associated with a history of local skin trauma or inflammation. Nodular amyloidosis is associated with AL,[147] and evidence of nodular deposits may be an important clinical clue to an underlying life-threatening process. Degraded keratin molecules are the source of macular and papular amyloid deposits.[148] Dermabrasion and other forms of local therapy adequately control cutaneous amyloidosis.

Carpal tunnel amyloidosis may be observed in systemic AL and AF, but it may also be localized.[149,150] For patients who present

with carpal tunnel syndrome as the only manifestation of amyloidosis, the median survival is 12 years. Virtually all patients with carpal tunnel amyloidosis have localized disease, and one study reported that only 2 of 124 patients with localized carpal tunnel amyloidosis had development of AL.[151] TTR is often found in localized carpal tunnel amyloid deposits.

Localized amyloidosis is seen in the conjunctiva and orbits. The best treatment is surgical excision. Amyloid has also been localized to breasts,[152] mesenteric lymph nodes, colonic polyps, thyroid,[153] retroperitoneum, and ovaries. Localized deposits of amyloid commonly are observed in trace amounts within the cartilage on the hip surface after a total hip arthroplasty.[154] Similarly, localized deposits are found in resected knee arthroplasty specimens. These deposits are not associated with systemic disease.[155]

AA is a consequence of poorly controlled, long-term systemic inflammation. From a simple syndrome standpoint, its presentation is similar to that of AL. AA is more common than AL in underdeveloped countries because of the persistence of tuberculosis,[61] syphilis, malaria, and leprosy, but in the United States, AA is not easily distinguished from AL. AA is not associated with a monoclonal protein or clonal marrow plasma cells. Patients with AA most commonly present with nephrotic-range proteinuria.[156] At Mayo Clinic, AA accounts for only 2% of all patients with amyloidosis.[157]

The underlying cause of AA most commonly includes ankylosing spondylitis,[158] juvenile rheumatoid arthritis,[159] psoriatic arthritis,[160] and rheumatoid arthritis[161]; for most patients with AA, the cause is clear because the arthritis is disabling and develops a median of 15 years before the development of AA.[162] Of patients with rheumatoid arthritis, AA develops in 3.1%.[163] With the introduction of anti-TNF therapies for inflammatory arthropathy, the prevalence of AA in industrialized nations continues to decrease as these disorders are better controlled. AA is also seen in patients with Crohn disease,[164] bronchiectasis[165] (including long-term survivors of cystic fibrosis), and chronic osteomyelitis.[166] These are conditions in which the infected tissue is not amenable to surgical excision and antibiotic therapy results in poor control. For most patients with AA and Crohn disease, the inflammatory bowel disorder has been present for decades. The first clinical manifestation is proteinuria. No monoclonal protein is detectable. AA has been described in individuals who subcutaneously inject contaminated illegal substances (i.e., "skin poppers").[167,168] Skin abscesses develop at the site of injection and cause the inflammation that is necessary for the development of AA. Patients with Hodgkin lymphoma[169,170] or hypernephroma[171,172] and paraplegic patients with chronic infected decubitus ulcers or chronic urinary tract infection[173,174] have been reported to have AA. Amyloid deposits are identified during autopsy for half of all patients who sustained a spinal cord injury 10 years or more before death.[175] AA from Castleman disease has been recognized. Surgical excision leads to remission.[176,177] AA has also been reported for patients with hyperimmunoglobulin D syndrome and periodic fever syndromes, so-called TRAPS.[178]

AF is more common than AA in the United States. Presentation of AF is clinically indistinguishable from AL; patients may have cardiomyopathy,[179,180] neuropathy,[181] and nephrotic syndrome.[182] The most common form of AF is attributable to *TTR* mutations. More than 100 different mutations in the *TTR* gene have been involved in amyloid neuropathy.[183] Nearly half of the patients with AF seen at Mayo Clinic do not have a family history of the disease, but absence of a family history is a poor screening method to exclude AF.[184] The most common TTR mutation seen at Mayo Clinic is Thr60Ala, caused by a nucleotide substitution in *TTR* DNA of 238A>G. Amyloid neuropathy without monoclonal protein or clonal plasma cell disorder should raise clinical suspicion of AF. Cardiac amyloid deposition may occur with mutated and wild-type *TTR* genes.[185] Cardiac amyloid deposits[186] that consist of normal TTR proteins occur in 8% to 25% of people older than 80 years. In this form of senile systemic amyloidosis, only cardiac symptoms are seen.

AF involving only the heart (without peripheral neuropathy) was first described in a Danish kindred.[187] Since then, AF cardiomyopathy has been described throughout the world. The US patients in AF pedigrees usually have symptoms after age 60 years. Patients with cardiomyopathy from AF present with heart failure or arrhythmias, and the clinical picture is virtually indistinguishable from that of senile cardiac amyloidosis or AL. Twenty-one percent of patients older than 90 years (the general patient population) have senile systemic amyloidosis from deposition of wild-type TTR.[188] The Val122Ile mutation of *TTR* is a major cause of inherited cardiac amyloidosis for African Americans. The first report of the mutation described an African American man aged 68 years.[189] The *TTR* Val122Ile allele is carried by 3.9% of African Americans, which translates to 1.3 million people in the United States.[190] Therefore, a finding of cardiac amyloidosis without monoclonal gammopathy could represent AF-based cardiomyopathy (even without a family history), and clinicians should not assume that the patient is affected by AL.[191]

Mutations in the fibrinogen,[192] lysozyme,[193] or apolipoprotein A1 and A2[194–196] and LECT2 proteins may produce inherited forms of renal amyloidosis. The amyloidosis associated with these mutations has a much better prognosis than that of renal AL. We have regularly seen patients who have proteinuria for more than a decade without renal failure. Because these patients present with proteinuria and the renal biopsy specimen shows amyloid deposits, their condition is easily confused with AL. The absence of a monoclonal immunoglobulin disorder or the absence of free light chains in the serum is an important distinguishing feature. However, only immunohistochemical staining or sequencing of the amyloid can differentiate these entities definitively. Of 285 renal amyloid samples, 31 were unclassified and subsequently 7 were found to be LECT2 related by tandem mass spectrometry.[197] Isolation of genomic DNA and polymerase chain reaction amplification of LECT2-encoding exons showed no mutations. However, all were homozygous for the G allele encoding valine at position 40 in the mature protein. LECT2-associated renal amyloidosis represents a unique form of renal amyloidosis, especially in Mexican Americans, and has only recently been recognized.

The treatment of TTR-derived AF includes liver transplantation, which makes the distinction between AF and AL critical for treatment decisions.[198] TTR is produced in the choroid plexus and the liver. Regression of amyloid deposits has been reported[199] when liver transplantation is performed before the development of disabling peripheral neuropathy, autonomic neuropathy, or advanced cardiomyopathy. Patients with the Val30Met mutation in the *TTR* gene appear to have the best outcome after liver transplantation.[200] Progressive cardiac amyloidosis has been reported after liver transplantation for patients with other *TTR* mutations.[201] After mutant TTR is deposited in the myocardium, it may serve as a nidus for further deposition of native TTR produced by the transplanted liver. Autopsy findings show cardiac amyloid fibrils with mutant and wild-type TTR.[202,203] AF may be initially diagnosed as AL unless the patient has a clear family history of AF. When the referral diagnosis was AL, 34 of 350 patients (9.7%) were reported to have AF.[204] The most common mutation in AF was identified in the gene encoding the fibrinogen A-α chain, and the second-most common mutation occurred in the gene encoding TTR. A low-grade monoclonal gammopathy was detectable in eight patients. All patients who have clinical syndromes consistent with AF should be screened for a genetic cause when AL cannot be confirmed unequivocally.[204] Of 178 consecutive patients referred for amyloidosis, 54 underwent screening with polymerase chain reaction assays to detect AF variants.[205] Three patients had monoclonal gammopathy and a hereditary variant; this finding justified routine screening of patients with apparent AL for hereditary variants and showed the necessity of

immunohistochemical or mass spectroscopic confirmation of the type of amyloid protein subunit.

Screens for mutant forms of TTR may be performed using immunoaffinity chromatography and immunoprecipitation; both are convenient methods for assessing circulating TTR in serum.[206] In addition, TTR variants may be examined using immunoprecipitated serum proteins and matrix-assisted laser desorption ionization mass spectrometry.[207]

The gold standard for protein identification is mass spectroscopic analysis of the tissue and direct sequencing to identify the amyloid protein, and this evaluation is now standard for all pathologic specimens that test Congo red positive seen at Mayo.[208,209] The procedure can be performed on subcutaneous fat. The distinction between immunoglobulin and nonimmunoglobulin amyloidosis is important because nonimmunoglobulin amyloidosis does not benefit from chemotherapy.

In summary, any patient with amyloidosis who does not have a detectable monoclonal light chain in the serum or urine and does not have a clonal population of plasma cells in the bone marrow should be considered for AA, AF, or localized amyloidosis. Laser capture microdissection mass spectroscopic analysis is the most direct method to identify the protein subunit comprising the amyloid and is recommended for all positive tissue biopsies.

PRESENTATION AND CLINICAL FEATURES

We reviewed records of all patients who received a diagnosis of AL over a 10-year period at Mayo Clinic. All patients received the diagnosis within 30 days of presentation at our institution. All had a clonal plasma cell disorder and histologic proof of amyloid deposits. Patients with overt multiple myeloma were excluded. The male preponderance of AL (67.3%) has been constant at our institution for 40 years, and we believe this finding reflects a true higher prevalence of the disorder in men. Multiple myeloma also is more common in men, but the male-to-female ratio is 52:48. Although we have seen patients with amyloidosis who were as young as 27 years, the median age of patients with amyloidosis was 67 years (range, 39 to 89 years). The median age of patients who present with AL in Olmsted County, Minnesota, is 73 years[63]; this age difference suggests that a referral bias to amyloidosis treatment centers may exist.

Echocardiographic examinations have dramatically increased the ability to recognize cardiac amyloid deposits.[210,211] Cardiac amyloidosis was seen in 37.4% of patients with AL at Mayo Clinic. Congestive heart failure was present in only half of these patients; for the other half, the presenting symptoms of cardiac amyloidosis were fatigue and dyspnea. These patients had poor cardiac filling and low cardiac output, but the ejection fraction was preserved. Syncope and arrhythmias also occurred.

Renal amyloid deposits were seen in 30% of patients with AL; kidneys were the second-most common organ affected by AL.[212] Nephrotic-range proteinuria was observed for 95% of patients with renal AL; the other 5% had amyloid deposits in the interstitium and mesangium of the kidney but not the glomeruli, so proteinuria was not present. Sensorimotor symmetrical ascending peripheral neuropathy was present in 15.3% of AL patients.[24] Palpable hepatomegaly was observed in 17.7% of AL patients, but a dominant hepatic syndrome was seen in only 4.6%. Gastrointestinal tract amyloidosis occurred for 7.1% of patients with AL, and they presented with intestinal bleeding, pseudo-obstruction, or diarrhea. The other 7.8% of patients had amyloid deposits that were identified in only the tongue, lung, joints, or soft tissues.

At Mayo Clinic, 29.9% of AL patients had two or more organs affected, 6% had three affected organs, and 0.5% had four or more affected organs.[213] When multiple organs were involved, the liver was most likely to be affected. Clinically significant bleeding (excluding purpura) occurred for only 2.3% of our patients.[214,215] Congestive heart failure was observed for 22% of patients, and carpal tunnel syndrome was observed for 21% of patients.[212] Edema was noted for 44.8% and fatigue for 46.4%. Lower-extremity paresthesias, nephrotic-range proteinuria, orthostatic hypotension, and weight loss were observed for 34.9%, 21.0%, 12.5%, and 51.7% of patients, respectively. The median survival of our entire cohort was 12 months, and the 2- and 5-year survival rates were 33.6% and 14.9%, respectively.

Amyloidosis is rarely associated with anemia.[216] The hemoglobin level was greater than 100 g/L for 90% of patients and greater than 120 g/L for 64.4%. Only 1.5% had hemoglobin levels less than 90 g/L, and the cause was usually active gastrointestinal tract bleeding or renal failure. The median platelet count of patients with AL was 257×10^9/L (range, 46×10^9/L to 809×10^9/L). A platelet count greater than 500×10^9/L was seen for 5.5% of patients. The most common cause of thrombocytosis in AL is hepatic involvement with associated hyposplenism.[217,218] A serum creatinine value of 2 mg/dl or greater was present for 13.6% of patients, and 6.7% had alkaline phosphatase levels greater than twice the maximum normal value. The number of patients with elevated alkaline phosphatase levels was close to the number of patients with clinical hepatic amyloid involvement.

The median bone marrow plasma cell percentage of patients with AL is 7% (range, 1% to 30%; Fig. 99.8).[212] In 11.3% of patients with AL, greater than 20% of plasma cells were found in the bone marrow, but no other clinical evidence of multiple myeloma was observed. Proteinuria is exceedingly common in AL, and the median urine protein loss is 790 mg per 24 hours (Fig. 99.6).[219] Monoclonal λ and κ light chains (in the serum and urine) were found in 70.1% and 18.9% of patients, respectively, and 11% had no detectable light chains. For patients with intact monoclonal γ globulins, the serum heavy chain was IgG, IgA, and IgM for 58%, 10%, and 8.2% of patients, respectively. The presence of an IgM monoclonal protein in 8.2% is important because we have seen many referred patients with a diagnosis of Waldenström macroglobulinemia, for whom the amyloid syndrome was overlooked.[220] Amyloid arthropathy occasionally occurs in amyloidosis. Synovial membrane biopsy may establish the diagnosis, and chemotherapy may effectively alleviate the joint manifestations.[221]

Heart

The heart is the organ that determines the patient outcome, and it is the organ most frequently involved in AL.[222–224] Amyloid is deposited extracellularly and results in a noncompliant and thickened left ventricle (Fig. 99.9).[225,226] The clinical presentation is infiltrative cardiomyopathy with restricted diastolic ventricular filling. Many patients with cardiac AL present only with fatigue and unexplained weight loss. Early cardiac AL produces diastolic dysfunction without systolic dysfunction,[227,228] and chest radiographs do not show evidence of pulmonary vascular

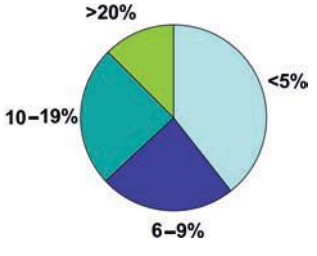

FIGURE 99.8. Distribution of bone marrow plasma cells of patients with primary amyloidosis (*N* = 486).

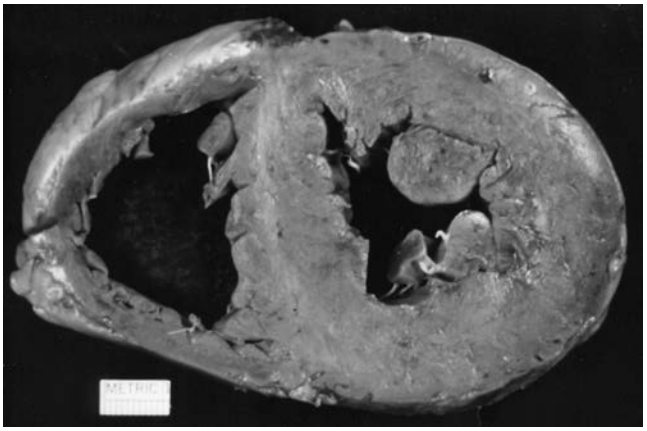

FIGURE 99.9. Myocardial wall diffusely thickened with amyloid. The whitish deposits represent the amyloid and are the lardaceous changes first recognized by Rokitansky. (From Gertz MA, Kyle RA. Amyloidosis [AL]. In: Wiernik PH, Goldman JM, Dutcher JP, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003. Used with permission.)

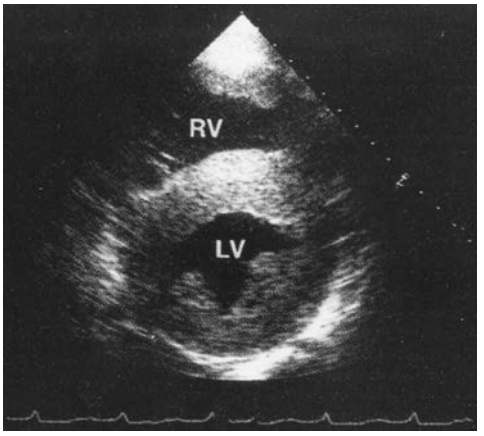

FIGURE 99.10. Echocardiographic image of concentric thickening of the wall of the left ventricle (LV) due to amyloid. RV, right ventricle. (From Gertz MA, Kyle RA. Amyloidosis [AL]. In: Wiernik PH, Goldman JM, Dutcher JP, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003. Used with permission.)

congestion or cardiomegaly. Moreover, the ejection fraction is preserved because amyloid deposition is an infiltrative process with diastolic dysfunction only.[229] Indeed, because of a low stroke volume, a hyperdynamic myocardium may develop with an elevated ejection fraction. This constellation of findings is frequently misinterpreted, and the presence of amyloid may be overlooked completely. An echocardiographic examination usually shows that contractility is normal, but because of poor diastolic filling, the end-diastolic volume is reduced and cardiac output is low. The electrocardiogram shows low voltage, but this also may be easily overlooked.[230] The pseudoinfarction pattern of amyloidosis, with nearly two thirds of patients showing loss of anterior forces in V_1 through V_3,[230] may be misinterpreted as ischemic heart disease. Electrocardiographic findings are clinically suspicious of silent ischemic disease, and patients invariably undergo coronary arteriography. Coronary angiogram findings are generally normal.[231] A characteristic echocardiogram shows wall and valve thickening, diastolic dysfunction, and a sparkling myocardium (Fig. 99.10). The median septal thickness for patients with AL was 14 mm.[210] The septal wall thickness was less than 15 mm for 52.9% and greater than or equal to 15 mm for 47.1%.[210] Wall thickening frequently is misinterpreted as concentric left ventricular hypertrophy or asymmetrical septal hypertrophy, rather than infiltrative cardiomyopathy.[232–234] When ventricular hypertrophy is diagnosed from the thickened walls, the electrocardiogram typically shows low voltage and does not reflect hypertrophy.[235] Screening tests for monoclonal protein in the serum or urine should be performed for any patient with diastolic heart failure, restrictive hemodynamics, or thickened walls.

Patients with cardiac amyloidosis have restriction to blood inflow that is characteristic of the disease. Doppler studies are best for accurate assessment of myocardial function for AL patients. The Doppler filling patterns accurately indicate the extent of amyloid infiltration.[236] For patients with advanced cardiac amyloidosis, a short deceleration time is consistent with restrictive physiologic characteristics, but in the early stages of cardiac amyloidosis, abnormal relaxation is observed.[237] Decreased fractional shortening and increased ventricular wall thickness are the best predictor of outcome in AL. Patients with a wall thickness greater than 15 mm and a fractional shortening less than 20% have a median survival of 4 months. An important measurement is the deceleration time; a short deceleration time is indicative of restrictive physiologic characterisitics, and a deceleration time shorter than 150 milliseconds is associated with worse outcomes than that of a deceleration time longer than 150 milliseconds.

The most common echocardiographic feature of cardiac amyloidosis was thickening of the right ventricular wall, septum, and left ventricular free wall. The size of the left ventricular cavity was reduced. Approximately 20% of patients had congestive heart failure, but echocardiographic studies showed that twice as many had cardiac amyloid deposits. Patients with overt cardiac amyloidosis often presented with mild symptoms of fatigue and dyspnea on exertion. The median survival time of patients with cardiac amyloidosis and a septal thickness greater than or equal to 15 mm or less than 15 mm at diagnosis was 1 year and 4 years, respectively. Syncope with exercise developed for almost one third of patients with cardiac AL. A median survival time of 2 months is reported with exercise-induced syncope in AL.[238] Immunofixation of the serum and urine and a free light-chain assay are required for any patient who presents with cardiomyopathy or congestive heart failure that does not have an obvious ischemic cause.[74] The echocardiogram is the diagnostic standard for recognizing amyloid cardiomyopathy; occasionally, a patient has a nondiagnostic echocardiogram and amyloidosis is subsequently proven through endomyocardial biopsy, but these occurrences are rare.[239] Pulsed tissue Doppler imaging, when combined with strain imaging, may disclose early signs of amyloidosis. However, functional abnormalities may be detected before any morphologic echocardiographic abnormalities are evident. Both the left- and right-side heart functions may be affected.[240]

A poor prognosis is associated with right ventricular dilatation and atrial systolic failure.[241] For patients who are assumed to have hypertrophy because of thickened ventricular walls, the finding of thickened mitral and tricuspid valves is a common and important clue: thickened valves are not found in hypertensive cardiomyopathy.[242] Valvular regurgitation is commonly seen by Doppler echocardiography, but it does not appear to have a clinically significant effect on myocardial performance.[242] Atrioventricular sequential pacing does not benefit cardiac hemodynamics.[236] Implantation of a cardioverter-defibrillator does not prevent death from cardiac amyloidosis.[243] Distinguishing pericardial disease from restrictive cardiomyopathy may be difficult.[244] It is rare for surgical pericardiectomy to provide clinical benefits to patients with AL. The hazards of surgery for patients with cardiac amyloidosis are well established.[244,245] As discussed previously, a bone marrow biopsy and a fat aspirate will establish the diagnosis of cardiac amyloidosis for most patients with the disease, but for those with infiltrative cardiomyopathy, endomyocardial biopsy will provide the correct diagnosis for all patients when at least three endomyocardial specimens are obtained.[246] Magnetic resonance imaging may be a useful diagnostic technique.

The combination of subtle, widespread heterogeneous myocardial enhancement on delayed postcontrast inversion recovery in T1-weighted images, with ancillary features of restrictive cardiac disease, may be highly suggestive of cardiac amyloidosis.[247] The presence of a positive cardiac magnetic resonance imaging in AL was associated with a significantly increased risk of death, in particular of cardiac origin, but was not independent of clinical congestive heart failure.[248]

Ventricular thrombi may develop in AL patients because of stasis of blood within the cardiac chambers. Embolism may result, and the first manifestation of AL may be a stroke.[249] For AL patients in sinus rhythm, atrial thrombi may develop.[250] Anticoagulation therapy is indicated for AL patients with atrial standstill. Most AL patients present with cardiac muscle infiltration and pump failure, but patients rarely present with symptoms of exertional angina and myocardial infarction from amyloid deposition in the coronary arteries.[251] Angiographic findings are normal because epicardial coronary arteries are spared. For such patients, standard exercise tests show ischemia,[231] but the diagnosis of intracoronary amyloid is difficult to establish before death. Right ventricular myocardial biopsy may show amyloid deposits in small intramural vessels. We previously have described 11 AL patients who presented with angina or an unstable coronary syndrome.[252] A classic low-voltage electrocardiogram was seen in only two patients. The median survival after symptom development was 18 months. Virtually all patients were assigned the diagnosis of cardiac amyloidosis during autopsy, which reflects the difficulty of recognizing small-vessel coronary arteriolar amyloidosis. A follow-up report of obstructive intramural coronary amyloidosis showed that 63 of 96 patients (66%) did not have obstruction of epicardial coronary arteries.[253] Myocardial ischemia affected 25% of patients with obstructive intramural coronary amyloidosis. Most patients with primary systemic amyloidosis and cardiac involvement have obstructive intramural coronary amyloidosis and microscopic changes of myocardial ischemia.[253]

Not all patients with cardiac amyloid have AL. Familial amyloid cardiomyopathy, particularly in elderly African American men, must be distinguished from AL.[191] The clinical presentations are similar,[254] but patients with AF do not have a monoclonal protein in the serum and urine. The most common mutation identified in patients with AF in the United States is TTR Val122Ile. A screen for TTR mutations helps differentiate between patients with AF (have the mutation) and AL (do not have the mutation). Senile cardiac amyloidosis, which results from the deposition of nonmutated TTR, must also be distinguished from AL.[255] Echocardiographic features of AL, AF, and senile cardiac amyloidosis are indistinguishable. All amyloid deposits are positive for Congo red stain, so positive staining cannot be used as a criterion to classify patients with different types of amyloidosis. The main distinguishing clinical feature is the presence of the monoclonal protein for patients with AL (patients with the TTR forms of cardiac amyloid lack monoclonal protein).[186]

Patients with senile systemic amyloidosis tend to be older than those with AL, and virtually all patients with senile systemic amyloidosis are men. Proteinuria is not present. Patients tend to have a greater left ventricular wall thickness. The severity of heart failure is less, and the median survival time is much longer than that of patients with cardiac AL.[256] The mechanism of amyloid deposition in senile systemic amyloidosis is not understood. A quarter of patients older than 90 years (general patient population) have cardiac amyloid deposits. Clinicians must remember that all forms of cardiac amyloidosis are not derived from immunoglobulin light chains.[188]

Kidney

When a patient has free monoclonal light chains in the urine, the differential diagnosis is cryoglobulinemia,[257] amyloidosis, Randall-type light-chain deposition disease,[258] and myeloma cast nephropathy.[259] The presence of proteinuria does not always indicate albuminuria. All patients presenting with proteinuria should have immunofixation of the urine performed during the first evaluation to exclude light-chain–associated syndromes. Kidneys are affected in 28% of AL patients. An Italian group has reported that amyloid deposits affect the kidneys for half of their patients with AL.[260] For nondiabetic adults with nephrotic syndrome, amyloidosis is observed in 12% of renal biopsy specimens[261]; 2.5% to 2.8% of all kidney biopsy specimens contain amyloid deposits.

The serum creatinine level at AL diagnosis has prognostic value. Patients with a creatinine value less than or greater than 1.3 mg/dl had a median survival time of 25.6 or 14.9 months, respectively. Urinary protein loss did not affect survival. Patients with higher levels of albumin loss have a shorter time from diagnosis to the development of end-stage renal disease.[219] The presenting serum creatinine value exceeded 2 mg/dl for 14% of patients. The median urinary protein excretion for all AL patients was 0.75 g in 24 hours, but 30% had greater than 3 g of urinary protein in 24 hours. Only 5% of AL patients had urinary protein loss in the reference range. Monoclonal light-chain proteins were more likely to be found when the urinary protein loss was high; for example, 85% of patients with urinary protein loss exceeding 1 g/day had detectable monoclonal light chains.

The ratio of patients with underlying λ clones to patients with κ clones is 5:1 among those with nephrotic-range proteinuria. Median urinary protein loss for patients with κ or λ amyloidosis is 1.1 or 4.6 g/day, respectively. The λ light chain may predispose patients to a higher level of renal involvement, but no difference in the frequency of renal failure in κ or λ amyloidosis is observed. The median survival of patients with urinary λ light chains, urinary κ light chains, or no detectable urinary light chains is 1, 2.5, and 2.5 years, respectively. Severe hypoalbuminemia is the result of nephrotic-range proteinuria.[77] Diuretics typically are required to control edema, but diuretics further aggravate intravascular volume contraction, increase hypotension, and decrease renal blood flow. Bilateral catheter embolization of renal arteries reduces the loss of urinary protein and increases the serum total protein of patients with advanced anasarca.[262]

Continuous urinary protein loss results in tubular damage, and the principal long-term complication is end-stage renal disease.[263] Prognostic factors for development of end-stage renal disease were serum creatinine value at presentation and 24-hour urinary protein loss. The median time from the diagnosis of AL nephrotic syndrome to dialysis was 14 months. After initiation of dialysis, the median survival time was 8 months. Most deaths of dialysis patients with AL were attributable to cardiac amyloid. No survival difference has been recognized between hemodialysis and peritoneal dialysis.[264] The 1-year survival rate from the start of dialysis was 68%.

Patients younger than 45 years had a better survival rate. Chemotherapy slowed progression to end-stage renal disease and showed a trend toward improved survival. In addition to younger age, normal values of serum calcium and creatinine at presentation favor longer survival. Heart failure, cardiac arrhythmias, and refractory hypotension are the most common extrarenal complications of AL. Cardiac amyloidosis with renal failure regularly results in dialysis that is complicated by severe hypotension (a difficult clinical condition to manage). The amount of protein in the urine and the extent of amyloid deposits in a kidney biopsy specimen correlate poorly.[265] Severe nephrotic syndrome may occur, even with low levels of amyloid deposits. All patients with nephrotic syndrome undergo ultrasonography, and the kidneys of patients with AL are virtually always normal size.[266] The urine of patients with AL contains fat or fatty acid crystals but no casts or red blood cells.[267] Of 118 patients with monoclonal gammopathy undergoing renal biopsy, 30% had AL. In that cohort, the median time from diagnosis to dialysis was 15 months, the median overall

survival time was 24 months, and the main cause of death was cardiac amyloidosis.

Only 2% of patients with amyloidosis have proteinuria eventually if it is not present at diagnosis. Of patients with cardiac AL who underwent cardiac transplantation and antirejection therapy, we have seen nephrotic syndrome develop in two patients. It is possible that patients treated before routine organ transplantation might not have survived long enough for renal amyloid nephrotic syndrome to develop. Amyloid deposits penetrate the glomerular basement membrane and result in proteinuria.[268] Adult Fanconi syndrome,[269] renal vein thrombosis,[270] and retroperitoneal fibrosis have been reported with renal amyloidosis. Fibrillary (immunotactoid) glomerulopathy refers to the deposition of fibrils in the kidney that initially may be confused with AL.[271] However, examination by electron microscopy shows that the fibrils of fibrillary glomerulopathy are twice the width of amyloid fibrils,[272] and extrarenal disease does not develop in patients with fibrillary glomerulopathy. The fibrils are negative for Congo red stain. Monoclonal protein typically is not detected in the serum or urine. Randall-type light-chain deposition disease indicates granular deposition of nonamyloid immunoglobulin light chain along the glomerular basement membrane.[273] It produces nephrotic syndrome and renal insufficiency. Light-chain deposition disease and amyloidosis in the same patient has been reported.[274] Electron microscopy studies of tissues affected by light-chain deposition disease do not show fibrils.

Fifteen patients with systemic amyloidosis who underwent renal transplantation had SAP scintigraphy studies.[275] Abnormal uptake of radioactive iodine in the transplanted kidney was observed in 4 of 10 patients, and none had a reduction in the level of fibril precursor protein. Patients with renal amyloidosis had a high prevalence of adrenal dysfunction. Of 22 patients with renal amyloidosis, poor cortisol reserves were identified for 7, and hypoadrenalism resulted in the death of 4.[276] Amyloid deposits are regularly found in the adrenal glands at autopsy.

Liver

In one fourth of patients with AL, hepatomegaly is noted during physical examination.[277] Hepatomegaly is not synonymous with hepatic involvement because the high prevalence of right-sided heart failure may produce congestive hepatomegaly. One sixth of patients had a symptomatic hepatic amyloid syndrome, which typically included an increased serum alkaline phosphatase or γ-glutamyltransferase level and unexplained hepatomegaly. Most clinicians suspect that unexplained hepatomegaly is due to hepatic metastases, but radionuclide imaging, computed tomography, or magnetic resonance imaging demonstrate homogeneous patterns. A high proportion of patients with hepatic amyloidosis also have renal involvement.

Half the patients with hepatic amyloidosis have proteinuria in excess of 1 g every 24 hours. A patient who presents with an increased serum alkaline phosphatase value and proteinuria may have liver dysfunction resulting from a systemic disorder such as amyloidosis. Several key clues may be helpful in establishing the diagnosis of hepatic amyloidosis: (1) hepatomegaly out of proportion to the degree of liver function abnormality; (2) presence of Howell-Jolly bodies in a peripheral blood film (suggestive of reduced splenic function, a consequence of splenic replacement with amyloid deposits); (3) monoclonal protein (detectable by immunofixation) in the serum or urine; (4) proteinuria; and (5) increase of the alkaline phosphatase value with minimal increase in transaminase values. Biochemically, patients with hepatic amyloidosis tend to have low levels of aspartate aminotransferase and alanine aminotransferase—almost always less than twice the maximum normal value at diagnosis—and the bilirubin value is typically normal. Hyperbilirubinemia, when present, is usually a preterminal finding.

Hepatic rupture is rare but results in massive intra-abdominal hemorrhage that is generally fatal. Computed tomography is useful for diagnosing hepatic rupture with subcapsular hematoma.[278] On physical examination of patients with a confirmed diagnosis of hepatic AL, the median measurement of the liver edge extending below the right costal margin was 7 cm. Hepatomegaly was not present in one tenth of patients with biopsy-proven liver AL involvement. Hepatic AL was usually diagnosed in these patients on the basis of an increased alkaline phosphatase value. At diagnosis, the median increase of the serum alkaline phosphatase level was 2.3 times the maximum normal value. The serum alkaline phosphatase value was the most important screen for determining whether a patient had clinically significant hepatic involvement. Thirty-six percent of patients with hepatic AL excreted more than 3 g of protein in the urine per day. Patients with hepatic AL also have higher levels of C-reactive protein than those without hepatic involvement.[279] The proportion of patients with hepatic AL whose amyloid deposits were derived from κ clones was identical to that of patients with other affected organs. It has been suggested that an increased incidence of κ light chain may be seen in hepatic AL,[280] but this suggestion was not supported by our data. In a study of 98 patients,[281] 72% had involuntary weight loss and 89% had proteinuria. Clinicians considered amyloidosis as the cause of the hepatic dysfunction in only 26% of patients. None had hepatic rupture or death resulting from liver biopsy, and only 4% had bleeding. The predictors of a poor prognosis were heart failure, elevated bilirubin levels, and thrombocytosis.

Although symptomatic hepatic amyloid is identified in only 16% of AL patients, SAP scans show that hepatic amyloid is present in virtually all AL patients.[282] Cholestatic jaundice is a preterminal finding.[283] In hepatic AL, portal hypertension with varices and bleeding is rare.[284] Presumably, patients succumb to hepatic or extrahepatic complications of AL before portal hypertension develops.[285] It is common to see ascites in patients with hepatic AL, but most of these patients also have nephrotic-range proteinuria, hypoalbuminemia, or congestive heart failure, all of which are more likely to cause ascites. Amyloid deposits are found in liver biopsy specimens distributed in the portal tract and perisinusoidally.[286] At autopsy, involvement of the portal triad vasculature frequently is seen, but the effect of amyloid deposits in the vasculature is not clinically significant.[287] After the diagnosis of AL is confirmed by liver biopsy, the median survival time is less than 1 year.

Scintigraphy generally is not useful for establishing the diagnosis of hepatic AL. The findings are nonspecific and include irregular distribution of the radionuclide and, occasionally, splenic uptake is absent.[288–290] Sinusoidal amyloid deposits may compress branches of the hepatic artery, which results in the angiographic appearance of luminal irregularity and abrupt changes in vascular caliber.[291]

Amyloidosis is not a contraindication for liver biopsy. Although spontaneous hepatic rupture has been described,[292] rupture after a percutaneous liver biopsy has not been reported. The risk of complications after liver biopsy ranges from 0.31% to 3.00%.[281] In our experience, 4% of patients with amyloidosis had bleeding after liver biopsy and none died of the bleeding. Physicians should remember that biopsy specimens from subcutaneous fat or bone marrow show amyloid deposits in 85% of patients with AL. Despite the relative safety of the procedure, if amyloidosis is suspected appropriately, liver biopsy usually is not required.

In a statistical analysis, hepatomegaly had a significant impact on survival within the first year after diagnosis, perhaps because hepatomegaly for some patients may be due to congestive heart failure rather than hepatic infiltration. In an autopsy series of nine patients with amyloidosis and hepatomegaly,[293] three did not have anatomical evidence of deposits, and liver enlargement was attributable to passive congestion. In a second autopsy study,[293] 20% of patients with palpable hepatomegaly and amyloidosis did not have histologically evident deposits.

In patients with AL, the finding of Howell-Jolly bodies is highly specific for splenic involvement, but their absence does not exclude it. Twelve patients with autopsy-proven diffuse splenic involvement have been reported in whom Howell-Jolly bodies were not found.[294] Scanning of the spleen also does not correlate well with the presence of Howell-Jolly bodies observed on a peripheral blood smear. In patients with hepatic AL, splenomegaly is present in 11%. Splenic rupture is a recognized complication in patients with hepatic amyloid.[295,296]

In summary, the cardinal features of hepatic AL are hepatomegaly, monoclonal protein in serum or urine, proteinuria, an increase of the alkaline phosphatase value with minimal increase of transaminase values, and Howell-Jolly bodies in the blood smear of patients with advanced hepatic and splenic involvement.

Gastrointestinal Tract

No correlation exists between the presence of gastrointestinal tract amyloid deposits and liver amyloid deposits. Only 15% of our patients with gastrointestinal tract amyloidosis had hepatomegaly, and less than one third had increased alkaline phosphatase values.[297] When routine screening biopsies are performed on the rectum or intestinal tract, amyloid deposits are found in most patients with AL.[118] Generally, deposits are vascular, but occasionally, they are in the submucosa of the bowel; they produce symptoms (e.g., steatorrhea, nausea, vomiting, abdominal pain, hematemesis, and hematochezia) for only a few patients.[298] Bowel dysfunction in AL may result from direct infiltration of the bowel lining or from a motility disturbance attributable to damaged regulatory nerves of the intestinal tract.[299] The high prevalence of anorexia and weight loss does not correlate with the presence of gastrointestinal tract amyloid deposits. Typically, patients had a median delay of 7 months between the onset of gastrointestinal symptoms and the histologic recognition of AL, although one patient had a delay of 4 years. Four of our 19 patients with gastrointestinal tract AL underwent laparotomy for evaluation of intestinal symptoms. For three of these four patients, diagnosis was delayed because the surgical specimens were not routinely stained with Congo red.[297]

Steatorrhea and low serum carotene levels were seen in less than 5% of patients with gastrointestinal tract amyloidosis. These patients were not distinguishable clinically from those with celiac sprue, Whipple disease, or bacterial overgrowth. Small-bowel biopsy findings showed amyloid deposits for 19 of our patients with AL. This number constitutes only 1% of the AL population at our institution,[297] and it does not include patients who had clinical evidence of malabsorption, for whom a small-bowel biopsy was not performed (widespread amyloidosis was evident in other organs). Diarrhea, anorexia, dizziness, and abdominal pain were the most common symptoms. All patients had weight loss (median loss, 30 pounds). Half the patients had orthostatic hypotension. A prolongation of prothrombin time, primarily from malabsorption of vitamin K, was present in one fourth of patients. Factor X deficiency also was seen in one fourth, but only one patient had factor X activity below 30%. A multivariate analysis showed that the degree of weight loss and the hemoglobin value at diagnosis affected survival. For patients presenting with a weight loss of 20 pounds or more, the median survival was 10 months. Ten patients died as a consequence of nutritional failure and five died of heart failure. The severe diarrhea of patients with systemic amyloidosis could not be explained by malabsorption generally, bacterial overgrowth, or malabsorption of electrolytes by epithelial cells. Transit of polyethylene glycol was 10 times faster than that of healthy subjects. Autonomic neuropathy was the likely cause of rapid gastrointestinal tract transit.[300]

Patients with amyloidosis may have esophageal dysmotility or gastroesophageal reflux of the upper gastrointestinal tract.[301] Multiple reports describe patients who had surgical intervention for obstruction, only to have amyloid deposits identified histologically.[302,303] The most frequent symptoms of pseudo-obstruction are nausea (even during fasting) and emesis,[304] and abdominal distention and pain are common.[305] Dilatation of small-bowel loops is rare.[306] The typical radiographic findings of a patient with intestinal amyloid deposits include increased fluid accumulation in the small bowel, loop dilatation with delayed transit, and thickening or nodularity. Computed tomography may show mild splenomegaly or lymphadenopathy, but it generally does not help establish the diagnosis. Esophagitis, duodenitis, and gastritis are commonly found during endoscopic procedures.[307] It is rare for these changes to cause symptomatic bleeding.

Ischemic colitis rarely is the presenting feature of AL.[308] The amyloid deposits obstruct vessels of the muscularis mucosa and lamina propria. The obstructed blood supply leads to mucosal ischemia, sloughing of the bowel lining, and hemorrhage.[309] Barium studies show luminal narrowing, mucosal fold thickening, and ulcers. The most common location of ischemia is the rectosigmoid and descending colon.[310] Vascular obstruction from AL has been reported to cause duodenal perforation.[311] Hematemesis and hematochezia were rare in patients who did not undergo stem cell transplantation. In our experience, treatment of the underlying AL does not result in recovery of intestinal motility after pseudo-obstruction develops. For patients with pseudo-obstruction, extensive replacement of the muscularis propria by amyloid is prominent.[312]

Nervous System

In 1938, the first description of peripheral nerve amyloidosis was published.[313] Among patients with AL, 15% to 20% have paresthesias and neuropathy symptoms.[314] The clinical picture is often dominated by cardiac or renal involvement, and the peripheral neuropathy is minimally symptomatic. Echocardiographic abnormalities are found in 44% of patients who present with AL neuropathy. When a predominant neuropathy is seen in a patient with biopsy-proven amyloidosis, the possibility of AF should be considered. The absence of a monoclonal protein in the serum or urine is clinically useful for distinguishing between AL and AF.[315] Paresthesias, pain, numbness, muscle weakness, impotence, urinary retention, and orthostatic symptomatology are the most frequent symptoms of amyloid neuropathy.[316] Twelve percent of the patients have syncope. Dysesthesia that manifests as distal burning is present in one fourth of the patients. Of those with peripheral neuropathy, autonomic neuropathy is seen in two thirds, and lower-extremity involvement precedes upper-extremity involvement for nearly 90%. Involvement of the cranial nerves in AL is rare.[317,318] Half the patients with amyloid peripheral neuropathy also have carpal tunnel syndrome, a soft-tissue manifestation of amyloidosis. Frequently, it is difficult to distinguish electrodiagnostically between upper-extremity neuropathy and carpal tunnel syndrome. Weight loss was recognized in one third of patients. Rarely is painful sensory neuropathy, mononeuropathy multiplex, or demyelinating polyneuropathy the presenting manifestation of AL neuropathy.[319]

An important diagnostic clue for amyloid neuropathy is its association with autonomic neuropathy.[320] Voiding difficulties are often due to detrusor weakness and impaired bladder sensation. The underlying mechanism of urinary dysfunction seems to involve postganglionic, cholinergic, and afferent somatic nerves.[321] However, when patients present with peripheral neuropathy, amyloidosis usually is not considered in the differential diagnosis. The median delay between onset of paresthesias and biopsy proof of amyloidosis is 29 months.

Amyloidosis typically causes loss of small myelinated and unmyelinated fibers. Electromyography does not sensitively detect changes in small unmyelinated fibers. Consequently, patients may have symptoms of amyloid neuropathy and have normal

electromyographic findings. As it progresses, the neuropathy of amyloidosis is axonal and demyelinating. The loss of myelin results in an elevation of cerebrospinal fluid protein value in one third of patients. Axonal degeneration is detected in 96% of patients with amyloid myopathy. Typical electromyographic changes consist of reduced amplitude of compound muscle action potentials, decreased or absent sensory responses, mild slowing of nerve conduction velocity, and fibrillation potentials on needle examination.[322]

Although sural nerve biopsy is the standard method of diagnosing amyloid neuropathy, less invasive fat or bone marrow biopsies may also confirm the diagnosis.[316] With sural nerve biopsy, amyloid deposits are found in the endoneurial capillaries or in the epineurium.[323] Teased fibers show axonal degeneration and a marked decrease in myelin fiber density. Although Mayo Clinic uses sural nerve biopsy as the standard diagnostic method, the biopsy is not 100% sensitive. Nine patients were reported to have amyloid neuropathy, but six had negative sural nerve biopsy findings.[324] Amyloid proteins may have been deposited at the nerve root, which resulted in distal demyelination without recognizable deposits in the sural nerve. Amyloid is deposited focally in the nerve, and multiple sections of the sural nerve need to be examined to confirm the diagnosis.

For AL patients who present with a dominant neuropathy, the median survival time is 25 to 35 months.[325,326] Clinical improvement in peripheral neuropathy is rare with traditional chemotherapy, and it is infrequent even with high-dose therapy. The clinical course for most cases of peripheral neuropathy is progressive neuropathy over time. One third of patients ultimately are bedridden, and three fourths have marked restriction in their mobility and a reduced ability to perform the activities of daily living. The serum albumin value is the only prognostic factor that is associated with survival for patients who present with a dominant neuropathy. The median survival was 31 months for patients with an albumin value greater than 3 g/dl but only 18 months for those with serum albumin levels less than 3 g/dl (Fig. 99.11).

All patients who present with a peripheral neuropathy should be screened with immunofixation assays of serum and urine and with immunoglobulin free light-chain measurement. A patient with peripheral neuropathy and monoclonal light chains has a restricted differential diagnosis that includes (1) amyloidosis; (2) cryoglobulinemia; (3) the polyneuropathy, organomegaly, endocrinopathy, M protein, and skin change syndrome (POEMS-osteosclerotic myeloma)[327]; and (4) neuropathy associated with monoclonal gammopathy of undetermined significance.

Prognosis of patients with primary systemic amyloidosis who present with dominant neuropathy. Am J Med 1998;104:232–237. Used with permission.)

Respiratory Tract

We have reviewed our experience with pulmonary deposition of amyloid.[136] Most patients who present with amyloidosis involving the respiratory tract have only localized tracheobronchial or nodular pulmonary amyloid deposits. A patient with laryngeal amyloidosis was treated with adjuvant external beam radiation to a dose of 45 Gy. At 11 months, the patient's voice, breathing, and swallowing had improved substantially.[328] Neither localized tracheobronchial nor nodular pulmonary amyloid deposits are associated with systemic disease, and both have a good prognosis.[220,329,330] Nodular pulmonary amyloidosis, if recognized, does not always require intervention. It frequently may be nonprogressive for 5 years or longer.[331]

Patients who present with systemic amyloidosis may have diffuse, interstitial pulmonary involvement and concomitant cardiac involvement that usually overshadow any respiratory symptoms.[332] Gas exchange is preserved until amyloid deposition in the alveolar interstitial space is advanced.[333] Diffuse alveolar septal amyloid deposits rarely cause hemoptysis.[334] Minor salivary gland involvement is shown histologically in a high proportion of patients with AL,[335] and many patients report xerostomia.[336,337] Patients with AL have received incorrect diagnoses of Sjögren syndrome. Skeletal muscle and diaphragmatic involvement can produce muscular weakness and ventilatory failure.[336,338,339] Rarely, pleural deposits of amyloid cause pleural effusions.[340,341] Bevacizumab has been used to treat effusions in AL.[342] Occlusive amyloid deposits in the pulmonary circulation system may occasionally cause pulmonary hypertension with resultant right-sided cardiac failure.[343,344] After a diagnosis of diffuse interstitial pulmonary amyloidosis was established, the median survival time was 16 months; for the small percentage of patients with pulmonary hypertension, the median survival was 2.8 years.

Patients whose amyloidosis is associated with an IgM monoclonal protein or Waldenström macroglobulinemia have a higher prevalence of pulmonary amyloid deposits.[220] Monoclonal protein is not seen in nodular pulmonary amyloidosis or tracheobronchial amyloidosis; only interstitial pulmonary amyloidosis is associated with free immunoglobulin light chains in serum or urine. Pulmonary involvement, when part of a systemic immunoglobulin light-chain amyloid syndrome,[345] appears radiographically as a nonspecific interstitial or reticulonodular pattern.[346] The diagnosis is easily obtained by a transbronchial lung biopsy, which is not associated with excessive bleeding.

Autopsy studies of pulmonary amyloidosis have been published.[347] In one study,[348] histologic specimens from 11 of 12 patients had deposits in the lung. Deposition was seen in blood vessel walls and the alveolar septum. Only 4 of the 12 had clinical dyspnea, and pulmonary amyloidosis was responsible for the death of 1 patient. Thus, patients with unexplained dyspnea or fluid overload who have normal left ventricular diastolic and systolic function should be evaluated for pulmonary hypertension attributable to AL.

Coagulation System

Amyloidosis increases the fragility of blood vessels because of infiltration of the vessel wall,[349] and complications may include clinically significant hemorrhage[215] or thrombosis. The most common manifestation of hemorrhage is purpura. Prolonged thrombin time is a frequently observed abnormality of amyloidosis,[350] and it is attributed to the presence of an inhibitor of fibrin polymerization in the plasma or the effects of prolonged nephrotic-range proteinuria with severe serum hypoalbuminemia. Acquired hemostatic abnormalities include coagulation factor deficiencies, hyperfibrinolysis, and platelet dysfunction.

Acquired factor X deficiency is an uncommon, but well-documented, complication of AL[81,214,351,352]; nevertheless, bleeding is unlikely if factor X levels are higher than 25%. Fewer than

5% of patients have a serious deficiency of factor X with plasma levels less than 10% of the reference level for factor X,[81,214] and patients with cardiac and renal involvement in the absence of hepatic involvement do not show clinically significant reductions in factor X levels. However, clinically significant bleeding complications may occur, especially for patients with ischemic colitis attributable to vascular occlusions.[351,352] For one patient, factor X deficiency was treated with recombinant human factor VIIa during preparation for surgical splenectomy.[353] Bleeding disorders resulting from low levels of α_2 plasmin inhibitors, increased levels of plasminogen activators, and abnormal platelet aggregation also have been reported.[354] Life-threatening bleeding from acquired factor V deficiency has been reported.[355] Fatal retroperitoneal hemorrhage developed, despite infusions of fresh frozen plasma. Autopsy findings showed that the patient had massive deposits of AL in the liver, spleen, and heart.

In one study, 36 AL patients were evaluated for coagulation disorders.[350] Only one patient had severe bleeding, and mild to moderate hemorrhage was observed in nine patients. The most common abnormalities were prolongation of the reptilase and thrombin times. A severe factor X deficiency was seen in only one patient. The activated partial thromboplastin time was prolonged for 25 patients, and the prothrombin time was prolonged for 8. A lupus anticoagulant was not detected in any patient.

Black et al.[356] described patients with amyloidosis who had documented episodes of thromboembolism. Similarly, Halligan et al.[357] described patients with documented thromboembolism. Of 2,132 patients, those with myocardial infarction, peripheral vascular disease, and stroke were excluded, and records of 40 patients (19 women, 21 men; median age, 65 years) with documented thromboemboli were examined. In 11 of the 40 patients, thromboembolism preceded the diagnosis of amyloidosis, and for 9 of these 11 patients, the thromboembolic event occurred 1 month or more before the diagnosis of amyloidosis was established. In 20 of the 40 patients, the thromboembolism occurred 1 month or more after the diagnosis of AL was established. The thrombosis was venous for 29 patients and involved (in decreasing order of frequency) vessels in the calf, subclavian veins, popliteal regions, inferior venae cavae, common femoral veins, and atrioventricular fistulae. Arterial thrombosis was seen in 11 and involved femoral, popliteal, or multiple arteries, and the atria were affected in 2 patients. Of the 40 patients, 37 had additional risk factors for thrombosis, including nephrotic syndrome (20 patients), immobilization (13 patients), tobacco use (6 patients), heart failure (8 patients), estrogen therapy (1 patient), obesity (4 patients), aortic aneurysm (1 patient), prosthetic material (4 patients), and disseminated intravascular coagulation (2 patients). Five patients had activated protein C resistance. Eight patients died within a month of the thrombosis, and 18 of the 40 died within the first year. Thus, thrombosis appears to be a strong predictor of imminent death within the first month (or perhaps the first year) after the event for patients with AL. The type of heavy or light chain and the organ distribution of amyloid deposits did not predict the development of a thromboembolic event.

PROGNOSTIC FEATURES

After amyloidosis has been confirmed (histologic evidence from a fat aspirate or bone marrow biopsy specimen, a compatible clinical syndrome, and monoclonal protein in the serum or urine), the patient needs to be advised of his or her prognosis. Congestive heart failure (caused by progressive cardiomyopathy) and sudden death (caused by asystole or ventricular fibrillation) are the most common causes of death for patients with AL. The most important determinant of clinical outcome is the extent of cardiac involvement. Other recognized adverse predictors of survival include referral status, heart failure, hyposplenic peripheral blood film, free light chains in the urine, elevated serum creatinine level, bone marrow plasmacytosis greater than 30%, circulating plasma cells in the peripheral blood, elevated bone marrow plasma cell labeling index, and increased β_2-microglobulin levels.

Exertional syncope is a predictor of early death.[238,358] More subtle cardiac findings also have prognostic value. Echocardiography is an important tool for assessing the prognosis of patients with AL. Two-dimensional and Doppler echocardiography shows that 40% of AL patients have cardiac involvement, although only 17% have symptoms of heart failure. In a Mayo Clinic study of 64 patients,[359] cardiac relaxation was abnormal in the early stages of amyloidosis, but patients with advanced amyloidosis had restrictive filling and a shortened deceleration time.[360] Doppler echocardiography may be performed serially to monitor diastolic dysfunction in cardiac AL. The 1-year survival rate of patients who had a deceleration time greater than 150 milliseconds (measured by Doppler echocardiography) was 92%; in contrast, the 1-year survival rate was 49% for patients with a deceleration time less than 150 milliseconds. The Doppler-measured left ventricular diastolic filling parameters[359,361] are also independent prognostic features. Doppler studies of right ventricular diastolic function show filling abnormalities that correlate with the degree of amyloid infiltration (measured by right ventricular free-wall thickness).[362,363] Patients with elevated serum cardiac troponin levels have a shortened overall survival.[364]

Detection of Howell-Jolly bodies during examination of a peripheral blood film indicates advanced splenic involvement that usually is associated with advanced hepatic involvement and a median survival of 4.4 months.[365] Findings from a renal biopsy may provide prognostic information.[366] Patients have a better prognosis if they have a lower percentage of thickened glomerular capillary walls, a higher incidence of amyloid deposits in vessels but not glomerular capillaries, and deposits of IgG and C3 in mesangial and glomerular capillary walls. The serum creatinine value at diagnosis and the presence of a urinary light chain are both important prognostic indicators. If the serum creatinine value at diagnosis is abnormal, the median survival is 15 months. Patients who have free light chains in the urine have a shorter survival (12 months) than those who do not (35 months).

In a multivariate analysis, heart failure and orthostatic hypotension were associated with a median survival of less than 1 year in a cohort of 229 patients.[73] An analysis was performed for 147 AL patients to identify cytoplasmic immunoglobulin–positive plasma cells by using a sensitive slide-based immunofluorescent technique. The percentage of circulating cytoplasmic immunoglobulin-positive cells was calculated by measuring the number of circulating monoclonal plasma cells. Circulating blood plasma cells were observed for 16% of AL patients. The median survival of patients with and without circulating cells was 10 and 29 months, respectively.[367] Independent prognosticators of survival included the presence of peripheral blood plasma cells and the serum β_2-microglobulin value. When AL patients with coexisting multiple myeloma and dominant cardiac amyloidosis were excluded, the presence of peripheral blood plasma cells had independent prognostic value. A slide-based immunofluorescence technique was used to detect circulating peripheral blood plasma cells in 16% of AL patients.[368] Overall survival was 13 or 31 months for patients with or without circulating blood plasma cells, respectively. The identification of circulating peripheral blood plasma cells may help select treatment for patients with AL.[368]

When serum β_2-microglobulin levels were compared, AL patients with values within the reference range had a median survival time of 33 months, and patients with elevated values had a median survival of 11 months.[369] The prognostic value of β_2-microglobulin levels was independent of the presence of renal failure or heart failure. The median survival of patients with normal renal function and elevated β_2-microglobulin values was 9 months, but it was 39 months for patients with normal β_2-microglobulin

values. Congestive heart failure and serum β_2-microglobulin values remain important predictors of outcome (Fig. 99.12).[370]

In a cohort of 153 patients with AL, the median survival time of the entire group was 20 months; the 5-year survival rate was 20%.[371] Of the patients who presented with congestive heart failure, the 5-year survival rate was 2.4% and the median survival time was 8 months. When peripheral neuropathy was the sole manifestation of AL, the 5-year survival rate was 32% and the median survival time was 40 months. When assessing the long-term prognosis, the investigators found it useful to classify patients into four groups by clinical manifestations of AL: (1) heart failure, (2) peripheral neuropathy, (3) nephrotic syndrome, and (4) other. Women had a slightly longer survival time than men.

Referral bias definitely is evident at large treatment centers for amyloidosis. To be treated at a distant center, the patient a priori must physically be able to travel. This type of information must be considered when attempting to interpret the results of clinical trials reported from a single center. Of patients with amyloidosis who were evaluated at Mayo Clinic, the median survival was 2 years. If the cohort was limited to patients who were evaluated within 30 days of diagnosis, however, the median survival decreased to 13 months.[212]

When uniform statistical criteria were applied to a large cohort of patients with AL, the median survival of the entire group was 12 months (range, 4 months [for patients with congestive heart failure] to 50 months [for patients with peripheral neuropathy]).[370] Within the first year after diagnosis, the significant prognostic factors included heart failure, urinary light chains, multiple myeloma, and hepatomegaly. After the first year, the predictors of poor outcome were an increased serum creatinine value, multiple myeloma, monoclonal serum protein, and orthostatic hypotension. When studies of treatment outcomes are compared, stratification of variables that affect survival is important.

All patients being assessed for AL should have an echocardiographic evaluation that includes Doppler studies of diastolic performance, ejection fraction, and mitral deceleration time. The absolute values of immunoglobulin free light chains have prognostic value for patients with AL. Patients with higher baseline levels of free light chains have an increased risk of death (hazard ratio, 2.6), and achievement of a free light-chain response is a better predictor of survival than the standard defined complete hematologic response.[372] A staging system that includes serum cardiac troponin levels and N-terminal probrain natriuretic peptide (NT-proBNP) levels was developed for patients with AL. Depending on whether troponin and NT-proBNP levels were both low, both high, or high for only one component, three stages were defined with median survivals of 26.4, 10.5, and 3.5 months, respectively (Fig. 99.13). This staging system should facilitate more consistent and reliable comparisons of therapeutic outcomes.[373] A similar result was seen when this staging system was applied to patients who underwent stem cell transplantation. Patients with stage 3 who underwent transplantation had a median survival of 26.1 months, but patients with stage 1 and stage 2 who underwent transplantation had a median survival of 66 months.[374] Reducing the level of amyloidogenic free light chain by more than 50% has been associated with substantial survival benefit, regardless of the type of chemotherapy used. Organ improvement is delayed, but the treatment strategy may be guided by the early effect of therapy on the free light-chain concentration.[375]

The 4-year overall suvival after AL diagnosis has improved during every recent decade of follow-up: 21%, 24%, and 33%, respectively, for the decades 1977 through 1986, 1987 through 1996, and 1997 through 2006 ($P < .001$).[376] Yet, the 1-year mortality rate continued to be high during these three decades. A risk stratification score that used cardiac troponin *T*, NT-proBNP, and uric acid identified the patients at risk for early death. The 1-year mortality rate was 19%, 37%, 61%, and 80%, respectively, for patients with zero, one, two, or three risk factors.[376]

A 90% reduction in dFLC (the involved less the uninvolved free light-chain level) after stem cell transplant best predicted survival at 3 or 5 years. The median overall survival among those patients with a 90% decrease was not reached compared with 37.4 months for the rest of the patients ($P < .001$). The free light chain level used as a response criterion is a more useful measure than M-protein response. A minimum of a 90% reduction in the dFLC is associated with the best outcomes.[377] One study reported that interphase-fluorescence in situ hybridization coupled to cytoplasmic staining of specific Ig is an important test for patients with light-chain amyloidosis[378] in whom t(11;14) is an unfavorable prognostic factor. Risk of death for patients who had t(11;14) translocation was 2.1 (95% confidence interval, 1.04 to 6.4), which on multivariate analysis was independent of therapy received.

TREATMENT

Supportive Therapy for Amyloidosis

Cardiac Amyloidosis

Diuretic agents are the mainstay of therapy for patients with cardiac AL.[379] Diuretic therapy is complicated because many patients have orthostatic hypotension and intravascular

volume contraction, which are consequences of the nephrotic syndrome.[380,381] Diuretic therapy may precipitate a decrease in renal blood flow; the associated increase in serum creatinine concentration may induce syncope.[382] Loop diuretics are typically used to control edema. Doses of furosemide may be as high as 120 mg three times per day. If loop diuretics fail to control edema, metolazone may be beneficial.

Patients with recurrent syncope may receive permanent pacemakers.[383,384] Those with exertional syncope should be considered for the placement of an implantable cardioverter-defibrillator because most patients with cardiac AL die within 2 months after syncope develops.[238,359] For some patients with recurrent syncope, an implantable cardioverter-defibrillator has been placed.[385]

The standard treatment of patients with heart failure includes orally administered angiotensin-converting enzyme inhibitors.[386] Whether these agents result in similar survival benefits for patients with cardiac AL is unknown.[387,388] Their use is problematic for AL patients because of the high incidence of associated hypotension. Sudden cardiac death is well recognized in patients with cardiac AL.[389] Congestive heart failure may be precipitated by use of calcium channel blockers, such as nifedipine and diltiazem. Amyloid fibrils selectively bind nifedipine, which could result in high intracellular levels of the medication.[390,391]

Fludrocortisone acetate (0.1 mg orally two or three times per day) may be used to treat AL orthostatic hypotension.[392] The dose has been escalated from 0.4 to 2.0 mg daily.[393] Adverse effects of fludrocortisone include supine hypertension, increased fluid retention with aggravation of heart failure, severe hypokalemia, and edema.[394] Fludrocortisone is not well tolerated in elderly patients with AL. Midodrine is another agent that has been used to treat hypotension in AL patients.[395] Midodrine dosage starts at 2.5 mg three times per day at 4-hour intervals. Supine hypertension is an adverse effect of midodrine, and the drug is normally given only during waking hours.[396] The drug is absorbed rapidly from the intestinal tract, and peak serum levels are attained within 30 minutes. The initial dose may be increased as needed to achieve therapeutic endpoints. The maximum recommended daily dose for midodrine is 40 mg. Active metabolites of midodrine are excreted by the kidney, and patients with renal insufficiency should begin with a reduced dose. Evidence of midodrine toxicity includes restlessness, supine hypertension, and tachycardia. Severe orthostatic hypotension that was not affected by midodrine and fludrocortisone may be treated successfully with erythropoietin, but success is not correlated with the correction of anemia.[397]

Patients with cardiac AL have received heart transplants. Seven patients who received cardiac allografts had a mean age of 46 years.[398] For five of the patients, the mean survival time after transplantation was 32 months. Recurrent amyloid deposits were reported in the allograft for two patients at 3.5 and 4.0 months; one died 13 months after transplantation. There was one operative death. One patient retained heart function (class I) 1 year after transplantation, but amyloid deposits were seen in an endomyocardial biopsy specimen at 14 weeks after transplantation. A successive report of 10 patients[399] noted that 4 of 9 patients survived longer than 1 month, and patients had a high prevalence of recurrent amyloid deposition in the transplanted heart. One patient with amyloidosis survived 9 years after cardiac transplantation, and we have experience with a patient who did well 11 years after cardiac transplantation.

A report of 10 patients who received a cardiac transplant between 1984 and 1997 indicated a 20% perioperative mortality rate; the 8 surviving patients had a 50-month follow-up period.[400] Endomyocardial biopsy specimens showed recurrent amyloid deposits in the grafted heart for five of the eight patients at 5, 11, 12, 28, and 30 months. No patient had echocardiographic evidence of amyloid deposits. Overall, 7 of the 10 patients died after transplantation (median survival, 32 months; range, 3 to 116 months). For four of these seven patients, extracardiac amyloid deposits developed. The 1- and 5-year survival rates were 60% and 30%, respectively. The perioperative mortality rate of 20% was attributable to extracardiac amyloid deposits.

Heart transplantation is feasible technically, but treatment to eliminate the underlying plasma cell proliferative disorder is necessary for a favorable outcome.[400] Thirteen Mayo Clinic patients with cardiac AL have received a heart transplant.[401] The actuarial 5-year survival rate was 50%, which was inferior to the survival of patients who underwent transplantation for primary cardiomyopathy. Eleven cardiac transplant recipients have received stem cell transplantation at our institution; of these patients, six are alive at 2 to 7 years after the transplantation.

Heart transplantation has been reported by a number of groups for the management of amyloid cardiomyopathy. The United Network for Organ Sharing database contained records of 69 patients with a diagnosis of amyloidosis who received a heart transplant. The records noted 5 operative deaths and 29 late deaths. Nine recipients died of amyloid-related complications. Patient sex influenced survival: The 1-year survival rate was 84% for men and 64% for women.[402] Five patients had sequential heart transplantation and stem cell transplantation in an effort to prevent recurrent amyloid deposition. Two patients died of progressive amyloidosis at 33 and 90 months after heart transplantation. Three of five patients were without biopsy evidence of amyloid accumulation.[403] One patient had successful allogeneic bone marrow transplantation and cardiac transplantation.[404] In the United Kingdom, 24 patients with amyloid heart disease had cardiac transplantation; of these patients, 17 had AL. Survival was superior for seven patients with AL who also received chemotherapy; the 1-, 2-, and 5-year survival rates of the seven patients were 86%, 86%, and 64%, respectively. Two were alive at the end of the study period. These survival rates were less than those of patients undergoing transplantation for other indications. Progression of amyloidosis contributed substantially to the increased mortality rate.[405] In a single-center report of five patients (four of whom received a heart transplant),[406] two were alive at 60 and 41 months. One patient had a combined heart–liver transplantation, and two patients died after intervention at 23 months.

Nine patients underwent heart transplantation. Eight of the patients received high-dose chemotherapy followed by an autologous stem cell transplant. Six of seven evaluable patients achieved a hematologic complete remission, and one was a partial remission. At a median follow-up of 56 months from heart transplant, five of seven patients are alive without recurrence. Their survival was compared with 17,389 patients who received heart transplant for nonamyloid heart disease: 64% in nonamyloid versus 60% in amyloid patients at 7 years ($P = .83$). Seven of eight patients who receved a transplant have had no evidence of recurrent amyloid in their cardiac allograft.[407]

Renal Amyloidosis

Diuretics, compressive support hose, low-sodium diets, and selective use of albumin diuresis are the mainstays of renal therapy for amyloidosis. Angiotensin-converting enzyme inhibitors may reduce proteinuria for patients with nephrotic syndrome. The mechanism appears to be postglomerular vasodilatation. Symptoms of toxicity of angiotensin-converting enzyme inhibitors include hyperkalemia and hypotension. Enalapril and lisinopril have been reported to decrease proteinuria and corticosteroid-resistant nephrotic syndrome that is due to focal segmental glomerulosclerosis. The possibility that angiotensin-converting enzyme inhibitors may be active in amyloid nephropathy has not been explored.[408,409]

The results of hemodialysis for AL patients are inferior to those for patients with primary kidney disorders. The 2-year survival rate for all dialysis patients is 76%, but it is 53% for patients

with renal AL.[410] The first report of patients with amyloidosis who underwent continuous ambulatory peritoneal dialysis was published in 1984; the three patients survived between 10 to 18 months.[411] One of the three patients received a renal transplant and survived 57 months; however, autopsy findings showed widespread amyloidosis. In a review of 61 AL patients receiving dialysis, 18 died within a month after initiating dialysis.[412] Of the 43 other patients, the median survival time was 61 months. Hemodialysis and chronic ambulatory peritoneal dialysis had identical long-term survival rates. Younger patients had superior outcomes. Patients most commonly succumbed to development of extrarenal amyloid deposits in the gastrointestinal tract and heart. In the Mayo Clinic experience, two thirds of the deaths of dialysis patients with AL resulted from extrarenal progression (mostly cardiac amyloidosis). Most reports of the outcome of dialysis for renal amyloidosis describe patients with AA.[275,413,414] In a report of 12 patients (2 with AL), only 4 survived 2 years after kidney transplantation. Renal biopsy specimens from two of the four survivors showed amyloid deposits. Among patients presenting with renal AL, 42% received renal replacement therapy compared with 5% of patients who did not present with renal involvement. Patients with kidney amyloid who ultimately required dialysis support had significantly higher serum creatinine and 24-hour urine protein levels at diagnosis. Patients with λ light chains were significantly more likely to have kidney involvement and had significantly greater urinary protein loss than those with κ light chain. Serum creatinine level was an independent predictor of survival even when corrected for heart involvement. For the 38 patients reported who received dialysis, median survival from the initiation of dialysis was 10.4 months and 26% of patients with AL ultimately received renal replacement therapy compared with 42% of patients who presented with renal AL.[415]

The development of amyloidosis in a transplanted kidney is well recognized.[416] Eleven amyloidosis patients were studied after undergoing renal transplantation.[417] Three amyloid recurrences were observed at 11, 28, and 37 months. Two AL patients who underwent renal transplantation died; one had renal failure attributable to new deposits of amyloid in the grafted kidney, and the other had cardiac amyloidosis (renal function was stable). Another report described 45 patients with amyloidosis who underwent kidney transplantation.[418] The 3-year survival rate of these patients was 51%. Patient age greater than 40 years was the major determinant of a poor outcome. The median age of AL patients in the study was 62 years. Recurrent amyloid deposits in the allograft were established histologically for four patients. The authors of the study estimated that the chance of amyloidosis recurrence at 1 year after transplantation was 20%. Two AL patients had renal biopsies showing recurrent amyloid deposition after transplantation.[419] In that study, no factors predicted recurrence. Two additional AL patients receiving renal transplants were reported. Glomerular amyloidosis developed in one and caused renal failure and death. The other patient died of cardiac amyloidosis. Pasternack et al.[418] reported inferior survival of patients with renal AL.

Living-donor kidney transplantation and autologous stem cell transplantation have been reported in patients with amyloidosis. Eight patients underwent living-donor kidney transplantation. Two had complications and died 3 and 10 months after the procedure. Stem cells were harvested successfully for six patients, and five underwent stem cell transplantation. Renal function was stable for four patients; it was reduced for one patient because of infections and bleeding complications. Sequential living-donor kidney transplantation and autologous stem cell transplantation are feasible,[420] although there is controversy about whether the stem cell transplantation should precede the kidney transplantation.[421] Nineteen patients with AL underwent living (n = 18) or deceased (n = 1) kidney transplantation at our institution from 1999 to 2008 (median age, 57 years[422]). Six of the patients were women. Outcome data were stratified in accordance with three treatment regimens: group 1, kidney transplantation followed by autologous stem cell transplantation (n = 8); group 2, autologous stem cell transplantation followed by kidney transplantation (n = 6); and group 3, kidney transplantation after complete remission achieved with nonmyeloablative therapy (n = 5) (median follow-up, 41.4 months). At the time of the study, 79% of the patients were still alive. The treatment groups did not differ in their survival rates. Recurrent amyloidosis was diagnosed through biopsy in a patient in group 2 (before an autologous stem cell transplantation) and in another patient in group 3.

Hepatic and Gastrointestinal Tract Amyloidosis

No specific supportive care measures are available for hepatic amyloidosis. Ascites seen in these patients is more commonly associated with concurrent right-sided heart failure or nephrotic syndrome because portal hypertension is not common. Diuresis and, on occasion, paracentesis are the mainstays of support. Patients with hepatic AL have been treated with transjugular intrahepatic portal systemic shunting,[423] which results in resolution of ascites and hydrothorax. For a patient with renal and hepatic amyloidosis, bilateral nephrectomy resulted in markedly improved liver function and normalization of a previously elevated bilirubin value.[424] The median survival of 98 patients with amyloidosis (histologically proven with liver biopsy specimens) was 8.5 months.[281] Stem cell transplantation performed in tandem at 10 and 14 months after liver transplantation resulted in a good clinical outcome 28 months after liver transplantation.[425]

Amyloid deposits are commonly seen in the gastrointestinal tract. Intestinal symptoms include alternating diarrhea and constipation in the same patient. Bowel disturbances may result from massive deposits in the gastrointestinal tract; malabsorption syndrome or dysmotility may be a consequence of autonomic involvement. Therapy for diarrhea includes diphenoxylate, tincture of opium, loperamide, or paregoric, but results vary. Octreotide (a somatostatin analog) has been reported to reduce diarrhea. In the short-acting form, the dose is 200 to 300 μg/day, divided into two or three doses. A long-acting form of octreotide, which comes in 10-, 20-, and 30-mg doses, may be used. (This is a sustained-release formulation of injectable octreotide that lasts for 2 months.) A dose may be given on a monthly basis for 2 months, and it may then be adjusted according to the patient's response. Patients who are disabled because of diarrhea and fecal incontinence may undergo a diverting colostomy, which may result in excellent patient satisfaction. Patients with intestinal AL sometimes have such severe nutritional failure that long-term total parenteral nutrition is required. We have not found metoclopramide or cholinergic agents to be effective. A colon biopsy showing amyloid deposits might be localized, not systemic, disease.[426]

Respiratory Amyloidosis

For patients with localized tracheobronchial or laryngeal amyloidosis, neodymium:yttrium–aluminum–garnet laser therapy is standard treatment. Low-dose irradiation has been reported to improve obstructive symptoms.[137] Nodular pulmonary amyloidosis may be observed or be treated with surgical excision. For patients with diffuse interstitial pulmonary amyloidosis and true disruption of the alveolar arterial gradient, low doses of prednisone produce symptomatic benefits, although radiographic changes are not evident. The therapy for pulmonary hypertension includes vasodilators and calcium channel blockers. Many patients with amyloidosis are intolerant of these medications because of the associated orthostatic hypotension. Pulmonary amyloidosis may be part of systemic amyloidosis or may be organ limited. Interstitial amyloid deposits affect gas exchange. Airway stenosis from tracheobronchial amyloid deposits may necessitate iterative laser treatment.[427]

Factor X Deficiency

Therapy for factor X deficiency has included the use of oral melphalan, prednisone, and stem cell transplantation.[428] For a patient who is an appropriate candidate, splenectomy results in improvement of factor X levels,[429] and infusion of activated factor VII can temporarily normalize coagulation factors and permit safe splenectomy.[359] The management of factor X deficiency with recombinant human factor VII and splenectomy has resolved intractable hematuria.[430] Prothrombin complex concentrates containing high levels of factor X have also been used before performing a hemicolectomy in AL.[431]

Nonchemotherapy Treatment

Dimethyl Sulfoxide

The best results of DMSO treatment were achieved when it was used in topical applications for patients with cutaneous amyloidosis[432] and after cystoscopic treatment for patients with bladder amyloidosis.[142,433] DMSO is not used in the management of AL today.[434]

Colchicine

FMF is associated with the development of AA in an autosomal dominant inheritance pattern. Clinical features of FMF are pleuritis, peritonitis, synovitis, and migratory skin rash.[435] This disorder is rarely seen in the Western hemisphere, and it primarily affects individuals of Sephardic Jewish, Armenian, Arabic, and Turkish ethnicity. Recurrent attacks of polyserositis are not required for development of amyloidosis. Fully one fourth of patients in whom AA develops do not have any history of arthritis or polyserositis. In the Middle East, one fourth of renal amyloidosis cases are attributable to the presence of FMF.[77] With the introduction of colchicine therapy, the survival of FMF patients has improved (median, 25 months) and the 5-year survival rate is 20%. For patients with FMF, the clinical manifestation of AA is proteinuria, nephrotic syndrome, and dialysis-dependent renal failure. Colchicine has been shown to prevent attacks of polyserositis effectively in two double-blind placebo-controlled studies[436,437]; the frequency of attacks was reduced by 82% and 78%.

Colchicine decreased the incidence of renal amyloidosis by nearly two thirds for patients with FMF.[438,439] When patients were adherent with colchicine therapy, development of amyloidosis was rare. Occasionally, colchicine in FMF reversed the proteinuria associated with established renal amyloidosis. When 350 children younger than 16 years (with clinically evident FMF) were given prophylactic colchicine, amyloidosis developed in none.[440] After renal failure develops from AA in FMF, colchicine prevents recurrent amyloid deposition in the grafted kidney. Colchicine can be administered safely to children and pregnant women.[441] The classic clinical picture of FMF is recurrent, acute, short-lived, febrile, and painful attacks. The gene that causes FMF (*MEFV*) has been fully sequenced.[442] Hereditary periodic fevers with amyloidosis have also been described as a cryopyrin-associated periodic syndrome. Colchicine is only effective in the management of FMF and is not effective for any other periodic fever syndrome.[50]

Measuring Responses in Primary Amyloidosis

Surrogate measurements typically are used to assess responses in amyloidosis. For example, responses to treatment may be defined by clinical improvement in dysfunctional organs or by reduced levels of the amyloid precursor protein. The latter involves measuring the monoclonal protein component and applying criteria that were established for patients with multiple myeloma. The third method of defining response is by SAP scan findings, but this technique is not widely available. All patients who have detectable serum or urine monoclonal proteins or free light chains must have this variable monitored after any therapeutic intervention. A reduction in the size of the M component peak or light chain suggests that production of amyloid precursor protein is decreased. The immunoglobulin free light-chain nephelometric assay has been invaluable for quantifying monoclonal proteins that previously were classified only as present or absent. In assessment of response with the free light-chain assay, the criterion conventionally accepted as a partial response is a 50% reduction in the concentration of the free light chains. A very good partial remission is defined as a dFLC less than 40 mg/L. When the free light-chain assay findings are negative (<2% of AL patients) and the M component is not measurable, a response is defined as the disappearance of light chains when examined by immunofixation.[443] The median number of plasma cells at diagnosis is 5%, which makes estimation of plasma cell reductions difficult. In addition, even when the percentage of plasma cells is 1% or 2%, sophisticated studies using immunofluorescent assays to detect a clonal population through gene rearrangements suggest that molecular complete responses are rare.[444]

The quantitative serum free light-chain assay has become mandatory for assessing the treatment response of patients with AL. Patients with a hematologic partial response can show evidence of improved cardiac function by echocardiography and by reduction of cardiac biomarkers. The decreased concentration of free light chains is associated with improved survival. Similarly, when free light-chain levels are not reduced after chemotherapy, patients have a high risk of early death.[445] The free light-chain test is also useful after histologic tissue diagnosis of amyloidosis to determine whether the patient has AL.[446] We have found that absolute values of immunoglobulin free light chains have prognostic value for patients undergoing stem cell transplantation. Achievement of a free light-chain response was a better predictor of survival than achievement of a complete hematologic response as defined by serum and urine immunofixation assays. The free light-chain measurements before and after stem cell transplantation are important predictors of outcome.[372] When the free light-chain analysis was performed after chemotherapy for 25 patients, the levels of free light chain decreased significantly, and all patients with a κ-to-λ ratio of 0.26:1.65 had a good prognosis.[447] The circulating free light-chain concentration was measured in 262 patients with AL. Of the 86 patients who had at least a 50% decrease in free light-chain concentration, the 5-year survival rate was 88%; in contrast, patients who did not have a light-chain decrease of 50% had a 5-year survival rate of 39%.[375] Used to measure hematologic response, the free light-chain response is a more useful gauge than the M-protein response. Attaining a dFLC reduction of 90% or more is important to improved outcome of patients with light-chain AL.[377] Amyloid deposition in fat tissue undergoes substantial histologic regression only after normalization of the level of serum free light chain.[448]

Organ response criteria have been defined. Ideally, a response in amyloidosis is accompanied by improved function of a previously involved organ. A 50% reduction in the amount of albumin excreted in the urine within 24 hours, with no increase in serum creatinine levels and no decrease in serum albumin concentration, is the generally accepted definition of a response for patients with renal amyloid nephrotic syndrome. A 50% reduction in serum alkaline phosphatase with no increase in transaminase or bilirubin levels is considered an organ response for hepatic AL. Reduction in liver size is less common. Documentation of amyloid regressions in the heart is difficult with echocardiography. A reduction in wall thickness of 2 mm, measured by two-dimensional echocardiography, has been proposed as confirmation of a response. Interprocedural variability is considerable, however, and caution is required when confirming a cardiac response or progression on the basis of echocardiographic criteria only. New criteria using NT-proBNP define cardiac response

as a reduction of more than 30%, with a minimum decrement of 300 pg/ml. Although rare, a response in amyloid peripheral neuropathy should be documented by an electromyogram showing improved nerve conduction velocities. A consensus definition of organ involvement and treatment response incorporating the free light-chain assay was developed at the Tenth International Symposium on Amyloid and Amyloidosis.[449]

Chemotherapy for Amyloidosis

To date, most therapies for AL have been directed toward killing the underlying plasma cell clone. The cornerstone of therapy, described in the following section, has been alkylation or corticosteroid based. However, with advances made in the last decade for myeloma treatment, new regimens have been tested, but none have been subjected to randomized clinical trials. Successful cytotoxic chemotherapy to induce regression of AL was reported in 1972.[450] The use of alkylating agents to suppress plasma cell clones in the bone marrow of AL patients occurred after the recognized success of these agents in the treatment of patients with multiple myeloma.[451] More recently, high doses of chemotherapy with peripheral blood stem cell support have been applied.[452] Unlike in multiple myeloma, recognition of an organ response in AL may take up to 1 year. In the case of intermittent low-dose chemotherapy, it is difficult to distinguish between patients who will respond after longer exposure to therapy and those who will not benefit from therapy and who should be offered an alternative therapeutic approach.[453,454] In vitro studies of the plasma cells from AL patients show aberrant light-chain synthesis. In one study,[455] the cytoplasm of the plasma cells contained light-chain tetramers. After successful alkylating agent–based chemotherapy, light-chain synthesis was suppressed and a clinical response was observed.

The two earliest reports of melphalan and prednisone therapy[456,457] showed responses and prolongation of survival for a minority of patients. Patients with renal, cardiac, or liver AL appeared to benefit, but elevated β_2-microglobulin levels and cardiac involvement were predictors of failure of response.[458,459] Although therapy with melphalan and prednisone has been shown repeatedly to benefit a subgroup of patients with AL, the majority of patients did not respond. Even with subset analysis, no cohort had a response rate that exceeded 40%, including patients with single-organ renal involvement and normal serum creatinine values. Moreover, even when patients showed an organ response, follow-up tissue biopsy specimens showed persistent deposits of amyloid.[460] Because follow-up biopsies are performed infrequently, it is unclear whether clinical improvement is regularly associated with histologic regression. SAP scans suggest, however, that these deposits may be mobilized and that the total amyloid body burden is reduced.

When the Mayo Clinic experience with melphalan and prednisone therapy was reviewed,[371] the overall response rate was only 18%. Increased serum creatinine concentration also had an adverse impact on survival; patients with serum creatinine values that exceeded 3 mg/dl at the initiation of therapy did not have a response. The highest response rate (39%) was observed with the small group of patients with nephrotic syndrome, no extrarenal involvement, normal serum creatinine values, and normal echocardiographic findings. Responses were noted for patients with amyloid cardiomyopathy, suggesting that no patient is too ill for treatment. The response rate, however, was low (15%).[371] Clinical regression of neuropathic symptoms, such as pain, paresthesias, and numbness, is rare after melphalan-based chemotherapy. Although only 18% of patients responded to melphalan, their median survival time was 89 months. The 5-year survival rate of this small subgroup was 78%. The median time to response was 1 year. Nonresponders had a median survival of 15 months. It is often difficult to know when to discontinue low-dose melphalan-based therapy. If alternative therapies, such as high-dose chemotherapy with peripheral blood stem cell support, are not viable, a trial of alkylating agent–based chemotherapy for AL may be beneficial and is a reasonable consideration for virtually all patients.

Long-term survival is possible for patients with AL. One report described 841 patients with AL who were studied over a 21-year period.[461] The actuarial survival rate for the patients at 1, 5, and 10 years was 51%, 16%, and 4.7%, respectively. The 10-year survivors (30 patients) received treatment with melphalan and prednisone. Fourteen had a documented hematologic response with eradication of M protein from the serum and urine. Ten patients had nephrotic-range proteinuria, and four had a reduction in urinary protein excretion of greater than 50%. Unfavorable prognostic features for 10-year survival included heart failure, older age, creatinine values greater than 2 mg/dl, greater than 20% bone marrow plasma cells, and a platelet count greater than 500×10^9/L. In a report of 10 patients with AL, 8 were treated with cyclophosphamide and melphalan.[462] No patient responded to treatment. Four patients received infusion of vincristine, doxorubicin, and dexamethasone over 96 hours. Two patients showed a 50% reduction in the serum M component level.

A randomized crossover study of melphalan and prednisone versus colchicine was reported.[456] The 101 eligible patients were stratified by the clinical manifestation of amyloidosis: (1) heart failure, (2) neuropathy, (3) nephrotic syndrome, and (4) other. Patients were also stratified by age. Significant differences that favored melphalan and prednisone therapy were observed.

Two prospective, randomized noncrossover studies were performed to evaluate melphalan and prednisone therapy for patients with AL. In one study, 219 patients were enrolled.[457] Patients were stratified by age, sex, and clinical manifestation. Half of the patients had nephrotic-range proteinuria, and 20% had heart failure. The median survival was significantly longer in the groups treated with melphalan and prednisone (17 months) than in the colchicine group (8.5 months).

The second study[463] randomly assigned 100 patients to receive colchicine therapy or a combination of melphalan, prednisone, and colchicine. The overall survival of the patient group was 6.7 months in the colchicine-only group and 12.2 months in the melphalan group. With multivariate analysis, melphalan had a significant impact on survival when heart failure was not present.

Although melphalan is a superior therapy in the treatment of AL, the frequency of response with melphalan is low, and the treatment itself is potentially leukemogenic. Of 153 patients receiving melphalan, cytogenetic abnormalities were recognized in 10.[464] All cytogenetic changes were consistent with damage to hematopoietic stem cells. Eight of the 10 patients died of pancytopenia, one died of progressive renal amyloidosis, and one was alive at the time of publication. Morphologically, four patients had acute leukemia and five had myelodysplasia. Overall, bone marrow damage consistent with alkylation-induced toxicity was observed for 7% of the patient population. The actuarial risk was 21% for myelodysplasia or acute leukemia developing 42 months after initiation of therapy. The median survival period was 8 months after receiving the diagnosis of leukemia or myelodysplasia.

In one study, nine consecutive patients were treated with dexamethasone alone (dosage, 40 mg on days 1 through 4, days 9 through 12, and days 17 through 20, every 5 weeks for three to six cycles).[465] This treatment was followed by maintenance levels of interferon. Three patients received maintenance levels of dexamethasone (dosage, 40 mg on days 1 through 4, every month for 1 year). An AL organ improvement was reported in eight of the nine patients. Of seven with nephrotic-range proteinuria, six had a 50% reduction in proteinuria, with a median time to response of only 4 months. Organ function improvement was reported in amyloid neuropathy, hepatic involvement, and gastrointestinal involvement. Neither patient with heart failure

showed improvement. Dexamethasone has no tendency to cause leukemia, and the responses are faster than with melphalan. When we treated 19 patients with high-dose dexamethasone in an identical regimen without interferon, only 3 had an objective organ response.[466] The median survival of the entire group was 11.2 months. When cardiac amyloid is not present, high-dose dexamethasone treatment may produce benefit in some patients with AL. We also have used dexamethasone when melphalan and prednisone therapy failed.[466] Among 25 patients who received high-dose dexamethasone treatment, three objective responses with organ-specific improvement were observed. The median survival of the entire group was 13.8 months. Dexamethasone may be beneficial when treatment with melphalan fails,[467] but toxicity may be formidable and may include fluid retention, gastrointestinal bleeding, and colonic perforation.

The combination of melphalan with high-dose dexamethasone treatment has been reported in the management of amyloidosis.[468] Patients were selected on the basis of their ineligibility for stem cell transplantation. Of 46 patients, a hematologic response was seen in 31 (67%); of these, a hematologic complete response was seen in 15 (33%). Improvement in organ dysfunction was observed in 22 patients (48%). A strong correlation was noted between hematologic response and organ response. Of the patients who achieved a hematologic complete response, 87% had organ improvement. Among the patients who achieved a hematologic response (at least 50% reduction of the M component), organ function improved in 56% of patients. The 15 who had no response also had no improvement in organ function. Advantages of this regimen included a 4% mortality rate on day 100 and resolution of cardiac failure for 6 of 32 patients. The median time to response was short (4.5 months), and only 11% had adverse effects. Using a similar melphalan- and dexamethasone-based regimen, physicians at Weill-Cornell School of Medicine reported a median survival of only 10.5 months. Outcomes appear to be strongly linked to the proportion of patients with cardiac amyloidosis.[469] With melphalan administered parenterally with dexamethasone in patients who had immunoglobulin light-chain amyloidosis, the median survival of 61 patients was 17.5 months. The 3-month all-cause mortality rate was 28%.[470] In Boston, a study of 70 patients who were treated with melphalan and dexamethasone showed that, among 48 patients who survived and returned for follow-up assessment, 6 patients (13%) had a full hematologic response and 12 patients (25%) had a partial response. Responses of the patients who received weekly "low-dose" dexamethasone treatment were not inferior compared with those who received 4-day pulses. Median survival for the 70 patients has not yet been reached (median follow-up, 17 months).[471] There appear to be two factors that help account for at least some of this difference. First, the assessment of response using the immunoglobulin free light-chain assay did not exist in the early studies of melphalan-based therapy but has been used regularly since 2005, resulting in improved ability to monitor hematologic responses. Second, the mix of patients, particularly those with cardiac amyloidosis, is very important in determining overall outcomes.

Reduced-dosage dexamethasone produces high response rates for patients with AL[472] compared with response rates of patients receiving the traditional dosage.[473] Among 93 patients with biopsy-proven AL, hematologic complete remissions were observed for 24%, and improvement in AL-related organ dysfunction occurred for 45%.[473] Median survival of the entire cohort was 31 months, and the 2-year event-free survival rate was 52%. Heart failure and the β_2-microglobulin levels were predictors of adverse outcome. Front-line therapy with dexamethasone may lead to durable reversal of AL-related organ dysfunction and to prolonged survival.

Use of thalidomide has been explored in the treatment of amyloidosis. Sixteen patients (median age, 62 years) were treated,[474] and the median maximum tolerated dose was 300 mg. Exacerbation of peripheral neuropathy and pulmonary edema occurred frequently, and 50% of patients had Grade 3 or 4 toxicity. No patient had a complete hematologic response; 25% had a significant reduction in light-chain proteinuria. Twelve patients at our institution were treated with thalidomide.[475] Nine patients had cognitive difficulty, edema, and constipation, and two had deep vein thrombosis and syncope. The median time receiving thalidomide therapy was 72 days. Two patients died, and the other 10 withdrew from treatment (6 because of toxicity and 4 because of disease progression). Patients with AL had poor tolerance of thalidomide. In another study,[476] thalidomide was combined with dexamethasone in doses of up to 400 mg per day. A hematologic response was achieved in 48% of patients , 19% had a hematologic complete response, and 26% had organ responses. The median time to response was 3.6 months. Treatment-related toxicity occurred for 65%. Thalidomide, dexamethasone, and cyclophosphamide have been reported to produce a hematologic response rate of 74%.[477]

A phase 2 trial of 35 patients receiving lenalidomide showed therapeutic activity when lenalidomide was combined with dexamethasone.[478] When lenalidomide was used alone, four patients showed a response. Eight of 13 evaluable patients had a measurable hematologic response. Three responses were complete or near complete. Lenalidomide is well tolerated by patients with AL and may result in excellent hematologic responses. In an update, progression-free survival of patients with complete response was 49.8 months.[479] In a second study, 41% of patients receiving salvage treatment with lenalidomide who had renal amyloid had a reduction in urinary protein, but the response duration and overall survival were not reported.[480] In that study, high-risk patients were less likely to respond to lenalidomide. Therapy with lenalidomide can change cardiac biomarkers[481] and alter renal function in amyloidosis.[482]

Lenalidomide also has been combined with melphalan and dexamethasone.[483] The maximum tolerated dose of lenalidomide is 15 mg. This three-drug oral combination produced hematologic responses in 58% and complete responses in 42%. The 2-year event-free survival rate and the overall survival rate were 54% and 81%, respectively. In addition, lenalidomide was combined with cyclophosphamide and dexamethasone in the treatment of 35 patients.[484] Hematologic response rate was 60%. In those patients receiving at least 4 treatment cycles, the response rate was 87% (median overall survival, 16.1 months).

A randomized study of cyclophosphamide–thalidomide–dexamethasone treatment compared with melphalan–dexamethasone treatment suggested a greater complete response rate with the three-drug regimen, albeit with greater toxicity.[485] One cautionary note when using lenalidomide or thalidomide in patients with AL is that the NT-proBNP level appears to increase after the initiation of therapy. Recognition of potential immunomodulatory drug-induced cardiac toxicity is important when these agents are used. High levels of NT-proBNP are predictive of an inability to tolerate immunomodulatory agents for amyloidosis.[486]

Pomalidomide, a derivative of thalidomide with structural similarity to thalidomide and lenalidomide, was given to 29 evaluable patients in one study.[487] All patients had received treatment previously and 13 of the patients had received a prior autologous stem cell transplantation. Previously, an immunomodulatory agent was given to 15 patients and bortezomib to 12. Twenty-nine patients evaluable for hematologic response were seen. The overall response rate was 38% (11 patients). Combined treatment with pomalidomide and dexamethasone is promising. One-year survival and progression-free survival rates were 77% and 56%, respectively. Pomalidomide was considered effective and safe for patients, including those in whom prior lenalidomide or thalidomide therapy had failed.

Eighty percent of evaluable patients in the first reported study of bortezomib for amyloidosis had a hematologic response.[488]

Among 18 patients, the hematologic response rate was 77%, with a 16% complete response rate. A phase 1 dose-escalation study of bortezomib given either twice weekly on days 1, 4, 8, and 11 every 21 days or on days 1, 8, 15, and 22 every 35 days reported hematologic responses in 50% of patients. The weekly regimen was associated with decreased neurotoxicity. There was a 1-year hematologic progression-free rate of 72.2% and 74.6% and a 1-year survival rate of 93.8% and 84%, respectively, for the twice-weekly and once-weekly doses.[489] Among 70 patients, 29% had renal responses and 13% had cardiac responses. Discontinuation and dose reduction due to the toxicity were greater with the twice-weekly than once-weekly dose. Both dose schedules represent active, well-tolerated regimens in relapsed AL.[490]

The combination of bortezomib and dexamethasone has been used after stem cell transplantation as consolidation to improve the depth of response.[491] Of 23 patients, 17 received bortezomib posttransplantation; 74% achieved a complete response and 58% achieved an organ response. A multicenter study of 94 patients receiving bortezomib and dexamethasone showed hematologic responses in 71% of patients; responses were complete in 25%.[492] Cardiac response was seen in 29% of patients. The NT-proBNP predicted survival. In a study of bortezomib–dexamethasone therapy in 26 patients, the overall response rate was 54%, with complete responses in 31% of patients. Median time to response was 7.5 weeks, but the median progression-free and overall survivals were 5 and 18.7 months, respectively, suggesting short durability with bortezomib combined with dexamethasone. No grade 3 to 4 neuropathy was observed.[493]

Stem Cell Transplantation

Hematopoietic stem cell transplantation for AL is inherently different from transplantation for other hematologic cancers.[494] Patients with lymphoma, multiple myeloma, or leukemia typically have considerable bone marrow abnormalities that manifest as multiple cytopenias, but these patients generally have excellent cardiac, hepatic, and renal function and a performance status of 0 or 1. In contrast, AL patients often have clinically significant visceral organ dysfunction, which puts them at a high risk for complications after high-dose chemotherapy. Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are uncommon.

Syngeneic transplantation was reported in the treatment of a patient with AL in 1995.[495] A SAP scan showed a reduction in amyloid deposits. In one report, two AL patients had ablative allogeneic bone marrow transplantation.[496] The first had a hematologic response and underwent an allogeneic transplantation after melphalan treatment (110 mg/m^2) and total body irradiation (1,200 cGy). The patient achieved a complete hematologic response and was alive 29 months after transplantation. The second patient received a stem cell transplant from a human leukocyte antigen–identical sibling after treatment with melphalan (140 mg/m^2) and total body irradiation (800 cGy). The urinary protein loss decreased from 9.15 to 1.3 g/day. The patient had chronic graft-versus-host disease of the skin and liver but was alive 18 months after transplantation.

Allogeneic stem cell transplantation may be a promising treatment, but the mortality rate is high. The European Group for Blood and Marrow Transplantation reported 19 patients with AL.[497] Fifteen underwent allogeneic transplantation: seven had full-intensity conditioning and eight had reduced-intensity conditioning. Overall survival and progression-free survival at 1 year were 60% and 53%, respectively. The treatment-related mortality rate was 40%. Eight patients had a complete response and two had a partial response. For five of seven evaluable patients who had a complete response, chronic graft-versus-host disease was observed, which implied existence of a graft-versus-amyloidosis effect. Cardiac failure was a clinically significant problem. It is unlikely that allogeneic or nonmyeloablative allogeneic transplantation will be applicable to a large proportion of AL patients because of the age restrictions and the need for good performance status and adequate renal function. Allogeneic hematopoietic cell transplantation after reduced-intensity conditioning should be discussed as a treatment option for relapse after autologous hematopoietic cell transplantation in patients younger than 60 years with preserved organ functions and a HLA-identical donor.[498]

Most reported experiences with myeloablative chemotherapy involve progenitor cell replacement with autologous peripheral blood stem cells. The blood stem cells are used because they are easy to collect and have relatively rapid engraftment kinetics. Most AL patients who receive blood stem cells show clonotypic cells in the apheresis product. CD34$^+$ cell selection to eliminate the clonotypic stem cells may be performed, but its impact on outcome is uncertain.[499] It is known that CD34$^+$ selection yields no survival benefit for patients with multiple myeloma who undergo stem cell transplantation,[500] and we have no reason to believe that the outcome would be different for patients with AL. Clinicians at Boston University first reported five patients with AL receiving stem cell transplants, and all showed a clinical response.[501] When the cohort was expanded to 25 patients, a hematologic response was reported for 62% and an organ response for 65% of surviving patients.[502]

Another report described 250 patients who received melphalan (100 to 200 mg/m^2) before stem cell transplantation.[503] The median patient age was 57 years, and 53% of patients had echocardiographic evidence of amyloidosis. The 3-month transplant-related mortality rate was 14%; 11% of patients who initiated stem cell collection did not undergo transplantation because of death or mobilization toxicities that precluded safe transplantation. During mobilization, 23 patients had major morbidities; 18 did not undergo stem cell transplantation. Four patients had cardiac arrest during stem cell infusion, and six additional cardiac arrests were noted during the weeks after transplantation. Febrile neutropenia occurred in 62 patients, 17 had gastrointestinal tract hemorrhage, and 12 had progressive renal failure that required dialysis. At a mean follow-up time of 23 months, 66% of the patients were alive. The best responses were from patients with isolated renal amyloidosis. Lower toxicity grades were observed in patients who received lower conditioning doses of melphalan (100 mg/m^2).

Multicenter surveys that reported the outcome of transplantation were first published in 1998.[504] In France, 21 patients with systemic AL received transplants: 18 were treated with melphalan alone and 3 had regimens that included total body irradiation. The death rate was 43%, and 9 of the 21 died within 1 month after transplantation. All deaths were attributable to multiorgan failure, including one patient with intractable bleeding. Of the 12 survivors, 10 achieved a response. Patient selection clearly affected the results because the median time between diagnosis and transplantation was 11 months. We suggest that the lengthy period before transplantation excluded patients with a worse prognosis. Outcome was predicted by the number of organs involved at the time of transplantation. For patients with two or more affected organs, the 4-year survival rate was 11%. The risk of toxic death when two organs were involved was 75%, which reflected the need for careful patient selection. One study from the United Kingdom described 27 patients who received high-dose melphalan therapy before stem cell transplantation.[505] Eight treatment-related deaths (30%) occurred: four deaths were attributable to multiorgan failure, two to gastrointestinal tract hemorrhage, one to sepsis, and one to cardiac complications. Despite the high death rate, a clonal response of the bone marrow plasma cells was seen in 64% and organ regression in 57%. Seventeen of the 27 patients were alive at the end of the study. Of the nine patients who received a transplant, four died within a year after transplantation (treatment-related mortality rate, 44%).[506] Three of the four deaths were attributable to cardiac amyloidosis; the fourth death was of a patient with amyloid involvement of the kidney, nerve,

and intestinal tract. The median follow-up of the five survivors was 12.6 months; four patients responded to therapy and one patient had disease progression.

Multiorgan failure and gastrointestinal tract bleeding are more common in transplantation for AL than transplantation for any other indication. Gastrointestinal tract bleeding appears to be highly specific for AL. We reviewed the first 45 patients who received transplants for AL at our institution.[507] Eleven died after transplantation (median survival time, 2 months). Gastrointestinal tract bleeding was observed in nine (20%). The median time to onset of bleeding was 9 days after transplantation, and the median platelet count was 22×10^9/L. Bleeding was seen in the upper gastrointestinal tract for two patients, the lower tract for three, and the lower and upper tract for four. Endoscopy was performed for five patients, and all had inflamed, friable gastric and esophageal mucosa. Four of the nine patients with bleeding died, three of multiorgan failure. Gastrointestinal tract bleeding was associated with female sex and poor engraftment of platelets. During the first 100 days after transplantation, the median number of packed red blood cell units administered was 20 for those with gastrointestinal tract bleeding. The exact mechanism underlying bleeding after stem cell transplantation is unknown. The widespread vascular deposits of amyloid may render the vessels rigid and friable, however. High-dose chemotherapy, which causes clinically significant mucosal damage, may also cause bleeding. In our patient cohort, abnormalities of the coagulation system were not involved in the bleeding.

We have described three patients who did not undergo stem cell infusion because of complications related to mobilization.[508] Two patients died of progressive amyloidosis at 1 and 3 months after mobilization. In the past, we have used two different mobilization schemes. One used filgrastim only (10 μg/kg/day), and apheresis commenced on day 5. The other scheme used cyclophosphamide (1.5 g/m^2) on 2 consecutive days, followed by sargramostim (5 μg/kg/day), and apheresis began when the white blood cell count exceeded 1,000 cells/μl. The median overall yield was 6.4×10^6 CD34$^+$ cells/kg. Of patients who received mobilization treatment with cyclophosphamide, the median number of apheresis was three. Of patients receiving filgrastim alone, the median number of apheresis was two, a statistically significant difference.

At Mayo Clinic, 434 patients with amyloidosis received their transplants at a median of 4.0 months after histologic diagnosis: One fourth within 3 months and three fourths within 6.6 months (median actuarial survival for the entire group, 94.9 months). Predictors of survival included weight gain of greater than 2% during stem cell mobilization and an absolute lymphocyte count at day 15 of greater than 500 cells/μl. The number of organs involved appeared to be relevant to predicting the outcome successfully. Patients with two-organ involvement had a median survival rate of 70% at 60 months; and those with three-organ involvement, a median survival of 58 months. The levels of serum creatinine, troponin *T*, and NT-proBNP and the septal thickness were all significant predictors of outcome.[509]

Engraftment kinetics were similar to those of patients with multiple myeloma. We did not administer growth factor after transplantation because of its impact on fluid retention and the ability of growth factors to precipitate congestive heart failure in amyloidosis patients. A neutrophil count of 500 cells/μl was achieved at a median of 14 days (range, 7 to 116 days). Twenty-five percent of patients showed engraftment on or before day 13, 75% by day 16, and 90% by day 22. A platelet count of 20×10^9/L was achieved at a median of 14 days (range, 6 to 406 days); 25% of patients achieved 20×10^9/L by day 12, 75% by day 19, and 90% by day 27. A platelet count of 50×10^9/L was achieved at a median of 18 days; 25% achieved the count by day 14, 75% by day 27, and 90% by day 47. CD34$^+$ cell collection had an important impact on the time to platelet engraftment (Fig. 99.14). When the

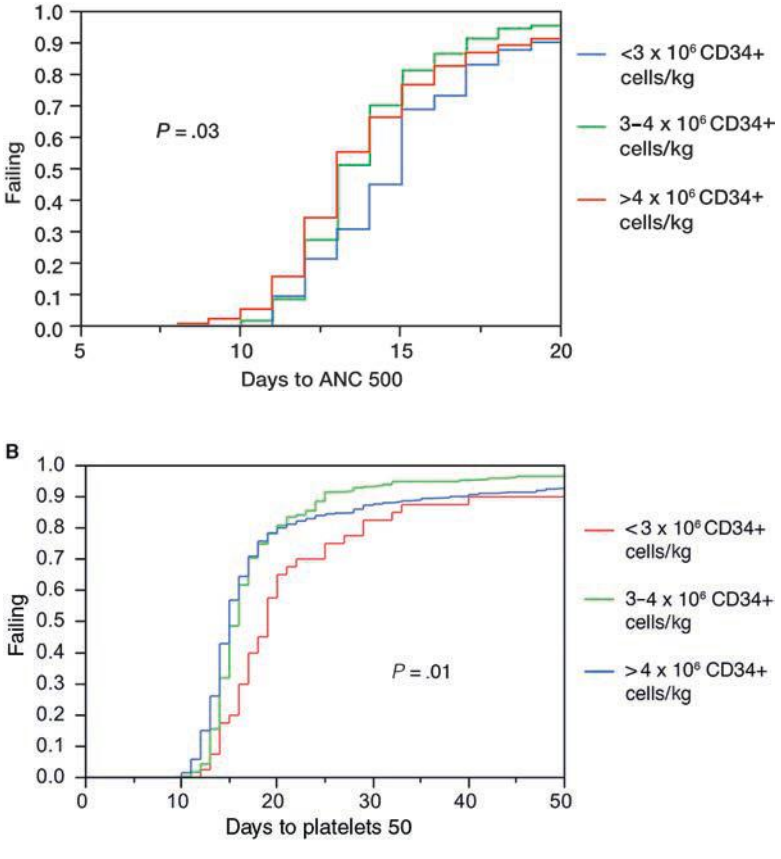

FIGURE 99.14. Engraftment kinetics for neutrophils (A) and platelets (B) posttransplantation. The ideal minimum for CD34$^+$ cells is $>3.0 \times 10^6$ cells/kg. ANC, absolute neutrophil count.

number of infused $CD34^+$ cells was greater than 3×10^6 but less than 4×10^6, engraftment was not significantly different from that of patients who received an infusion with more than 4×10^6 $CD34^+$ cells. However, the time to engraftment was significantly longer for platelets and neutrophils when 2×10^6 to 3×10^6 $CD34^+$ cells were infused. We therefore set a goal of more than 3×10^6 stem cells for rapid engraftment. Safe engraftment may be achieved by infusing only 2×10^6 cells, but the time to engraftment is prolonged, and the risk of infection, bleeding, and an increased number of transfusions is increased.

Studies have demonstrated that patients with stage III disease should be excluded from transplant studies. The troponin level predicts early death from stem cell transplantation and can be used as an exclusion criterion for this therapy.[510] Troponin *T* levels should be measured in all patients before transplantation. Data have recently been reported on 10-year survivors: 25% of patients who received a transplant survived 10 years, and the 10-year survival rate was 53% for complete responders. Transplant-related mortality rates are decreasing from as high as 40% to the now-reported 7%. The median actuarial survival for the entire group was 94.9 months.

Our conditioning regimens are typical of those used for patients with multiple myeloma: 62% receive melphalan at a full dose of 200 mg/m^2, 26% receive a dose of 140 mg/m^2, and 12% receive lower doses primarily because of advanced cardiac amyloidosis or elevated creatinine levels. We have previously reported that the intensity of chemotherapy is important for the overall outcome and that patients receiving full-dose melphalan appear to survive longer.[511] It is difficult to exclude the possibility that patients selected for reduced-intensity chemotherapy had more advanced amyloidosis. At Mayo Clinic, only one quarter of AL patients ultimately undergo stem cell transplantation. Our case-matched control study[512] compared 63 patients who underwent stem cell transplantation with 63 patients who received conventional treatment. The patients were matched for age, sex, cardiac function, creatinine level, and urinary protein loss. We identified an overall survival advantage for patients who underwent transplantation. The Center for International Blood and Marrow Transplant Research reported data results of 107 patients with primary systemic amyloidosis from 48 transplant centers.[513] The day-30 treatment-related mortality rate was 18%, whereas the Mayo Clinic day-30 mortality rate was 7.4%. The center reported high response rates, and only 11% of patients had disease progression after transplantation. The median projected survival was 47 months; the clinical experience of the centers was the most important predictor of survival. Patients who underwent transplantation within the study's last 5 years survived longer than patients who underwent the procedure more than 5 years earlier. The response rate was 34%, and 33% of patients had stable disease.

An unanswered question is whether transplantation for AL patients should be performed preferentially in specialized centers that have extensive amyloidosis experience or in centers that have extensive transplantation experience for nonamyloidosis diseases. An Eastern Cooperative Oncology Group study suggested that treatment-related mortality rates were not higher in multicenter cooperative group settings.[514,515] Stem cell transplantation is not a proven therapy in the management of amyloidosis, despite reports of organ disease remission for 50% of patients.[516,517] One study has also shown an improvement in the quality of life of patients who underwent stem cell transplantation.[518] A Group Myélome-Autogreffe and Intergroupe Francophone du Myélome study suggested that overall survival after stem cell transplantation may not be better than survival after a regimen of melphalan and high-dose dexamethasone.[519] This trial randomly assigned 100 patients; the median actuarial survival was 57 months with melphalan and high-dose dexamethasone and 49 months after stem cell transplantation. The patients who underwent transplantation received melphalan (140 or 200 mg/m^2) and were mobilized only with granulocyte colony-stimulating factor. The hematologic response rates were 65% and 64% for the patients who did and did not undergo transplantation, respectively. Caution is required when interpreting these results, however; the treatment-related mortality rate was high (24%). Furthermore, only 29 of the 100 patients who underwent transplantation were evaluable for response. On the basis of these small numbers, it is premature to abandon transplantation as a treatment modality for amyloidosis.

The extent of cardiac amyloidosis measured with echocardiography in the transplant population is less than that expected of an unselected nontransplant cohort. The median intraventricular septal thickness was 12 mm; one quarter of patients had a septal thickness of 10 mm or less, and three quarters had less than 14 mm.[509] The median ejection fraction was 65%; three quarters of patients had an ejection fraction of less than 70%, and one quarter had an ejection fraction of less than 60%. The median actuarial survival is depicted in Figure 99.15. The absolute lymphocyte count 15 days after stem cell transplantation may have an impact on survival.[520] The number of organs involved appeared to be a relevant prognostic factor (Fig. 99.16). Other prognostic factors included the intraventricular septal thickness; the levels of serum creatinine, serum troponin *T*, and NT-proBNP; and excessive weight gain during stem cell mobilization.[521] The NT-proBNP levels have profound effects on survival after transplantation, presumably because they reflect progression due to cardiac failure.[522] The median level of NT-proBNP among 117 amyloidosis patients at Mayo Clinic was 170 pg/ml; using this concentration as a threshold, the difference in survival is highly significant (Fig. 99.17).

Response has a profound impact on overall survival.[523] Patients who have a 50% reduction of light-chain levels have superior survival compared with those who do not have a 50% decrease. The pretreatment free light-chain value also affects outcome and survival. In a proportional hazards model, overall survival is linked to the pretransplantation free light-chain levels and the number of organs involved. In large medical centers that perform stem cell transplantation, the treatment-related mortality rate is 6% to 18%. Hematologic responses range from 16% to 50%, and reported organ responses range from 34% to 64%. Organ response is a time-dependent variable, and organ responses may be delayed up to 36 months after transplantation. Tandem stem cell transplantations are feasible and have been performed in patients with amyloidosis, but the ultimate effect on outcome is unknown.[524] In a published meta-analysis of stem cell transplantation in AL, transplantation did not appear to be superior to conventional chemotherapy in improving survival for

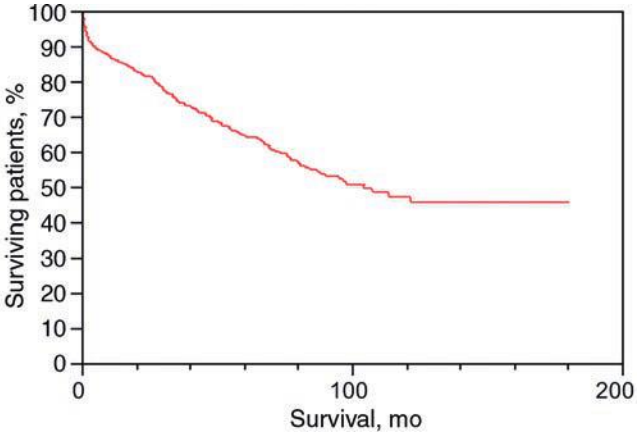

FIGURE 99.15. Survival of patients with primary amyloidosis who underwent stem cell transplantation at Mayo Clinic ($N = 492$). The median survival time was 80 months. Mortality rate at day-100 was 11%.

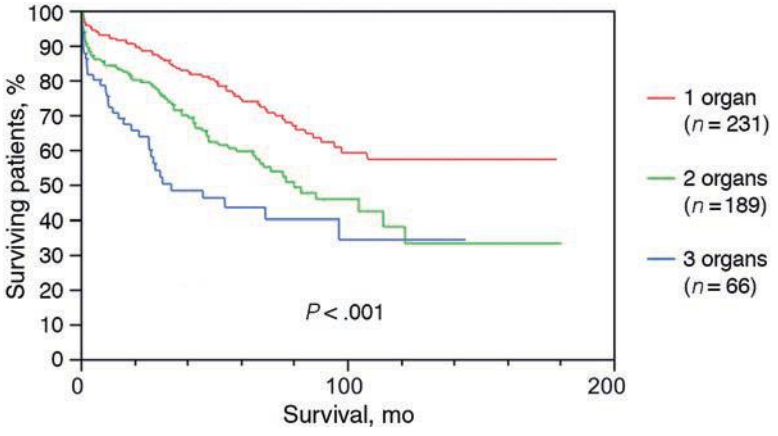

FIGURE 99.16. Effect of the number of affected organs on survival (*N* = 486). Tick marks indicate censored patients (alive).

patients. But the quality of evidence is low, indicating a need for well-designed and adequately powered randomized clinical trials to better address the role of autologous hematopoietic cell transplantation in AL.[525]

The toxicities associated with high-dose chemotherapy are listed in Table 99.5. The response rates that we observed exceeded those of our previous experience with conventional-dose chemotherapy. However, patients receiving high-dose chemotherapy were highly selected, and it is difficult to predict the response rate or survival of an age- and organ-matched population. The most common type of response is the resolution of nephrotic syndrome. Table 99.6 summarizes reported data on stem cell transplantation in nearly 300 patients. Comenzo and Gertz[517] published a risk-adapted strategy for selecting patients with AL and assigning melphalan doses. A review of four single-center studies showed that the day-100 mortality rate was 21%. The contraindications for stem cell transplantation are given in Table 99.7, and the risk-adapted approach is shown in Table 99.8.

Patients with AL who undergo transplantation are highly selected by age, number of organs involved, the absence of advanced heart failure, and performance status. Therefore, a true control group is lacking for comparison. Dispenzieri et al.[533] reviewed 1,288 AL patients seen at Mayo Clinic between 1983 and 1997 and identified patients ineligible for stem cell transplantation using the criteria in Table 99.7. Eligible patients had to have symptomatic amyloidosis without multiple myeloma, an age less than 70 years, an interventricular septal thickness no more than 15 mm, and an ejection fraction greater than 55%. In addition, the serum creatinine value had to be less than 2 mg/dl and the direct bilirubin value had to be less than 2 mg/dl. After the application of these selection criteria, only 229 patients (18%) were eligible for transplantation. The median survival of this nontransplantation cohort was 42 months, and the 5- and 10-year survival rates were 36% and 15%. Clearly, patients who were eligible for transplantation had much better outcomes than those who were ineligible. The predictors of survival included the amount of M protein in the 24-hour urine measurement and the number of involved organs (Fig. 99.18). The alkaline phosphatase value, performance status, and degree of weight loss were also factors that influenced survival. Patients eligible for stem cell transplantation inherently are a low-risk population; certainly, their anticipated median survival time far exceeds the 18 months reported by other studies of patient cohorts that received melphalan and prednisone.[216,534]

CONCLUSION

Amyloidosis should be considered in the differential diagnosis of any patient with nephrotic-range proteinuria, monoclonal gammopathy, heart failure, neuropathy, or hepatomegaly. The symptoms of amyloidosis are vague and not useful for establishing a diagnosis. The pathognomonic physical findings are seen in less than one fifth of patients and therefore are not reliable for disease detection. When a patient has a compatible clinical syndrome, the best screening tests include immunofixation of the serum and urine and a free light-chain assay. Monoclonal light chains may be detected in the serum or urine (or both) of nearly 90% of AL patients, and 99% of those who have free light-chain assays of the serum have abnormal findings. Noninvasive studies, such as fat aspiration and bone marrow biopsy, confirm the diagnosis for

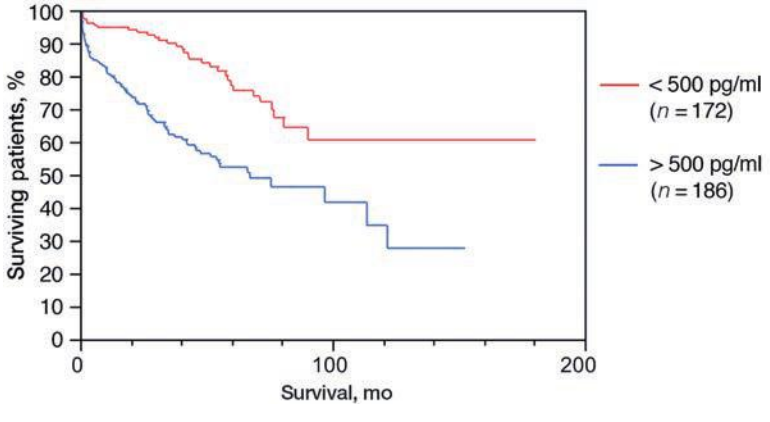

FIGURE 99.17. Effect of N-terminal brain natriuretic peptide level on survival (*N* = 358).

GI, gastrointestinal.

85% of patients with AL. For patients with biopsy-proven amyloidosis who do not have detectable monoclonal protein in the serum or urine, a nonimmunoglobulin form of amyloidosis should be considered. The prognosis should be assessed by two-dimensional Doppler echocardiography, and levels of NT-proBNP, troponin *T*, and β_2-microglobulin should be measured. Systemic therapy is appropriate for most patients. Treatment with melphalan and prednisone provides marginal survival benefit for a minority of patients. High-dose dexamethasone therapy with or without melphalan may be beneficial for a subset of patients. The role of thalidomide and lenalidomide is investigational. Bortezomib appears to have significant activity as a single agent.

TABLE 99.7

CONTRAINDICATIONS FOR STEM CELL TRANSPLANTATION

Absolute contraindication
- Clinical congestive heart failure
- Total bilirubin >3.0 mg/dl
- Echocardiographic ejection fraction <45%
- Troponin *T* > 0.06 ng/ml

Relative contraindication
- Serum creatinine >2.0 mg/dl
- Interventricular septal thickness >15 mm
- Age >65 y
- More than two visceral organs involved

TABLE 99.6

PUBLISHED SERIES OF AUTOLOGOUS TRANSPLANTS FOR AMYLOIDOSIS

Reference	No. of Patients	100-d Treatment-Related Mortality	Overall Survival (Intention-to-Treat)	Evaluable	Follow-up	Hematologic Response	Amyloid Disease Organ Involvement

TABLE 99.8

RISK-ADAPTED APPROACH TO STEM CELL TRANSPLANTATION FOR AMYLOIDOSIS

Low risk (all of the following)
1 or 2 organs involved
No cardiac involvement
Creatinine clearance ≥51 ml/min
Any age
Intermediate risk (all of the following)
1 or 2 organs involved
Asymptomatic cardiac or compensated cardiac involvement
Creatinine clearance <51 ml/min
Age <61 y
High risk (1 of the following)
3 organs involved[a]
Advanced cardiac involvement

Melphalan Dosage (mg/m^2) Based on Risk Group and Age

Low Risk	Intermediate Risk	High Risk
200 if age ≤60 y	140 if age ≤50 y	Standard therapy
140 if age 61–70 y	100 if age 51–60 y	Clinical trials
100 if age ≥71 y	–	–

[a]Organ involvement includes heart, kidney, nerves, liver, and vascular or soft tissue; it does not include bone marrow, skin, tongue, or gastrointestinal tract.
Modified from Comenzo RL, Gertz MA. Autologous stem cell transplantation for primary systemic amyloidosis. Blood 2002;99:4276–4282. Used with permission.

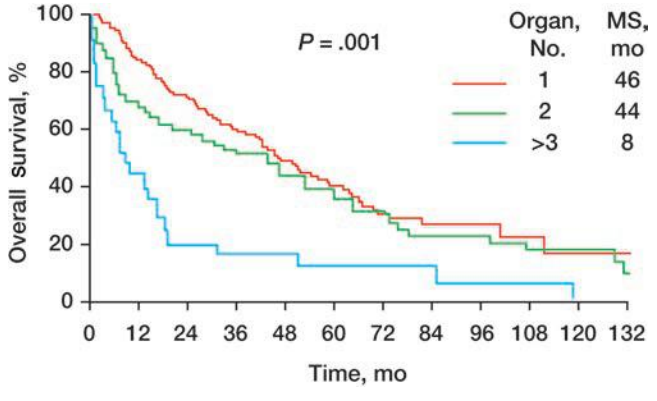

FIGURE 99.18. Effect of the number of involved organs on survival. Patients with amyloidosis were eligible for stem cell transplantation but were treated with melphalan and prednisone. MS, median survival. (From Dispenzieri A, Lacy MQ, Kyle RA, et al. Eligibility for hematopoietic stem-cell transplantation for primary systemic amyloidosis is a favorable prognostic factor for survival. J Clin Oncol 2001;19:3350–3356. Used with permission.)

The more aggressive approach of stem cell transplantation may have long-term benefits. Response rates with stem cell transplantation approach 60%, and responders have the potential for long-term survival. However, firm evidence-based data that prove the survival benefit of stem cell transplantation do not exist.

CHAPTER 100

WALDENSTRÖM MACROGLOBULINEMIA

Rafael Fonseca, Suzanne R. Hayman, Stephen M. Ansell

INTRODUCTION

Waldenström macroglobulinemia (WM) is a malignancy of mature B cells characterized by a monoclonal IgM in the serum and the presence of lymphoplasmacytic lymphoma (LPL) in the bone marrow.[1,2,3] The disease is now defined at the molecular level by the near-universal presence of mutations of the myeloid differentiation primary response gene *MYD88,* believed to be the key step in disease pathogenesis. The classical clinical findings in this disease include anemia, organomegaly, lymphadenopathy, and hyperviscosity. The vast majority of patients typically present with a monoclonal IgM in the serum and anemia.[1,2,3] In this chapter, we review the biology and management of WM, including discussions of its preceding state IgM monoclonal gammopathy of undetermined significance (IgM MGUS).

EPIDEMIOLOGY

General Principles

WM is rare in the United States, with only 1,500 new cases diagnosed per year,[4,5] an incidence of only one sixth that of multiple myeloma (MM). Although it is now possible to conclusively identify patients by the presence of the *MYD88* mutation, this aberration is not exclusively seen in WM[6] and can be present in other B-cell neoplasms. In future classification schemes for the disease, it is likely that molecular confirmation will be needed. Patients with WM need to be distinguished from patients with a monoclonal IgM in the serum, but no evidence of LPL and no disease-related symptoms or signs (Table 100.1). These patients are felt to have an IgM MGUS.[7] The disease is slightly more common in males than females, and more common with advancing age (median age at diagnosis 63 years).[4] WM is rare in patients of Mexican-mestizo or African descent, and more common among Caucasians.[4,5,8]

Kristinsson identified an association between WM and autoimmunity using a population-based registry from Sweden, finding that WM patients were more likely to have a history of autoimmunity.[9] This risk was observed both in patients with a personal history of WM, but also in those with a familial predisposition. Among the various autoimmune disorders, Sjögren syndrome and autoimmune hemolytic anemia were notable risk factors for subsequent development of WM. Recent observations by Koshiol and colleagues using a large database from the US Veterans Administration showed that there is a heightened relative risk (RR) for WM among patients who have a history of autoimmunity (RR, 2.23), autoimmune antibodies (RR, 2.3 to 2.5), hepatitis (RR, 3.39), human immunodeficiency virus infection (RR, 12.05), and rickettsiosis (RR, 3.35).[10] Because of the rarity of the disease, these increased relative risks do not pose major consequences for individuals with these conditions. However, these observations present an hypothesis that chronic stimulation may either drive excessive traffic through the germinal center, with an increased risk of clonal establishment or that a cytokine-enriched milieu allows for further expansion of WM precursor clones normally dormant.

Familial Disease and Genetic Predisposition

In some WM, there appears to be a familial component with more than one member of the family affected.[11–16,17] This implies that a single gene defect may be capable of creating heightened susceptibility. The relationship between this heightened susceptibility and *MYD88* mutations has yet to be elucidated. McMaster has shown that the prevalence of IgM monoclonal gammopathies is as high as 10% among relatives of individuals diagnosed with WM.[18] They also showed that the risk of monoclonal gammopathy decreases with genetic distance, further indicating genetic predisposition. Linkage analyses that include IgM MGUS have shown positive associations.[19] McMaster studied 11 high-risk WM families with WM informative for linkage and collected DNA samples from 122 individuals. Genotypic analysis using microsatellite mapping showed linkage at chromosomes 1q and 4q. In addition, chromosomes 3 and 6 were also suggested as linked.[19]

In another study, Kristinsson and colleagues looked at genetic predisposition for WM by studying 2,144 LPL/WM patients diagnosed in Sweden (1,539 cases with WM (72%) and 605 cases of LPL (28%).[20] They compared them with 8,279 population-based matched controls, and linkable first-degree relatives of patients

TABLE 100.1

RELATION AMONG IGM-MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE, SMOLDERING WALDENSTRÖM MACROGLOBULINEMIA, AND WALDENSTRÖM MACROGLOBULINEMIA

	IgM-MGUS	SWM	WM
Monoclonal serum protein	Usually <1.5 g/dl	Usually >1.5 g/dl	Usually >3 g/dl
Anemia	Not seen	Common but mild	Common
Other cytopenia	Not seen	Rare (15%)	Rare (15%)
Organomegaly	None	May be present	~15–20% of patients
Hyperviscosity	None	None	~15% of patients
Constitutional symptoms	None	None	Present
Bone marrow clonal cells	Usually <5–10%	Usually >20%	Usually >20%
Therapy	Not needed	Not needed	Indicated

IgM MGUS, IgM monoclonal gammopathy of undetermined significance; SWM, smoldering Waldenström macroglobulinemia; WM, Waldenström macroglobulinemia.

(n = 6,177) and controls (n = 24,609). They reported that first-degree relatives of LPL/WM patients have a 20-fold increased risk for LPL/WM.

To further investigate familial predisposition and environmental factors, Royer and colleagues used a questionnaire-based survey in the hope of identifying environmental influences that could modulate this predisposition.[21] They analyzed data on 103 WM patients and 272 unaffected relatives from 35 multiple-case WM and 46 mixed WM/B Cell disorders (BCD) kindred and 28 nonfamilial (sporadic) WM patients. Once more, autoimmunity was notable (overall response [OR], 2.27), as well as infections (OR, 2.13). Other factors identified included farming (OR, 2.70), pesticide exposure (OR), exposure to wood dust (OR, 2.86), and exposure to organic solvents (OR, 4.21). Although the net effect of these risks is small, they do point to possible environmental modification of germline genetic susceptibility.

DIAGNOSIS AND LABORATORY TESTING

The diagnosis in WM is confirmed by the presence of a monoclonal IgM protein in the serum in association with bone marrow infiltration by monoclonal lymphoplasmacytic cells. These diagnostic criteria are the consequence of various consensus meetings to establish standardized diagnostic criteria for WM (see below).[22] As mentioned above, the utilization of molecular techniques will likely become essential in the final confirmation of the diagnosis.

The use of the serum monoclonal protein is a cornerstone of disease diagnosis and monitoring, similar to its use in MM. There are multiple laboratory tests that exist for monitoring the serum concentration of the protein. The treating physician needs to be consistent in using the tests that are used for monitored. The serum protein electrophoresis (SPEP) is the preferred method of detecting the monoclonal protein, but quantitative detection of the IgM is also appropriate because the baseline concentration of the normal IgM (polyclonal) is low enough that it does not substantially alter the monoclonal protein concentration. Initially, immunofixation is needed to characterize a new monoclonal protein (in cases where no IgM has been measured) and also to confirm a complete response (CR). In our practice, we measure both the quantitative IgM and the SPEP because discrepancies are sometimes associated with technical aspects of the measurement. The β_2-microglobulin should be determined, in addition to standard laboratory testing, as it is a prognostic factor for the disease (see below).[23,24]

At the time of diagnosis, serum viscosity should be determined and repeated as needed. For any given patient, it is usually possible to determine a level at which an IgM protein will result in hyperviscosity.[25] Determining viscosity, therefore, at each visit is not really needed (see section "Hyperviscosity, Neurologic and Retinal Complications"). Urine collections can be performed to measure the monoclonal light chain excreted, but the clinical value of this is not clear. Many series have shown that a significant fraction of patients who have WM can have Bence-Jones proteinuria (i.e., light chains).[7] For unknown reasons, WM patients rarely develop intrinsic renal failure despite elevated serum-free light chains (SFLC) in some. Perhaps the large size of the monoclonal IgM prevents most of the intact molecule from reaching kidney tubules, unlike myeloma where the intact immunoglobulin molecule can also be detected in the urine, and possibly contributes to cast formation when large amounts of free light chains are excreted. Studies are not available that address the clinical significance of serum-free light-chain detection; however, it is clear that this assay can be used as a surrogate tumor marker as well.

The use of the serum-free light chain (SFLC) has also been explored in WM.[26] Leleu studied 72 patients (15 new diagnosis and 57 previously treated) and found a correlation between the serum concentration of sFLC and negative prognostic indicators.[27] Itzykson reported on 42 cases of WM (all at diagnosis) and observed similar associations, with elevated levels predicting shorter times to treatment initiation.[28] Larger studies are needed to better quantify these associations and associateds clinical implications.

It is useful to obtain a computed tomographic (CT) scan of the chest, abdomen, and pelvis at baseline to assess the spleen and liver size and the presence or absence of lymphadenopathy. Obtaining a metastatic bone survey for patients with WM has little value because, in most cases of WM, bone disease is not present. Obtaining a bone survey is recommended in cases with bone symptoms or in those where the bone marrow pathology is purely plasmacytic.[29,30,31,32,33] The use of positron emission tomographic scan is not considered routine, but can be useful in determining the extent of disease bulk in selected patients.[34] In some cases, discordant results have been observed, however, a global recommendation for its use has not been made. In patients with proven bone lesions, a diagnosis of IgM myeloma rather than WM needs to be considered. Until recently, the entity of IgM myeloma had not been defined at the genetic level, making the distinction between WM and IgM myeloma extremely difficult (see below).

IgM MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE AND SMOLDERING WALDENSTRÖM MACROGLOBULINEMIA

Diagnosis

Having a minimal concentration of a monoclonal protein (e.g., 1.5 or 3.0 g/dl) has classically been required to establish the diagnosis of WM; however, a consensus panel eliminated this requirement.[22] The rationale was that having a required minimal concentration could underdiagnose patients early in the course of their disease who may already be symptomatic. It is still unclear how to differentiate IgM MGUS from WM.[7] Inasmuch as most patients with a monoclonal IgM do not necessarily have WM, better diagnostic tools are needed, perhaps including molecular detection of *MYD88* mutations. Asymptomatic patients with a small monoclonal protein and minimal involvement of the bone marrow by lymphoplasmacytic cells or clonal lymphocytes (e.g., less than 10%), still need to be considered as having an IgM MGUS. Patients like these, according to many epidemiology studies, may have no disease progression for decades.[35] One study found that patients with IgM MGUS, as well as patients with asymptomatic WM, have a better survival than patients with symptomatic WM, emphasizing the critical importance of symptoms over laboratory values.[36] The importance of segregating IgM MGUS from symptomatic WM is highlighted by this last study.

Evolution to Waldenström Macroglobulinemia from Asymptomatic Stages

The evolution of the monoclonal gammopathy is different for patients with non-IgM disease versus those with IgM MGUS.[35] IgM MGUS, in contrast to non-IgM disease, tends to evolve to WM and not to myeloma[35] (Table 100.1). Therefore, the greatest risk factor for the development of WM is having an IgM MGUS.[35] These patients have a 46-fold greater risk of developing WM than the general population.[35] Identification of risk factors for the progression of IgM MGUS is therefore needed. Identification of such risk factors will not only shed new light on the mechanisms of progression, but will also provide a mechanism by which to monitor patients at risk for progression.

In another series, Kyle reported on the outcome of patients with IgM MGUS.[37] In contrast to those with non-IgM MGUS, these

patients have a heightened risk of progression to WM (and not myeloma per se). He identified a total of 213 patients with IgM MGUS seen at the Mayo Clinic—Rochester from 1960 to 1994.[37] These patients were followed for a median of 6.3 years (cumulative 1,567 person-years). Interestingly, a lymphoma not otherwise specified developed in 17 patients (RR 14.8), and WM developed in 6 (RR, 262). Risk factors predictive of progression included the concentration of the serum monoclonal protein and albumin at diagnosis (for progression to lymphoma or a related disorder).

Morra reported on risk factors for progression from IgM MGUS to WM.[38] She studied 384 asymptomatic IgMMGUS and a total of 74 other IgM-related disorders.[38] At 5 and 10 years, the risk of progression was 8% and 29%, respectively for IgM MGUS. A total of 41 patients evolved to WM after a median follow-up of 45 months. Factors predictive of progression included the extent of bone marrow infiltration, sedimentation rate, hemoglobin, serum concentration of the IgM, and lymphocytosis. However, in the multivariate analysis, only the serum IgM concentration and lymphocytosis remained predictive. Among patients with smoldering Waldenström macroglobulinemia (SWM), the risk of progression seems to be greater in patients who have a monoclonal spike greater than 3 g/dl, and/or a lymphoplasmacytic infiltrate of the bone marrow, greater than 30%, or diffuse infiltration of the bone marrow, or anemia.[39] Likewise, Alexanian reported that a hemoglobin less than 11.5, M-spikes greater than 3 g/dl, and an elevated β_2-microglobulin correlate with a heightened risk of progression.[40]

Gobbi and colleagues reported on a large series of patients with various IgM monoclonal gammopathies.[36] A large cohort of 698 patients with IgM gammopathy was subdivided into 4 unique clinical entities; IgMMGUS, SWM, WM, and other IgM-related disorders (excluded from further analysis). Not surprisingly, IgM MGUS and SWM had median survivals similar to that of the general population. The standardized mortality rate for patients with symptomatic WM was 5.4.

Baldini and colleagues evaluated 217 patients with IgM MGUS and another 201 patients with SWM.[41] The median time to progression was not reached for IgM MGUS, and was 142 months for those with SWM (median duration of follow-up of 56 and 60 months). Progression was more likely in patients with elevated serum monoclonal proteins, anemia, and male sex.

Likewise, Greco et al. evaluated risk factors for progression from IgM MGUS and SWM to active disease.[42] Their series included a total of 287 patients: 201 with IgM MGUS, and 86 with SWM. After a median of 50 months, 32 cases evolved (11.1%): 26 to WM and 6 to other non-Hodgkin lymphoma. In the univariate analysis, risk factors for progression included the degree of bone marrow infiltration, elevated sedimentation rate, the concentration of the serum monoclonal protein, and IgA levels. The highest risk of progression was identified for patients with SWM, serum monoclonal protein ≥3 g/dl and/or those with ≥10% BM infiltration.

Kyle presented a recent update on the risk of transformation from SWM to WM.[43] SWM was defined as those patients having an elevated monoclonal IgM to greater than 3 g/dl and/or greater than 10% involvement of the bone marrow by the clonal process. By definition, these patients must have no evidence of end organ damage (anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly). A total of 48 patients were identified who fulfilled these criteria. After a median follow-up of 15.4 years, a total of 34 patients progressed to WM. In two other patients, other complications were observed (amyloidosis [AL] in one and lymphoma in the other). Based on these data, the cumulative risk of progression was estimated at 6% at 1 year, 39% at 3 years, 59% at 5 years, and 68% at 10 years. Risk factors predictive of progression included the degree of bone marrow involvement (hazard ratio [HR] 1.31), concentration of the serum M-spike (HR 2.1), reduction of the serum IgA (HR 2.4), and hemoglobin (HR 0.7). As in the Greco et al. study, it seems that progression is a stochastic event and, therefore, tumor bulk (i.e., cells at risk) predicts likelihood of progression.

PATHOLOGY

The WHO classification and the Revised European–American Lymphoma classify WM as LPL because of its immunophenotypic and morphologic characteristics.[44] Some cases of LPL have no associated monoclonal protein,[45] a more aggressive clinical course, and a different set of genetic abnormalities.[23] It is now believed that there are several subsets of LPL, of which WM is only one subtype.

Estimation of clonal involvement in the bone marrow is routinely performed at diagnosis with a unilateral trephine aspirate and biopsy. The disease is typically a pleomorphic infiltrate of lymphoplasmacytic cells,[46–48] and variability in cell morphology is common (Fig. 100.1). The infiltrate can range from purely lymphocytic to one that is predominantly plasmacytic.[46–48] The co-existence of mast cells in association with the lymphomatous infiltrate is a unique feature of WM.[46,47,48,49,50] The role of these mast cells as part of the disease pathogenesis has not been fully elucidated. A complex network of interactions between the WM cells and the bone marrow microenvironment has been suggested in preliminary observations.[50] In addition, infiltration by malignant B cells can be seen in lymphoid structures and multiple other organs (giving rise to organomegaly and lymphadenopathy).[44] The detection of clonal cells in other organs is not known to have particular prognostic implications; however, clinically evident organomegaly is usually a negative prognostic factor for the disease[51,52] and usually indicates a large tumor burden.

The nature of the clonal B-cell populations is remarkable.[53,54] Sahota has identified the normal counterpart of WM cells as mature B cells that have undergone somatic hypermutation, but that have not yet completed isotype class switching.[55] In that particular study, they did not find evidence of intraclonal heterogeneity. It is notable that in many cases of WM, one can observe co-existent populations of monoclonal B cells and plasma cells. Recently, Zehentner and colleagues demonstrated that only in 40% of cases are the clonal B-cell and plasma cell populations related.[56] Conversely, in 60% of cases, they represent two separate and independent clones. By performing sequencing of the immunoglobulin genes, and in some cases using fluorescence

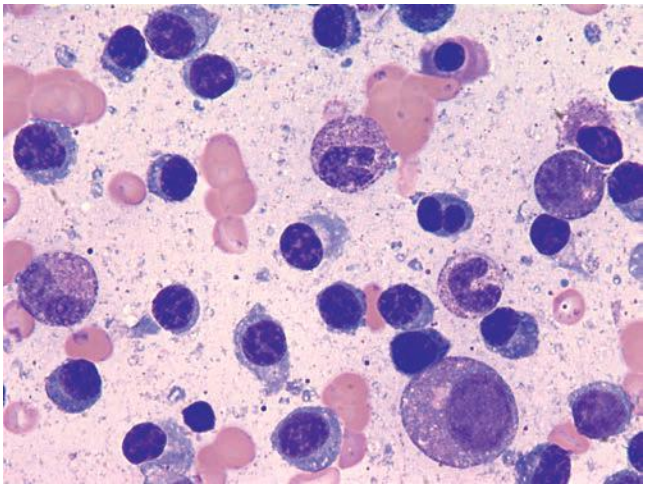

FIGURE 100.1. Lymphoplasmacytic morphology of the clonal cells of Waldenström macroglobulinemia. As shown in the graph, the cells have variable morphology but most show transition between mature lymphocytes and plasma cell morphology. The cells have been called in the past "plymphs." The morphology can be variable with some cases showing more extreme plasma cell morphology, whereas others have more lymphocytic predominance.

in situ hybridization (FISH) analysis, they conclusively show the separate nature of these clones in 60% of cases.

Flow cytometry is usually indicated as part of the pathologic work-up to make the diagnosis of WM. Flow cytometry is helpful in differentiating WM from other morphologically similar neoplasms, such as mantle cell lymphoma, marginal zone lymphomas, and B-cell chronic lymphocytic leukemia (CLL).[49,57–59] WM cells are characterized by the surface expression of CD19, CD20, CD22,[49,57–61] are light chain restricted, and commonly express CD79a. They are also typically CD10 and CD23 negative, in contrast to follicular lymphoma and B-cell CLL, respectively. The associated plasma cells are monoclonal and express CD138.[49,57–60] CD5 is not expressed on the malignant cells (in contrast to mantle cell lymphoma and B-cell CLL) in the majority of cases; however, some cases can be positive.[49,57–60]

Cell proliferation markers are usually indicative of the indolent nature of the disease. The fraction of cells incorporating 5-bromo-2'-deoxyuridine (BrdU),[62] indicating cell replication, is usually minimal, and frequently no such fraction is detected at all. The evolution of WM to a more aggressive lymphoproliferative disorder has been previously reported,[63,64] and the presence of a highly proliferative fraction may suggest transformed disease. The role of karyotype analysis in the clinical management of patients is not felt to be necessary and, in most patients, the metaphases will be normal.[65–67] Therefore, this analysis should be reserved for patients suspected of having treatment-associated myelodysplasia.[68]

WM variants have been described where patients have a similar pathology to WM, but present with IgG monoclonal proteins.[69] These patients appear to be clinically different from WM and tend to have a lymphocytosis present in the peripheral blood. It is not clear if these diseases have a similar pathogenesis, as only one series of patients with this variant tumor has been reported. Also, some patients have been described as having WM with associated bone lesions.[29,30,33] This makes distinguishing WM from IgM myeloma very difficult. Given the availability of molecular testing that can identify MYD88 mutations and also chromosome abnormalities seen in IgM MM, this distinction should now be possible. If some cases of true WM indeed have bone lesions, it is likely that these will be due to the same mechanisms operative for myeloma.[70] In a recent study of patients with IgM myeloma, it was found that the t(11;14)(q13;q32) was nearly universally present.[71] Another recent study did not find it as universal, but still common in IgM myeloma patients (38%).[72] Also, the t(14;16)(q32;q23) has been reported in one case of IgM myeloma.[73] In addition, we have found that translocations of the *IGH* locus seen in IgM myeloma are not typically observed in patients with WM, and when present, they are secondary genetic events, seen only in cell subsets.[67] This, along with the new-found mutation of *MYD88*, clearly separates WM and IgM myeloma as separate disease entities.

BIOLOGY AND GENETICS

Somatic Mutations

There is compelling evidence for a postgerminal center origin of the clonal B cells in WM.[31,32,74–76] To ascertain the lack of class switch rearrangements involving the mu switch region, we studied cases using a Southern blot assay, with no rearrangements identified (concordant 5′ and 3′ switch μ bands after digestion).[67] The aggregate of these studies thus shows that cell arrest just prior to class switching is the likely stage of neoplastic transformation, and genetic defects of the class switch machinery may be involved in the disease pathogenesis. It is important to note that lymphoplasmacytic cells of WM can mature to clonal plasma cells in vitro[77] suggesting that additional mechanisms may play a role.

MYD88 L265P

Just recently, a mutation of the gene *MYD88* has been described by Treon et al. in almost all cases of WM.[78] The mutation is associated with intracellular signaling and is believed to be key in the pathogenesis of the disease.[78] The prevalence of this mutation in IgM MGUS cases is still being investigated. In the initial reports it was felt to be uncommon in IgM MGUS cases, but the actual prevalence is still being investigated, with some reports showing up to 50% of IgM cases harboring the mutation. The *MYD88* L265P activating mutation has been reported in 90% of WM cases.[78] *MYD88* encodes for an adapter protein that affects the interleukin (IL)-1 and Toll-like receptor pathway, and the L265P leads to the dysregulation of the nuclear factor kappa B (NF-κB) and JAK signaling pathways.[6]

Other Mutations

Two other genes have been found to be inactivated in WM: *TNFAIP3* and *TRAF3*. *TNFAIP3* is a tumor suppressor gene whose inactivation results in the constitutive activation of NF-κB.[79] We reported biallelic inactivation/deletion of *TNFAIP3* in 5% of WM patients.[80] In addition, 38% of patients were found to have monoallelic deletions of *TNFAIP3* with associated diminished transcription of the gene, with proposed associated haploinsufficiency. Inactivating mutations of *TRAF3* (located at 14q32.32) have been described and also result in the constitutive activation of NF-κB in about (~5%) of patients.[79] *TRAF3* is a negative regulator of the noncanonical NF-κB signaling pathway, with a consequent increase in serine/threonine protein kinase NIK.[79,81,82] Similar observations have been made using novel high-throughput genomic tools.[83]

6q Deletions and Other Genetic Changes

The most common cytogenetic abnormality in WM is deletion of 6q. We know through multiple studies that in at least one half of cases, large deletions of chromosome 6 are observed in WM by a combination of FISH and aCGH (array comparative genomic hybridization).[66, 67,84,85] Usually, these deletions involve chromosome bands 6q21-q23, with the most commonly deleted being the q23 region. These deletions are clonally selected in the majority of cases.[67] The clinical relevance of the presence of a 6q deletion has not been well defined, but a recent study suggested that these patients tend to have more aggressive disease and a shorter survival.[86] These observations, however, need to be confirmed in additional studies.[67] Although the data are limited, chromosome 6q deletions seem to be rare in cases of IgM MGUS, suggesting that deletions in 6q are involved in the progression to WM[87] (Fig. 100.2). Although there is no direct link yet made between 6q deletions and *MYD88* mutations, and given the ubiquitous nature of the latter,

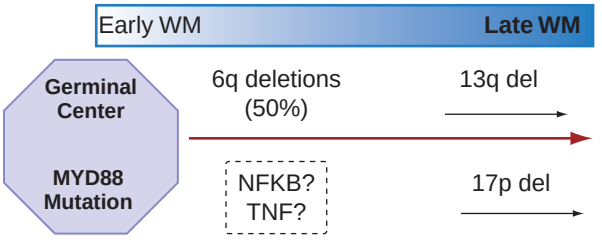

FIGURE 100.2. Biology of progression for Waldenström macroglobulinemia (WM). Mutations of MYD88 are likely founder lesions for the disease. In 50% of cases, deletion of the long arm of chromosome 6 may be the culprit in the initiation of the clonal process of Waldenström macroglobulinemia. In some cases, deletions of chromosomes 13 and 17 may represent progression events. Emerging data suggest that abnormalities of tumor necrosis factor (TNF) and nuclear factor kappa B (NF-κB) signaling may also be contributing factors in the pathogenesis of the disease.

and the high prevalence of the former, it is only logical to conclude that both are important in disease pathogenesis. The second most common observation by aCGH was the gain of 6p (16.6%), always occurring as a secondary event following the loss of 6q.[79]

Originally, due to the presence of LPL in the bone marrow, it was believed that WM must contain the t(9;14)(p13;q32) (described originally in at least 50% of LPL cases, none of which had detectable IgM monoclonal protein).[88] The t(9;14)(p13;q32) results in upregulation of *PAX-5,*[89–91] implicating this gene as a putative oncogene in the pathogenesis of LPL cases without monoclonal IgM.[45,92] *PAX-5* prevents expression of high levels of immunoglobulin and diminishes production of the J-peptide needed for the pentameric IgM assembly; therefore, the presence of *PAX-5* up-regulation by this translocation is inconsistent with the phenotype of WM. In contrast to many other B-cell malignancies, it has been shown that WM never harbors the t(9:14), or any other 14q32 translocations.[67] In a significant number of cases, review of the karyotype also failed to identify *IGH* translocations on chromosome 14.[65–67] Although some rare cases have clones with *IGH* translocations,[93] these events are now believed to be secondary genetic events associated with disease progression. In most WM cases, the karyotype results are usually normal.[65–67,94–96]

In sporadic cases of WM, the t(11;18)(q21;q21), usually associated with a subset of marginal zone lymphomas, has been reported.[97] Using an interphase FISH-based strategy, others have been unable to detect this translocation.[67] Again, molecular confirmation of *MYD88* mutations will be important in redefining whether these entities should be considered under the WM diagnosis. Other chromosomal abnormalities, such as deletions of 17p13.1 and 13q14, are not common at the time of diagnosis, but at the time of disease progression, may be observed in 15% of patients.[98] The clonal cells of WM are usually diploid,[67] and this has been confirmed by DNA content analysis in a subset of patients.[99]

Additional data have suggested that WM may have features in common with other disease entities, as well as with MM. At the gene expression level, WM resembles B-cell CLL more than it does MM.[100] In addition, studies of patients with IgM MGUS show clustering together with WM.[100] Furthermore, the clonal cells of WM express high levels of IL-6, which likely would explain the clinical observation of high C-reactive protein levels in the serum of WM patients.[100,101] In a manner similar to the anemia of chronic disease, the high levels of IL-6 likely contribute to the anemia, of WM.[102] Experiments of gene expression profiling in WM were performed, separating the CD19+ cells from the CD138+ cells, and have found remarkably similar patterns of gene expression.[103]

Epigenetic Aberrations; Micro-ribonucleic Acid and Histone Acetylation

Roccaro et al. reported on a unique miRNA profile in WM cells, something that was different from the normal B-cell counterparts.[104] Their studies showed that miRNA-363*, -206, -494, -155, -184, -542–3p were up-regulated and miRNA-9* was underexpressed.[104] Many of the predicted targets for these miRNAs include genes associated with the cell cycle, apoptosis, transcription factors and oncogenes. Because of its previous descriptions in other B-cell malignancies, miRNA-155 has been more extensively studied in WM.[104] For a more detailed analysis, the reader is referred to a recent review article.[105,106] Likewise, alteration of the balance between histone acetyl transferases and histone deacetylases has been postulated as important in the pathogenesis of WM. This is important as two miRNAs are associated with histone acetylation: miRNA-206 and -9*.[107]

Cytokines and B-cell Signaling

A tumor necrosis factor family member, B-lymphocyte stimulator (BLyS), is critical for maintenance of normal B-cell development and homeostasis. Elsawa and colleagues found that WM cells variably express the BLyS receptors BAFF-R, TACI, and BCMA and bind soluble BLyS.[108] Also, they documented elevated serum BLyS levels in patients with WM and expression of BLyS in bone marrow samples by immunohistochemistry.[108] BLyS, in vitro, increased the viability and proliferation of WM cells and stimulated secretion of the monoclonal IgM. She also found that chemokine (C-C motif) ligand 5 (CCL5), granulocyte colony-stimulating factor, and soluble IL-2 receptor are overexpressed in WM, with CCL5 correlating quite closely with the serum levels of IL-6. As mentioned earlier, up to 50% of WM have up-regulation of IL-6, a cytokine critical in B-cell development and implicated in various B-cell malignancies. Furthermore, WM cells also express the IL-6 receptor, and CCL5 results in increased secretion of IL-6 by bone marrow stromal cells in WM, further enhancing IL-6 stimulation, occurring both in an autocrine and paracrine fashion. This stimulation resulted in increased secretion of IgM in a process mediated via JAK/STAT signaling.

AKT

Leleu et al. reported increased activity of AKT in the clonal cells of WM.[109] They also showed that down-regulation of AKT and use of an AKT inhibitor, perifosine, resulted in diminished proliferation and induction of apoptosis.[109]

CLINICAL FEATURES

It is best to differentiate the clinical symptoms of this disease based on their causes: those signs and symptoms secondary to the effects of the monoclonal protein and other paraneoplastic phenomena, and those related to the clonal proliferation in the bone marrow and other lymphoid organs.[3] It should be noted that most patients with WM have a limited symptom complex at the time of diagnosis, consisting of a monoclonal IgM and various degrees of anemia.[24,110] This anemia is often secondary to the clonal expansion of cells in the bone marrow, but may also be due to hyperviscosity (by reducing erythropoietin production) or the increased plasma volume.[111] In many cases, anemia can be a consequence of treatment. Recent data suggest that some patients may have an anemia secondary to elevated levels of IL-6 emanating from the clonal cells, and will present with a picture reminiscent of the anemia of inflammation.[100] Given the high level of expression of IL-6 and IL-6 receptors in at least half of WM, it is not surprising that elevated levels of hepcidin have been postulated as key mediators in the anemia of WM.[102] In cases with significant involvement of the bone marrow by the WM clonal cells, thrombocytopenia may also be observed.[24,110]

In 20% of cases, the clonal cells of WM can infiltrate other organs and result in hepatomegaly and splenomegaly in 15% of patients.[23,24, 51,52,110,112] Splenomegaly can result in hypersplenism, with worsening pancytopenia. Although patients may have liver involvement, this is usually asymptomatic. Lymphadenopathy can be seen in 15% to 20% of patients,[23,24,51,110,112] and involvement of other organs, such as the lung, can be seen in WM, although this is present in only a minority of cases.[113,114]

Hyperviscosity, Neurologic and Retinal Complications

Hyperviscosity is one of the most characteristic features of WM; however, it is only seen in 15% of cases.[25, 115,116] The details of the physical properties of the pentameric IgM molecule leading to hyperviscosity have been previously described.[25,116] The large dimensions of the IgM molecule make the serum more viscous, and results in slower transit in capillaries.[25] The increased viscosity is not just the result of the large size of the IgM molecule, as

other large particles such as albumin do not have the same effect on the serum viscosity.[25] Although the overt clinical syndrome of hyperviscosity is obvious, subtler symptomatology can also be seen. Typical symptoms include neurocognitive effects (sometimes with overt hemorrhage and neurologic abnormalities), retinal bleeding, and mucosal bleeding in gums and nose. In different patients, different serum concentrations of the monoclonal IgM will give rise to hyperviscosity, and there is no absolute value at which hyperviscosity will be observed.[25, 115,116] However, for a given patient, a given IgM level will usually again result in symptoms when the serum IgM reaches that level again.[25, 115,116] Despite having a high serum viscosity, some patients will have no symptoms, whereas others will have prominent symptoms at lower viscosity levels. To see symptoms of hyperviscosity at values less than 4 cps is uncommon. In contrast, nearly all patients with a viscosity greater than 8 will be symptomatic, and most patients with a viscosity of 5 to 8 cps will have symptoms.[25, 115,116] Also, to have hyperviscosity with an IgM less than 4,000 mg/dl is very rare.[25] The patient's hydration and the red cell mass are other factors that contribute to blood viscosity. Red cell transfusions should therefore be used with caution, and sometimes in conjunction with pre-transfusion plasmapheresis, in patients with high IgM concentrations.

Since the original reports by Waldenström,[117] neurologic abnormalities in patients with WM have been described (Bing–Neel syndrome). Plasma exchange should be entertained in any patient presenting with a focal or global neurologic deficits that potentially could be attributed to hyperviscosity, even if a clear causal association is not immediately established. The symptoms may be nonspecific and the spectrum can include headache, fatigue, impaired cognition, confusion, stroke, or frank dementia.[118,119]

Peripheral neuropathies associated with the presence of monoclonal proteins include, demyelinating polyneuropathy (both associated and not with antimyelin-associated glycoprotein antibodies),[120,121] other demyelinating neuropathies, cryoglobulinemia-associated symptoms, and neuropathies associated with light-chain AL. The monoclonal protein, in most cases, has affinity for the myelin sheath and results in demyelinization,[122] which can be observed in up to one half of WM patients with peripheral neuropathy.[123] Patients can also have abnormalities of proprioception resulting in ataxia, in addition to the sensory deficits.[123,124] Some of the new therapeutic agents, namely bortezomib, can also be associated with treatment-induced peripheral neuropathy. As a direct consequence of the increased viscosity, patients can have retinal complications of WM, and these present on physical examination as venous engorgement, hemorrhage, and cotton-wool exudates.[125,126] In some severe cases, WM can precipitate retinal vein occlusion.[125,126]

Clinical features of light-chain–associated AL can develop in some patients with WM.[7,127,128] In these cases, there appears to be a higher incidence of pleural and pulmonary AL, and a greater tendency for amyloid-associated cardiomyopathy than in other AL cases (44% vs. 27%).[127,128] In these patients, therapy should be tailored to control the WM rather than the AL. The fact that AL can be observed in association with WM suggests that AL is merely a complication of any monoclonal protein-producing neoplasm.

PROGNOSIS

The prognosis of WM is highly variable, and until recently, there were few models validating putative prognostic factors. The median survival for patients with WM has been estimated to be 5 years,[51, 68] however, 10% of patients remain alive at 15 years.[68] Although the survival appears short for a disease felt to have an indolent nature, the fact that patients present at an advanced age presents a significant problem in determining the survival associated with this disease. The precise disease-specific survival is often difficult to determine, as these patients have "competing causes for death." One study addressed disease-specific survival associated with WM, with the median felt to be closer to 11.2 years.[52] In this study, organomegaly and age > 65 years were associated with poor prognosis in a multivariate analysis. Similarly, a longer survival of 108 months has been reported in another series, suggesting that this disease may truly behave in an indolent fashion.[129] It is likely that the survival of patients continues to increase given the availability of various new therapeutic classes of agents.

Several prognostic models for WM have been previously proposed. Morel[51] and Facon[110] studied 232 patients treated prior to 1989 (mostly alkylators and no purine nucleoside analogues [PNAs]). They found that the prognostic factors associated with a shorter survival were age > 65, albumin < 40 g/L, hemoglobin < 12 g/dl, platelet count < 150×10^9/L, and WBC < 4×10^9/L. They developed a prognostic model based on a point system that discriminated groups with different outcomes. If the patients had one cytopenia, they were assigned 1 point, and if they had two or more, they were given 2 points. The proportion of patients alive at 5 years was 87% (0 to 1 points; 27% of cases), 62% (2 points; 27% of cases), and 25% (3 to 4 points; 46% of cases) for the low-, intermediate-, and high-risk groups, respectively. Differences in outcome based on time of therapy initiation (initial observation vs. initial treatment) were not found in this series. It is interesting that they did not find systemic symptoms, pathologic features, or splenomegaly to be useful in determining prognosis. This prognostic model has been further validated by Kyrtsonis[129] and by the same group (Morel and colleagues) in a separate cohort of patients with advanced WM.[130]

A second model was developed by Gobbi and colleagues.[131] They were able to show that the following variables were associated with a shorter survival: anemia (hemoglobin less than 10 g/dl), age greater than 70, weight loss, and cryoglobulinemia.[131] This model divided patients into low- and high-risk groups, the latter defined by patients having two or more adverse prognostic factors.

Dhodapkar proposed a different model, studying 182 patients treated with fludarabine in a clinical trial.[23] He showed that patients with an elevated serum β_2-microglobulin (≥3 mg/dl), low hemoglobin (<12 g/dl), and low IgM (<4,000 mg/dl) fared the worst. From this model, it is unclear why patients with a lower concentration of the monoclonal protein would fare worse; but it may be explained by the inclusion of patients with LPL, which may be a different biologic entity. In a follow-up report, they reported that overall survival (OS) and event-free survival in the presence of lower levels of serum β_2-microglobulin were significantly longer in all cohorts.[132] It is interesting that achieving a response, or the time needed to achieve this response, did not predict event-free survival or OS.[132] Unfortunately, the Dhodapkar model was not reproduced in a series of patients with advanced WM reported by Levy and colleagues.[130]

Recently, Dhodapkar updated the SWOG series, with a median follow-up of 10 years for live patients.[133] Of the 59 previously untreated patients who initially were observed, only 12 patients (21%) required therapy, at a median follow-up of 100 months.[133] Among the 183 patients requiring therapy, the long-term observations confirmed that advancing age (>70), previous treatment, and the serum concentration of β_2-microglobulin (3 mg/dl or greater) were negative factors, but with additional follow-up, an elevated serum LDH became important too. They propose a new and improved model that uses advanced age, β_2-microglobulin, prior treatment, and LDH (above upper limit of normal) to segregate patients into 3 groups, with 8-year OS of 55%, 33%, and 5% ($P < 0.001$). In the multivariate model, a low serum monoclonal protein did not remain significant.

TABLE 100.2

INTERNATIONAL PROGNOSTIC INDEX

Factors Associated with Prognosis	Value
Age (years)	>65
Hemoglobin (g/dl)	≤11.5
Platelet count (n/μl)	≤100,000
β_2-Microglobulin (mg/L)	>3
Monoclonal IgM (g/dl)	>7

Risk Stratum and Survival

Risk Category	Score	Median Survival (Months)
Low	0 or 2 (except age)	142.5
Intermediate	2 or age >65 years	98.6
High	>2	43.0

One point is assigned for each risk factor and the risk score is the sum of these factors. Adapted from Morel P, Duhamel A, Gobbi P, et al. International prognostic scoring system for Waldenstrom macroglobulinemia. Blood 2009;113:4163–4170 and Morel P, Duhamel P, Gobbi PG, et al. International prognostic scoring system for Walndenstrom macroglobulinemia. Haematologica 2007;92:84.

An international effort has been focused on the development of an international prognostic model for WM. A total of 587 patients were entered into this model who fulfilled the diagnostic criteria recommendations by the Second International Workshop of WM.[134,135] In the univariate model, seven factors were associated with a shortened survival, and included age over 65, platelet count ≤ 100 (n/μ1), β_2-microglobulin greater than 3 mg/dl, M-spike greater than 7 g/dl, granulocytes ≤ 1.5 $\times 10^9$/L, hemoglobin ≤ 11 g/dl, and albumin ≤ 3.5 g/dl.

An updated model has been published by the same group.[136] Using a bootstrap analysis, the following factors were selected to develop a risk-factor–based classification: age, hemoglobin, platelet count, β_2-microglobulin, and M-spike.[136] Low risk was defined as having only one risk factor or less, high risk as having greater than two, and all others, intermediate, or if only age was greater than 65. The 5-year survival rates were 87%, 68%, and 36% ($P < 0.0001$). (Table 100.2)

CONVENTIONAL TREATMENTS AND MANAGEMENT

No standard response criteria in WM have been available until recently. A consensus statement regarding criteria for response was published and subsequently updated.[137,138] Aside from defining CR and PR (partial response), these criteria define a "minor response" (MR) category, thereby recognizing that patients may sometimes have a dramatic clinical improvement with only a minor decrease in the serum monoclonal protein. The criteria also stressed the importance of delayed responses and recommended an assessment of response over an extended duration follow-up period.

The development of novel therapeutics in WM has had to rely solely on the results of clinical trials, as no good pre-clinical models for the study of WM have existed. Clinical trials have had slow accrual rates due to the small numbers of patients with this disorder, and many therapeutic strategies have been extrapolated from observations in other lymphoid neoplasms. A potential pre-clinical model of WM was published by Tassone and colleagues.[139] They were able to develop a SCID-Hu murine model that mimics human WM. Human fetal bone grafts (embedded subcutaneously) were used to support the ex vivo growth of WM cells. In this study, the model reflected the usual response to rituximab as is observed in patients. It is hoped that this model will allow pre-clinical testing of novel compounds or combinations for use in WM prior to initiating clinical studies.

Observation

Many patients with WM may not be in need of immediate treatment, and for many, the disease may follow an indolent course.[23,36,131] Although no specific criteria exist, the absence of overt symptoms or complications may be used as reason for continuing careful monitoring of patients. Because WM is considered an incurable malignancy, the goal of treatment must be to provide symptom relief for patients, as those without symptoms are not known to benefit from therapy. This paradigm has, however, been challenged in other similar disease settings, and it is possible that in the future, recommendations will be made for the treatment of the asymptomatic patient with impending progression. Previous studies have clearly described pre-symptomatic stages for WM (including IgM MGUS),[36,117,140] and the treating physician should first decide whether the patient really needs therapy.

Alkylating Agents

Classic Alkylators

Chlorambucil is a well-tolerated oral agent used in the treatment for WM.[141] This drug is currently used in selected situations, predominantly in the treatment of the elderly, given the high tolerability of the drug, its ease of administration, and despite the leukemogenic potential. For a summary of response rates of most published clinical trials in WM, see Table 100.3. The aforementioned study by Facon (n = 167), demonstrated a median survival of 5 years for patients treated with chlorambucil as initial therapy.[110] The only prospective randomized phase III clinical trial for WM patients was performed at Mayo Clinic by Kyle and colleagues.[68] In this study, patients received oral chlorambucil, either continuously at a dose of 0.1 mg/kg/day, or pulsed doses in an intermittent fashion every 6 weeks (0.3 mg/kg/day for 7 days). The median OS was the same (5.4 years, P NS) and the response rates between both groups were similar (79% and 68%, respectively; P NS). This is the first trial that highlighted that response to any therapy in WM can occur late, and that usually at least 6 months of therapy are needed prior to concluding lack of efficacy.[68]

Other alkylator-based combinations, such as VBMCP (vincristine, carmustine, melphalan, cyclophosphamide, and prednisone), have resulted in high response rates.[142–144] In recent years, alkylators have been used less frequently, as a result of a study by Leblond and colleagues that showed the superiority of fludarabine over a cyclophosphamide containing regimen (higher response rate and duration of response),[145] and a number of other therapeutic options for patients. In addition, the risk of myelodysplasia with long-term use makes alkylators a less desirable option for younger patients. However, given the convenience of oral dosing and the minimal toxicity, alkylators are particularly suitable for the elderly.

Bendamustine

Bendamustine has been used with success in the treatment of WM. Rummel reported on the use of bendamustine in low-grade B-cell lymphomas, which included patients with WM. In a phase II study (n = 63 patients) of mantle cell lymphoma and low-grade B-cell neoplasias, he reported an overall response rate (ORR)

TABLE 100.3

TREATMENT REGIMENS

Investigator	Regimen	*N*	Response Rate (%)
Alkylators/Cytotoxic			
Facon[110]	Chlorambucil	167	75
Kyle[68]	Chlorambucil	22–24	68–79
Case[143]	VBMCP	33	82
Petrucci[144]	Cyclophosphamide + melphalan + prednisone	34	74
Leblond[145]	Cyclophosphamide + doxorubicin	45	11
Fludarabine			
Kantarjian[146]	Fludarabine	11	45
Leblond[145]	Fludarabine	45	30
Dhodapkar[23]	Fludarabine	182	36
Dimopoulos[147]	Fludarabine	28	36
Zinzani[148]	Fludarabine	12	41
Leblond[149]	Fludarabine	71	30
Thalhammer-Scherrer[150]	Fludarabine	7	86
Foran[151]	Fludarabine	19	79
Dimopoulos[152]	Fludarabine + cyclophosphamide	73	55
Tamburini[153]	Fludarabine + cyclophosphamide	14	85
Vargaftig[154]	Fludarabine + cyclophosphamide + rituximab	21	76
Tam[155]	Fludarabine + cyclophosphamide + rituximab	9	56
Cladribine			
Liu[156]	Cladribine	20	55
Betticher[157]	Cladribine	25	40
Dimopoulos[158]	Cladribine	29	59
Delannoy[159]	Cladribine	18	39
Dimopoulos[160]	Cladribine	26	85
Hellman[161]	Cladribine	22	41
Laurencet[162]	Cladribine + cyclophosphamide	3	100
Thomas[163]	Rituximab + cladribine + cyclophosphamide	18	94
Rituximab			
Dimopoulos[164]	Rituximab	27	44
Gertz[165]	Rituximab	69	52
Weber[138]	Rituximab	8	75
Byrd[166]	Rituximab	7	43
Treon[167]	Rituximab	30	27

of 90% with 60% CRs.[168] In a larger study, Rummel compared bendamustine in combination with rituximab, with cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) chemotherapy.[169] Of a total of 546 patients, 40 had WM.[169] Among WM patients the ORR was 96% for bendamustine-R and 94% for R-CHOP. After a median of 26 months, 87% of bendamustine-treated patients, (20/23) remained free of progression, and only 53% of those treated with R-CHOP were so (9/17) (M Rummel, *International WM Workshop,* 2012). Treon et al. reported on a retrospective analysis of 30 previously treated WM patients who received bendamustine.[170] Bendamustine was given on days 1 and 2 of a 28-day cycle, along with rituximab (in most cases, n = 24). The median number of treatment cycles was 5. The reported ORR was 83%, with 5 (17%) very good partial responses (VGPRs) and 20 PRs (67%). The estimated median time to progression was 13 months. The contribution of the addition of rituximab still needs to be elucidated. In at least a quarter of patients, therapy had to be discontinued due to toxicity, and sometimes, prolonged myelosuppression.

Purine Nucleoside Analogues

Fludarabine

Among the most active agents available for the treatment of WM are PNAs. Most patients treated with PNAs will respond within 3 to 6 months of therapy initiation, however, a small fraction of patients will show delayed responses (5% after 12 months).[170] Kantarjian first reported the treatment of 11 patients with fludarabine (10 previously treated) and 5 responded, having a median duration of response >1 year.[146] Dimopoulos, in a later publication, reported on the treatment of 28 patients (only 2 were treatment naive) where he showed a response rate of 36%,[147] and many of the responses were durable (median duration of response 38 months). Leblond reported on the treatment of 71 patients with relapsed WM treated with a median of 6 cycles of fludarabine, resulting in a response rate of 30% (21/71 cases).[149] In a separate study, 78 patients with previously untreated WM were given fludarabine at 25 mg/m^2 daily, for 5 days every 4 weeks[151] resulting

in an ORR of 79% (15% CR), many of them durable (median 30 months). The treatment-related mortality was 5% in this study, predominantly due to infection. It should be noted that patients treated with almost all active agents in WM, including PNAs, can take a long time to respond to treatment,[171] and concluding early in the treatment course that a therapy has failed may be a mistake.

These high response rates were, unfortunately, not confirmed in a subsequent larger series. Dhodapkar studied 231 patients of whom 182 required therapy, 118 were treatment naive, and 64 were relapsed cases.[23] Patients treated with 4 to 8 cycles of fludarabine at a dose of 30 mg/m^2 daily for 5 days repeated monthly. They reported a response rate of 36%, and only 2% of cases were complete responders. Prior treatment did not predict for a lower likelihood of response, but older age was associated with a low likelihood of response. The treatment-associated myelosuppression led to a 4% mortality from infections, similar to what was previously reported. It should be noted that the use of purine nucleoside analogues should be done with caution in patients needing to collect hematopoietic stem cells.[172] More recently, the development of treatment-associated myelodysplasia has been reported in patients treated with fludarabine combinations, although the definitive risk of development has yet to be defined.[173]

A prospective randomized trial comparing fludarabine against chlorambucil is ongoing, and was reported in a preliminary fashion at the 2011 ASH meeting.[174] Leblond reported that fludarabine is more effective than chlorambucil as initial therapy for WM, including significantly greater disease-free survival (DFS), progression-free survival (PFS), and OS. Patients were randomized to 8 mg/m^2 oral chlorambucil administered for 10 days every 28 days (to a maximum of 12 cycles), or to 40 mg fludarabine (5 days every 28 days for a maximum of 6 cycles). Response rates were higher with fludarabine than with chlorambucil (PR 47% vs. 41%; CR 6% vs. 2%, NS). Fludarabine resulted in a significant advantage in PFS (36.3 vs. 27.1 months; $P = 0.012$), DFS (38.3 vs. 19.9 months; $P = 0.0005$) and OS at 5 years (69.4% vs. 61.8%; $P = 0.046$). The median duration of response was longer with fludarabine (38.3 vs. 19.9 months; Leblond Personal Communication IWMW, August, 2012). Negative predictive factors included, age >70, low albumin (<4 g/dl), and treatment arm (OR 1.34). The main toxicity was, as expected, greater myelosuppression in the fludarabine arm. She also reported that secondary malignancies were less common in the fludarabine arm (3.7% vs. 21% at 6 years). This trial included other entities other than WM, such as LPL and marginal zone lymphomas.

Cladribine (2-Chlorodeoxyadenosine)

Cladribine also has documented activity against WM and is structurally similar to fludarabine. In one series, Dimopoulos treated 29 patients with a continuous intravenous infusion of 2-CDA (2-chlorodeoxyadenosine) 0.1 mg/kg/day for 7 days, for a total of two courses.[158] An ORR of 59% (100% in previously untreated patients; 40% for relapsed patients) was reported. Likewise, Delannoy and colleagues reported an ORR of 39% in 18 patients treated with cladribine.[159] Cladribine can also be administered intermittently, obviating the need for an intravenous central catheter with similar response rates.[156] Using the intermittent schedule, Liu et al. reported a median duration of response of 28 months. In another study, the OR to cladribine was 41% in 22 patients with WM.[161] A very high response rate was seen in 10 newly diagnosed patients treated with 2-CDA (followed by interferon). In this study, all patients responded (1 CR, 8 PR, and 1 MR).[157] Another multicenter study treated 25 naive patients, and attempted to use a longer duration of cladribine, for up to 6 cycles (median 3 cycles).[175] They reported a response rate of 40%, with a median remission duration of 8 months.

Very limited data exist documenting the value of using different PNAs in patients who progress after treatment with a purine analogue.[176] In one study, 14 patients were treated with cladribine after prior fludarabine exposure. Only 1 of 10 patients with fludarabine-resistant disease responded. In the patients who had demonstrated a previous response (and subsequently progressed) to fludarabine, however, 3 of 4 patients responded. In another study, 6 patients were treated with fludarabine who were resistant to cladribine, and 2 responded.[177] It seems who those who are refractory to a PNA, overall, are unlikely to respond to an alternate agent in this class.

Monoclonal Antibody Therapy

Rituximab

All WM cells express CD20, which allows for the use of anti-CD20 monoclonal antibody-based strategies. Initial studies using rituximab documented a tumor burden reduction, resulting in improved cytopenias,[178] neurologic symptoms,[179] and a decrease in the clonal cells in the bone marrow.[180] Byrd and colleagues then documented PRs to rituximab by treating seven patients with relapsed disease.[166] Treon and colleagues also treated 30 patients with relapsed disease,[167] 14 of whom (47%) had been previously treated with a PNA. They showed convincing evidence of antitumor activity by documenting reductions of the serum monoclonal protein (median IgM decline 2,403 to 1,525 mg/dl), increases in the hematocrit (19/30, 63%), and increases in the platelet count (15/30, 50%). In Treon's study, the ORR was 60%, with 8 of 30 patients achieving a PR (27%).[167] Dimopoulos treated 27 patients with rituximab (15 that were treatment naive) with 4 infusions at standard doses (375 mg/m^2).[164] Patients received an additional 4-week course 3 months after the first course, if they had not progressed. The probability of response was the same in relapsed patients as in treatment-naive patients (44%), with a median time to response of 3.3 months and a median duration of response of 16 months.

It has become clear that the best response to rituximab may be seen only after several months of drug administration. We believe that the true clinical benefit of rituximab may be greater than that originally reported in these clinical trials because the response rates may have been underestimated due to the responses being evaluated too early in the treatment course. This delayed response effect is likely to be observed with other biologic therapies as well. This delayed effect was partially addressed by administering an extended course of therapy with rituximab in a study by Treon.[181] Treon et al. evaluated the administration of 8 cycles of rituximab (as opposed to four infusions) in this study. They reported on 26 patients who completed the intended therapy: 14 (48.3%) patients had a PR, and 5 (17.2%) patients achieved an MR. The median time to best response was 17 months, with 2 of 19 responding patients subsequently progressing at the time of the report (median follow-up of 29 months).[181]

The identification of patients likely to respond to therapy has become of paramount importance given the increased usage of rituximab. Because of its overall ease of administration it is important to recognize those patients who are not likely to respond, and in whom pursuing other treatment alternatives may be preferable. Dimopoulos reported on the higher likelihood of response to rituximab among patients with lower serum IgM (<4 g/dl) and higher β_2-microglobulin.[182,183] Although the median time to progression was 14 months, these variables predicted patients with shorter duration of response.[182] In the study by Treon et al., patients were more likely (75% response rate, 18/24 cases) to respond to rituximab monotherapy if they had an IgM of <6,000 mg/dl, compared to a response rate of only 20% with higher protein concentrations.[181] Polymorphisms in the Fcγ receptor have similarly been postulated to predict the likelihood of response.[184]

Rituximab has become the de facto first-line treatment for most patients with WM because of a favorable profile and

risk–benefit ratio.[185] In addition, rituximab can be easily combined with other chemotherapeutic agents because of the lack of additive toxicity, and is now commonly used in combination regimens for WM. Also, rituximab retains activity when patients are given repeated courses of therapy and can be administered in a maintenance fashion. Unfortunately, the use of radiolabeled anti-CD20 monoclonal antibodies is limited in WM due to the larger extent of bone marrow involvement by the clonal cells and the risk of significant toxicity. A strategy for using radiolabeled monoclonal antibodies will therefore require an initial "debulking", with clearance of the bone marrow using rituximab or other agents, followed by the use of a radioactively labeled monoclonal antibody.

A total of 50% of patients will have a paradoxical rise of the monoclonal protein after rituximab administration: the so-called rituximab flare.[186,187] This phenomenon was first reported in two patients treated with cladribine,[188] but has been reported more frequently in patients treated with rituximab. The elevations of the serum concentration of the IgM can be of such magnitude that patients might experience symptoms of hyperviscosity. Patients who have higher concentrations of the IgM should be considered for prophylactic or concurrent plasmapheresis when treated with rituximab.[164] Reports have also emerged of patients who have worsening of peripheral neuropathy after treatment with rituximab, and the hypothesis is that this is also a manifestation of the flare phenomenon.[189–191]

Rituximab Maintenance

Treon has shown the benefit of maintenance rituximab in patients with WM.[192] He studied 248 rituximab-naive WM patients who showed disease sensitivity after receiving rituximab. Of these 86, (35%) went on to receive maintenance. In 36 of 86 (41.8%) patients receiving maintenance, the quality of the responses improved. PFS (56.3 vs. 28.6 months; $P = 0.0001$) and OS (not reached vs. 116 months; $P = 0.0095$) were longer for patients receiving maintenance. Although this study was retrospective, it does provide compelling evidence to consider rituximab maintenance after prior rituximab-containing regimens.[192] Prospective studies will be needed to address this question fully in WM.

Corticosteroids

WM historically has not been considered a steroid-responsive malignancy; however, reports exist suggesting that steroids alone can be beneficial, particularly in patients who are not candidates for cytotoxic therapy or who have severe pancytopenia. Steroids have also had an additive effect when used in combination with other agents. Gomez et al. treated two patients with WM with vincristine, 0.25 mg/m^2, and bleomycin, 5 units, given for 4 consecutive days with prednisone, 1,000 mg/m^2, given orally on alternate days.[193] In both patients, the bone marrow tumor cell infiltration was reduced by 50% (remission duration 4 to >35 weeks) and they had a greater than 50% decrease in the M protein. Two additional patients with resistant WM demonstrated marked decreases in viscosity and total M protein after short periods of high-dose dexamethasone.[194] Steroids have been reported to be particularly useful in patients with WM with an associated cryoglobulin because of their anti-inflammatory properties and effect on immune complex vasculitis.[195]

Combination Therapy

Overview

Despite an overall higher response rate to combination therapy for the up-front treatment of WM, its ultimate clinical worth is clouded by the difficulty of being able to document an impact on patient outcome due to the indolent nature of WM. The response rates undoubtedly seem superior with combination strategies and the duration of response is also likely to be longer. However, these combinations burden patients with additional toxicities. How does one decide on the best treatment approach for patients? Most trials available for WM are phase II clinical trials with a primary endpoint of ORR, but no assessment of long-term outcome. Therefore, the identification of novel combinations capable of retaining a favorable toxicity profile and increasing the duration of response would likely constitute significant progress in this field. Combinations that include rituximab would seem most likely to increase the quality and duration of responses and result in the best safety profile. At a minimum, combination therapies need to show a very substantial enhancement of OR to be considered suitable for use in the "off-study" setting.

The value of combination treatment has been the focus of a recent panel review.[170] This review stressed that the results of combination strategies were encouraging enough that they would be considered reasonable treatment[170] options for patients with WM (alongside extended treatment with rituximab) in a nonstudy setting. However, the panel properly recognized the need for additional clinical trials to better evaluate their clinical utility. For patients with evidence of slowly evolving progression, but no significant cytopenias or organomegaly, it would seem that single-agent rituximab may be more appropriate than combination approaches. Combination strategies should be considered for individuals in need of rapid reduction of tumor burden. Secondary gains, such as blunting of a rituximab flare, will also have important practical implications that may favor the use of secondary agents with rituximab.

Purine Nucleoside Combinations

In an attempt to combine PNA with alkylating agents, Laurencet and colleagues used IV cyclophosphamide 500 mg/m^2 and oral prednisone monthly, in combination with 2-CDA at 0.1 mg/kg/day SQ, for 3 consecutive days, for up to six courses.[162] The ORR was 88%, with grade 4 neutropenia seen in 11% (2/19) of patients, but no treatment-related deaths. A dose-escalation study of the combination was subsequently performed: 2-CDA 5.6 mg/m^2 QD was given as a 2-hour IV infusion, followed by a 1-hour infusion of cyclophosphamide QD for 3 days.[196] A dose of cyclophosphamide 200 mg/m^2 was given initially and was escalated in 100 mg/m^2 increments. The maximal tolerated dose of cyclophosphamide was 300 mg/m^2, and an ORR of 58% was seen. Neutropenia was the dose-limiting toxicity and severe infections were seen in 4% of cycles. A total of 31% of patients could not be given repeated cycles because of prolonged thrombocytopenia.

Tamburini and colleagues described 49 patients with WM treated with cyclophosphamide and fludarabine, 14 of whom were treatment naive.[153] The doses used were cyclophosphamide 300 mg/m^2 IV and fludarabine 30 mg/m^2 IV, days 1 to 3, every 4 weeks, for a median of 4 cycles. The ORR was 78% (38/49 cases all PRs), 2 had progressive disease, and 9 had stable disease. The median time to treatment failure was 27 months. It is interesting that the two factors associated with an adverse outcome were a serum monoclonal protein concentration of less than 4 g/dl and age greater than 65 years (an observation previously made in the Dhodapkar model, but not repeated since).[23]

Purine Nucleoside, Alkylators, and Rituximab Combinations

Hensel and colleagues reported on 14 patients with WM treated with the combination of pentostatin, cyclophosphamide, and (in 8 cases) rituximab.[197] There were eight patients who had been

previously treated with 1 to 3 regimens, and nine patients were untreated. Patients received pentostatin 4 mg/m^2 plus cyclophosphamide 600 mg/m^2. Rituximab was administered at the standard dose of 375 mg/m^2 on day 1 (every 3 weeks). Two patients achieved a CR (12%) and the ORR was 65%. The ORR for patients receiving rituximab was increased at 77%. Three patients had further improvement with additional follow-up.

Tam and colleagues described a group of 18 patients with WM treated with fludarabine, cyclophosphamide, and rituximab (FCR) (n = 5); fludarabine plus mitoxantrone (n = 3); plus cyclophosphamide (n = 9); or rituximab alone (n = 1).[198] The median response duration in this study was 38 months, with an ORR of 76%. In a follow-up report, they expanded, the report to include an additional nine patients with WM who were treated with the same FCR combination. The attained ORR was 56% (5/9 patients), but no CRs were observed.[155]

Weber and colleagues have reported on the combination of Rituximab (375 mg/m^2 q week × 4 weeks), cyclophosphamide (40 mg/m^2 PO BID for 7 days), plus cladribine (1.5 mg/m^2 SQ TID for 7 days), repeated at 6 weeks.[138,199] With a median follow-up of 69 months, they reported an ORR of 94% and a CR rate of 17%.[138,199] The median time to remission was reported at 2.4 months, with duration of remission of 58.6 months, clearly surpassing the median response duration of 26 months reported by the same authors when the combination did not include rituximab. Likewise, the time to re-treatment was not reached at 56.3 months when the combination without rituximab was used.[138,199]

Tedeschi reported on a phase II trial of the combination of fludarabine, rituximab, and cyclophosphamide.[200] A total of 43 WM patients (new diagnosis and previously treated) received rituximab on day 1; and fludarabine 25 mg/m^2 and cyclophosphamide 250 mg/m^2 intravenously on days 2 through 4. Treatment was administered monthly and patients could receive a total of up to 6 cycles of treatment. The ORR was 79%, and the quality of responses was high: 12% of patients achieved a complete remission and 21% had a very good partial remission. However, nearly one half of patients (45%) had grades 3 and 4 neutropenia, and in a similar proportion, this neutropenia was long lasting. Only one patient had progressive disease.

Dimopoulos and colleagues have also explored the combination of rituximab (375 mg/m^2 repeated every 21 days for a total of 6 cycles) plus cyclophosphamide (100 mg/m^2 PO BID for 5 days), given with concurrent dexamethasone (20 mg IV).[201] They report an OR of 70% with 7% of patients achieving a CR. With a median follow-up of 24 months 60% of patients remain free of progression.

A study by Treon addressed the therapeutic benefit of rituximab combined with CHOP chemotherapy.[202] There were 13 patients with WM who were treated with R-CHOP, 10 of whom had been previously treated.[202] The intended treatment was 6 cycles, and then they received rituximab as maintenance therapy. They reported 3 CRs, 8 PRs, 1 MR, and concluded that the regimen was highly effective. Currently, an Eastern Cooperative Oncology Group study is testing the combination of bortezomib, rituximab, dexamethasone, and temsirolimus in relapsed WM (and other malignancies) in a phase I/II study.

New Treatment Options

Thalidomide and Lenalidomide

Thalidomide is an antiangiogenic and immunomodulatory agent that has been found to be effective as salvage therapy of MM.[203] Dimopoulos and colleagues have reported the results of a phase II trial of thalidomide for 20 patients with WM (10 untreated, 10 previously treated).[204] Patients received thalidomide 200 to 600 mg/day and the ORR was 25% (5 of 20 patients, 2 previously treated). The time to progression was less than 3 months however, suggesting that thalidomide as a single agent has minimal activity in WM. One study by Treon and colleagues explored the combination of lenalidomide with rituximab as primary treatment for WM. Although 50% showed antitumor activity, there was a sharp drop in hematocrit in most patients, and further study of the combination is warranted.[205]

Bortezomib

Responses to the proteasome inhibitor, bortezomib, have been documented in WM. Bortezomib's precise mechanism of action is largely unknown, although it is thought to exert its antitumor effects by deregulating the NF-κB pathway. Bortezomib has been used alone or in combination with rituximab and corticosteroids.

Dimopoulos and colleagues reported on the use of bortezomib in patients with WM.[206] They used the medication in 10 previously treated patients (3 patients treated with 3 prior lines of therapy) and 6 achieved a PR.

Treon reported on the outcome of bortezomib as treatment for relapsed and refractory WM in a multicenter study (WMCTG Trial 03–248).[207] A total of 27 patients were treated with single-agent bortezomib on days 1, 4, 8, and 11. The OR was 85% with 13 (48%) patients achieving a major response, and 10 (37%) patients having an MR. The median time to response was 1.4 months. The main toxicity was sensory peripheral neuropathy: grade 2 in 5/27 (22.22%) and grade 3 in 6/27 (22.2%) of patients. The study reported that, in most cases, peripheral neuropathy improved after treatment. In a recent study, Chen and colleagues treated symptomatic WM patients (treatment naive and relapsing) with bortezomib at doses 1.3 mg/m^2 intravenously days 1, 4, 8, and 11 on a 21-day cycle. The response rate in this study was low (26%), probably due to treatment discontinuation due to neuropathy. There were 20 patients (74%) who developed new or worsening peripheral neuropathy (5 patients with grade 3, no grade 4).[208,209]

Bortezomib has also been used in combination strategies against WM. Treon and colleagues were able to show a high response rate, including CRs, in one study of bortezomib in combination with rituximab and dexamethasone.[210] They treated 23 patients with bortezomib, weekly dexamethasone at 40 mg, and rituximab 375 mg/m^2 on day 11. The treatment schedule first used an induction phase with monthly cycles, followed by maintenance treatment (one same treatment) every 3 months.[210] The reported ORR was 96% with 83% of patients attaining a deep response (3 CR, 2 near CR, 3 VGPR, 11 PR, and 3 MR). At a median duration of follow-up of 23 months, 78% of patients remained free of disease progression (18 of 23). As is true in other situations where bortezomib is used, herpes zoster was a common complication. All patients treated with bortezomib should receive acyclovir-based prophylaxis. Similar results have been reported by Ghobrial in two separate phase II trials addressing the role of bortezomib, but administered in a weekly schedule to prevent peripheral neuropathy, in combination with rituximab, in both treatment-naive and previously treated WM.[211,212] For untreated patients (n = 26), she reported a MR or better in 23 (88%) with 1 CR (4%), 1 near CR (4%), 15 PR (58%), and 6 MR (23%). She also reported an estimated 1-year event-free rate of 79%, and no grade 3 or 4 peripheral neuropathy.[211] Among previously treated patients, (n = 37) an MR or better was observed in 81%, 2 CR or near CR (5%), 17 in PR (46%), and 11 (30%) in MR.[212] The median time to progression was 16.4 months. Peripheral neuropathy was again lessened by the weekly administration of bortezomib, and grade 3 occurred in only 2 patients (5%). PFS was 16 months, and estimated at 57% at 12 months, and 45% at 18 months.[212] Agathocleous also

reported as well a high level of activity in 10 WM patients treated with bortezomib.[213]

Everolimus and Perifosine

A phase II study of everolimus reported 42% PRs and 70% minimal responses or better.[214] The main toxicities seen were myelosuppression, but up to 50% of patients required dose reductions due to toxicity. Roccaro et al. have shown that everolimus interacts with and inhibits TORC1 and induces cell cycle arrest and apoptosis (both caspase-dependent and -independent).[215] The mTOR kinase system is responsive to AKT and ultimately signals via TORC1. As mentioned earlier, AKT has been found to be up-regulated in WM. Furthermore, the same group proposes that dual targeting of the PI3K/mTOR pathway may be advantageous in treating WM, such as with the dual inhibitor NVP-BEZ235.[216]

Because of the increased activation of AKT, perifosine has been explored in the clinic for WM.[214] In a phase II study, 37 patients were treated with single-agent perifosine (oral agent) for a total of up to 6 cycles. There were 4 PRs (11%) and 9 minimal responses (24%). Correlative studies showed that perifosine did inhibit AKT and also down-regulate NF-κB.

Alemtuzumab

The use of anti-CD52 monoclonal antibodies (alemtuzumab) has also been proposed by Hunter and colleagues.[217] In one pilot study, the investigators were able to show that clinical responses can be observed, but there appears to be significant toxicity. Alemtuzumab as treatment for WM is being further evaluated, but it may have more of a role in patients with relapsed and refractory disease. The WMCTG has reported on the use of a monoclonal antibody targeting CD52 in patients with WM. They enrolled 28 patients in the study WMCTG 02–079 where patients were treated with 30 mg alemtuzumab, 3 times per week, for up to 12 weeks.[218] Among evaluable patients, the ORR was 81%, including 1 CR (4%) and 10 PR cases (37%). The major toxicities included myelosuppression (more common among previously treated patients), anemia, fatigue, and infection. Of note, two patients had treatment-related death, including one CMV infection, and the other with thrombocytopenia complications.

Imatinib Mesylate

Another trial conducted by the WMCTG (05–140) addressed the role of imatinib in the treatment of WM. A phase II study using imatinib started at 400 mg per day and, if tolerated, the doses were escalated to 600 mg per day for up to 2 years.[218] The reported ORR was 26%, with 2 PR and 5 MR cases. Further studies of imatinib in the setting of relapsing disease are warranted.

Sildenafil

Anecdotal observations have suggested that for some patients, sildenafil results in clinical improvement of WM.[219] To better define its activity in WM, additional studies are needed.

Oblimersen Sodium

Gertz and colleagues have reported on early data using oblimersen sodium, a BCL-2 antagonist.[220] It is an antisense oligonucleotide to the first 6 codons of the B-cell leukemia gene 2 (*BCL-2*) that prevents the expression of the *BCL-2* gene. This process alone can enhance vulnerability of cells exposed to fludarabine, dexamethasone, and rituximab, and is believed to enhance apoptosis. To assess the value of this therapy for WM, the final results of ongoing clinical trials will be needed.

HIGH-DOSE CHEMOTHERAPY WITH STEM CELL SUPPORT

Autologous

Although there are limited data regarding long-term outcomes of WM after autologous or allogeneic transplant in WM, it has been recently argued that autologous (stem cell transplantation [SCT]) should be more often considered in suitable candidates.[221] It is unlikely that SCT will be fully vetted using a randomized phase III trial, however, the utilization of the procedure in related conditions, such as CLL and MM, has made this a safe and, arguably, routine procedure. It has been shown that higher doses of chemotherapy can be safely administered to patients with WM, resulting in disease control.[222, 223,224]

Registry series have been reported describing the outcome of WM patients after autologous stem cell transplant.[222,225,226] Overall, the nonrelapse mortality at 1 year was 6% in the largest series thus far reported. Kyriakou and colleagues reported a retrospective analysis of 158 patients treated with high-dose chemotherapy and autologous stem cell support.[225] The median age of patients was 49 years, and they reported 23 PR, 77 VGPR, and 34 CR.[227] It seems that, given the availability of other effective regimens, stem cell transplant done as up-front treatment for the disease should still be done in the context of clinical trials. Stem cells need to be collected in patients who may be potential stem cell transplant candidates, and high-dose chemotherapy with stem cell support is an effective disease-controlling strategy for patients experiencing relapsing disease. However, a stem cell transplant should be considered more often in cases of first relapse, where the disease is still chemosensitive, and where the clinical results have been thus far encouraging. For a summary of published SCT series on WM, please refer to Table 100.4.[172, 222,225,226, 228,229] The optimal conditioning regimen has not been identified, but both BEAM and high-dose melphalan have been used.

Allogeneic

There are even fewer reports of allogeneic transplantation in WM. The overwhelming majority of patients may not be eligible to be treated with this modality because the median age at onset of WM is 65 years. The originally reported series have been small and predominantly retrospective cases.[230,231] Anagnostopoulos and colleagues reported on 26 patients with WM treated with SCT between 1986 and 2002.[222] Over one half (58%) of patients were treated with myeloablative conditioning regimens. The relapse rate at 3 years was no different between those undergoing an allogeneic versus an autologous SCT (24% vs. 29%). The survival at 3 years was 46% in the allogeneic group and 70% in the autologous group. These data indicate that allogeneic strategies may only be appropriate for select patients with WM and probably should not be pursued for WM patients outside the context of a clinical trial. In an updated report from the European Bone Marrow Transplant (EBMT) registry, Kyriakou and colleagues describe the outcome of 106 patients treated with allogeneic stem cell transplant.[232] A total of 30 patients had nonrelapse mortality (28%). A second report of 37 patients undergoing myeloablative therapy, and 49 with reduced-intensity conditions, showed similar results.[227] For a more detailed discussion on the various high-dose therapy options, please refer to Gertz et al. (Table 100.5).[221,222,233] In our opinion, although allogeneic strategies may be feasible, the high treatment-associated mortality suggests this treatment should be mostly conducted in the setting of clinical trials and not as up-front therapy for the disease.

OTHER THERAPEUTIC INTERVENTIONS

Splenectomy

There are patients with hypersplenism or spleen-dominant disease who benefit from splenectomy, despite the fact that a splenectomy does not address the marrow infiltration associated with WM.[234] Splenectomy has also been reported as correcting a factor VIII deficiency in a WM patient.[235] Furthermore, some anecdotal cases have been reported of patients with disease limited to the spleen who had long durations of response after splenectomy.[236]

Plasma Exchange

Plasmapheresis with total plasma exchange as treatment for the symptoms of the hyperviscosity syndrome in WM is very useful, but has no impact on the tumor burden. When acute hyperviscosity symptoms develop, usually with a viscosity value above 4, small changes in plasma volume can produce large reductions in serum viscosity because the serum viscosity is not linearly correlated with IgM. IgM reductions as small as 20% can result in viscosity reductions of as much as 50%. Dramatic effects on symptoms can occur with even small reductions in serum viscosity.[237] In a survey conducted in Canada from 1981 to 1997, WM was among the top five indications for plasma exchange.[238] Plasma exchange has also been used as a long-term maintenance treatment in patients who become resistant to cytotoxic drugs.[239]

TOXICITY OF STANDARD THERAPY

WM patients have baseline immunosuppression because of decreased levels of uninvolved immunoglobulins and treatment-related granulocytopenia, all of which increase the risk of infection. In addition, treatment with PNA increases the risk of opportunistic infections, and there are occasional reports of post-transplant-like lymphoma[240] secondary to a reduction in the level of circulating CD4+ T cells.[241,242] Other infections, such as opportunistic viral enteric infection[243] and *Cryptococcus* meningitis, have been reported in WM patients treated with fludarabine.[244] Furthermore, 2-CDA interferes with lymphocyte proliferation and activity resulting in associated fever and potential infection.[242,245] Autoimmune phenomena in patients exposed to 2-CDA have been reported and may be the result of suppression of T-lymphocyte function. Four WM patients have been reported in whom immune-mediated hemolysis developed after 2-CDA therapy (median, 40 months after initial administration). Hemolytic anemia has also been reported.[246] In a small series, one patient responded to oral corticosteroids and two died.[247] Neurologic, renal, and local skin reactions have also been reported.[248]

Cladribine and fludarabine are both associated with myelosuppression,[175] including severe neutropenia and thrombocytopenia. In one study using cladribine, grade 3 or 4 neutropenia was seen in 60% of patients.[156] Similarly, high rates of neutropenia (77%) and thrombocytopenia (32%) have been reported in other studies.[161] We therefore recommend that when cladribine is to be used, it should be limited to 2 cycles and empiric preventive antimicrobial and antiviral prophylaxis be considered.

Alkylating agents are well known to induce chromosomal changes and to be mutagenic. Acute myelogenous leukemia or the development of myelodysplasia are clearly the most devastating complications associated with alkylating agent therapy; although these occur in a small minority of patients. Reports of acute leukemia appeared shortly after the introduction of alkylating agents for the management of WM.[249–251] In a study of 46 patients, acute leukemia or refractory anemia developed in 4 patients.[68] Acute leukemia has also been reported with chlorambucil treatment.[252] Two patients, without any prior exposure to alkylating agents, have been reported with myelodysplastic syndrome (MDS) and chromosomal abnormalities, including monosomy-5 and monosomy-7.[253] A metabolite of cyclophosphamide, acrolein, is toxic to the urinary bladder, and bladder cancer has been reported in patients treated with oral cyclophosphamide (50 to 100 mg/day).[254]

Treatment has also been reported as being associated with an increased risk of secondary malignancies. Several reports have shown an increased incidence in retrospective series of patients treated with these agents, with rates ranging from 0% to 7%. The validity of these observations has been questioned due to the retrospective nature of these reports, which lacked controls. The baseline rate of secondary malignancies plus the increment associated with the use of alkylators has not been fully elucidated. In one of the largest series, Facon reported a rate of 1.2% (2/167 patients). It is possible to conclude that, as single agents, PNAs have a low incremental risk of MDS and acute myeloid leukemia. However, the risk may be higher when they are combined with alkylators such as cyclophosphamide[155, 255,173] (Table 100.6).

Studies on the use of fludarabine reported an incidence of secondary malignancies of 1.4% to 8.9%. Once more, these studies were small in size and retrospective. Morel and colleagues reported an increased incidence of second cancers in WM patients.[51] An Italian group reported a large incidence of secondary malignancies of 12%, at 10 years and 17% at 15 years.[256] One report using the Surveillance, Epidemiology, and End Results (SEER) database evaluated 1,618 WM patients and found an increased risk of myeloma, melanoma, and colon, uterus, lung, and kidney cancers.[257] However, the Leblond study (a randomized study) showed a rate of secondary malignancies of 3.7% at 6 years versus 20.6% ($P = 0.001$) for those treated with chlorambucil, with a combination of both solid tumors and hematologic

malignancies (Personal communication, V Leblond, International Waldenström Macroglobulinemia Workshop, August, 2012). In this same study, there was no evidence of an effect of PNAs on the risk of Richter transformation (Table 100.7).

Rituximab is also associated with toxicity that is thought to be secondary to the immunosuppressive effects of the medication. It has been reported that reactivation of a variety of viral infections, including hepatitis B, can occur after rituximab treatment.[258–263] One patient with WM developed a fatal adenoviral hepatitis after rituximab treatment. Reports also exist of rituximab-associated progressive multifocal leukoencephalitis.[264,265] A case of nasal skin necrosis after rituximab therapy has also been reported.[266]

MAYO CLINIC TREATMENT RECOMMENDATIONS

It remains of paramount importance to identify patients who have IgM MGUS or smoldering WM who do not need therapy, and for whom expectant observation is appropriate. It is important to emphasize, however, that close monitoring is indicated, as there can be substantial decrements in quality of life of individuals who progress to symptomatic WM. In our institution, most patients who require initial therapy and who cannot, or do not want, to be enrolled in clinical trials, are treated with the combination of rituximab, cyclophosphamide, and dexamethasone. This is a very well-tolerated regimen that will not interfere with subsequent collection of stem cells. In suitable candidates, stem cells are collected for a future SCT. In some rare instances, the use of single-agent rituximab can be considered, but in the majority of cases, combination therapy is indicated. In elderly patients who have significant comorbidities or limited mobility, single-agent chlorambucil can be considered as well. Plasma exchange is only indicated in cases of symptomatic hyperviscosity, and is used only as a "bridge" procedure until effective cytotoxic therapy is instituted. Our consensus group recommendations have been published and presented as Figure 100.3.

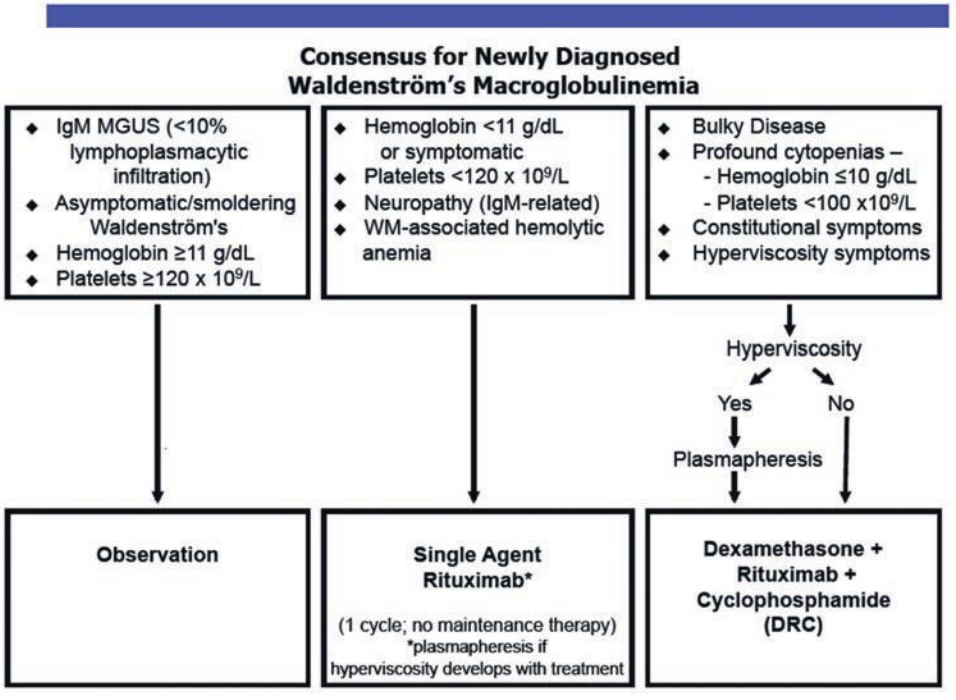

FIGURE 100.3. Consensus for newly diagnosed Waldenström's macroglobulinemia. MGUS, monoclonal gammopathy of undetermined significance. From Ansell SM, Kyle RA, Reeder CB, Fonseca R, et al. Diagnosis and management of Waldenström macroglobulinemia: Mayo stratification of macroglobulinemia and risk-adapted therapy (mSMART) guidelines. Mayo Clinic Proc 2010;85:824–833.

CONCLUSIONS

The mainstay of therapy for WM has changed recently and more broadly uses rituximab-based combinations with other novel agents, such as bortezomib and others. The new developments in understanding disease biology, mainly by the identification of *MYD88* as a disease-defining mutation, will allow a more rational approach to disease identification, classification, and possibly targeted therapy. A recent consensus statement discussed this dilemma and conceded that single-agent therapy or combination approaches were equally appropriate treatment for WM patients. Issues to be considered when selecting therapy include factors associated with the disease, such as tumor bulk, hyperviscosity, and cytopenias, as well as patient-related factors, such as comorbid diseases and prior therapy. For some patients, achieving rapid cytoreduction of tumor may be important (and may favor a combination therapy approach), but for most, this is not necessary and single-agent therapy may be more appropriate. It is also important to remember that there may be a long latent period before one observes the full clinical benefit of the selected treatment. Based on the small population of patients with this disease and the paucity of information available regarding the best therapy, however, patients should be considered for clinical trials whenever possible.

CHAPTER 101

POEMS SYNDROME, CRYOGLOBULINEMIA, AND HEAVY-CHAIN DISEASE

Angela Dispenzieri, David Dingli, Morie A. Gertz

INTRODUCTION

This chapter addresses three types of immunoglobulin-based orphan diseases: the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes), cryoglobulinemia, and immunoglobulin heavy-chain disease (HCD). These diseases are characterized by lymphoproliferative, lymphoplasmacytic proliferative, or plasma cell proliferative disorders and specific serum immunoglobulin findings that serve as markers to define each entity.

POEMS SYNDROME

POEMS syndrome is a rare paraneoplastic syndrome due to an underlying plasma cell disorder. The acronym, which was coined by Bardwick in 1980,[1] refers to several, but not all, of the features of the syndrome: polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes. There are three important points that relate to this memorable acronym: (1) not all of the features within the acronym are required to make the diagnosis; (2) there are other important features not included in the POEMS acronym, including *p*apilledema, *e*xtravascular volume overload, *s*clerotic bone lesions, *t*hrombocytosis/erythrocytosis (P.E.S.T.), elevated vascular endothelial growth factor (VEGF) levels, a predisposition toward thrombosis, and abnormal pulmonary function tests; and (3) there is a Castleman disease variant of POEMS syndrome that may be associated with a clonal plasma cell disorder. Other names of the POEMS syndrome that are less frequently used are osteosclerotic myeloma, Takatsuki syndrome, Crow-Fukase syndrome, and PEP syndrome.[2,3]

The disease was initially thought to be more common in patients of Japanese descent, given the most numerous initial reports from Japan.[2,3] However, over the years, large series have also been reported from France, the United States, China, and India.[4,5,6,7,8] A national survey conducted in Japan in 2003 showed a prevalence of approximately 0.3 per 100,000.[9]

ETIOLOGY OF POEMS SYNDROME

The pathogenesis of the syndrome is not understood. Distinctive presenting characteristics of the syndrome that differentiate POEMS syndrome from standard multiple myeloma (MM) include the following: (1) dominant symptoms have little or nothing to do with bone pain, extremes of bone marrow infiltration by plasma cells, or renal failure; (2) dominant symptoms are typically neuropathy, endocrine dysfunction, and volume overload; (3) VEGF levels are high; (4) sclerotic bone lesions are present in the majority of cases; (5) overall survival is typically superior; and (6) λ clones predominate.[10]

To date, VEGF is the cytokine that correlates best with disease activity,[11,12–14,15,16,17,18,19,20] although it is likely not the driving force of the disease, based on the mixed results seen with anti-VEGF therapy.[21–27] VEGF is known to target endothelial cells, induce a rapid and reversible increase in vascular permeability, and be important in angiogenesis. It is expressed by osteoblasts, in bone tissue, macrophages, malignant plasma cells,[28,29,30] and megakaryocytes/platelets.[31] Both IL-1β and IL-6 have been shown to stimulate VEGF production.[28] Little is known about the plasma cells in POEMS syndrome except that more than 95% of the time they are λ-light chain restricted with restricted immunoglobulin light chain variable gene usage (*IGLV1*).[32,33,34] Aneuploidy and deletion of chromosome 13 have been described, but hyperdiploidy is not seen.[35]

DIAGNOSIS OF POEMS SYNDROME

The diagnosis is established based on a composite of clinical and laboratory features. The most notable symptoms include the constellation of neuropathy and any of the following: monoclonal protein (especially λ-light chain), thrombocytosis, anasarca, or papilledema. All the features of the acronym are not required to make the diagnosis. The requirements set forth in Table 101.1 are designed to retain both sensitivity and specificity, potentially erring on the side of specificity. Making the diagnosis can be a challenge, but a good history and physical examination followed by appropriate testing—most notably radiographic assessment of bones,[38] measurement of VEGF,[13,17,20,39,40] and careful analysis of a bone marrow biopsy[41]—can differentiate this syndrome from other conditions like chronic inflammatory polyradiculoneuropathy (CIDP), monoclonal gammopathy of undetermined significance (MGUS) neuropathy, and immunoglobulin light chain amyloid neuropathy.[42] Figure 101.1 demonstrates several classic findings among patients with POEMS syndrome.

CLINICAL PRESENTATION OF POEMS SYNDROME

Polyradiculoneuropathy

The peripheral neuropathy is the dominant characteristic,[2,3,5,7,36] and it is ascending, symmetrical, and affecting both sensation and motor function.[43] In our experience, pain may be a dominant feature in about 10% to 15% of patients, and in one report as many as 76% of patients had painful neuropathy.[9,44] Nerve conduction studies in patients with POEMS syndrome show slowing of nerve conduction that is more predominant in the intermediate than distal nerve segments as compared to CIDP, and there is more severe attenuation of compound muscle action potentials in the lower than upper limbs.[9,45,46,47,48] In contrast to CIDP, conduction block is rare.[9,46,48] The conduction findings suggest that demyelination is predominant in the nerve trunk rather than the distal nerve terminals, and axonal loss is predominant in the lower limb nerves.[9] Axonal loss is greater in POEMS syndrome than it is in CIDP.[48] The nerve biopsy is not specific, but uncompacted myelin lamellae, endothelial cytoplasmic enlargement, opening of the tight junctions between endothelial cells and presence of many pinocytic vesicles adjacent to the cell membranes, and absence of macrophage-associated demyelination have been described.[49–55,64]

TABLE 101.1

CRITERIA FOR THE DIAGNOSIS OF POEMS SYNDROME[a]

		% Affected[b]
Mandatory major criteria	1. Polyradiculoneuropathy (typically demyelinating)	100
(both required)	2. Monoclonal plasma cell disorder (almost always λ)	100[c]
Other major criteria	3. Castleman disease[d]	11–25
(one required)	4. Bone lesions, usually sclerotic	27–97
	5. Vascular endothelial growth factor elevation[e]	
Minor criteria (one required)	6. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)	45–85
	7. Extravascular volume overload (edema, pleural effusion, or ascites)	29–87
	8. Endocrinopathy (adrenal, thyroid[f], pituitary, gonadal, parathyroid, pancreatic[f])	67–84
	9. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails)	68–89
	10. Papilledema	29–64
	11. Thrombocytosis/polycythemia[g]	54–88
Other symptoms and signs	Clubbing, weight loss, hyperhidrosis, pulmonary hypertension/restrictive lung disease, thrombotic diatheses, diarrhea, low vitamin B_{12} values	

POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes.
[a]The diagnosis of POEMS syndrome is confirmed when both of the mandatory major criteria, one of the three other major criteria, and one of the six minor criteria are present.
[b]Summary of frequencies of POEMS syndrome features based on largest retrospective series.[2,3,5,7,36,37]
[c]Takasuki and Nakanishi series are included even though only 75% of patients had a documented plasma cell disorder. Since these are among the earliest series describing the syndrome, they are included.
[d]There is a Castleman disease variant of POEMS syndrome that occurs *without* evidence of a clonal plasma cell disorder that is not accounted for in this table. This entity should be considered separately.[42]
[e]A plasma VEGF level of 200 pg/ml is 95%specific and 68%sensitivity for a POEMS syndrome.[20]
[f]Because of the high prevalence of diabetes mellitus and thyroid abnormalities, this diagnosis alone is not sufficient to meet this minor criterion.
[g]Approximately 50% of patients will have bone marrow changes that distinguish it from a typical MGUS or myeloma bone marrow.
From Dispenzieri A. How I treat POEMS syndrome. Blood 2012;119(24):5650–5658, with permission.

Organomegaly, Endocrinopathy, Skin Changes, Papilledema, and Extravascular Overload

Depending on the series, 45% to 85% of patients will have any combination of splenomegaly, hepatomegaly, and/or lymphadenopathy. With the exception of lymph node biopsies, the histology of the liver and spleen tends to be nonspecific. Lymph nodes may appear reactive or reveal frank Castleman's Disease or merely "Castleman's Disease-like" changes. Historically, it was estimated that between 11% and 30% of POEMS patients with documented clonal plasma cell disorder also have documented Castleman disease or Castleman-like histology.[1,3,5,7,36,42] More recent data would suggest that among individuals with POEMS who undergo lymph node biopsy, about 50% show angiofollicular hyperplasia typical of Castleman disease,[3,7] and 84% of these are hyaline vascular type.[7] Only those with peripheral neuropathy AND a plasma cell clone should be classified as standard POEMS syndrome; without both, patients can be classified as Castleman disease variant of POEMS if they have other POEMS features.[56]

Endocrinopathy is a central but poorly understood feature of POEMS. In a recent series,[37] approximately 84% of patients had a recognized endocrinopathy, with hypogonadism as the most common endocrine abnormality, followed by thyroid abnormalities, glucose metabolism abnormalities, and lastly by adrenal insufficiency. The majority of patients have evidence of multiple endocrinopathies in the four major endocrine axes (gonadal, thyroid, glucose, and adrenal). Gynecomastia may be present on physical examination.

The characteristic skin changes include hyperpigmentation, a recent outcropping of hemangioma, hypertrichosis, dependent rubor and acrocyanosis, white nails, sclerodermoid changes, facial lipodystrophy, flushing, or clubbing.[2,4,5,6,7,8,57,58] Rarely, calciphylaxis is also seen.[59,60] The histologic findings of the dermis have been reported to range from nonspecific to glomeruloid hemangiomata to vascular abnormalities in apparently normal dermis.[61,62–64]

Papilledema is present in at least one-third of patients[65]; the majority of these patients do not have specific symptoms relating to this finding but a minority will report blurred vision, diplopia, or ocular pain.

Peripheral edema, ascites, and effusions are the symptoms and signs that cause the next most morbidity after peripheral neuropathy. The manifestations of extravascular overload occur in 29% to 87% of patients with POEMS syndrome and are not typically associated with severe hypoalbuminemia. Severe third spacing can lead to worsening renal function. Serum creatinine levels are normal in most cases, but serum cystatin C, which is a surrogate marker for renal function, is high in 71% of patients.[66] In our experience, at presentation, fewer than 10% of patients have proteinuria exceeding 0.5 g/24 hours, and only 6% have a serum creatinine greater than or equal to 1.5 mg/dl. Four percent of patients developed renal failure as preterminal events.[36] In another series from China, however, 37% of patients had a creatinine clearance (CrCl) of less than 60 ml/minute, 9% had a CrCl of less than 30 ml/minute, and 15% had microhematuria. In POEMS syndrome, the renal histologic findings are diverse, with membranoproliferative features and evidence of endothelial injury being most common.[67] On both light and electron microscopy, mesangial expansion, narrowing of capillary lumina, basement membrane thickening, subendothelial deposits, widening of the subendothelial space, swelling and vacuolization of endothelial cells, and mesangiolysis predominate.[68,69–74] Standard immunofluorescence is negative,[69,75] which differentiates it from primary membranoproliferative glomerulitis.[67] Rarely, infiltration by plasma cell nests or Castleman-like lymphoma have been described.[74]

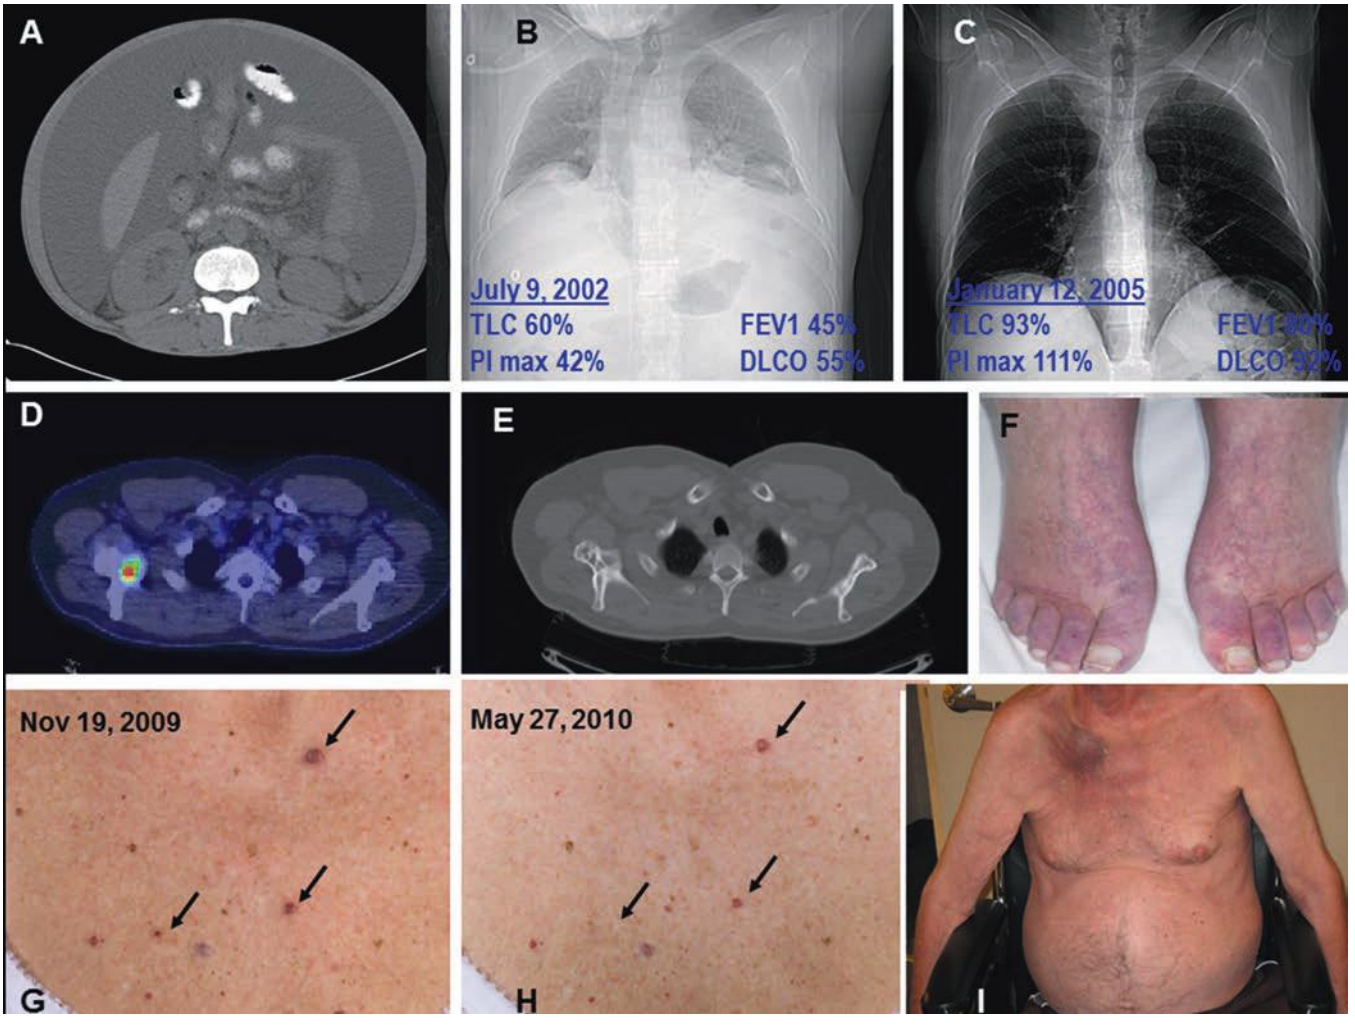

FIGURE 101.1. Classic findings of POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes) syndromes. A: Massive ascites and lipodystrophy. **B:** Chest radiograph and pulmonary function test results demonstrating reduced lung volumes due to neuromuscular weakness, small effusions, and reduced diffusing capacity of carbon monoxide. **C:** Improved chest radiograph and pulmonary function tests 2.5 years after ASCT (same patient as **H**). **D:** Fusion CT PET of mixed lytic/sclerotic lesion in right scapula. **E:** Bone windows of CT of mixed lytic/sclerotic lesion in right scapula. **F:** Hyperemia of extremities and white nails. **G:** Outcropping of cherry angiomata at diagnosis. **H:** Shrinkage and disappearance of cherry angiomata after radiation to solitary osteosclerotic lesion right femur. **I:** Plasmacytoma right scapula with overlying erythema as well as gynecomastia, muscle wasting, and ascites. Also present but unrelated is florid tinea corporis due to chronic steroid used for the incorrect diagnosis of CIDP. (From Dispenzieri, A. How I treat POEMS syndrome. Blood 2012;119(24):5650–5658, with permission.)

Monoclonal Plasma Cell Disorder, Sclerotic Bone Lesions, and Myeloproliferation

Among patients with POEMS syndrome, the CBC is notable for an absence of cytopenias. In fact, nearly half of patients will have thrombocytosis or erythrocytosis.[36] In a recent series from China, 26% of patients had anemia, which the authors attributed to impaired renal function.[7] Their series was enriched with Castleman disease cases (25%), which may have also contributed to this unprecedentedly high rate of anemia.

The bone marrow biopsy reveals megakaryocyte hyperplasia and megakaryocyte clustering in 54% and 93% of cases, respectively.[41] These megakaryocyte findings are reminiscent of a myeloproliferative disorder, but *JAK2* V617F mutation is uniformly absent. One-third of patients do not have clonal plasma cells on their iliac crest biopsy. These are the patients who present with a solitary or "multiple solitary" plasmacytomas. The other two-thirds of patients have clonal plasma cells in their bone marrow, and 91% of these cases are clonal λ. The median percent of plasma cells observed is less than 5%. Immunohistochemical staining is more sensitive than is 6-color flow cytometry, since the former provides information on bone marrow architecture, which is key in making the diagnosis in nearly half of cases. In our study of 67 pretreatment bone marrow biopsies from patients with POEMS syndrome, lymphoid aggregates were found in 49% of cases. Of these, there was plasma cell rimming in all but one, and in 75% and 4% the rimming was clonal λ and κ, respectively. This finding was not seen in bone marrows from normal controls or from patients with MGUS, MM, or amyloidosis. Overall, only 8/67 (12%) of POEMS cases had normal iliac crest bone marrow biopsies, i.e., no detectable clonal plasma cells, no plasma cell rimmed lymphoid aggregates, and no megakaryocyte hyperplasia.

Osteosclerotic lesions occur in approximately 95% of patients and can be confused with benign bone islands, aneurysmal bone cysts, nonossifying fibromas, and fibrous dysplasia.[3,36,76,77] Some lesions are densely sclerotic, while others are lytic with a sclerotic rim, while still others have a mixed soap-bubble appearance. Occasionally patients will have a lytic lesion without any evident sclerosis. Bone windows of CT body images are often very informative, often even more so than FDG-uptake, which can be variable and most useful when there is an obvious lytic component to the bone lesion.

Elevated Vascular Endothelial Growth Factor and Other Cytokines

Plasma and serum levels of VEGF are markedly elevated in patients with POEMS[11,20,28,78] and correlate with the activity of the disease.[13,17,20,28] The principal isoform of VEGF expressed is VEGF165.[13] VEGF levels are independent of M-protein size.[13] IL-1β, TNF-α, and IL-6 levels are often also increased. Serum VEGF levels are 10 to 50 times higher than plasma levels of VEGF,[79] making it unclear which test is preferred. In patients with POEMS, VEGF is found in both plasma cells[29,30] and platelets.[78] The higher level observed in serum is attributable to the release of VEGF from platelets in vitro during serum processing. Our group has recently demonstrated that a plasma VEGF level of 200 pg/ml had a specificity of 95% with a sensitivity of 68% in support of a diagnosis of POEMS syndrome. Other diseases with high VEGF include connective tissue disease and vasculitis.[20]

Pulmonary and Coagulation Abnormalities

Respiratory complaints are usually limited, given patients' neurologic status impairing their ability to induce cardiovascular challenges.[80] The pulmonary manifestations are protean, including pulmonary hypertension, restrictive lung disease, impaired neuromuscular respiratory function, and impaired diffusion capacity of carbon monoxide, but improve with effective therapy.[7,80,81] Whether the digital clubbing seen in POEMS is a reflection of underlying pulmonary hypertension and/or parenchymal disease is yet to be determined. Fingernail clubbing is seen in about 4% to 49% of cases.[3,80]

Patients are at increased risk for arterial and/or venous thromboses during their course, with nearly 20% of patients experiencing one of these complications.[10,82] Ten percent of patients present with a cerebrovascular event, most commonly embolic or vessel dissection and stenosis.[83] Thrombocytosis and increased bone marrow infiltration are associated with risk for cerebrovascular accidents.[83] Aberrations in the coagulation cascade have been implicated in POEMS syndrome, but are not usually clinically apparent.[55]

TREATMENT OF POEMS SYNDROME

Despite the relationship between disease response and dropping levels of VEGF, the most experience with successful outcomes has been associated with directing therapy at the underlying clonal plasma cell disorder rather than solely targeting VEGF with anti-VEGF antibodies. The treatment algorithm is based on the extent of the plasma cell infiltration (Fig. 101.2). The approach to therapy differs based on whether there is bone marrow involvement as determined by blind iliac crest sampling.[84]

The course of POEMS syndrome is usually chronic, with modern estimated median survivals of nearly 14 years.[36,80] Only fingernail clubbing, extravascular volume overload—i.e., effusions, edema, and ascites[36]—and respiratory symptoms[80] have been associated with a significantly shorter overall survival. The number of POEMS features does not affect survival.[5,10] In our experience and in a recent report from China, patients with coexisting Castleman disease may have an inferior overall survival as compared to patients without.[7] In a series of 11 patients, lower VEGF levels predicted for better response to therapy, with resolution of the skin changes, improvement of the neuropathic disturbances, and improvement of all of the features assumed to be related to increased permeability, like papilledema and organomegaly.[17]

Management of POEMS Syndrome without Disseminated Bone Marrow Involvement

In the case of patients with an isolated bone lesion without clonal plasma cells found on iliac crest biopsy, radiation is the recommended therapy, as it is in the case of a more straightforward solitary plasmacytoma of bone. Not only does radiation to an isolated (or even two or three isolated) lesion(s) improve the symptoms of POEMS syndrome over the course of 3 to 36 months, but it can be curative.

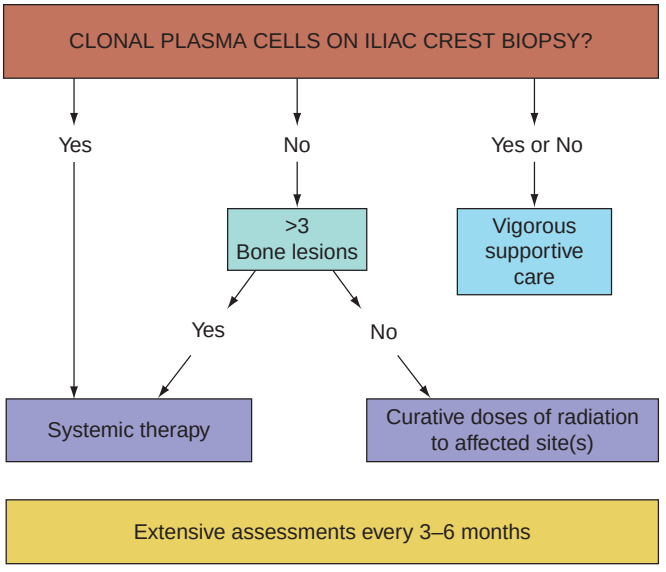

FIGURE 101.2. Algorithm for the treatment of POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes) syndrome. (From Dispenzieri, A., How I treat POEMS syndrome. Blood 2012;119(24):5650–5658, with permission.)

Management of POEMS Syndrome with Disseminated Bone Marrow Involvement

Once there is disseminated bone marrow involvement, albeit even with a low plasma cell percentage, radiation is not expected to be curative. Typically, once there is disseminated disease identified, systemic therapy is recommended with the caveat that large bony lesions with a significant lytic component may require adjuvant radiation therapy.[84] Decisions about adjuvant radiation should be made on a case by case basis, and typically not until a minimum of 6 months after completing chemotherapy. It is important to remember that there is a lag between completion of successful therapy and neurologic response, often with no discernible improvement until 6 months after completion of therapy. Maximal response is not seen until 2 to 3 years hence. Other features like anasarca, papilledema, and even skin changes may improve sooner. Optimal FDG-PET response may also lag by 6 to 12 months.

Since there are no randomized clinical trials among patients with POEMS syndrome, treatment recommendations are based on case series and anecdote. The treatment armamentarium is borrowed from other plasma cell disorders, most notably MM and light chain amyloidosis. Table 101.2 summarizes regimens and observed outcomes. Corticosteroids may provide symptomatic improvement, but response duration is limited. The most experience has been with alkylator-based therapy, either low-dose or high-dose, with peripheral blood stem cell transplant. The first prospective clinical trial to treat POEMS syndrome was reported from China.[89] They treated 31 patients with 12 cycles of melphalan and dexamethasone and found that 81% of patients had hematologic response, 100% had VEGF response, and 100% had at least some improvement in neurologic status. A limitation of this study is that follow-up was only 21 months, so long-term outcomes are not yet available. Personal experience and retrospective reports of the use of cyclophosphamide-based therapy are also promising.[84]

TABLE 101.2

ACTIVITY OF THERAPY FOR THE TREATMENT OF POEMS SYNDROME

Regimen	Outcome
Radiation[36,85–88]	≥50% of patients have significant clinical improvement
Mel-Dex[89]	81% hematologic response rate; 100% with some neurologic improvement
Corticosteroids[56]	≥15% of patients have significant clinical improvement
ASCT[56]	100% of surviving patients have significant clinical improvement
Thal after MP[90]	No hematologic response but improved ascites; stabilized PN, splenomegaly, pulmonary hypertension
Thal + Dex after CAD[91]	CD/POEMS: improved ascites, effusions, pulmonary hypertension, PN, renal function, IL-6 level
Thal + Dex[92]	*Nine patients.* VEGF improved in all; PN improved in 66%; stable in 33%; improved edema; no HCR
Thal after VAD, CTX, Bev[25]	Improved cardiopulmonary status, but no improved PN and rising VEGF
Len + Dex[93]	Improved ascites, PS, PN, VEGF, testosterone, pulmonary function tests
Len + Dex[94]	*Nine patients.* All had hematologic response; clinical responses in all evaluable patients including PS, neurologic syndrome, edema, and VEGF
Len ± Dex[95]	*Ten patients.* All had prior therapy a median of 4 mo (range 1–36 mo) prior to starting len. For 7, only Pred and IVIG were used as prior therapy, making it improbable that the salutatory effect was related to anything other than len. After a median of 7.5 cycles of len, all had clinical improvement despite the fact that only half achieved CR. Five were consolidated with ASCT
Len + CTX + Dex[96]	After 4 cycles of therapy, patient was able to walk without support, and after 6 cycles, papilledema and IgA disappeared. 1 y after 9 cycles, she remains in remission
Bortez+AD after VAD, CTX, Mel-Pred, + AD[97]	Improved M-protein, VEGF, paresthesias, splenomegaly, effusions, muscle strength, gynecomastia, and skin changes
Bortez + Dex[98]	Improved M-protein, polyneuropathy, hepatomegaly, testosterone; no change in electromyelography
Bortez x 5 cycles + Thali added at cycle 6 (prior Dex and Mel-Pred)[99]	Improvement of anasarca, PN, VEGF, and PET scan with Bortez alone, but thali added because of persistent edema, M-protein, PN, and barely elevated VEGF. With thali, disappearance of pleural effusion, ascites, and M-protein and normalization of VEGF
Bortez Dex[a][100]	Improvement by 3 cycles, but continued for 6. Complete remission 4 y after completing therapy. Improvement in adenopathy, pleural effusion and ascites, hepatosplenomegaly, and IL-6
Bortez, CTX, Dex[101]	Clinical response of anasarca within 6 wk and tolerated therapy for 18 mo achieving a near complete response and a VEGF response. PN, hyperpigmentation, pulmonary hypertension improved significantly
Bev alone[21]	Death within 6 wk
Bev + mycophenolate + Dex[102]	One month after starting therapy, patient deteriorated further with worsening ascites and shortness of breath. Bev and Dex were discontinued. Mel and Pred were begun. Patient died 1 mo later
Bev alone[22]	Worsening PN, anasarca, multiorgan failure; died of pneumonia 5 wk after therapy
Bev alone[23]	Improved pain, breathing, and walking
Bev + Mel-Dex[24]	Improved effusions/ascites
Prior VAD/CTX[25]	Improved edema, pain, weakness, and VEGF
Bev + CTX-Dex[26]	Initial worsening; repeat with Bev → improved pulmonary HTN, anasarca, skin changes
Bev + CTX-CS[27]	Initial improvement, but multiorgan failure and death
Bev + CTX-radiation[103]	*Two patients.* First patient treated with radiation and CTX and then Bev. Clinical improvement started before Bev. At radiologic relapse, Bev no use, so lenalidomide plus Dex used with benefit. Second patient treated with same sequence, but course complicated by sepsis. Biochemical and early neurologic response before Bev started
Bev +CTX[20]	Clinical and biochemical relapse. No response to CTX, so bevacizumab added. Death

Bev, bevacizumab; Bortez, bortezomib; CS, corticosteroids; CTX, cyclophosphamide; Dex, dexamethasone; HCR, hematologic complete response; HTN, hypertension; Len, lenalidomide; Mel, melphalan; PN, polyneuropathy; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes; Pred, prednisone; PS, performance status; Thali, thalidomide; VAD, vincristine, doxorubicin, dexamethasone; VEGF, vascular endothelial growth factor.
[a]Castleman's variant of POEMS syndrome.

High-dose chemotherapy with peripheral blood stem cell transplant can also be quite effective, but selection bias may confound these reports. Case series suggest 100% of patients achieve at least some neurologic improvement.[18,57,67,104,105,106,107,108,109,110,111,112,113,124,125] Doses of melphalan ranging from 140 mg/m^2 to 200 mg/m^2 have been used, with the lower doses used for sicker patients. In addition, tandem transplant has been applied in one patient, but again, no information is available regarding any added value of the second transplant.[126] Anecdotally, responses are durable, but relapses have been reported.[27,127] Of the 59 patients with POEMS syndrome treated at the Mayo Clinic Rochester, progression-free survival was 98%, 94%, and 75% at 1, 2, and 5 years, respectively.[128] Symptomatic progressions were rare, whereas radiographic and VEGF progressions were most common. Treatment-related morbidity and mortality can be minimized by recognizing and treating an engraftment-type syndrome characterized by fevers, rash, diarrhea, weight gain, and respiratory symptoms and signs that occur anytime between days 7 and 15 post–stem cell infusion.[113]

Other promising treatments include lenalidomide, thalidomide, and bortezomib, all of which can have anti-VEGF and anti-TNF effects. Enthusiasm for the latter two therapies should be tempered by the high rate of peripheral neuropathy induced by these drugs. We have observed dramatic improvements in one patient

treated with lenalidomide.[93] In France, nine patients, one of whom was newly diagnosed, were treated with lenalidomide and dexamethasone.[94] Serious side effects were noted in three patients, with two hematologic toxicities and a cutaneous allergy. All patients evaluable for hematologic response had at least a partial hematologic response. Clinical responses, including improvement in performance status and neurologic symptoms, were documented among the 8 who had sufficient follow-up. One patient relapsed 5 months after discontinuing therapy, but responded to reintroduction of the drug. Bortezomib use has been reported in three patients.[97,98,101] The first report is difficult to interpret, since the patient had a number of chemotherapies prior to receiving a bortezomib, doxorubicin, and dexamethasone combination. There was early evidence of improvement even before starting the bortezomib regimen. The second and third reports are more convincing: in the first, 7 cycles of bortezomib and dexamethasone resulted in patient improvement; and in the second, 18 months of cyclophosphamide, bortezomib, and dexamethasone resulted in dramatic improvements in a patient with refractory paracentesis-dependent ascites. Although an anti-VEGF strategy is appealing, the results with bevacizumab have been mixed.[22–27] Five patients who had also received either radiation or alkylator during and/or predating the bevacizumab had benefit,[24–26,103] including three who had improvement but were then consolidated with high-dose chemotherapy and autologous stem cell transplant.[25,103] Three patients receiving bevacizumab died.[21,22,27]

Both our experience and the literature would support that single-agent IV IG or plasmapheresis is not helpful. Other treatments like interferon (IFN)-α, tamoxifen, transretinoic acid, ticlopidine, argatroban, and strontium-89 have been reported as having activity, mostly as single case reports.[10]

Managing Symptoms of Disease

Attention to supportive care is imperative. Orthotics, physical therapy, and CPAP all play an important role in patients' recovery. Ankle foot orthotics can increase mobility and reduce falls. Physical therapy reduces the risk of permanent contractures and leads to improved function both in the long and short term. For those with severe neuromuscular weakness, CPAP and/or BiPAP provides better oxygenation and potentially reduces the risk of complications associated with hypoventilation like pulmonary infection and pulmonary hypertension.

Monitoring Response

Patients must be followed carefully on a quarterly basis, tracking the status of deficits and comparing these to baseline.[128] VEGF responses may occur as soon as 3 months,[124] but they can be delayed. VEGF is an imperfect marker since discordances between disease activity and response have been reported,[137] so trends rather than absolute values should direct therapeutic decisions. Serum M-protein responses by protein electrophoresis, immunofixation electrophoresis, or serum immunoglobulin free light chains also pose a challenge. The size of the M-protein is typically small, making standard MM response criteria inapplicable in most cases. In addition, patients can derive very significant clinical benefit in the absence of an M-protein response.[89,113] Finally, despite the fact that the immunoglobulin free light chains are elevated in 90% of POEMS patients, the ratio is normal in all but 18%,[66] making the test of limited value for patients with POEMS syndrome.

Recommendations about how to approach organ response have recently been suggested for the purposes of clinical trials, since there are more than two dozen parameters that can be assessed in a given patient with POEMS syndrome, given the multisystem nature of the disease.[128,138] Alternatively, response criteria for POEMS syndrome could be abridged as follows: (1) hematologic response using modified amyloid response criteria; (2) VEGF response; and (3) a simplified organ response, which is limited to those systems causing the most morbidity, like peripheral neuropathy assessment, pulmonary function testing (diffusion capacity of carbon monoxide), and extravascular overload (grading ascites and pleural effusion as absent, mild, moderate, or severe).

CRYOGLOBULINEMIA

In 1933, Wintrobe and Buell[139] originally reported observing cryoglobulins in a serum sample from a patient with MM. These cold precipitable immunoglobulins were observed in some patients with vasculitis, viral infection, or lymphoproliferative disorders, and were found to be byproducts of lymphoid dysfunction—unchecked and misdirected stimulation and proliferation that cause dysfunction and pathologic changes. An understanding of cryoglobulins and the cells that produce them, along with their interaction with tissue matrix, systemic cytokines, and the remainder of the immune system, may provide insight into basic control pathways and the earliest steps of malignant transformation.

The term "cryoglobulin" was coined by Lerner and Watson[140] in 1947. Precipitation of cryoglobulins is dependent on temperature, pH, cryoglobulin concentration, and weak noncovalent factors.[141] Meltzer and others delineated a distinct syndrome of purpura, arthralgias, asthenia, renal disease, and neuropathy—often occurring with immune complex deposition or vasculitis, or both.[129,142] Brouet et al.[120] popularized a system of classifying cryoglobulinemia on the basis of the components of the cryoprecipitate: type I, isolated monoclonal immunoglobulins; type II, a monoclonal component, usually IgM, that binds to the Fc component of polyclonal IgG (i.e., has rheumatoid factor activity); and type III, polyclonal immunoglobulins of more than one isotype.[120] This classification provided a framework by which clinical correlations could be made. Associated conditions, such as lymphoproliferative disorders, connective tissue disorders, infection, and liver disease were observed in some patients[121,143] (Table 101.3). Since early studies failed to identify an associated underlying condition in 34% to 71% of cryoglobulinemia cases, the majority of patients were thought to have *essential* or primary cryoglobulinemia[120,121,144]; however, with the discovery of hepatitis C virus (HCV) came the recognition that the majority of these cases were actually related to HCV.[145,146] (Fig. 101.3). Essential cryoglobulinemia now accounts for fewer than 10% of cases of cryoglobulinemia.[134]

EPIDEMIOLOGY OF CRYOGLOBULINEMIA

It is difficult to determine the prevalence of cryoglobulinemia since the syndrome is clinically heterogenous and it may be difficult to distinguish incidental laboratory findings from the symptomatic disease state. Although only a minority of patients with serum cryoglobulins have symptoms referable to them, cryoglobulins may be found in patients with cirrhosis (up to 45%), alcoholic hepatitis (32%), autoimmune hepatitis (40%), subacute bacterial endocarditis (90%), rheumatoid arthritis (47%), Sjögren syndrome, IgG myeloma (10%), and Waldenström macroglobulinemia (19%).[120,121,122,123,136,143] The presence of cryoglobulins should alert the physician to the possibility of undiagnosed chronic infections such as subacute bacterial endocarditis, Lyme disease, and Q fever.[143] Case reports describe cryoglobulinemia associated with hepatitis A virus, hepatitis B virus, Hantavirus, cytomegalovirus, Epstein-Barr virus, human T-cell lymphotropic virus type I, hepatitis G virus, human immunodeficiency virus,

and parvovirus B19.[116,143,147] The association with HCV was reported in 1990 and 1991,[145,146] and the majority (42% to 100%) of patients with mixed cryoglobulinemia were found to be infected with HCV.[146,148,149,150,151–155]

Results of most studies show that the median age at diagnosis is the early to mid 50s.[136,156,157] In some studies, the female predominance for cryoglobulinemia is greater than 2:1 (Table 101.4). No racial preference has been noted, but the incidence is higher

in regions where HCV occurs at higher frequencies (for example, southern Europe).

ETIOLOGY OF CRYOGLOBULINEMIA

Cryoglobulinemia is driven primarily by 4 classes of disease: liver disease (predominantly HCV), infection (again, predominantly HCV), connective tissue disease, and lymphoproliferative disorders. Type I and II cryoglobulins are associated with monoclonal expansion of B cells or plasma cells, while type III cryoglobulins result from polyclonal B cell expansion. Infection and/or inflammation ostensibly induce a nonspecific stimulation of B cells, frequently resulting in polyclonal hypergammaglobulinemia. When these various antibodies are produced, antibodies to autoantigens may also result. In animal models, a strong B cell stimulus disrupts the sequential order of idiotype–anti-idiotype interactions, resulting in both immunosuppression and idiotype–anti-idiotype immune complexes.[159] Furthermore, poorly regulated production and clearance of IgM-rheumatoid factor contributes to immune complex formation.[141,121] Deposition of these antibody complexes in tissue leads to a variety of pathologic conditions, including vasculitis, nephritis, and vascular occlusion.

Complement components, fibronectin, and lipoproteins have been found along with antigen-antibody complexes within cryoprecipitates. Although hepatitis B virus, Epstein-Barr virus, and bacterial products may also be present, by far the most common pathogen within cryoprecipitates is HCV.[160] HCV-RNA, HCV-specific proteins, and anti-HCV antibodies are found in the supernatant of the cryoprecipitate and in the cryoprecipitate itself in 42% to 98% of patients with essential mixed cryoglobulinemia.[149,150,151–155] Cryoprecipitates contain 20 to 1,000 times more HCV-RNA than is present in the supernatant.[161] The IgG component to which the IgM-rheumatoid factor fraction binds is directed against the HCV proteins.[162]

The biochemical basis for the temperature-dependent precipitation of these proteins is not completely understood. They may precipitate at temperatures substantially higher than the 4°C that is used to determine their presence in the laboratory. Precipitation also depends on temperature, pH, the ionic strength, and the structure (sequence) of the immunoglobulin components.

Relationships among Predisposing Conditions and Cryoglobulinemia

Hepatitis C Virus

The exact relationship between HCV and cryoglobulinemia is unknown, although the lymphotropism of HCV is well established. The virus can infect B lymphocytes through CD81 or the LDL receptor.[163,164] There is considerable evidence that (1) HCV can serve as a chronic immune stimulus, (2) cryoglobulins are present in up to 50% of HCV-infected patients,[165,166,167,168] (3) HCV is associated with autoimmune phenomena even in the absence of cryoglobulinemia, and (4) HCV may predispose patients to lymphoma.[143,169–172] Predisposing factors for cryoglobulinemia in HCV patients are female gender, alcohol consumption, detectable serum HCV-RNA, longer duration of hepatitis, higher serum γ-globulin levels, higher rheumatoid factor levels, steatosis, and extensive liver fibrosis or cirrhosis.[155,165,166,173–176]

The major envelope protein of HCV (HCV-E2) binds with high affinity to CD81, a tetraspanin expressed on several cell types, including B and T lymphocytes.[163] CD81 expression on $CD19^+$ B lymphocytes is significantly higher in patients with mixed cryoglobulinemia compared to those without mixed cryoglobulinemia, patients chronically infected with hepatitis B virus, and healthy controls.[177] Moreover, CD81 expression is higher on CD5 positive B cells relative to other circulating B cells.[178] Engagement of CD81 on human B cells by a combination of HCV-E2 and an anti-CD81 monoclonal antibody triggers the JNK pathway and leads to the preferential proliferation of the naive ($CD27^-$) B cell subset.[179] The interaction between CD19/CD21 and CD81 provides a strong activation signal for B cells that drives the polyclonal proliferation of naive B lymphocytes and may be a key initiating factor for the development of the HCV-associated B lymphocyte disorders.[179] This interaction may explain the frequent finding of clonal B cells in patients with HCV in the absence of an overt malignancy.[180,181] These B cells have a biased usage of rheumatoid factor encoding V_H*1–69* and *Vκ3–20* gene segments, similar to what is observed in patients with HCV-related lymphoma.[182] Interestingly, these cells express low levels of CD21 and are associated with an anergic phenotype.[183] Eradication of HCV infection by IFN therapy leads to normalization of the activation markers' expression on B lymphocytes[179] as well as restoration of immune homeostasis, especially after therapy with rituximab.[184,185] The potential host-specific predisposing factors for the development of cryoglobulinemia are being deciphered. In a large series of patients with HCV-related cryoglobulinemic glomerulonephritis, HLA DRB1*11 was more frequent in patients with nephrotic syndrome, while HLA DRB1*7 appeared to be protective.[158]

Connective Tissue Disease

The incidence of cryoglobulinemia, most commonly type II or III, in relation to specific connective tissue diseases is quite variable.[129] Among patients with systemic lupus erythematosus, 25% have detectable cryoglobulins,[186] and cryoglobulins have been detected in 12.5% of patients with systemic sclerosis.[122,187] Measurable amounts of cryoglobulins, usually polyclonal, can be found in up to 46% of patients with active rheumatoid arthritis.[188] Among patients with Sjögren syndrome, 16% to 37% have serum cryoglobulins[122,189,190]; conversely, 5% to 15% of patients with mixed cryoglobulinemia have Sjögren syndrome.[120,121,144] Patients with Sjögren syndrome and mixed cryoglobulins have a 7-fold risk of lymphoma developing (86% versus 12.5% in patients without cryoglobulins) and a worse survival.[189,191]

Lymphoproliferative Disorders

The relationship between cryoglobulinemia and lymphoproliferative disorders is complex; cause can be difficult to distinguish from effect. At a minimum, approximately 31% of all cases of secondary symptomatic cryoglobulinemia already have a diagnosis of lymphoproliferative disorder when cryoglobulinemia is diagnosed.[144] Higher percentages are found in series in which bone marrow biopsies, flow cytometry, Southern blot tests, and polymerase chain reaction are performed routinely.[192–194,195,196] In another 6% to 28% of patients, symptomatic lymphoma develops at follow-up[170,195,197,198]; 50% of these are intermediate- or high-grade lymphoma.[198] The most common histologic diagnoses among the remaining low-grade lymphomas are immunocytoma,[192,199] followed by mucosa-associated lymphoid tissue (MALT) and centrocytic follicular lymphoma.[200] Among patients whose conditions transform to overt lymphoma, the malignant clone is derived from one of the dominant baseline B cell clones in only a minority of patients,[194] implying a predisposition for clonal production and evolution.

Associations among Cryoglobulinemia, Hepatitis C Virus, Connective Tissue Disease, and Lymphoma

A recognized model for progression from chronic antigenic stimulation to benign or malignant lymphoproliferation is *Helicobacter pylori* and MALT lymphoma.[201] HCV, Sjögren syndrome, cryoglobulinemia, and immunocytoma may abide by this model. There is remarkable conservation of and homology among the antigen-combining sites (variable regions) of the IgM-κ rheumatoid factors in patients with HCV, HCV-associated lymphoma, and cryoglobulinemia.[202–208] Similar degrees of homology are seen between the immunoglobulin receptors in the lymphoproliferation of patients with Sjögren syndrome and those in the lymphomas of HCV-infected patients with or without type II mixed cryoglobulinemia.[209] This finding supports the concept that the combination of chronic antigenic stimulation, ineffectively regulated autoreactive B cells (which make restricted rheumatoid factor), and continued B cell proliferation may predispose B cells to subsequent oncogenic mutation and transformation to malignant lymphoma.

Among HCV-positive patients with mixed cryoglobulinemia, HCV-RNA is detected in peripheral blood mononuclear cells in up to 81% of patients[210] and in bone marrow cells in up to 100% of patients.[195,211–215] Clonal immunoglobulin gene rearrangements can be detected by reverse transcriptase polymerase chain reaction in all HCV-positive patients with type II mixed cryoglobulinemia and in 24% of HCV-infected patients without cryoglobulinemia.[196] These clones are usually, but not always, associated with the presence of type II cryoglobulins. In one series, HCV-infected patients with clonal B cell proliferation in both the blood and liver were older and had longer duration of HCV infection, higher serum cryoglobulin levels that were more frequently symptomatic, and liver disease that was more severe than that in patients without a clonal B cell population.[180]

In a series of 1,255 patients in Italy with HCV and symptomatic mixed cryoglobulinemia, there was a 35-fold increase over the general population, with 224.1 new cases of aggressive non-Hodgkin lymphoma (NHL) subtypes per 100,000 patient-years.[216] The median time from the diagnosis of cryoglobulinemia to the clinical onset of NHL was 6.3 years (range, 0.81 to 24 years). The clinical course and response to chemotherapy in the patients with cryoglobulinemia and NHL were similar to those usually described for patients with NHL without cryoglobulinemia.

Productive t(14;18) translocations with resultant BCL-2 overexpression occur in about 12% to 38% of HCV-positive patients without symptomatic cryoglobulinemia and in 39% to 85% of their cryoglobulin-positive counterparts.[217–220] Patients with cryoglobulinemia in whom lymphoma develops have been found to have genomic sequences of HCV in their lymphoma specimens.[200,221–223] The NHL subgroup most commonly observed in patients with HCV is lymphoplasmacytoid lymphoma/immunocytoma.[224] An increased rate of HCV infection (8% to 50%) has also been reported in idiopathic B cell NHL by many investigators.[143,169–171] Splenic lymphoma with villous lymphocytes has been associated with HCV and mixed cryoglobulinemia.[172]

CLINICAL PRESENTATION OF CRYOGLOBULINEMIA

Involvement of the skin, peripheral nerves, kidneys, and liver is common (Table 101.4). Lymphadenopathy is present in approximately 17% of patients.[129,121] On autopsy, widespread vasculitis involving small and medium vessels in the heart, gastrointestinal tract, central nervous system, muscles, lungs, and adrenal glands may also be seen.[121,225] The interval between the onset of symptoms and the time of diagnosis varies considerably (range,

0 to 10 years).[121] Type I cryoglobulinemia is usually asymptomatic. When symptomatic, it most commonly causes occlusive symptoms rather than the vasculitis of types II and III.[120,121,129] Symptoms of hyperviscosity may occur (Fig. 101.4). Type II cryoglobulinemia is more frequently symptomatic (61% of patients) than type III (21% of patients).[266] The most common causes of death include renal failure, infection, lymphoproliferative disorders, liver failure, cardiovascular complications, and hemorrhage.[120,121,131,135,144,] With improved therapy, the main cause of death appears to be cardiovascular disease.[158]

In a series of 231 patients seen between 1972 and 2001, the mixed cryoglobulinemia syndrome followed a relatively benign clinical course in more than 50% of cases, whereas a moderate-severe clinical course was observed in one-third of patients whose prognosis was severely affected by renal or liver failure. For 15% of individuals the disease was complicated by malignancy: B cell NHL was more common than hepatocellular and thyroid malignancies. Ten year overall survival was 56%. Lower survival rates were seen in males and in individuals with renal involvement.[133]

Dermatologic and Joint Manifestations of Cryoglobulinemia

Purpura is the most frequent symptom, being present in 55% to 100% of patients with mixed cryoglobulinemia[120,121,131,144] (Table 101.4 and Fig. 101.4). The incidence varies from 15% to 33% in type I, from 60% to 93% in type II, and from 70% to 83% in type III.[267] Petechiae and palpable purpura are the most common lesions, although ecchymoses, erythematous spots, and dermal nodules occur in as many as 20% of patients. Bullous or vesicular lesions are distinctly uncommon.[120] Successive purpuric rashes, which may be preceded by a burning or itching sensation, occur most commonly on the lower extremities, gradually extending to the thighs and lower abdomen. Occasionally the arms are involved, but the face and trunk are generally spared.[120] Head and mucosal involvement, livedoid vasculitis, and cold-induced acrocyanosis of the helices of the ears are more frequently observed in type I; infarction, hemorrhagic crusts, or ulcers, occur in 10% to 25% of all patients with mixed cryoglobulinemia.[268] Showers of purpura last for 1 to 2 weeks and occur once or twice a month. Cold precipitates these types of lesions in only 10% to 30% of the patients.[120,268] Raynaud phenomenon occurs in about 19% to 50% of patients[120,121,131,144]; in a quarter of these, the symptoms may be severe, including necrosis of fingertips.[120] Skin necrosis, urticaria, and livedo, which are all rare, are more commonly associated with exposure to cold.

Arthralgias are common, affecting 35% to 92% of patients, with the highest incidence in type III cryoglobulinemia (Table 101.4). The small distal joints are affected more frequently than the larger proximal joints. Symmetrical polyarthralgia is often exacerbated by the cold. Frank arthritis is rare.[120,121,131,134,144]

Nervous System Manifestations of Cryoglobulinemia

Peripheral neuropathy is the more common presentation, although central nervous system involvement may occur. Peripheral nerve involvement is described in 12% to 56% of patients[120,121,131,134,144] (Table 101.4). Signs and symptoms of sensory neuropathy usually precede those of motor neuropathy.[120,269] The presentation may be an acute or subacute distal symmetric polyneuropathy or a mononeuritis multiplex[269–271] with a chronic or chronic-relapsing evolution.[272] The neuropathy is most often characterized by axonal degeneration. Epineurial vasculitis is a common finding on sural nerve biopsy.[270,271,273–275] Even when other manifestations of mixed cryoglobulinemia are stable over time, there is typically worsening of the peripheral neuropathy.[276]

Central nervous system abnormalities are not uncommon in patients with mixed cryoglobulinemia. Casato et al. compared 40 patients with mixed cryoglobulinemia vasculitis and chronic active HCV infection with normal controls and HCV patients without mixed cryoglobulinemia. Twenty-four of the 27 (89%) patients with HCV-mixed cryoglobulinemia had a deficiency in one or more of 10 cognitive domains examined. The most commonly involved domains were those of attention (70%), executive functions (44%), visual construction (37%), and visual spatial functions (33%). Magnetic

FIGURE 101.4. Cryoglobulin-associated physical findings. **A:** Hyperviscosity manifested as retinopathy with venous engorgement and hemorrhage. **B:** Purpura. **C:** Gangrene.

resonance imaging analysis showed that HCV-mixed cryoglobulinemia patients had a higher mean number of total and periventricular white matter high intensity signals than HCV controls and healthy controls, respectively.[277] Cappellari et al. have also found central nervous system abnormalities in a majority of patients studied.[278]

Renal Manifestations of Cryoglobulinemia

Approximately 21% to 39% of patients with mixed cryoglobulinemia have renal involvement.[120,134,279] The incidence of renal injury is highest in patients with type II cryoglobulins.[144,280] Although renal and extrarenal manifestations may occur concurrently, renal involvement usually follows the onset of purpura by approximately 4 years.[121,281] Proteinuria greater than 0.5 g/d and hematuria are the most common features of renal disease at diagnosis (present in 50% of patients)[282]; nephrotic syndrome affects approximately 20% of patients and acute nephritic syndrome affects approximately 25% of patients.[281,282] Although cryopathic membranoproliferative glomerulonephritis portends a poor prognosis,[121,122,280,282,283] progression to end-stage renal failure due to sclerosing nephritis is uncommon.[282] Among patients with mixed cryoglobulinemia-associated membranoproliferative glomerulonephritis followed up for a median of 11 years, 15% had disease progression to end-stage renal failure, and 43% died of cardiovascular, hepatic, or infectious causes.[282]

Liver Manifestations of Cryoglobulinemia

Approximately 39% of patients with symptomatic cryoglobulinemia[144] and as many as 77% with mixed cryoglobulinemia[121,284] have documented liver abnormalities at the time of diagnosis (Table 101.4). Furthermore, hepatomegaly is present in up to 70% of patients, and splenomegaly is present in up to 52% of patients.[121,130,142] Among patients with symptomatic cryoglobulinemia, liver failure is the cause of death in 2.5% to 7.6% of patients[121,132,282] and in 5.6% to 29% of all reported deaths.[121,132,282]

Histologic findings include portal fibrosis, chronic persistent hepatitis, chronic active hepatitis, chronic active hepatitis with cirrhosis, and postnecrotic cirrhosis.[158,284] Most specimens are characterized by a diffuse lymphocytic infiltrate ranging from minimal periportal to extensive infiltration with nodule formation. These changes correlate with the severity of other pathologic findings. Plasma cell infiltration has also been noted in several specimens.[266,284] The lymphoid population in the liver may show the histologic and immunophenotypic findings of lymphoplasmacytoid lymphoma/immunocytoma, and frequently the lymphoid elements arrange in pseudo-follicular structures in the liver with morphologic features similar to those previously reported in chronic HCV without cryoglobulinemia.[198] These liver lymphoid nodules contain B cells predominantly with a $CD5^+/Bcl\text{-}2^+/Ki67^-$ phenotype—that is, low apoptotic and proliferative rates.[285]

Other Manifestations of Cryoglobulinemia

Given the propensity of immune complexes to deposit in blood vessels and activate complement, in principle, cryoglobulinemic vasculitis can affect any vascular distribution including the mesenteric vessels,[134,286] leading to intestinal ischemia, cholecystitis, and pancreatitis. Pulmonary vascular involvement in severe cases may lead to acute alveolar hemorrhage and diffuse pulmonary infiltrates.[287,288] Rarely, coronary vasculitis may lead to myocardial infarction.

DIAGNOSIS OF CRYOGLOBULINEMIA

By definition, all patients with cryoglobulinemia have serum cryoglobulins. The collection and processing of the specimens are critical because these cold-induced reversible precipitates can be lost with improper handling.[143,289] A minimum of 10 ml of blood is required, and the specimen must be allowed to clot at 37°C for 30 to 60 minutes before centrifugation. The serum supernatant is stored at 4°C for up to 7 days and inspected daily for cryoprecipitate. Methods to evaluate the composition of the cryoglobulin include immunoelectrophoresis, immunofixation, immunoblotting, and capillary electrophoresis.

Concentrations of cryoglobulins tend to vary by type: type III, less than 1 mg/ml; type II, 1 mg/ml or greater; and type I, greater than 5 mg/ml.[120,290] The type or quantity does not reliably predict the presence or nature of symptoms. On serum protein electrophoresis, polyclonal hypergammaglobulinemia is the most common finding, although normal patterns or hypogammaglobulinemia may also be seen.[121,129,136] Even among patients with type II cryoglobulinemia, only 15% have a visible monoclonal spike on serum protein electrophoresis. Frequently, serum IgM levels are elevated; cryoprecipitable IgM may comprise up to one-third of the total serum IgM concentration.[121] Hyperviscosity occurs only occasionally.[142] Marked depression of complement CH50, C1q, and C4 in the presence of relatively normal C3 levels is usual.[121,134,291] Neither C4 concentrations nor cryoglobulin levels correlate with overall clinical severity, although for individual patients the cryoglobulin level can sometimes serve as a marker for disease activity.[121,242,291,292] Rheumatoid factor activity—that is, anti-Fc activity—is detectable in the sera in 87% to 100% of patients with mixed cryoglobulinemia,[120,129,132] and levels may decrease with response to therapy[293] An elevated erythrocyte sedimentation rate and a mild normochromic, normocytic anemia are fairly common.[121,242] Cytopenias have been described, as have pseudoleukocytosis and pseudothrombocytosis.[142] Among patients with cryoglobulinemia, the antinuclear antibody results may be positive in as many as two-thirds of the patients[294] and in as many as one-third of the HCV-positive patients.[134] Because HCV is frequently concentrated in cryoglobulins,[149] serial measurements of plasma or serum HCV-RNA levels in these patients are not reliable.[175]

TREATMENT OF CRYOGLOBULINEMIA

Since cryoglobulinemia has a fluctuating course with spontaneous exacerbation and remission, it is essential that controlled clinical trials are used to evaluate the response to therapy. Unfortunately, such studies are rare in the field of cryoglobulinemia. Although there are several "accepted" or "standard" treatments that have no randomized trials to support their practice, there are several reported strategies (Table 101.5) that have questionable, if any, benefit.[143] Although therapies such as use of histamine (H) H1 and H2 blockers and penicillamine have sound scientific basis for consideration, they have shown no clear clinical benefit.[121,143] Figure 101.5 outlines a strategy for managing symptomatic cryoglobulinemia.

The standard treatment of mild symptomatic cryoglobulinemia (purpura, asthenia, arthralgia, and mild sensory neuropathy) has included bed rest, analgesics, low-dose corticosteroid therapy, low-antigen content diet, and protective measures against cold; the treatment of severe disease (glomerulonephritis, motor neuropathy, and systemic vasculitis) has included plasmapheresis, high-dose corticosteroid therapy, and cytotoxic therapy. With the recognition of the association between HCV and mixed cryoglobulinemia, immunosuppressive therapy has been viewed less favorably, and IFN with or without ribavirin has generally been considered to be first-line therapy for HCV-positive patients who are in nonemergent situations.[226,227,228–230,295] For patients with symptomatic type I cryoglobulinemia, anti-CD20 therapy or cytotoxic therapy appropriate for the lymphoproliferative disorder remains the therapy of choice. Similarly, treatment of an underlying connective tissue disease or infection would be first-line

TABLE 101.5

TREATMENT STRATEGIES FOR SYMPTOMATIC CRYOGLOBULINEMIA

Reference	Treatment	Effective?
226,227,228,229,230,231,232	Interferon/PEG-Interferon	Yes
233	Ribavirin	Probably
234–238,239,240	Rituximab	Yes
241	Low-antigen diet	Probably (mild disease)
242–248	Plasmapheresis, plasma exchange	Probably
121,122,130,142,249,250	Low-dose corticosteroids	Probably
251,252	High-dose corticosteroids	Probably
243	Chlorambucil	Probably
248,253,254,255	Cyclophosphamide	Probably
249	Melphalan	Probably
256,257	Thalidomide	Probably
258	anti-TNF-α antibody	Probably not
121	Azathioprine	Possibly
198,259	Cyclosporin	Possibly
260	Colchicine	Probably not
261,262	Immunoglobulin IV	Variable[a]
263,264	Cladribine and fludarabine	Variable
142,253	Splenectomy	Variable
142	Chloroquine	Probably not
121	H_1 and H_2 blockers	Probably not
121	Penicillamine	Probably not

therapy in the appropriate situation. The importance of not overtreating patients must be emphasized.

Treatment of Life-threatening Disease

For emergent situations (acute nephritis or severe vasculitis), initial measures are aimed at reducing the inflammatory activity of renal lesions (corticosteroids), removing circulating cryoglobulins (plasmapheresis) and reducing the formation of new antibodies (e.g., cyclophosphamide).[281,296] Plasma exchange or plasmapheresis alone can reverse serious complications, but these procedures are typically used in combination with cytotoxic agents or corticosteroids for more durable responses.[292,243–245] According to case reports, responses may be seen in 60% to 100% of patients.[292,243–245] Skin manifestations and arthralgias usually respond the most quickly, whereas the degree of neural and renal responses depends on the acuity of their occurrence, with poorer responses occurring in chronic cases.[244] With combination immunosuppressive therapy and plasma exchange, reversal of catastrophic complications such as encephalopathy and acute glomerulonephritis has been documented.[244,292,297] High-dose pulse therapy with methylprednisolone is also a favored therapeutic intervention for acute events, with 90% response rates in rapidly progressive glomerulonephritis.[251,281] Once the acute exacerbation has been mitigated, antiviral strategies are implemented in HCV-positive patients to consolidate and maintain response. One should be cognizant of reports of peripheral neuropathy (personal observation and[298]), nephritis,[299] vasculitis,[300] and ischemic manifestations being exacerbated by IFN-α.[301]

Antiviral Therapy

Five randomized trials evaluating the efficacy of IFN therapy in HCV-positive patients with symptomatic type II mixed cryoglobulinemia conducted in the 1990s documented clinical responses in 60% to 89% of the patients.[226,227,228–230] However, when compared with HCV-related chronic hepatitis, treatment of mixed cryoglobulinemia with IFN monotherapy was associated with a relatively poorer response and a high relapse rate, especially in severe cases. A majority of patients relapsed within 6 months of discontinuation.[227,228–230,295,302] Lack of response after 3 to 4 months predicted for monotherapy failure.[295] Factors associated with a poorer response to therapy or rapid relapse include liver cirrhosis, advanced age,[230] male sex,[295] and high levels of

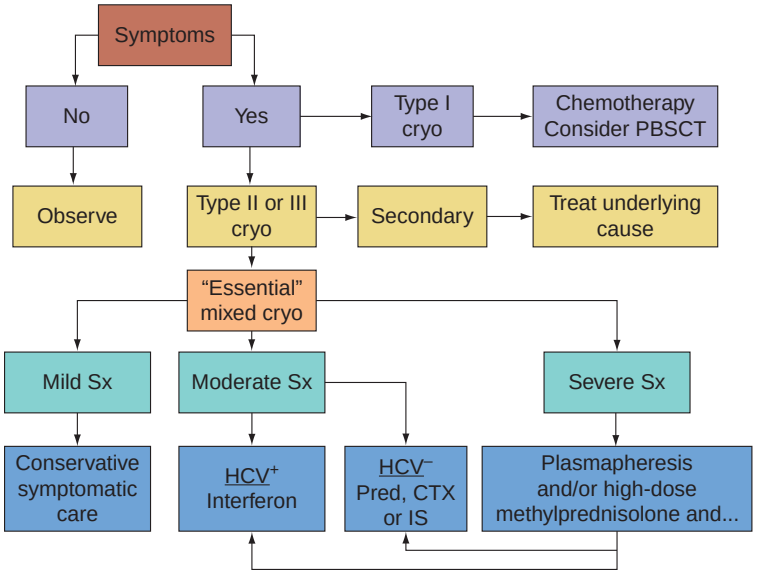

FIGURE 101.5. Possible treatment schema for cryoglobulinemia. If interferon therapy fails, combination therapy with interferon-α and ribavirin may help; however, contraindications for ribavirin should be considered. HCV-RNA at the onset of therapy.[228] Purpuric lesions and liver function abnormalities are the features that tend to respond rapidly (within weeks), but neuropathy and nephropathy respond more slowly.[295,298]

The frequent relapse of both HCV replication and mixed cryoglobulinemia syndrome at the end of IFN treatment suggested the combination with ribavirin: this therapeutic option appeared valid in several studies.[303,304,305,306] Even ribavirin monotherapy has been shown to decrease transaminase levels and mixed cryoglobulinemia-related symptoms. IFN-α and ribavirin is now the preferred strategy for patients with symptomatic HCV-associated cryoglobulinemia.[303,305,307] More than 60% of patients with symptomatic mixed cryoglobulinemia who do not respond to IFN therapy alone respond to combined therapy, and 80% of patients who relapse with IFN-α therapy alone respond to combined therapy.[303]

Ribavirin plus weekly pegylated IFN-α is at least as effective as the combination using standard three times weekly IFN-α.[231,232] Saadoun et al. compared the outcomes of 72 consecutive patients who received treatment with IFN-α (n = 32 patients) or pegylated IFN-α (n = 40 patients), both in combination with oral ribavirin, for at least 6 months. Compared with patients treated with IFN-α plus ribavirin, those receiving pegylated IFN-α plus ribavirin had higher sustained clinical (67.5% versus 56.3%), virologic (62.5% versus 53.1%), and immunologic (57.5% versus 31.3%) responses, regardless of HCV genotype and viral load. In multivariate analyses, an early virologic response was independently associated with a complete clinical response of mixed cryoglobulinemia. A glomerular filtration rate less than or equal to 70 ml/minute was negatively associated with a complete clinical response of mixed cryoglobulinemia.[232]

Rituximab Therapy

Anti-CD20 therapy with rituximab has been shown to produce responses in patients with all types of cryoglobulinemia[235–238]; however, those patients with HCV are at risk for increased HCV replication.[235,236] Initial studies reported responses in the majority of patients, including improvements in skin vasculitis manifestations (ulcers, purpura, or urticaria), subjective symptoms of peripheral neuropathy, low-grade B cell lymphoma, arthralgias, fever, nephritis, levels of rheumatoid factor, cryoglobulins, and C4.[308,309] In a randomized trial, 59 patients with cryoglobulinemia vasculitis were randomized to either rituximab or conventional therapy, which included glucocorticoids, azathioprine, cyclophosphamide, or plasmapheresis. Time to treatment failure at 1 year was superior in the rituximab group (64% versus 3%). The vasculitis activity also improved significantly on rituximab, whereas it did not for the other treatment arm. The median duration of response to rituximab was 18 months.[310]

The combination of pegylated IFN-α, ribavirin, and rituximab (the so-called PIRR regimen) has been tested in two trials.[185,311] Both studies reported similar results: the triple combination leads to a faster response with respect to symptoms, organ (renal) response, cryoglobulin clearance, and elimination of HCV viremia. The response was generally more durable, with a median duration of response in excess of 3 years.[185] The two trials used a similar regimen for the IFN-α and ribavirin but differed in the use of rituximab. While Saadoun et al. started therapy with rituximab alone (weekly for 4 doses),[311] Dammacco et al. started the triple combination simultaneously and subsequently give additional single doses of rituximab at 6 and 11 months after the initiation of therapy.[185] The addition of Rituxan to the combination of antiviral agents did not lead to an increase in the HCV burden as measured by quantitative PCR, and therapy was associated with a significant reduction or elimination of clonal B cells from the circulation.

Other Therapies for Cryoglobulinemia

Although not formally studied, high-dose therapy with autologous stem cell transplantation may be considered for patients with symptomatic, refractory cryoglobulinemia that results from a plasma cell proliferative disorder. There is an increased risk of lethal veno-occlusive disease in patients with chronic hepatitis C who are undergoing stem cell transplantation.[312]

Dramatic reductions in the cryocrit and the cryoglobulinemic symptoms, including membranoproliferative glomerulonephritis, have been reported in several patients who underwent splenectomy for hypersplenism.[253,313] In contrast, in the series reported by Meltzer and Franklin, the one patient who underwent splenectomy died of acute renal failure.[142] Because this intervention has not been studied thoroughly, and because of the high risk involved, it should not be considered as standard therapy, but rather as a potential option for patients without cirrhosis who have disease that is difficult to manage because of cytopenias resulting from hypersplenism.

HEAVY-CHAIN DISEASE

The HCDs are a rare group of disorders with diverse clinical presentations. The 3 conditions (α-, γ-, and μ-HCD) are discussed together because they are lymphoproliferative or plasma cell proliferative disorders that share the generation and secretion of an isolated heavy-chain fragment (Table 101.6). α-HCD (Mediterranean lymphoma or immunoproliferative small intestinal disease [IPSID]) is the most common and has the most uniform presentation; γ- and μ-HCD have variable clinical presentations and histopathologic features. In the majority of cases, the heavy-chain fragment is not secreted in large quantities and immunofixation or immunoelectrophoresis is required to detect the abnormality. Screening the serum and urine of patients with lymphoplasmacytoid NHL would most likely identify more patients with α-, γ-, or μ-HCD. Cases of α-, γ-, and μ-heavy–chain monoclonal gammopathy of unknown significance have been reported.[314,315,316]

α-Heavy-chain Disease

Mediterranean lymphoma, originally described in the 1960s as a condition in young adults, is a primary small intestinal lymphoma coupled with intestinal malabsorption.[317] An isolated IgA immunoglobulin heavy-chain fragment was recognized in association with this condition. Because some patients had benign-appearing lymphocytes in their small bowel, the term "α-HCD" was preferred over "Mediterranean lymphoma" by some authors.[318] A consensus panel in 1976 concluded that α-HCD and Mediterranean lymphoma represented a spectrum of disease with benign, intermediate, and overtly malignant stages, and the term "immunoproliferative small intestinal disease" came into use.[319] This entity has been recently reviewed.[320]

The majority of reported patients with α-HCD are from northern Africa, Israel, and surrounding Middle Eastern or Mediterranean countries, with fewer patients from central and southern Africa, eastern Asia, and South and Central America.[321] Patients present with malabsorption syndrome, weight loss, and abdominal pain. On physical examination, peripheral edema, clubbing, and an abdominal mass are not uncommon findings.[319,320,321,322] On endoscopy of the small intestine, one may find thickened mucosal folds, nodules, ulcers, a mosaic pattern, or submucosal infiltration. Intestinal parasites and bacterial overgrowth in the small intestine are common. Anemia, vitamin deficiencies, and hypogammaglobulinemia are also common. The IgA level is generally not increased, but on immunofixation or immunoelectrophoresis, a monoclonal component is present, especially in the earlier phases of the disease. An immunoglobulin

TABLE 101.6

FEATURES OF HEAVY-CHAIN DISEASES

	Type of Heavy-Chain Disease		
Feature	α	γ	μ
Monoclonal protein	IgA	IgG	IgM
Year described	1968[166]	1964[167]	1970[168,169]
Incidence	Rare	Very rare	Very rare
Median age	Young adults	61 y	57 y
Associated diseases	Bacterial overgrowth; malabsorption	Autoimmune diseases	-
Site	Small intestine; mesenteric lymph nodes	Lymph nodes, bone marrow, and spleen	Liver, spleen, lymph nodes, and bone marrow
Pathologic features	Extranodal marginal zone lymphoma (MALT or IPSID)	Lymphoplasmacytoid lymphoma	Small lymphocytic lymphoma/chronic lymphocytic leukemia
Therapy	Antibiotics; chemotherapy	Chemotherapy	Chemotherapy

IPSID, immunoproliferative small intestinal disease; MALT, mucosa-associated lymphoid tissue.

light chain is not found. The monoclonal IgA fragment may be found in jejunal secretions as well as in blood and urine.[322] The monoclonal protein in patients with α-HCD is of the α1 subclass and consists of multiple polymers. The length of the basic polypeptide subunit is typically between one-half and three-fourths that of a normal α-heavy-chain; the shortening results from an internal deletion involving most of the VH and the CH1 domain.[323] In about one-half the cases, the electrophoretic pattern of α-HCD protein contains a broad band extending from the α2 region to the β-globulin region because of the tendency of these chains to polymerize. The remainder of the patients may have a normal serum protein electrophoresis pattern.

Histologic features of IPSID range from early lymphoplasmacytic intestinal infiltration to overt malignant diffuse large B cell lymphoma. This entity shares morphologic features of MALT in that there are lymphoepithelial lesions, centrocyte-like cells, and plasma cell differentiation.[324] The histologic findings are classified into stages A, B, and C. Stage A includes a diffuse, dense, compact, and apparently benign lymphoplasmacytic infiltration of the mucosal lamina propria. Stage B has features of stage A but also has circumscribed "immunoblastic" lymphoma in either the intestinal or mesenteric lymph nodes. Stage C comprises a diffuse "immunoblastic" lymphoma with or without demonstrable lymphoplasmacytic infiltration.[319] Villous broadening or effacement and shortened sparse crypts are also observed. These histopathologic findings can be distinguished from those of celiac sprue because celiac sprue includes total villous atrophy, hyperplastic and elongated crypts, intraepithelial lymphocytosis, and surface epithelial flattening. The lymphoma that arises from celiac sprue is T-cell lymphoma[325] rather than B cell lymphoma, as in the case of α-HCD. A study of 11 cases of IPSID demonstrated higher expressions of syndecan-1 in Stage A samples relative to Stage B; conversely, Stage B samples showed higher expression of BCL-6 and p53.[326] IPSID lacks the t(11;18) translocation that is not uncommon in other MALT lymphomas. Other cytogenetic abnormalities have been seen including t(9;14), t(2;14), and t(5;9).[320]

The hypothesis that chronic antigenic stimulation by intestinal organisms is the cause of this disorder is credible and can be modeled after the MALT lymphoma paradigm. This hypothesis is further supported by the fact that the incidence of α-HCD (or IPSID) is most common in patients who live in areas with poor sanitation and who also have a high prevalence of intestinal microbial infestation. *H. pylori* had been a candidate organism,[327] but its association was subsequently challenged.[324] *C. jejuni* is now considered to be a possible offending organism,[328] but this will need to be confirmed.

Although no data exist from randomized prospective studies, the standard accepted treatment for the early stage is broad-spectrum antibiotics, with or without corticosteroids. This protocol has resulted in clinical or histologic remission (in 33% to 71% of cases), which is generally short-lived but occasionally durable.[320,321] In the absence of a documented parasite or an intestinal bacterial overgrowth, therapy with tetracycline or metronidazole and ampicillin is appropriate.[329,330] Any documented parasite should be eradicated. Treatment of *H. pylori* has led to complete remission in two patients with α-HCD,[331] one of whom was unresponsive to prior combination chemotherapy. Lecuit et al. demonstrated response of IPSID after clearance of *C. jejuni*.[328] Response to antibiotics usually occurs promptly; however, a minimum 6-month trial of tetracycline (1 to 2 g/d) is recommended for establishing responsiveness of the lesion.[332] In patients with more advanced stages, or unresponsive early stages, total abdominal radiation or combination chemotherapy, or both, have been used (remission rate, 64%).[320,333–338] Overall 5-year survival rates are 60% to 70%. Immunotherapy with rituximab, an anti-CD20 monoclonal antibody, has been a major advance in the treatment of indolent NHL,[339] but to date there have been no reports of rituximab use in patients with α-HCD.

μ-Heavy-chain Disease

First described in 1970, μ-HCD is a rare condition.[340,341] The median age of patients with μ HCD is about 57 years and equal numbers of males and females are affected.[314,342,343] Common clinical presentations include splenomegaly and hepatomegaly. Lymphadenopathy is less common. About one-third of patients have chronic lymphocytic leukemia. Some patients with μ-HCD have features resembling those of lymphoma or MM with amyloid arthropathy.[344] Hypogammaglobulinemia is present in about one-half of the patients and a free monoclonal IgM fragment is found in the serum of all patients. The μ-heavy-chain is missing most, if not all, of its VH region.[345] A free monoclonal light chain has been described in the urine in about one-half of the cases.[314,346] Lytic bone lesions or osteoporosis occurs in a minority of patients. Bone marrow plasma cells tend to be vacuolated. Survival ranges from less than 1 month to 11 years (median, 24 months).[314] There is no standard treatment for this disorder, but it is generally treated as a low-grade lymphoproliferative disease with observation alone

for asymptomatic patients and low-intensity chemotherapy for symptomatic patients.

γ-Heavy-chain Disease

First described in 1964 by Franklin et al.,[347] γ HCD has a diverse clinical phenotype. The median age of patients with γ-HCD is 61 years, with 54% of the patients being male.[343,348] Originally, γ HCD was considered to be merely a lymphoma-like illness; Kyle et al.[343] challenged this concept. Since the original description, there have been approximately 100 cases reported in the literature.[315] Although most patients present with weakness, fatigue, fever, lymphadenopathy (62%), hepatomegaly (58%), splenomegaly (59%), and lymphoma, other features, such as autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura, may also be seen.[315,343] Cutaneous and subcutaneous involvement is not uncommon.[349] Several cases have arisen in patients with long-standing connective tissue disorders such as rheumatoid arthritis,[315,350–352] lupus,[315,353] keratoconjunctivitis sicca,[354,355] vasculitis,[355] and myasthenia gravis.[315] A normochromic anemia is a presenting feature in about 79% of patients. About 10% have either a Coombs-positive or Coombs-negative autoimmune hemolytic anemia.[314,315,355] Lymphopenia and lymphocytosis each occur in less than 10% of patients. Thrombocytopenia may be present in as many as 22% of patients.[315]

The γ chain in this disorder is truncated with deletions at the CH1 domain.[356,357] The mobility pattern of the immunoglobulin fragment on protein electrophoresis is quite variable, with the band present anywhere from the α1-globulin region to the slow γ-globulin region; most commonly, however, it runs in the β region.[315] The subclass is IgG1 in 76%, IgG2 in 19%, and IgG4 in 5% of cases. With the normal distribution of subclasses, one would expect a higher occurrence of IgG2 and a lower occurrence of IgG3 and IgG1. Proteinuria can range from none to 20 g/d.

Bone marrow most commonly demonstrates an increase of plasma cells, lymphocytes, or plasmacytoid lymphocytes; occasionally eosinophilia is seen. The lymphoproliferative disorders range from benign lymphoplasma cell proliferative disorder to plasmacytoma, to chronic lymphocytic leukemia, to angioimmunoblastic lymphoma, to diffuse large cell lymphoma.[315,358] Lytic bone disease occurs rarely. Amyloid deposits may be present.[343]

The median survival is 7.4 years, with a range of 1 month to more than 25 years.[315] Treatment is not standardized. Single-agent therapy with prednisone and combination chemotherapy with cyclophosphamide, vincristine, and prednisone have been used with benefit. Wahner-Roedler et al. reported a rituximab response in one patient.[315] Patients with aggressive lymphomas should receive a regimen containing anthracycline.

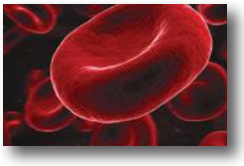
Transplantation



CHAPTER 102

HEMATOPOIETIC CELL TRANSPLANTATION

Richard A. Nash, Vijayakrishna K. Gadi

Transplantation of hematopoietic cell grafts containing pluripotent hematopoietic stem cells (HSCs) after myeloablative or nonmyeloablative conditioning regimens reconstitutes immunohematopoiesis. Sites from which HSC can be harvested and then used for transplantation include bone marrow, peripheral blood, and the umbilical cord. Patients may serve as their own donors (autologous) or may receive HSC from other individuals (related or unrelated). Hematopoietic cell transplantation (HCT) is done for a variety of therapeutic indications: (1) to support hematopoiesis after myeloablative doses of total body irradiation (TBI) and chemotherapy, (2) to establish a graft-versus-leukemia or tumor (GVL or GVT) reaction, or (3) to replace diseased tissues of hematologic or immunologic origins. The advances in supportive care after transplantation have resulted in improved outcomes, and HCT has become more accepted as a therapeutic modality that can be successful in otherwise life-threatening diseases. In the 2003–2007 period as compared with the 1993–1997 period, a 60% reduction in day 200 nonrelapse mortality and a 41% reduction in overall mortality was observed.[1] There were also significant reductions in severe graft-versus-host disease (GVHD), opportunistic infections, and organ damage.

The focus of this chapter is on the general indications for HCT, sources of stem cells, conditioning regimens, transplant biology issues, and complications of HCT; other chapters provide detailed discussions of the indications and results of HCT in relation to specific diseases (Table 102.1).

HISTORICAL PERSPECTIVE

Early Preclinical Studies

After the effects of radiation on hematopoiesis became evident during World War II, Jacobson and colleagues reported that mice survived an otherwise lethal exposure to TBI if the spleen was shielded (Fig. 102.1).[2] Radiation protection was also conferred by infusion of bone marrow.[3] A runting syndrome developed after recovery of hematopoiesis when the infused marrow was from a donor of a different mouse strain.[4] This syndrome was due to GVHD, a complication that was soon recognized to limit the use of allogeneic marrow transplantation in humans. In further studies in mice, methotrexate and 6-mercaptopurine were found to be effective in inducing immune tolerance or ameliorating the graft-versus-host (GVH) reaction.[5]

The dog served as a random-bred large animal model for studies of principles and techniques of bone marrow transplantation applicable to humans. The dog was the first random-bred species in which it was demonstrated that the results of in vitro histocompatibility typing could predict the outcome of marrow transplantation.[6] Littermates genotypically identical for the major histocompatibility complex (MHC) survived longer after marrow transplantation than did their MHC-nonidentical siblings. However, despite the MHC genotypic identity, GVHD was still potentially severe in many but not all dogs. This indicated that other factors identified as minor histocompatibility antigens (mHC) were involved in the development of GVHD. Pharmacologic immunosuppression with a calcineurin inhibitor

Data are from the Center for International Blood and Marrow Transplant Research. (Reprinted with permission from Appelbaum FR. Transplantation of bone marrow as compared with peripheral blood cells from HLA-identical relatives in patients with hematologic cancers. N Engl J Med 2007;357:1472–1475. Copyright 2007 Massachusetts Medical Society. All rights reserved.)

(i.e., cyclosporine or tacrolimus) or methotrexate for prevention of GVHD improved survival after allogeneic marrow grafting.[7,8] It was then established that methotrexate and cyclosporine in combination were more effective than either used alone.[9] The efficacy of a calcineurin inhibitor and methotrexate combined for GVHD prevention was subsequently confirmed in clinical trials and remains the standard in many transplant programs.

Early Clinical Studies

Bone marrow was the first commonly used source of HSC for transplantation. Bone marrow transplantation from human leukocyte antigen (HLA)-identical sibling donors was first successfully used by two groups in 1968 to treat patients with immunologic deficiencies.[10,11] After extensive preclinical studies of GVHD, Thomas et al. then reported the successful transplantation of marrow from a HLA-identical sibling donor for aplastic anemia in 1972.[12] Five years later, the same group reported their experience in 100 patients with end-stage leukemia treated with allogeneic marrow transplantation.[13] Allogeneic HCT from an HLA-matched related or unrelated donor is now considered standard therapy for many malignant and nonmalignant hematologic diseases.

HEMATOPOIETIC STEM CELLS

The HSC is defined as a cell with the ability to achieve long-term reconstitution of both myeloid and lymphoid lineages. To fulfill these criteria, HSC must be able to self-renew and be pluripotent. In vitro colony-forming units (e.g., CFU-GM, CFU-Meg, CFU-E, BFU-E) are progenitor cells that cannot reconstitute hematopoiesis, whereas populations of cells enriched for long-term culture-initiating cells can, at least in the mouse, rescue lethally irradiated recipients.[14,15] No accepted in vitro assays for human HSC are available currently. A population of small mononuclear cells enriched for HSC can be identified by (1) the presence of the CD34 and CD133 antigen, the absence of lineage-specific antigens, and high content of aldehyde dehydrogenase and (2) the exclusion of fluorescent vital dyes including Rhodamine[123] and Hoechst 33 342 (Table 102.2).[16–19,20] In humans and other species, successful sustained engraftment was achieved with isolated CD34-positive cells confirming that a true "stem cell" is contained within this population.[21,22–24]

The true extent of the pluripotency of adult marrow-derived stem cells remains under investigation. Several studies have reported that populations of HSCs may contribute to regeneration of muscle, osteoblasts, hepatocytes, and neuronal and nonneuronal cell types of the brain.[25–27] However, some of the

experimental observations may have resulted from cell fusion, technical artifact, or culture induced changes in cellular gene expression. Nevertheless, there is agreement that if "plasticity" of circulating HSCs occurs, it is likely to be a rare event.[28]

Identification of Cell Populations Enriched for Hematopoietic Stem Cells

The CD34 antigen is a cell surface type 1 transmembrane protein which is highly O-glycosylated and expressed primarily on hematopoietic progenitor cells and vascular endothelium from many tissues.[29,30,31] It is also expressed on stromal cell precursors identified by the STRO-1 antibody. Cell surface expression of CD34 is developmentally regulated in hematopoiesis and is inversely related to the stage of differentiation such that CD34 expression is absent beyond the committed progenitor stage. The functional significance of CD34 expression on hematopoietic progenitor cells, stromal cells, and developing blood vessels is unknown, except that CD34 on vascular endothelial cells binds to L-selectin.[32] The CD34 antigen is expressed on 1% to 5% of normal human adult marrow cells, up to 1% of mobilized peripheral blood cells, and by 2% to 10% of normal fetal liver and marrow cells.[29,33] Approximately 90% to 95% of the CD34-positive cells express antigens indicating commitment to the lymphoid or myeloid lineages.[34,35] Purified populations of HSC can be obtained with strategies that lineage-deplete a CD34-positive population of cells using monoclonal antibodies specific for DR, CD33, CD38, CD71, and B and T cell markers (Table 102.2). Other work suggests that human HSC are Thy-1^{low}, c-KIT^{low}, $Rhodamine^{123\ low}$, and CD133-positive.[36–41] In vivo preclinical models for studying populations of purified human HSCs based on the aforementioned characteristics include transplantation into SCID-Hu mice or into fetal sheep.[40,42,43]

Enriched populations of autologous CD34-positive marrow cells or blood cells, in both animal and human studies, have been shown to protect from myeloablative doses of radiation or chemotherapy.[22,44,45] Conversely, the CD34-negative subset of the marrow was not protective.[46,47] Complete and stable donor hematopoietic chimerism has also been shown in humans after transplantation with allogeneic CD34-enriched cells from the peripheral blood.[24,48] Thus, CD34-positive hematopoietic cells are capable of long-term stable reconstitution of multiple hematopoietic lineages.

Sites of Hematopoiesis and for Collection of Hematopoietic Stem Cells

In the developing human embryo, the production of hematopoietic cells shifts to the liver from the yolk sac after 6 weeks of gestation. At 16 weeks of gestation, the most active site of hematopoiesis is the fetal liver. At the end of gestation, essentially all hematopoietic production derives from the marrow with only small contributions from the liver and spleen. Umbilical cord blood is enriched for HSC. The number of progenitors in one cord blood unit were comparable to the number of progentiors from adult marrow that had been reported to achieve successful engraftment.[49]

Historically, the bone marrow served as the routine collection site for HSC.[50] Marrow is a clinically reliable and easily accessible source of long-term reconstituting cells. The presence of HSC in peripheral blood was first documented in preclinical studies.[51,52] In early clinical studies, transplantation of autologous peripheral blood HSC resulted in reconstitution of hematopoiesis following myeloablative chemotherapy or chemoradiotherapy; however, obtaining sufficient HSC required a prolonged period of collection.[53] To overcome this problem, granulocyte-colony-stimulating factor (G-CSF) can be administered to mobilize HSC from the marrow to the peripheral blood. Collections from G-CSF-mobilized peripheral blood yielded similar or greater numbers of HSC than that harvested from marrow.[54] Combining chemotherapy and G-CSF administration for mobilization resulted in higher yield of CD34-positive cells than G-CSF alone.[55] Plerixafor is a small molecule that reversibly inhibits chemokine stromal cell-derived factor-1α binding to its cognate receptor CXC chemokine receptor 4. In a randomized clinical trial, G-CSF with plerixafor was more effective than G-CSF alone for collection of stem cells in patients with myeloma.[56] In this study, a total of 54% of plerixafor-treated patients collected a target number of 6.0×10^6 $CD34^+$ cells/kg after one apheresis, whereas 56% of placebo-treated patients required 4 daily aphereses to achieve this target. Other cytokines have been demonstrated to mobilize HSC into peripheral blood, including stem cell factor, granulocyte/macrophage-CSF, interleukin-6 (IL-6), IL-8, and flt-3 ligand.[57,58] While most normal donors receive only G-CSF for mobilization of HSC for allogeneic transplant, mobilization strategies including plerixafor or chemotherapy are now routinely used for the collection of autologous HSC from the peripheral blood of patients with hematologic malignancy.[59,60,61] Plerixafor is not indicated for use in patients with acute leukemia.

Monoclonal antibodies specific to the adhesion molecule VLA-4 (very late antigen-4 or $\alpha 4\beta 1$ integrin) and VCAM-1 (vascular cell adhesion molecule-1) can also mobilize hematopoietic progenitors in nonhuman primates.[62,63] An essential step contributing to the release of hematopoietic progenitors from the marrow may be the cleavage of VCAM-1 expressed on stromal cells by neutrophil proteinases following the administration of G-CSF.[64] Hematopoietic progenitors reversibly downregulate VLA-4 expression and adhere significantly less to stroma and fibronectin during mobilization.[65] VLA-4 integrin expression is restored after progenitors are removed from the in vivo mobilizing milieu, which may account for their homing properties after transplantation.

SELECTION OF STEM CELL SOURCE

Autologous, syngeneic, and allogeneic are the three general categories of HSC grafts (Table 102.3). In general, the origin of HSC used for HCT is based on both the availability of the donor and the type of disease for which the patient is being transplanted. While autologous HSC should be available for most patients, extensive prior cytotoxic therapy or heavy involvement of marrow with malignant cells may preclude the use of this source of HSC. Although the preferred allogeneic donor is an HLA-identical sibling, fewer than 30% of patients have access to this source. Availability of HLA-identical sibling donors for pediatric patients may be less than this because of the smaller family sizes now compared to previous generations. Syngeneic donors are available in less than 1% of cases, and phenotypically HLA-matched or one-antigen-mismatched haploidentical family donors are available in less than 5% of cases.[66] Approximately 30% to 40% of patients may identify a phenotypically HLA-matched unrelated donor from the volunteer registries.[67] The availability of unrelated (or related) umbilical cord blood banks increases the chances of successfully identifying a compatible allogeneic graft source for both pediatric and adult patients.[68–70] HLA-haploidentical donors are also available for the majority of patients.

The disease for which transplantation is being considered is another important determinant for choice of stem cell source. Autologous, syngeneic, or allogeneic HSC can support hematopoietic recovery after myeloablative chemoradiotherapy for malignant hematologic and nonhematologic diseases. For acquired disorders of marrow function (e.g., aplastic anemia), syngeneic or allogeneic HSC are required.[71] Patients with congenital hematopoietic or immunologic defects (e.g., thalassemia, severe combined immunodeficiency (SCID) syndrome) require transplantation with allogeneic stem cells or gene-modified autologous stem cells.[72–75]

TABLE 102.3

POTENTIAL SOURCES OF HEMATOPOIETIC STEM CELL (HSC) FOR HEMATOPOIETIC CELL TRANSPLANTATION

	Relationship of Donor	MHC (HLA)-Matching	Genetically Identical Haplotype	mHC[a] Matching	Site of HSC Collection
I. Syngeneic	Sibling	Identical	2	Identical	Marrow or peripheral blood
II. Allogeneic	Sibling	Identical	2	Shared	Marrow, peripheral blood, or umbilical cord blood
	Sibling, Parent, Child	0–3 Antigen[b] Mismatch	1	Shared	Marrow, peripheral blood, or umbilical cord blood (sibling or child)
	Unrelated	Identical 1 Antigen Mismatch or 2 Allele Mismatch	0	Divergent	Marrow or peripheral blood
	Unrelated	0–3 Antigen Mismatch	0	Divergent	Umbilical cord blood
III. Autologous	Self				Marrow or peripheral blood

HLA, human leukocyte antigen; mHC, minor histocompatibility complex; MHC, major histocompatibility complex.
[a]Shared indicates a higher probability of sharing mHC antigens within the family. Divergent indicates that the probability of sharing mHC antigens is no better than what is expected by matching two unrelated individuals who were randomly chosen. There is currently no routine testing for mHC compatibility.
[b]Two or three antigen mismatched transplants of unmanipulated marrow grafts from adult or pediatric family donors have in general a higher transplant-related mortality.

Autologous Source of Stem Cells

Autologous marrow or mobilized peripheral blood stem cells are the grafts of choice for many patients. Autologous stem cell support is most commonly derived from "mobilized" peripheral blood stem cells instead of marrow because of faster hematopoietic recovery in the recipient.[60] Peripheral blood stem cell transplants have decreased the time required for hospitalization. Autologous stem cell support after myeloablative therapy has been successful for treatment of acute myelogenous leukemia (AML), non-Hodgkin lymphoma, and Hodgkin lymphoma.[76,77,78,79] Disease-free survival was prolonged in patients with multiple myeloma receiving a single autologous or two sequential autologous transplants.[80,81] Significant transplant-related complications encountered most frequently include infections and organ toxicity of the liver or lung, caused in large part by the high-dose myeloablative cytotoxic therapy. A GVHD-like syndrome (also known as the engraftment syndrome or pseudo-GVHD) of the skin and gastrointestinal tract has been described, but it is generally not frequent or severe.[82,83]

Allogeneic Source of Stem Cells

Transplantation from Related Donors

Hematopoietic cell grafts from related donors may be HLA-identical or HLA-haploidentical. The preferred allogeneic donor has been a genotypically HLA-identical sibling. A genetic match at the HLA loci between siblings is confirmed by the genotyping of 5 HLA loci including HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1. If an HLA-identical sibling is available, patients with hematologic malignancies should be transplanted with peripheral blood stem cells rather than marrow. Two phase 3 studies have now shown an improved disease-free and overall survival with transplantation of peripheral blood stem cells (Fig. 102.2).[84,85] Ten year follow-up of the study by Bensinger et al. showed that the benefit persisted for disease-free survival, but the likelihood of overall survival was not significantly different between the 2 groups.[86] The 10-year cumulative incidence of chronic GVHD and the duration of systemic immunosuppression were similar between the 2 groups. A third study concluded that peripheral blood was an equivalent source of HSCs compared with marrow if administered to patients with standard-risk leukemia, since a significant difference in survival could not be demonstrated.[87] All 3 studies showed an accelerated recovery of neutrophil counts in the group receiving peripheral blood stem cells. Although most studies have not shown a significant increase in the incidence of acute GVHD in the peripheral blood stem cell group, the incidence of chronic GVHD was significantly greater.[84,85,87,88] Higher doses of CD34-positive cells in the peripheral blood stem cell graft (>8.0 $\times$ 10^6/kg) have been significantly associated with the development of chronic GVHD.[89] Since outcome is unlikely to be improved if there is an increased risk of chronic GVHD from the use of peripheral blood stem cells, patients with nonmalignant disorders are still being transplanted with marrow in some centers. With a median follow-up of 6 years, survival of aplastic anemia patients transplanted with marrow was 88% (Fig. 102.3).[90] In a retrospective analysis by CIBMTR, rates of chronic GVHD and overall mortality were greater after transplantation with peripheral blood stem cells than marrow, especially in the younger patient population (<20 years of age).[91] Similar survivals to those observed after HCT for aplastic anemia have been reported in patients transplanted with marrow for hemoglobinopathies.[72,92]

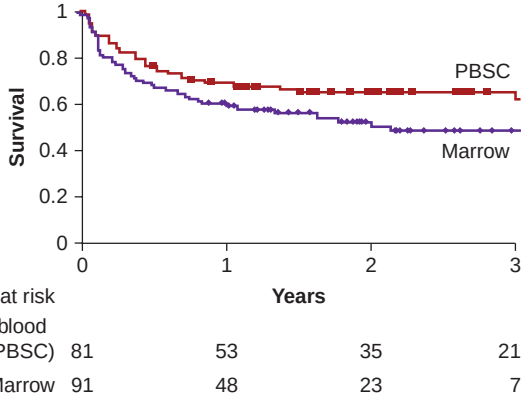

FIGURE 102.2. Probability of overall survival after myeloablative conditioning and transplantation with either peripheral blood stem cells or marrow. Survival at 2 years was improved in the peripheral blood stem cell group as compared to marrow (66% vs. 54%; $P = 0.006$). Disease-free survival was also improved in the peripheral blood stem cell group ($P = 0.003$). (Reprinted with permission from Bensinger WI, Martin PJ, Storer B, et al. Transplantation of bone marrow as compared with peripheral blood cells from HLA-identical relatives in patients with hematologic cancers. N Engl J Med 2001;344:175–181. Copyright 2001 Massachusetts Medical Society. All rights reserved.)

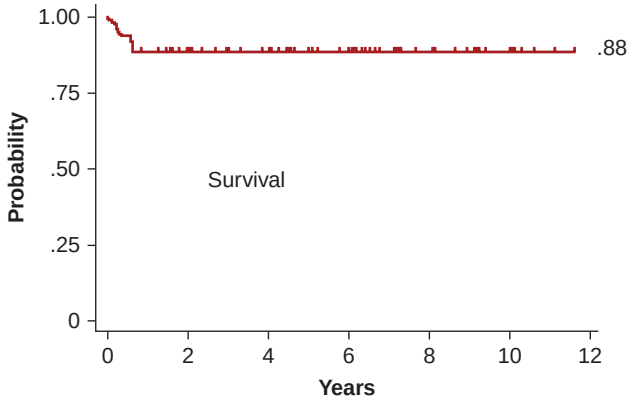

FIGURE 102.3. Overall survival among 94 patients with aplastic anemia who underwent transplantation from HLA-identical siblings after conditioning with cyclophosphamide (CY) and antithymocyte globulin. With a median follow-up of 6.0 (0.5 to 11.6) years, the Kaplan-Meier estimate of survival was 88%. Cyclosporine and methotrexate were administered after transplantation for graft-versus-host disease (GVHD) prophylaxis. (Reprinted with permission from Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. Biol Blood Marrow Transplant 2001;7:39–44.)

An HLA-haploidentical donor (parent, sibling, child) is available for almost all patients, but haplotype differences (genotypically identical at one HLA haplotype but nonidentical at the other HLA haplotype) are associated with a high risk of severe GVHD, graft rejection, and increased mortality with conventional post-transplant immunosuppression. However, transplants for hematologic malignancies from HLA-haploidentical family members mismatched for only one HLA antigen in the nonidentical HLA haplotype may have a similar overall survival to transplants from HLA-identical siblings.[93] In this situation, although the higher incidence of GVHD results in an increased transplant-related mortality, relapse is less frequent, resulting in no overall difference in long-term survival compared to transplants from HLA-matched siblings. Patients transplanted from HLA-haploidentical family members mismatched for 2 or more HLA loci had significantly lower overall survivals compared to patients transplanted from phenotypically HLA-matched unrelated donors.[94] In patients with advanced leukemia, transplantation with high-dose CD34-positive cell grafts which had been highly T cell-depleted resulted in 12 of 43 patients being alive and disease-free at 18 months.[95] Immune reconstitution after transplantation was poor, however.[96] High-dose cyclophosphamide (CY) early after HCT from an HLA-haploidentical donor appears effective in preventing the development of severe acute and chronic GVHD.[97,98] In a report of parallel phase 2 studies, transplantation of HLA-haploidentical marrow grafts appeared to have favorable outcomes at 1 year compared to transplantation of umbilical cord blood grafts.[99] Patients who lack a closely matched family donor should be offered a phenotypically HLA-matched unrelated donor before considering a transplant from an HLA-haploidentical donor.

Transplantation from Unrelated Donors

After the initial success with transplantation of marrow from matched unrelated volunteers, large databanks were established around the world, including the National Marrow Donor Program (NMDP) in the United States. Available through the world-wide registries and the NMDP are approximately 20 million volunteer donors who have been typed for HLA-A and -B antigens, and many of these are also typed for HLA-DR (www.bmdw.org). Certain racial and ethnic groups are underrepresented in the registry and therefore there is a lower probability that an HLA-matched donor will be found.

Outcomes have improved after HCT from HLA-matched unrelated donors because of improved supportive care and high-resolution HLA typing. Outcomes after HCT from an unrelated donor are now comparable to what is observed after HCT from an HLA-identical sibling. In a study of 2,223 adult AML patients, the overall survival after transplantation from 8/8 HLA-matched donors was similar to that observed after transplantation from an HLA-identical sibling ($RR = 1.03$; $P = 0.62$).[100] The risk of acute GVHD, however, was lower after transplantation from an HLA-identical sibling.

The relative importance of the various HLA loci has been defined for HCT from unrelated donors. In a study from CIBMTR of 3,857 transplants performed from 1988 to 2003, it was observed that high-resolution DNA matching for HLA-A, HLA-B, HLA-C, or HLA–DRB1 (8/8 match) was the minimal level of matching associated with the highest survival.[101] A single mismatch at HLA-A, HLA-B, HLA-C, or HLA–DRB1 (7/8 match) was associated with an increased mortality compared to an 8/8 match. A single mismatch at HLA-B and HLA-C appeared better tolerated than a mismatch at HLA-A and HLA-DRB1. A mismatch at HLA-DQ or HLA-DP loci did not have an effect on survival. Ninety-four percent of the transplants in this study were performed with marrow grafts. In a follow-up study, the association between HLA matching and outcomes was investigated for transplantation of peripheral blood stem cells from unrelated donors.[102] Survival was better with 8/8 HLA matching compared to 7/8 HLA matching. Single HLA-C antigen mismatches were associated with an increased risk of treatment-related mortality and grade III-IV acute GVHD. HLA-B antigen/allele mismatching was associated with an increased risk of grade III-IV acute GVHD with no effect on survival. No significant differences in outcomes were observed with HLA-C allele mismatches, HLA-A antigen/allele mismatches, or HLA-DRB1 mismatches compared to 8/8 HLA-matched pairs. The differences in the reported associations for HLA mismatches between marrow and peripheral blood stem cell grafts may result from differences in cell numbers in the graft as well as the graft composition.

Disease status is an important consideration in the search process. In patients with advanced malignancies, survival after transplantation from an HLA-matched or 1-antigen/allele HLA-mismatched unrelated donor was similar.[103] Therefore, when transplants cannot be delayed because of disease status, selection of a donor with the fewest HLA mismatches may be an alternative choice for patients without a completely HLA-matched donor.

Because of the possible higher risk of acute GVHD, studies of peripheral blood stem cell transplantation from unrelated donors started later than those done from HLA-identical donors. A recently completed randomized clinical trial (BMTCTN 0201) comparing marrow to peripheral blood stem cells observed that there was no difference in overall survival, disease-free survival, nonrelapse mortality, relapse, or acute GVHD outcomes at 2 years between the 2 arms. There was a significantly increased risk of chronic GVHD.

Transplantation with Umbilical Cord Blood Grafts

There are several advantages to the use of umbilical cord blood when compared to unrelated donor peripheral stem cell or marrow product harvested from adults. First, umbilical cord blood represents a potentially nonlimiting donor source for transplantation. At present, over 550,000 HLA typed cord bloods are banked and are conceivably available with several days notice (www.bmdw.org). Many of the banked specimens are from underrepresented ethnic and racial groups, thus expanding the potential donor pool for individuals poorly served by the unrelated donor marrow registries. The total nucleated cell dose required for successful engraftment is 10-fold less than that required for conventional peripheral blood or marrow transplant. The transmission

of Epstein-Barr virus (EBV) or cytomegalovirus (CMV) is negligible compared to conventional allogeneic transplantation. HLA allele mismatches (up to 2 to 3 loci) are permissible in cord blood transplantation. Notable disadvantages to cord blood transplantation are the potential for prolonged pancytopenia and lower rates of overall engraftment.

The first successful cord blood cell transplant in a pediatric patient was done in 1988.[69] Two studies were then successfully conducted of cord blood transplantation from HLA-matched or HLA-haploidentical allogeneic siblings (44 patients) and partially HLA-mismatched unrelated donors (25 patients).[104,105] In the first report of a large experience in 562 recipients (including 18% adults) after transplantation with umbilical cord blood grafts from unrelated donors, the probability of engraftment at 42 days and grade III-IV GVHD, was 81% and 23%, respectively.[106] It was concluded from this study that umbilical cord blood grafts regularly engraft and cause a low rate of GVHD relative to the number of HLA mismatches, and produced survival rates comparable to those with transplantation of marrow from unrelated donors. This experience was confirmed in a retrospective analysis of 541 children with leukemia transplanted with stem cell grafts from unrelated donors of which 99 were from umbilical cord blood.[107] Recipients of cord blood had an increased number of HLA mismatches but a lower risk of both acute and chronic GVHD compared to recipients of unmanipulated marrow from unrelated donors. The day 100 mortality was higher, however, in the cord blood group, possibly because of the significantly delayed recovery of hematopoiesis and immunity after transplantation. These results were later confirmed by another group.[108] It was concluded that the use of umbilical cord blood was an option for children with acute leukemia lacking an acceptably matched unrelated marrow donor. In children who had received umbilical cord blood or bone marrow grafts from HLA-identical siblings, the umbilical cord blood group had a lower risk of acute and chronic GVHD (relative risk 0.41 [$P = 0.001$] and 0.35 [$P = 0.02$]), respectively.[109] Survival was similar in both groups. The progenitor cell and CD34-positive cell content of the umbilical cord blood graft predicted the rate of neutrophil recovery after transplantation.[110]

The reported low incidence of severe GVHD after transplant of umbilical cord blood cells from unrelated donors (relative to the degree of HLA disparity) may be related to the decreased immunocompetence of the fetal blood cells compared to adult cells.[111] Two years after transplantation, T cell receptor rearrangement excision circles (TRECs), a measure of recent thymic output, were greater in recipients of umbilical cord blood than in recipients of marrow grafts, suggesting complete immune recovery despite the low number of cells infused.[112]

Initially, recipients of umbilical cord blood cell transplants had been mostly children. Even though, at first, there was a concern about the low cell count for the larger body size, outcomes in adults were comparable to those reported in children.[113] Prospective trials comparing cord blood transplantation to unrelated peripheral blood/marrow transplants are not available; however, two large registry or retrospective studies summarizing consortia experience for acute or chronic leukemias have been published.[114,115] Slower engraftment kinetics, reduced engraftment rates, and decreased acute and chronic GVHD rates and severity were observed in the cord blood transplantation groups. Rates of relapse reported for the two studies were similar between the 2 groups. Transplant-related complications, including delayed recovery of blood counts after cord blood transplantation, may be reduced in the adult population with reduced intensity conditioning.[116]

Transplantation of multiple cord blood units was investigated to determine if recovery of neutrophil and platelet counts after transplantation could be improved.[117] After the infusion of two umbilical cord blood grafts into adult patients, the median day to neutrophil recovery was 24 (range 12 to 28) in 23 adult patients compared to 27 (range 13 to 59) in another study of 68 adult patients transplanted with a single cord blood unit.[113] This observation of improved recovery times was not confirmed in a retrospective study at a single institution.[118] After transplantation with 2 cord blood units, only one unit eventually dominates and engrafts long-term.[119] Higher $CD3^+$ cell dose and percentage of $CD34^+$ viability were associated with unit dominance. Higher dominant unit total nucleated cells, $CD34^+$ cells, and colony-forming unit doses were associated with higher sustained engraftment and faster neutrophil recovery. Mechanistically, the dominant cord mounts an allogeneic immune response mediated by $CD8^+$ T cells against the nondominant unit.[120] Outcomes after double cord blood transplantation were compared with outcomes after transplantation from HLA-matched related donors, HLA-matched unrelated donors, and 1-antigen HLA-mismatched unrelated donors.[121] Leukemia-free survival at 5 years was similar for all donor types. The risk of relapse was decreased in the double cord blood transplantation group compared to the other donor types, but the risk of nonrelapse mortality was increased. The lower risk of relapse after transplantation from a double cord blood unit compared to a single cord blood unit had been previously seen in another retrospective study, although a significantly increased risk of acute GVHD was also observed.[118] Sharing of one or more HLA-A, B, or DRB1 loci between the inherited paternal MHC alleles (IPA) of the donor and the recipient after unrelated cord blood transplantation leads to superior leukemia-free survival with no increase in acute GVHD, a result attributed to maternally derived anti-IPA elements persisting in the cord blood.[122]

Umbilical cord blood grafts should be considered for both pediatric and adult patients lacking a suitably matched unrelated donor or unable to wait for an unrelated search to be completed.

COLLECTION OF HEMATOPOIETIC STEM CELLS FOR TRANSPLANTATION

Marrow

Marrow is obtained by multiple aspirations from the posterior iliac crest under general or epidural anesthesia.[123] The anterior iliac crest (or the sternum) may also be harvested if larger quantities of marrow are required. The target volume of marrow for transplant is 10 to 15 ml/kg of recipient or donor weight, whichever is the smaller individual. Marrow is collected with heparinized syringes through large bore needles and placed into small amounts of culture medium. The collected marrow must be filtered prior to intravenous transfusion into the recipient to remove small particles or clots. If the patient and donor are ABO-incompatible and there are high anti-A or -B titers, the marrow can be red blood cell–depleted or plasma-depleted, depending on whether it is a major or minor ABO mismatch.[124] In some cases of a major ABO mismatch, plasmapheresis of the recipient may be effective in reducing the high anti-A or anti-B titers so that RBC depletion of marrow is not required. Marrow is infused immediately after harvesting, but delays of 24 hours may occur without adverse consequences. Such delays are common when marrow is shipped to a transplant program after harvest from an unrelated donor. In an analysis of marrow harvest characteristics of 1,549 donors, the median total nucleated cell count from the marrow was 2.5 (range 0.3 to 12.0) $\times$ 10^8/kg recipient weight.[125] Life-threatening complications from marrow harvesting, usually related to the administration of anesthesia, were reported in 0.27% to 0.4% of the donors.[126]

Peripheral Blood

HSC circulate in the peripheral blood but the concentration is very low and it requires multiple apheresis to collect adequate

numbers. The number of aphereses may be reduced to one or two sessions when HSC are mobilized to the peripheral blood after the administration of cytokines alone or in combination with chemotherapy or plerixafor. An effective mobilization strategy of autologous HSC for patients with malignancy is chemotherapy in conjunction with G-CSF, 6 μg/kg/day.[61] After chemotherapy, patients are apheresed when the total white blood cell count has recovered to 1,000/μl or the CD34-positive cell count in the peripheral blood is at least >10/μl. For patients not requiring chemotherapy or normal allogeneic donors, mobilization is with G-CSF alone (5 to 16 μg/kg) by daily subcutaneous injections for 5 to 8 days.[48,127,128] These doses of G-CSF are generally well tolerated, with common side effects of bone pains, myalgias, and flu-like symptoms that are managed with acetaminophen or low-dose narcotics. Plerixafor in combination with G-CSF was effective for increasing the yields of circulating $CD34^+$ progenitor cells and is indicated for patients with lymphoma or multiple myeloma who are being collected for autologous HCT.[56] The recommended dose is 0.24 mg/kg/day administered subcutaneously 11 hours before the apheresis procedure. The maximum dose is 40 mg/day. Common side effects included diarrhea, nausea, fatigue, headaches, and arthralgias. Apheresis was performed as early as day 4 after the start of G-CSF using a continuous blood flow separation technique. Apheresed products may be cryopreserved in 5% dimethylsulfoxide (DMSO) for use after thawing on the day of transplant. A more rapid sustained hematopoietic recovery of both neutrophil and platelet counts occurs with increasing numbers of $CD34^+$ cells in the hematopoietic cell graft (up to 5×10^6/kg). Some investigators consider 2.5×10^6/kg of recipient weight a minimum dose of $CD34^+$ cells from the peripheral blood to achieve complete autologous recovery. Platelet recovery is more rapid at higher $CD34^+$ cell doses.[60,61] Since the cell dose used in the autologous transplant setting yields consistent and prompt engraftment, it is also considered an appropriate target for collection of allogeneic HSC from the peripheral blood. Donors of peripheral blood avoid general anesthesia and other complications of marrow harvesting. If peripheral veins are inadequate, a large bore double lumen catheter for vascular access may be required. In a large analysis of safety from the NMDP (n = 2,408 donors), it was concluded that collection of peripheral blood stem cells was safe but that nearly all patients will experience bone pain and 1 in 4 will have headache, nausea, or citrate toxicity.[129] Serious and unexpected toxicities were experienced by 0.6% of the donors, but complete recovery was universal.

Cord Blood

Umbilical cord blood cells are now being routinely collected and cryopreserved for storage in a cord blood bank.[130,131] Directed-donor banking of cord blood for siblings in a current good tissue practices environment has also now been reported.[132] After the separation of the placenta, umbilical cord blood cells are collected into a closed system which utilizes a sterile donor blood collection set. The placenta and umbilical cord can be suspended on a frame and the blood drained as a "standard gravity phlebotomy" into CPD (citrate, phosphate, dextrose) anticoagulant. The median volume of umbilical cord blood collected in one study of 44 patients was 100 ml (range 42 to 282 ml).[104] The median number of total nucleated cells per kilogram of recipient weight for banked umbilical cord blood is 2.5×10^7 (range 1 to 33) and corresponds to a $CD34^+$ cell dose of 1.5×10^5 per kilogram of recipient weight.[110]

ABO INCOMPATIBILITY

ABO incompatibility between the donor and the recipient occurs in about 30% of cases. A major ABO incompatibility is considered to occur when the isohemagglutinins in the recipient plasma are directed against the donor red blood cell antigens. A minor ABO incompatibility is when the isohemagglutinins in the donor plasma are directed against recipient red blood cell antigens. ABO incompatibility between the donor and the recipient has no significant effect on the incidence of graft rejection, GVHD, or survival, although bidirectional ABO mismatches were associated with a higher risk of grade III-IV acute GVHD.[133] ABO incompatibilities may result in severe hemolytic episodes after transplantation. For major ABO incompatibilities, if the recipient isohemagglutinin titers in the plasma are high, an acute hemolytic event can be prevented by red cell depletion of the graft. Conversely, plasmapheresis may be effective in reducing the anti-donor isohemagglutinin in the recipient plasma. If the latter approach is chosen, the goal should be to reduce the isohemagglutinin titer to 1:16 or lower.[134] If there is continued production of anti-donor isohemagglutinins in the recipient plasma after transplantation, delayed erythropoiesis or even pure red cell aplasia and persistent hemolysis may result.[135] Although plasmapheresis and erythropoietin may be of some benefit, the hemolytic episode may persist for months after transplantation. If there are no contraindications, early withdrawal of immunosuppression may result in a more rapid resolution of the delayed hemolytic event, possibly because of a GVH reaction against the isohemagglutinin-producing cells of the recipient.[136] To prevent hemolytic events related to minor ABO incompatibilities, the isohemagglutinins can be removed from the stem cell graft if the anti-recipient titers are high. The risk of hemolysis from a minor ABO mismatch appears to be increased after peripheral blood stem cell transplantation, possibly related to the higher content of lymphoid cells (B cells) in the graft. The development of severe hemolysis may be prevented with the administration of methotrexate after transplantation.[137]

CONDITIONING REGIMENS

Myeloablative

Myeloablative conditioning regimens are sufficiently intense that recovery of hematopoiesis would not be expected without the support of transplanted hematopoietic progenitor cells. The ideal myeloablative conditioning regimen should fulfill the following criteria: (1) eliminate or reduce the tumor load; (2) suppress the host immune system to prevent graft rejection (not applicable to hematopoietic support with autologous cells); and (3) have tolerable nonhematopoietic toxicity. The first conditioning regimens consisted of TBI, alone or in combination with cyclophosphamide (CY).[50] TBI is an effective antineoplastic modality that is both cell cycle nonspecific and immunosuppressive. CY is a chemotherapeutic agent with immunosuppressive properties that has few nonhematopoietic toxicities that are similar to TBI, and therefore can be used in combination. Other conditioning regimens which have since been developed include: (1) the replacement of CY with other chemotherapeutic agents (e.g., etoposide, Ara-C, and melphalan) in combination with TBI.[138,139]; (2) other chemotherapeutic agents in combination with both CY and TBI[140,141]; (3) chemotherapeutic agents used in combination with CY but without TBI, including busulfan (BU)/CY or carmustine-cyclophosphamide-etoposide (BCV)[142,143]; and (4) replacement of CY with fludarabine and used in combination with BU or melphalan.[144,145] In one study, BCV was associated with a significant incidence of transplant-related complications and mortality.[146] Other high-dose cytotoxic regimens have been used, especially with autologous stem cell support.[147,148]

Most preparative regimens used for the treatment of malignant diseases have not been tested in Phase III studies, so it is generally unclear if any one regimen represents an improvement over those previously used. Two Phase III studies in allogeneic marrow transplantation have compared differing intensities of TBI

(1,200 cGy versus 1,575 cGy).[149,150] The relapse rate was reduced in the group of patients receiving the higher dose of TBI, but was associated with an increase in complications from regimen-related toxicity and GVHD which negated any improvement in disease-free survival compared to the group receiving the lower dose of TBI. In a more recent study, conditioning with TBI 800 cGy and fludarabine was compared with TBI 1,200 cGy and CY and there was no difference in overall survival, relapse, or treatment-related mortality.[151] The combination of BU/CY was determined to be an acceptable alternative to CY/TBI for patients with leukemia in several studies.[152–154] However in one study, patients in the BU/CY group had an increased risk of sinusoidal obstruction syndrome (SOS) of the liver and other transplant-related complications.[155] Since this last study, it has been demonstrated that targeting of busulfan levels in the plasma may decrease the risk of relapse and severe regimen-related toxicities, contributing to an improved disease-free survival (Fig. 102.4).[156] Monitoring levels of metabolites from cyclophosphamide may also be important to decrease the risk of liver toxicity and nonrelapse mortality.[157,158]

In patients already profoundly immunosuppressed with SCID syndrome, engraftment of allogeneic stem cells from matched related siblings may occur without conditioning therapy.[159] High-dose CY in combination with antithymocyte globulin (ATG) as a preparative regimen for patients with aplastic anemia was associated with graft rejection in less than 5% of cases.[90] The actuarial survival rate was 88% at 6 years after transplantation (Fig. 102.3). For transplantation of patients with thalassemia or sickle cell disease, a myeloablative conditioning regimen, usually consisting of the combination of BU and CY, was thought to be necessary to prevent a high incidence of graft rejection, since most patients with these disorders had received multiple blood transfusions and were potentially sensitized to donor-derived mHC.[160,161] However, reduced intensity conditioning regimens have now been shown to successfully overcome the risk of graft rejection associated with these hematologic disorders.[162]

Although HSC engraftment may be achieved after transplantation and some patients are cured, relapse remains an important problem in patients with advanced hematologic malignancies. Since further intensification of the conditioning regimen using current modalities is unlikely to improve overall survival because of associated increases in toxicity, new strategies will be required to achieve a cure. Radiolabeled monoclonal antibodies (i.e., radioimmunoconjugates) specific for certain lineage-specific cell surface antigens on tumor cells or sites from which the malignancy originates might enhance the efficacy of the conditioning regimen and decrease the rates of relapse.[163–166]

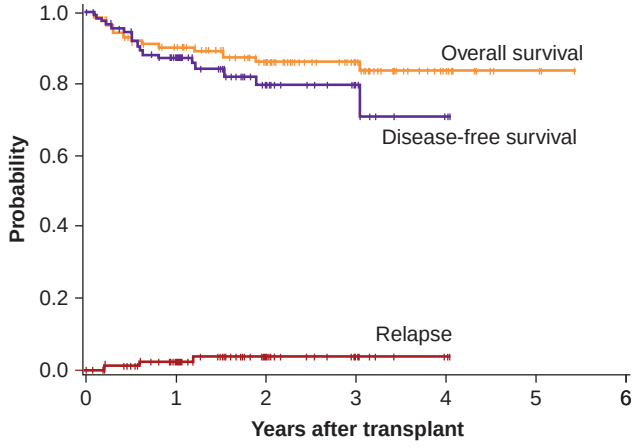

FIGURE 102.4. Outcomes for 131 patients after conditioning with cyclophosphamide and targeted busulfan followed by hematopoietic cell transplantation (HCT) from human leukocyte antigen (HLA)-identical siblings for chronic myelogenous leukemia in chronic phase. Graft-versus-host disease (GVHD) prophylaxis was with the combination of cyclosporine and methotrexate. The probability of survival was 86% at 3 years. Nonmyeloablative

The development of nonmyeloablative or reduced intensity regimens permitted the application of potentially curative allogeneic HCT to older patients and those patients with contraindications to intensive cytotoxic regimens.[167] The success of the nonmyeloablative conditioning regimens in preclinical and clinical studies established new biologic principles which formed the basis of our understanding of the engraftment process after allogeneic HCT. The findings in these studies were consistent with the following conclusions about successful engraftment:

1. Myeloablative therapy is not needed, since stem cell grafts can "create their own marrow space" with a GVH effect.
2. Engraftment is promoted by posttransplant suppression of the host-versus-graft reaction.

There are multiple different nonmyeloablative conditioning regimens which have been piloted. The conditioning regimens fall into 2 broad categories: (1) reduced intensity regimens and (2) minimally myelosuppressive regimens.[145,168–171,172,173] In general, after reduced intensity conditioning, recipients usually become aplastic from the regimen and complete chimerism is established early after transplantation. Reduced intensity conditioning regimens are of sufficiently low intensity that recovery of hematopoiesis would be expected without the support of hematopoietic progenitor cells. Although reduced in intensity, the regimen may contribute a substantial antitumor effect resulting in a tumor response early after transplantation. The minimally myelosuppressive or nonmyeloablative regimens rely on pretransplant and posttransplant immunosuppression to prevent graft rejection. After transplantation, a mixed chimeric state may persist for months before converting to full donor hematopoietic chimerism (Table 102.4).[172] The regimen may be only mildly myelosuppressive resulting in a reduction in the requirements for blood products (Fig. 102.5).[174] The conditioning regimen would not be expected to have a substantial antitumor effect, so efficacy of the treatment is largely from a GVT effect.

TABLE 102.4

MEDIAN PERCENT AND CHIMERISM STATUS

	Day 28[a]	Day 56[b]
Median % (range) of donor cells		
T cells	60 (10–100)	91 (5–100)
PB neutrophils	91 (0–100)	99 (4–100)
Bone Marrow	87 (0–100)	95 (2–100)
Chimerism		
% Mixed[c]	86	79
% Full Donor[d]	14	21

[a] 44 evaluable patients. One additional patient–donor pair had no identifiable DNA polymorphism, and evidence of donor cell engraftment was based on red blood cell polymorphisms.
[b] 41 evaluable patients.
[c] ≥1 and ≤ 95% T cells of donor origin.
[d] >95% T cells of donor origin.

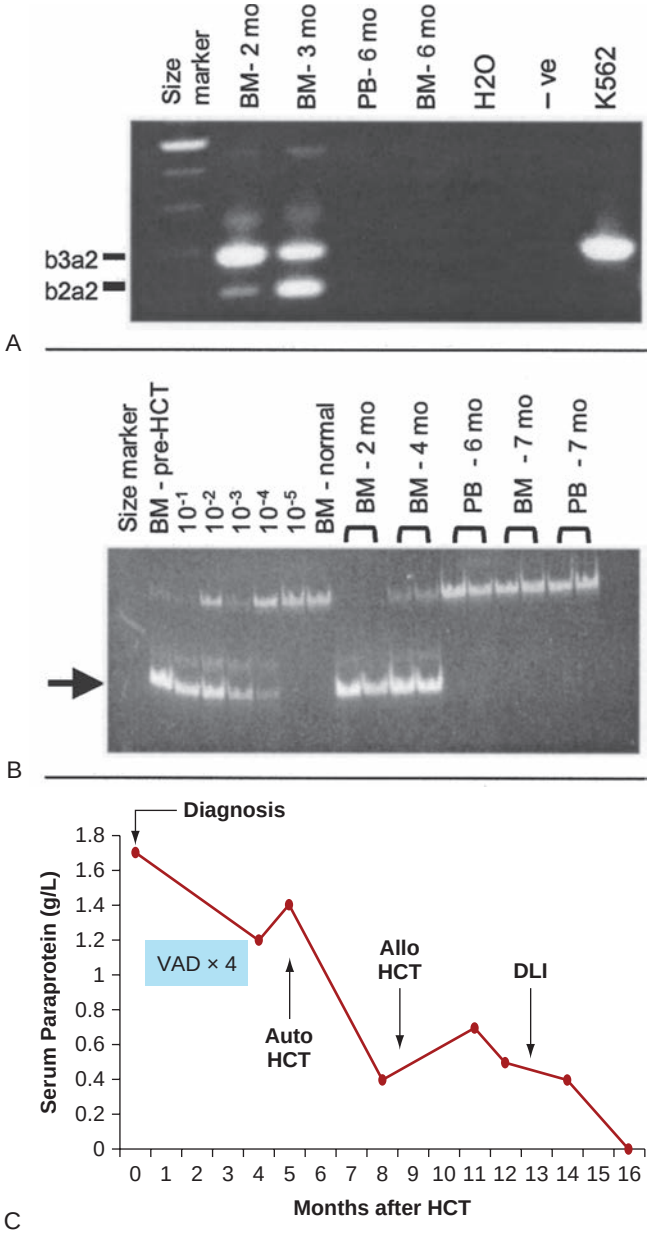

FIGURE 102.6. Complete disease responses after HCT. A: Example of molecular remission of chronic myelogenous leukemia (CML) induced by nonmyeloablative hematopoietic cell transplantation (HCT) without donor lymphoid infusion, as documented by failure of reverse transcription–polymerase chain reaction (PCR) to detect BCR-ABL transcripts. The lane described "*-ve*" is negative control of normal bone marrow (BM). *K562* is a positive control for BCR-ABL. **B:** Example of molecular remission of chronic lymphocytic leukemia (CLL) induced by HCT without donor lymphocyte infusion as documented by PCR to detect a tumor-specific immunoglobulin heavy-chain gene arrangement (*arrow*). Each posttransplantation sample was amplified in duplicate. The lanes designated 10^{-1} to 10^{-5} show a dilution series of the patient's pretransplantation sample (more than 90% tumor cells) into normal bone marrow. **C:** Example of complete remission of multiple myeloma after allogeneic HCT. The patient was initially treated with four cycles of vincristine, adriamycin, and dexamethasone. High-dose cytoreduction with melphalan 200 mg/m^2 and autologous transplantation was performed 3 months before allogeneic HCT. Donor lymphocyte infusion was given 4 months after HCT because of persistent tumor. After complete remission was achieved, trace levels of serum monoclonal paraprotein were detected by immunofixation intermittently in follow-up testing. DLI, donor lymphocyte infusions. (From McSweeney PA, Niederwieser D, Shizuru JA, et al. Hematopoietic cell transplantation in older patients with hematologic malignancies: replacing high-dose cytotoxic therapy with graft-versus-tumor effects. Blood 2001;97:3390–3400. Copyright American Society of Hematology, used with permission.)

Early studies of nonmyeloablative transplantation focused on patients with donors who were HLA-identical siblings because the risk of graft rejection and GVHD was considered less compared to other types of donors. Risk factors for graft rejection after conditioning with TBI 200 cGy alone were no prior intensive chemotherapy and a diagnosis of CML.[172] When fludarabine was added to low-dose TBI, the incidence of graft rejection decreased. Nonmyeloablative conditioning regimens have also been effective for transplantation from alternative sources including unrelated donors and umbilical cord blood.[175,176,177]

The allogeneic HSC graft can induce GVL/GVT effects. The effectiveness of the GVT effect can be best observed in the responses patients have had with the minimally myelosuppressive regimens (Fig. 102.6).[172,178,179] In patients not otherwise eligible for a myeloablative conditioning regimen, sustained responses have been noted with AML, the chronic leukemias, lymphoma, and myeloma. A minimally myelosuppressive conditioning regimen may be appropriate for indolent hematologic malignancies including CML, chronic lymphocytic leukemia, agnogenic myeloid metaplasia, and low grade lymphomas.[172,180,181,182] In those diseases in which some cytoreduction may be necessary, a reduced intensity regimen may be of more benefit. Another strategy is to use a cycle of chemotherapy or high-dose cytotoxic therapy and autologous transplantation to debulk the disease or induce a clinical remission followed by allogeneic nonmyeloablative transplantation.[183,184] The objective of this tandem approach is to consolidate the remission with a GVT reaction. The assessment of the patient, the disease type, and the disease status are required to determine the optimal approach. In retrospective comparisons

of patient populations after myeloablative and nonmyeloablative conditioning regimens, no difference in overall survival was observed.[185–187] However, relapse rates were higher in patient groups which had received a nonmyeloablative conditioning regimen.

GVHD and infections are the major reasons for transplant-related treatment failure after nonmyeloablative transplantation. Since these patients, in general, have been older and at higher risk of poor outcome based on preexisting complications at baseline, nonmyeloablative transplantation has been well tolerated compared to what could have been expected after myeloablative conditioning. The day 100 and year 1 treatment-related mortality has been reported as 3% and 16%, respectively, but significantly less than after myeloablative conditioning.[188] Earlier clinical trials of nonmyeloablative conditioning regimens had given short courses of immunosuppressive therapy or early administration of donor lymphocyte infusions (DLI). GVHD tended to develop later, with many cases developing at 3 to 6 months after transplantation.[189] The cumulative incidence of acute grade II-IV GVHD was less after a nonmyeloablative than a myeloablative conditioning regimen (64% versus 85%, $p = 0.001$). There was no difference in the incidence of chronic GVHD. GVHD developed in many patients as late as 6 to 12 months after nonmyeloablative conditioning and HCT. The incidence of acute GVHD decreased when GVHD prophylaxis was administered for a longer period after HCT.[190] Acute GVHD did not have a significant impact on the risk of progression but had an association with increased risk of nonrelapse mortality. Chronic GVHD was associated with a decreased risk of relapse or progression ($P = 0.006$) and an increased probability of progression-free survival ($P = 0.003$).[178] Strategies for the optimal management of GVHD are required so that complications are reduced but do not prevent an effective GVT response.

In the presence of a major ABO incompatibility, delayed development of donor red cell chimerism resulting in an increased need for red blood cell products has been reported.[136] Withdrawal of cyclosporine may induce a graft-mediated immune reaction against recipient isohemagglutinin-producing cells, thus resulting in a decrease in isohemagglutinin levels and improvement in donor red blood cell chimerism. The onset of CMV disease may be delayed after nonmyeloablative transplantation.[191,192] Patients after nonmyeloablative conditioning with a minimally myelosuppressive regimen can generally be managed in the outpatient setting.

ENGRAFTMENT

Stable engraftment of a hematopoietic cell graft requires the circulation, homing, and growth of HSC. The number of $CD34^+$ cells that are required to ensure prompt recovery of neutrophil and platelet counts is 2.5 to 5.0 $\times$ 10^6/kg. In addition, adequate suppression of the host immune system is required to prevent graft rejection after allogeneic HCT. To achieve adequate immunosuppression, conditioning regimens may be myeloablative or nonmyeloablative. Donor T cells are important to prevent graft rejection, even with the concomitant administration of substantial numbers of $CD34^+$ cells.[193] Although infrequently observed in humans, a single stem cell may substantially reconstitute hematopoiesis (clonal dominance) and demonstrates the considerable proliferative potential of a normal HSC.[194,195] In many clinical trials of HCT, engraftment has generally been defined as the achievement of a peripheral blood neutrophil count greater than 0.5 $\times$ 10^9/L and evidence of donor chimerism if engraftment is being assessed after allogeneic HCT. The rate of engraftment is dependent upon the number of HSC ($CD34^+$ cell content), purging strategies for autologous grafts, use of growth factors, and the use of methotrexate for GVHD prophylaxis.[61,196,197] Graft failure may result from either an infusion of inadequate numbers of HSC, drug toxicity, infection (CMV), or graft rejection (after allogeneic transplantation). Relapse also needs to be considered in a patient with decreasing peripheral blood counts.

Graft rejection is infrequent (<1% incidence) after HCT from HLA-matched siblings and was more common after HLA-mismatched related or unrelated HLA-matched donors (2% to 6%).[198] Luznik et al. reported a rejection rate of 13% after reduced intensity conditioning and HCT from an HLA-haploidentical donor.[98] All but 1 patient experienced recovery of autologous hematopoiesis after rejection in this study. As grafts are rejected, peripheral blood counts may drop, and chimerism studies demonstrate the loss of donor cells in the peripheral blood and marrow. Factors that influence the risk of graft rejection include T-cell depletion of the hematopoietic cell graft, increased HLA disparity, the intensity of the conditioning regimen and post-transplant immunosuppression, pretransplant sensitization of the host against donor alloantigens, and the number of HSC in the graft.[98,198–201] Previous chemotherapy has been associated with a reduced risk of graft rejection after nonmyeloablative conditioning.[202] T cell engraftment kinetics were also improved in patients with higher steady state concentrations of the active mycophenolate mofetil (MMF) metabolite (achieved with three times daily dosing instead of twice daily) without increased risk of relapse, albeit with a modest increase in the rate of CMV reactivation.[203] Clinically, hematopoietic growth factors have not been demonstrated to be effective in preventing graft rejection. Historically, the occurrence of graft rejection after a myeloablative conditioning regimen and an allogeneic HCT had been almost always fatal. Strategies utilizing noncytotoxic immunosuppressive conditioning regimens and HCT may salvage patients after rejection of the first graft.[204] Aggressive medical management during the prolonged neutropenic period is required to prevent death from infection after transplantation of the second hematopoietic cell graft. Although the rates of rejection have been higher in the studies of nonmyeloablative HCT for hematologic malignancy (2% to 7%), graft rejection has not been associated with a significant morbidity or mortality because the duration of the pancytopenic period before autologous recovery has in general been short.[172,205] When rejection occurs after reduced intensity conditioning, salvage HCT using a conditioning regimen of fludarabine and TBI (300 or 400 cGy) resulted in an engraftment rate of 87%.[206] A different donor was used for salvage HCT in 63% of the cases. Nonrelapse mortality at 2 years was 24%. The estimated survivals at 2 and 4 years were 49% and 42%, respectively. Graft rejection can be successfully overcome by salvage HCT from the same or different donor with a reduced intensity conditioning regimen consisting of fludarabine and low-dose TBI.

REGIMEN-RELATED TOXICITIES

The severity of regimen-related toxicities is related to the intensity of the myeloablative therapy, the type of cytotoxic therapy, the medical condition of the patient before transplantation, and the presence of posttransplant factors, including the use of methotrexate, calcineurin inhibitors, and amphotericin B. Reduced intensity conditioning regimens may decrease the severity of certain regimen-related toxicities.[188,207–210]

Oral mucositis occurs in more than 90% of patients after myeloablative conditioning, and most require pain relief with a continuous intravenous narcotic drug. Improvement occurs temporally, with marrow recovery approximately 2 to 3 weeks after transplantation. The severity of the oral mucositis depends on the intensity of myeloablative therapy and the use of methotrexate. Severe mucositis may result in upper airway obstruction or aspiration pneumonitis. A blinded randomized placebo control study of the recombinant human keratinocyte growth factor (palifermin) in patients receiving TBI plus high-dose chemotherapy followed by autologous stem cell rescue demonstrated a 35% reduction in severe mucositis and a 6-day reduction in the median time to

resolution of severe mucositis.[211] Furthermore, palifermin was associated with decreased opioid and total parenteral nutrition use. The role of palifermin in other types of HCT recipients has not been established. Gastroenteritis induced by chemotherapy and irradiation results in nausea, vomiting, and diarrhea, all of which may persist for up to 2 to 3 weeks after transplantation. Central lines are placed prior to transplant for administration of fluids, drugs, and hyperalimentation during the period of therapy-induced mucositis and gastroenteritis.

Renal dysfunction is common after HCT.[212,213] Some factors associated with the development of severe renal failure requiring dialysis were hyperbilirubinemia, significant fluid retention after transplant, amphotericin B administration, and pretransplant serum creatinine levels greater than 0.7 mg/dl. Renal dysfunction (as indicated by a doubling of the baseline serum creatinine) was most strongly associated with the use of amphotericin B administration and SOS of the liver.[213] In this study, calcineurin inhibitors, GVHD, sepsis, TBI, and CY were not found to be significant contributors to severe renal failure. Calcineurin inhibitors cause transient renal dysfunction that is generally reversible with aggressive hydration and eventual discontinuation of the drugs. Renal complications were decreased after HCT with a nonmyeloablative conditioning regimen.[208]

Lung and liver are the two organs that limit further escalation of the intensity of myeloablative therapy. Idiopathic interstitial pneumonitis occurs in 8% to 18% of patients after myeloablative conditioning and marrow transplantation.[214–216] Clinical manifestations include dyspnea, nonproductive cough, hypoxemia, and diffuse pulmonary infiltrates. This toxicity is most likely due to TBI, but preparative regimens containing high doses of chemotherapeutic agents such as CY, BU, and carmustine also contribute directly to toxicity in the lungs. Pulmonary veno-occlusive disease (VOD) is important to consider in patients with diffuse pulmonary infiltrates, since there may be a favorable response to corticosteroids.[217,218] Treatment for idiopathic interstitial pneumonitis consists of supplemental oxygen and ventilatory support. Survival is poor (3%) for patients requiring intubation and mechanical ventilation for greater than 24 hours.[219] Pulmonary complications are reduced after nonmyeloablative conditioning regimens.[207,209]

SOS (formerly known as veno-occlusive disease, or VOD) of the liver is an event characterized by damage to vascular endothelial cells and to hepatocytes in zone 3 of the liver acinus and is the most frequent cause of hyperbilirubinemia within 20 days following HCT.[220] Historically, the overall incidence of SOS was 53%, and 15% of patients had severe disease. The incidence of SOS has decreased in more recent years because of the reduced intensities of conditioning regimens and better selection of patients for myeloablative regimens. Risk factors for the development of severe SOS are pretransplant hepatitis with elevated serum levels of hepatocellular enzymes, the intensity of the conditioning regimen (TBI greater than 13 Gy), or the use of busulfan. Targeting strategies may have reduced the incidence of severe SOS in patients conditioned with busulfan. Patients receiving ursodeoxycholic acid after HCT had significantly lower rates of severe hyperbilirubinemia and elevated alanine aminotransferase levels, although the rates of SOS were similar compared to controls.[221] Furthermore, the rates of severe GVHD were less and mortality was significantly improved at 1-year posttransplant in the ursodeoxycholic acid group. For the treatment of SOS, responses to the administration of tissue plasminogen activator have been reported.[222,223] However, the risk of bleeding must be weighed against the potential benefit of this agent. Responses were also observed in patients treated with defibrotide which is a single-stranded polydeoxyribonucleotide with fibrinolytic and antithrombotic activity.[224] No randomized clinical trials of defibrotide for treatment of SOS have been conducted. However, in a randomized clinical trial of prophylactic therapy, administration of defibrotide to pediatric patients undergoing HCT demonstrated decreased rates of SOS at day 30 when compared to controls.[225]

Increasingly recognized as an important clinical problem are the delayed complications other than chronic GVHD after HCT (Chapter 106). Long-term risks associated with myeloablative conditioning include secondary malignancies, sterility, increased bone loss, delayed development in pediatric patients, neurocognitive changes, hypothyroidism, and cataracts.[226,227,228,229–232] After autologous HCT there is an increased risk of myelodysplastic syndrome.[233,234] Use of immunosuppression for chronic GVHD treatment was associated with an increased incidence of squamous cell cancer of the skin and oral cavity in allogeneic transplant recipients.[235] Risk factors for defective spermatogenesis are older age at transplantation and presence of chronic GHVD.[236] Rapid bone loss after transplantation can be partially corrected with the administration of bisphosphonate drugs.[237,238] Children may experience delays in growth and development particularly after exposure to TBI-based conditioning regimens which may be improved with growth hormone therapy.[239] Neurocognitive changes observed early after HCT largely recover at 1 year[240]; however, full recovery after HCT, especially psychological recovery, may be a 3- to 5-year process. Recovery might be accelerated by more effective interventions to increase work-related capabilities, improve social support, and manage depression.[241,242]

GRAFT-VERSUS-HOST DISEASE

GVHD is mediated by genetically disparate lymphocytes after transfer to an immunologically compromised recipient incapable of rejecting the donor graft (Chapter 105).[243] In the initial stages of GVHD, donor T cells recognize disparate histocompatibility antigens on host cells. Two primary classes of MHC exist. HLA class I antigens have a broad distribution and are expressed on all cells. HLA class II antigens are expressed on antigen-presenting cells, including macrophages, dendritic cells, B cells, and activated T cells. The mHC are genetic polymorphisms of endogenous cellular proteins that are presented to T cells as small peptides bound within the hypervariable grooves of MHC proteins. Some mHC which have been identified in humans as being associated with GVHD are HA-1 and the DBY (male-specific *mHA* gene).[244,245] The presence of multiple disparate mHC between the recipient and donor was associated with an increased mortality.[246] Single disparities of mHC may not be sufficient to result in a significantly increased risk of GVHD.[247]

The skin, liver, and gastrointestinal tract are the primary organs damaged by the GVH reaction. The cells which are targeted in the affected organs by the GVH reaction are primarily epithelial stem cells and their progeny.[248] In the liver, the epithelium of the small interlobular and marginal bile ducts is damaged by the GVH reaction. In tissues involved with GVHD, a lymphoid infiltrate is present and cell death occurs by apoptosis. In lymph nodes there is an absence of germinal centers which lasts for many months after HCT. Abnormal CD4:CD8 ratios can be found both in the lymph node as well as in the peripheral blood. The induction and release of signaling cytokines might be important in the development and severity of GVHD.[249] The IL-10 pathway may play an important role in controlling the severity of acute GVHD.[250,251] Plasma biomarkers for acute GVHD include IL-2-receptor-alpha, TNF-receptor-1, IL-8, and hepatocyte growth factor.[252] Regenerating islet-derived 3 α (REG3 α), secreted by Paneth cells, is a plasma biomarker for severe acute GVHD of the gastrointestinal tract.[253] In a multivariate analysis, stages 2 to 4 GVHD of the gastrointestinal tract, severe histologic damage, and high levels of REG3 alpha at GVHD diagnosis independently predicted nonrelapse mortality at 1 year.

GVHD has been traditionally classified into two different phases. Acute and chronic GVHD were defined as occurring before or after 3 months, respectively. However with increasing adoption

of nonmyeloablative conditioning regimens in which engraftment of donor T cells occurs more gradually, the distinctions between these two phases of GVHD has blurred.[189,254] Findings consistent with either diagnosis often occur concomitantly.

Acute

Clinical Evaluation

Acute GVHD involves three organ systems primarily—the skin, the gastrointestinal tract, and the liver. A maculopapular rash which can involve the palms and soles is often present and can be pruritic or painful. Bullae and epidermal separation may occur in severe cases and resembles toxic epidermal necrolysis. GVHD can also involve any part of the gastrointestinal tract. Symptoms and signs include nausea, vomiting, crampy abdominal pain, diarrhea, intestinal bleeding, and ileus. Lesions in the mouth may also occur. Patients may also present with persistent anorexia, nausea, and vomiting, and require endoscopy to evaluate the gastrointestinal tract for GVHD.[255,256,257] Permanent scarring with loss of mucosal regeneration may occur in very severe GVHD of the gastrointestinal tract.[258] Cholestatic jaundice is common in liver GVHD but hepatic failure due solely to GVHD of the liver is unusual unless the GVHD is long-standing. A biopsy of these organs may be required to confirm the diagnosis of GVHD and to distinguish it from other posttransplant complications.

The major determinant for the development of acute GVHD is the degree of HLA match. The increased incidence of acute GVHD in HLA-matched unrelated donor transplants is likely attributable to increased disparity in mHC antigens or unrecognized disparities of the phenotypically matched major histocompatibility loci. Other factors influencing the rates of acute GVHD include sex mismatch with the donor, parity of female donors, TBI dose, and acute GVHD prophylaxis regimen.[259,260,261] In peripheral blood HSC transplantation, the CD34-positive cell dose has been reported as an independent risk factor for acute GVHD.[262]

To facilitate the study and prognostication of acute GVHD, a clinical staging and grading system (Glucksberg) was developed and then updated in 1995 (Chapter 105).[50,263,264] Grade I or very limited acute GVHD has a favorable prognosis and does not require treatment. Therapy is usually required for grade II GVHD since it is moderately severe and usually affects multiple organs. Since patients with anorexia, nausea, and vomiting with positive biopsies for GVHD from the upper gastrointestinal tract usually require therapy, this was included as grade II. Grades III-IV GVHD are severe, affect multiple organs, and are associated with a decreased patient survival.[259] An acute GVHD severity index was also developed, grouping patients with patterns of organ involvement associated with similar risks of treatment-related mortality and treatment failure.[265] In a prospective evaluation of the two classifications, the performance was similar in explaining the variability in survival by acute GVHD grade.[266] An acute GVHD activity index has also been developed.[267] The activity index considers serum bilirubin, oral intake, treatment with prednisone, as well as performance, and may predict nonrelapse mortality better than either of the more commonly used clinical grading schema.

Prevention

The two major approaches to the prevention of acute GVHD after allogeneic marrow transplantation are pharmacologic immunosuppression and T-cell depletion. Agents for pharmacologic immunosuppression are generally more effective when used in combination. Methotrexate in combination with either cyclosporine or tacrolimus (both calcineurin inhibitors) are the pharmacologic agents used most commonly by transplant centers. In randomized controlled studies, the combination of tacrolimus and methotrexate was associated with a lower incidence of acute GVHD compared to cyclosporine and methotrexate, but there was no difference in the incidence of chronic GVHD or survival between the two groups (Fig. 102.7).[268,269] These agents may have significant adverse effects and therefore patients must be monitored closely. Methotrexate delays, but does not prevent, hematopoietic engraftment. Methotrexate also potentiates the mucositis associated with myeloablative conditioning regimens. Nephrotoxicity and neurotoxicity are complications associated with the administration of cyclosporine and tacrolimus.

Other immunosuppressive agents including corticosteroids and MMF have been studied in combination with cyclosporine. The addition of prophylactic corticosteroids to the combination of cyclosporine and methotrexate or to cyclosporine alone had only limited if any benefit, and in one study a paradoxical increase in chronic GVHD was observed in the corticosteroid arm.[270–272] MMF, a reversible inhibitor of inosine monophosphate dehydrogenase, has been successfully used in combination with cyclosporine for prevention of both GVHD and graft rejection after nonmyeloablative conditioning. The use of MMF instead of methotrexate in standard prophylaxis regimens after myeloablative conditioning regimens has been demonstrated to result in similar rates of acute GVHD, less mucositis, and faster neutrophil engraftment.[273,274]

Alternative methods of GVHD prophylaxis include ex vivo T cell depletion of the hematopoietic cell graft, in vivo T cell depletion and posttransplant cyclophosphamide. Strategies for ex vivo T cell depletion include the use of monoclonal antibodies which

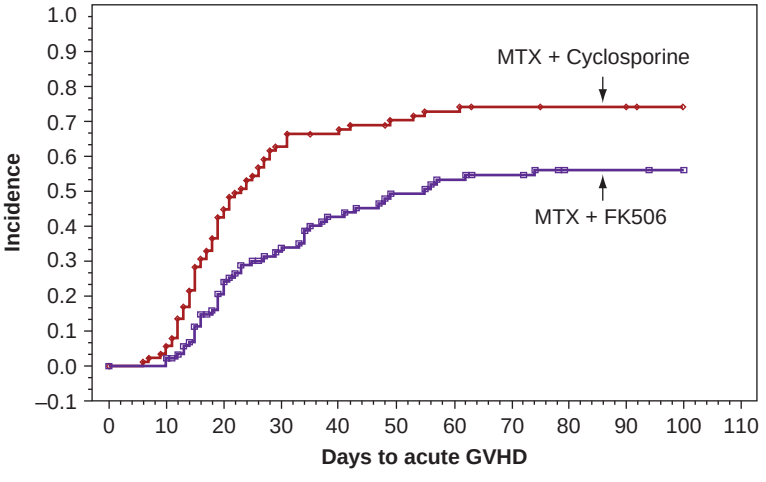

FIGURE 102.7. Kaplan-Meier estimate of acute graft-versus-host disease (GVHD). The combination of tacrolimus and methotrexate was compared to cyclosporine and methotrexate as GVHD prophylaxis after a myeloablative conditioning regimen followed by hematopoietic cell transplantation (HCT) from an human leukocyte antigen (HLA)-matched unrelated donor. There was less acute GVHD in the tacrolimus group at 100 days after HCT than the cyclosporine group (56% vs. 74%, respectively, $P = 0.0002$). (From Nash RA, Antin JH, Karanes C, et al. Phase 3 study comparing methotrexate and tacrolimus with methotrexate and cyclosporine for prophylaxis of acute graft-versus-host disease after marrow transplantation from unrelated donors. Blood 2000;96:2062–2068. Copyright American Society of Hematology, used with permission.)

are specific for T cells, selective agglutination to soybean lectin, and counter flow centrifugation elutriation. Although reduction in acute and chronic GVHD has been observed with transplantation of T cell-depleted marrow, there was an associated increase in graft rejection, infections, posttransplant lymphoproliferative disorders, and relapse. A randomized controlled trial did not demonstrate any survival benefits for ex vivo T cell depletion compared to standard pharmacologic immunosuppression for acute GVHD prevention after HCT from HLA-matched unrelated donors.[275] In vivo T cell depletion with pretransplant ATG and alemtuzumab was also effective for reducing the risks of severe acute and chronic GVHD after reduced intensity conditioning.[276] However, relapse rates were higher and overall survival was significantly decreased compared to the T cell replete group in the study. Relapses were not increased with in vivo T cell depletion if patients were conditioned with myeloablative regimens.

Posttransplant cyclophosphamide reduced the risks of both acute and chronic GVHD but until more experience has been obtained, it is not known if this approach will improve overall survival.[97,98]

Treatment

The most common agents used to treat acute GVHD have been corticosteroids and ATG. In many marrow transplant centers the administration of corticosteroids (methylprednisolone or prednisone-equivalent dose of 2 mg/kg/day) had been the standard initial treatment for acute GVHD.[277,278] In a retrospective analysis, it was observed that initial treatment with a lower dose of corticosteroids (methylprednisolone dose of 1 mg/kg/day) may be as effective as the higher dose, However, this needs to be confirmed in a prospective study.[279] Higher doses of methylprednisolone (10 mg/kg/day) did not improve outcomes.[280] Because complete remission of GVHD is seen in only 40% to 50% of the cases after initial or primary treatment, other immunosuppressive agents have been investigated in combination with prednisone. When a CD5-specific immunotoxin was added to prednisone for primary treatment, GVHD manifestations were more effectively controlled only during the first 5 weeks after start of treatment when compared to prednisone alone.[281] Similarly, no long-term benefit was observed when ATG was added to prednisone.[282] In a study of daclizumab in combination with prednisone as primary therapy, survival was significantly decreased compared to prednisone alone.[283] This suggested that caution must be used with approaches that intensify immunosuppression for primary treatment of acute GVHD. In a randomized clinical trial of primary treatment for gastrointestinal GVHD, a short course of prednisone in combination with either placebo or beclomethasone dipropionate (BDP), an oral topical agent with limited systemic absorption, was evaluated.[284] The use of BDP was associated with better control of upper gastrointestinal GVHD and improved survival at 200 days and 1 year posttransplantation. For steroid-refractory GVHD, immunosuppressive agents which have been studied include ATG, daclizumab, rapamycin, MMF, ABX-CBL (CD147-specific mAb), and pentostatin among others. Outcomes at 6 to 12 months after salvage therapy for steroid-resistant GVHD have been poor with a high transplant-related mortality.[285–290] There are no standard effective therapies for steroid-refractory GVHD which can be recommended.[291,292] Psoralen and ultraviolet A therapy for the skin may permit a decrease in systemic immunosuppression.[293] The massive secretory diarrhea of acute GVHD has been controlled in some cases with a somatostatin analog, octreotide acetate.[294]

Chronic

Clinical Evaluation

Chronic GVHD is a syndrome that may develop as early as 50 to 60 days or as late as 400 days after transplantation. The incidence of chronic GVHD is dependent on the degree of disparity in the MHC antigens. It was observed in 33% of HLA-identical sibling transplants, 49% of HLA-nonidentical related transplants, and 64% of HLA-matched unrelated transplants.[295] A prior history of acute GVHD is a significant risk factor for the development of chronic GVHD. Other risk factors for chronic GVHD are older age, female donor if male recipient, DLI, and use of peripheral blood stem cells.[296–298] Corticosteroid use for GVHD prophylaxis may also increase the risk of the development of chronic GVHD.[270,272]

Clinical features of chronic GVHD are skin lesions which may initially resemble lichen planus and may progress to generalized scleroderma, keratoconjunctivitis, oral mucositis, esophageal and vaginal strictures, intestinal abnormalities, chronic liver disease, pulmonary insufficiency secondary to bronchiolitis obliterans (BO), and a wasting syndrome.[299] If generalized scleroderma occurs, it may lead to joint contractures and debility. Elevations in alkaline phosphatase and serum bilirubin are often the first indication of hepatic involvement with chronic GVHD. Bile duct damage has a similar histopathology as that seen in primary biliary cirrhosis. Liver biopsies are often helpful in establishing a diagnosis. BO affects the small airways of the lung and may occur at less than 150 days (40%) or more than 150 days (60%) following HCT.[300] If serial pulmonary function tests show an evolving obstructive pattern, further testing is required including a high-resolution computed tomography scan to evaluate for the presence of BO. Keratoconjunctivitis sicca is a common but irreversible complication that is managed with frequent eye drops and tear duct ligation.

Screening studies and clinical manifestations of chronic GVHD are used in a clinical classification of chronic GVHD. Based on a retrospective clinical and pathologic review from 1980, a staging system was developed in which chronic GVHD was classified into limited and extensive. Extensive disease was associated with more frequent infections.[299] The utilization of this original classification system was difficult because many patients were not easily classifiable by strict organ criteria and thus other significant prognostic factors have since been identified. Poor prognostic factors were extensive skin involvement, thrombocytopenia, and progressive-type onset.[301,302] In 2005, the NIH consensus criteria were developed to standardize the criteria for the diagnosis of chronic GVHD.[303] A clinical scoring system (0 to 3) described the extent and severity of chronic GVHD for each organ or site at any given time, taking functional impairment into account. A global assessment of chronic GVHD severity (i.e., mild, moderate, or severe) was then calculated based on the number of organs or sites involved and the degree of involvement in the affected organs. Diagnosis of chronic GVHD required at least 1 clinical sign or manifestation of chronic GVHD confirmed by biopsy or other relevant test and the exclusion of other possible diagnoses for those clinical symptoms considered to be chronic GVHD. Subtypes of late GVHD (>100 days) were recognized, including late onset acute GVHD, classical chronic GVHD, and an overlap syndrome (clinical symptoms of both acute and chronic GVHD).

Prevention

Several strategies to prevent the development of chronic GVHD have been pursued but none have made a significant impact on long-term overall survival. Prolonged administration (24-month course vs. 6-month course) of cyclosporine demonstrated no significant differences between the groups in the incidence of chronic GVHD, transplant-related survival, or overall survival.[304] T cell depletion was associated with lower rates of chronic GVHD in HLA-matched sibling transplants, but not in the unrelated donor setting. No improvement in overall survival was associated with T cell depletion.[305] Inclusion of alemtuzumab or ATG in the conditioning regimen was associated with a reduction in chronic GVHD.[276,306,307]

Treatment

Extensive chronic GVHD that is left untreated has a poor prognosis. In general, based on the NIH consensus criteria, topical or local therapy is recommended for mild chronic GVHD, and systemic immunosuppression for moderate or severe chronic GVHD. In an original report of chronic GVHD, only 2 of 13 patients survived and there was the development of significant morbidity.[299] Prednisone given for 9 to 12 months reversed many of the signs and symptoms of disease. The mortality in the group treated with prednisone was 21%.[308] Patient survival was worse with the combination of azathioprine and prednisone compared to prednisone alone.[302] The combination of cyclosporine and prednisone was first used in patients with high-risk chronic GVHD who had a platelet count less than 100,000. The results of this study appeared promising compared to historical controls.[309] There was a trend toward improved survival and decreased morbidity. In contrast, a randomized study of combination therapy versus prednisone alone for standard-risk chronic GVHD suggested that more intense immunosuppression did not improve survival.[310] A report of a randomized clinical trial in 2009 comparing MMF plus prednisone to prednisone only as primary treatment for chronic GVHD did not show any benefit.[311] Standard practice for primary treatment of patients with moderate-severe chronic GVHD remains systemic immunosuppression with prednisone. There is no evidence that additional immunosuppression is beneficial. In practice, patients with extensive chronic GVHD are treated for a period of 9 to 12 months. At the end of this period, a reevaluation is done and, if there is no evidence of active chronic GVHD, the immunosuppressive agents are tapered. Other therapies which have been reported to have some limited efficacy for treatment of chronic GVHD are extracorporeal photopheresis for skin and oral GVHD and ursodeoxycholic acid treatment for GVHD of the liver.[312–314] There is insufficient data to make strong recommendations regarding treatment of steroid-refractory chronic GVHD.

By 3 to 5 years after initiation of therapy, many patients have inactive chronic GVHD and immunosuppressive therapy has been discontinued (Fig. 102.8).[90] Approximately 75% of patients treated for extensive chronic GVHD will survive with Karnofsky scores of greater than 80%. The major cause of excess mortality in patients with clinically extensive chronic GVHD is infections.

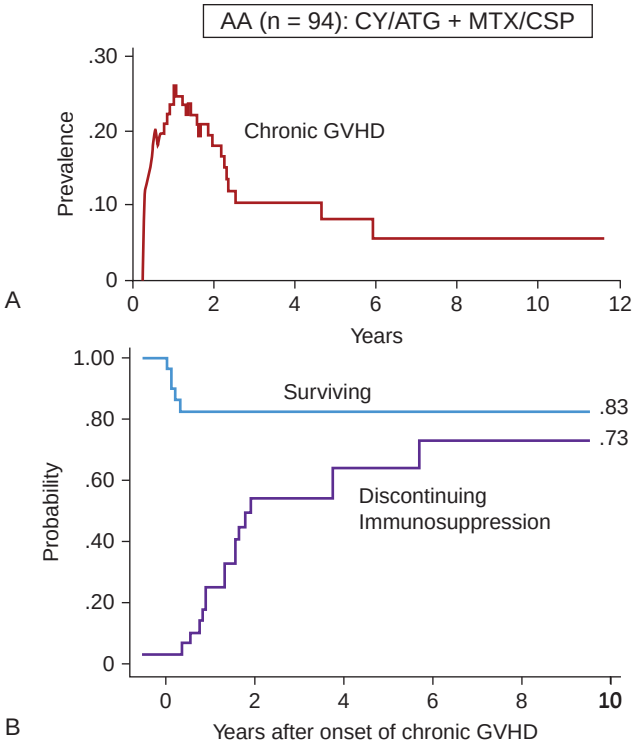

FIGURE 102.8. A: Prevalence of chronic graft versus host disease (GVHD) after allogeneic marrow transplantation from human leukocyte antigen (HLA)-identical sibling for aplastic anemia. The prevalence curve accounts for the time of onset of chronic GVHD and the time of its resolution in response to therapy. **B:** Probability of survival among the 29 patients with chronic GVHD (83%) and probability of discontinuing immunosuppression given for chronic GVHD (73%). (Modified from Storb R, Blume KG, O'Donnell MR, et al. Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. Biol Blood Marrow Transplant 2001;7:39–44. Used with permission.)

GRAFT-VERSUS-TUMOR EFFECT

Allogeneic immune surveillance or GVT reaction for malignancy contributes significantly to the therapeutic effectiveness of HCT. The term GVT refers to the GVL effect, the graft-versus-myeloma effect, as well as the effects on solid tumors by the graft. The first clinical report of a GVT effect after allogeneic marrow transplantation was published in 1979.[315] It was observed that patients who developed GVHD had a lower risk of relapse after transplantation. In 1990, Kolb and colleagues successfully treated 3 patients with CML who relapsed after marrow transplantation with DLI from the original HLA-identical sibling marrow donor.[316] In a subsequent report evaluating DLI in 135 patients with relapsed disease, complete remissions were achieved in 72% of CML patients and 29% of patients with AML.[317] No responses were observed in patients with acute lymphoblastic leukemia. Chemotherapy to induce remission before DLI was a more effective strategy for long-term disease control for some patients with acute leukemia. GVHD and myelosuppression developed in 41% and 34% of patients, respectively, after DLI. Fourteen patients (10%) died from complications related to GVHD or myelosuppression. Another large study of 140 patients with relapsed malignancy after marrow transplantation confirmed the effectiveness and risks of DLI after relapse.[318] Notably in both studies, GVHD after DLI correlated with disease response. The durability of the responses was confirmed with longer follow-up of patients who had achieved complete remission after DLI.[319]

The number of CD3-positive cells infused (or DLI dose) is an important parameter in determining clinical response and risk for development of GVHD.[320] Patients with CML had a lower risk of GVHD, and the efficacy of treatment was maintained with a strategy of escalating the dose of donor lymphocytes based on response of disease and development of GVHD.[321] Comparable results with DLI from unrelated donors have also been demonstrated.[322] The response, severity of GVHD, and the degree of myelosuppression were similar to that observed after DLI from HLA-matched sibling donors.

After nonmyeloablative conditioning and allogeneic HCT, the GVT effect is the main contributor to the disease response. Disease responses have been observed in both myeloid and lymphoid hematologic malignancies. Since the establishment of a GVT effect may not be achieved for 2 to 3 months after HCT, malignant disease needs to be controlled before HCT. Several retrospective studies have now shown comparable overall survival after either myeloablative or nonmyeloablative conditioning and HCT.[185–187,323] However, all these studies showed relapse was higher and transplant-related mortality was lower after a nonmyeloablative conditioning regimen. In a randomized clinical trial of reduced intensity conditioning with TBI (800 cGy) and fludarabine compared to TBI (1,200 cGy) and cyclophosphamide in patients with AML in first remission, there were no differences in transplant outcomes including relapse and nonrelapse mortality except for increased severity of oral mucositis in the TBI (1,200 cGy) group.[151]

Although patients may have an excellent response to allogeneic HCT, severe GVHD may occur. Separation of GVHD from GVT

effects may be possible because of disparate hematopoiesis-associated mHC molecules or tumor-restricted antigens on malignant cells.[324] These tissue or tumor-restricted antigens could serve as targets for T cell immunotherapy to enhance GVT activity without inducing GVHD. Peptides identified as minor histocompatibility molecules have been isolated and sequenced.[325,326–330] Cytotoxic T lymphocytes (CTL) clones specific for recipient mHC antigens have been generated ex vivo.[331] These were infused into 7 patients who had relapsed after HCT. Pulmonary toxicity was seen in three patients and in one it was severe. The CTL circulated for 21 days, and five patients had complete but transient remissions. The contribution of natural killer (NK) cells to the antitumor effect after allogeneic HCT has also been investigated.[332] For AML, a disease with sensitivity to NK-mediated activity, NK cells from unrelated donors encoding the activating killer-cell immunoglobulin-like receptor KIR2DS1 was associated with improved relapse-free survival in an HLA-C-dependent manner. These studies may help to explain the mechanisms associated with a GVT effect after allogeneic HCT, and in the future this information might be helpful for improving outcomes.

IMMUNE RECONSTITUTION

After myeloablative therapy and autologous or allogeneic transplant, both humoral and cellular immunity are impaired for months to years. After autologous HCT, NK cells in the peripheral blood recover by 1 month and B cells and CD8+ T cells recover by 3 to 6 months after HCT. However, CD4+ T cells are not restored to normal levels until 1 to 2 years after HCT.[333,334] After allogeneic transplantation, recovery of the immune system from the donor graft occurs in phases over a period of 1 to 2 years in patients who do not develop GVHD. There are significant delays in recovery of the immune system if GVHD develops.

The first phase of recovery is the increase in neutrophil counts which occurs 2 to 3 weeks after transplantation. Although the function of neutrophils is largely intact, impaired chemotaxis persists for a period up to 4 months.[335] Monocyte numbers in the peripheral blood return to normal within 3 to 4 weeks after transplantation. Monocyte counts in the peripheral blood were inversely correlated with infection rates between days 100 and 365.[336] Macrophages in the liver and lung have been shown to be of donor type by day 80. NK cells and other cell types capable of antibody-dependent cytotoxicity have recovered to normal levels by 30 days after transplantation. The recovery of the donor-derived immune system is important in the understanding of the GVT effect and complications after HCT, including graft rejection, GVHD, and infections.

B Cells

There are defects in serum immunoglobulin production initially after the transplant. Serum antibody responses to different antigens, including ØX174, keyhole limpet hemocyanin, pneumococcal antigen, and meningococcal antigen are lower than normal.[337–339] The defect in antibody production occurs in both T cell–dependent and T cell–independent systems. B lymphocytes respond to mitogenic stimulation including staphylococcal aureus and cross-linked anti-IgM antibodies after 2 months. By 3 months after transplantation, B lymphocytes with surface immunoglobulin have recovered to normal levels. Persistent deficiencies in B lymphopoiesis have been described in association with GVHD (acute or chronic) or its treatment.[340] The number of B cell precursors in the marrow was not related to CD34 cell dose, type of transplant, donor age, or recipient age.

Serum IgG and IgM have typically achieved normal levels 1 year after transplantation in the absence of chronic GVHD.[337] Serum IgA may remain low for a period of 2 years. If serum IgG levels are below 400 g/L, patients are generally treated with intravenous immunoglobulin.

T Cells

Reconstitution with donor T cells is poor initially in all recipients and remains defective in patients with chronic GVHD. Because of the faster recovery of CD8 positive T cells, a reversed CD4:CD8 ratio with low levels of CD4-positive cells has been demonstrated and persists in patients with chronic GVHD. In vivo cellular immunity, determined by skin testing to the recall antigens Candida, mumps, trichophyton, and the neo-antigen dinitrochlorobenzene, is diminished, but may be prolonged if chronic GVHD develops.[341] In in vitro assays, donor T cells from patients have a decreased proliferation to mitogenic stimulus with phytohemagglutinin (PHA) and CD3-specific antibody. After 3 months the addition of exogenous IL-2 can normalize the proliferative response to PHA stimulation.[342,343] By 6 months the response to PHA stimulation has normalized without the requirement for exogenous IL-2. T cell immunity to herpes simplex virus (HSV) can be detected by day 40.[344] CTL function against varicella-zoster virus (VZV) and CMV is acquired later (≥3 months). Acquisition of T cell immunity to herpes virus may be delayed by prophylaxis of viral infections with anti-viral agents or GVHD treatment.[345,346]

Immunity early after myeloablative conditioning and allogeneic transplantation is restored by the adoptive transfer of mature T cells and may establish cellular immunity to infectious agents such as the herpes viruses.[96,346,347,348] Vaccination protocols may also improve the pathogen-specific cellular immunity. An inactivated varicella vaccine given before, and during the first 90 days after, transplantation significantly reduced the risk for the development of varicella-zoster infections.[349] CD4 T cell proliferation in response to the VZV was greater in patients who received the vaccine. Immune function after HCT may also be improved with the use of a peripheral blood stem cell graft. There were higher lymphocyte subset counts after HCT, and the rate of definite infections was significantly decreased compared to marrow.[350] T cell–depleted HCT or therapy for active GVHD has been observed to delay the recovery of cellular immunity, thus resulting in an increased risk of infections. The thymus contributes to late immune reconstitution.

T cell recovery is improved in younger patients compared to older patients, an affect attributable to the improved thymic function in the former group. Increased thymic output (i.e., high TREC levels) was associated with an increased number of naive T cells and broader T cell repertoires, while low TREC levels correlated with the presence of chronic GVHD and severe opportunistic infections.[351,352] Thymic rebound correlated with the capacity to respond to vaccinations.[353] Measures to enhance thymic output after transplantation, especially in older patients, may enhance immune reconstitution and decrease the risk of infections.

CHAPTER 103

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR NONMALIGNANT DISORDERS

Jacob R. Garcia, Mark C. Walters

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) has expanded significantly over the past several decades as a consequence of broader utilization in the treatment of malignant and pre-malignant conditions such as acute leukemia and myelodysplastic syndrome, respectively.[1,2] A parallel wider application also has evolved for nonmalignant disorders, such as hemoglobinopathies, primary immunodeficiency disorders (PIDs), inborn errors of metabolism, marrow failure syndromes, and other acquired and hereditary hematologic disorders, particularly among pediatric recipients.[3–6] Although supportive care for many of these conditions also has improved over this same period of time, long-term toxicity and morbidity of nontransplant interventions (e.g., chronic blood transfusions and iron overload) have a negative impact on the quality of life and can also cause early mortality.[7] Thus, HSCT for nonmalignant disorders represents an alternative curative option for many patients who might otherwise succumb to complications of the underlying condition. In this chapter, we delineate and describe representative hereditary hematologic diseases for which HSCT is an option, review outcomes after HSCT in patients with these disorders, and outline the long-term effects of the therapy.

CONDITIONS SUITABLE FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION

A broad array of hereditary and acquired nonmalignant disorders derives from selected hematopoietic cell lineages, which by virtue of their origin in the hematopoietic stem cell, also are theoretically amenable to cure by successful HSCT. Rather than attempt to catalog all these disorders, three broad categories of disorders have been selected to illustrate how and when to apply this therapeutic intervention.

The first of these are the PIDs, which classically are illustrated by the child with severe combined immunodeficiency syndrome (SCIDS) where there is absent B- and T-lymphocyte function. In these individuals, life-threatening infections occur in the first months of life and portend early mortality.[8] Because there is no immunologic barrier to donor engraftment, marrow from an HLA-identical sibling can be infused in the absence of any pre-transplant immunosuppressive therapy. Thus, these were among the first cases in which the proof-of-principle of HSCT was demonstrated.

The next group of disorders are the hereditary bone marrow failure syndromes, of which Fanconi anemia (FA) is a prototypic example. Fanconi anemia is caused by a heterogeneous collection of defects in genes that encode proteins involved in DNA repair.[9] This deficiency is associated with a variable phenotype that includes progressive aplastic anemia, musculoskeletal and other congenital defects, and cancer predisposition (particularly to myelodysplastic syndrome, acute myelogenous leukemia, and carcinoma of the skin and oropharynx).[10] Although the hematologic manifestations of this condition are eliminated after successful HSCT, donor selection, modulation of the conditioning regimen, and the possibility of malignant transformation in the marrow together make this a challenging disease to treat by HSCT.

Finally, the broad category of hemoglobin disorders is discussed.[11] These disorders differ from the others because the immune and hematopoietic systems are intact before HSCT, and a proliferative marrow develops as a consequence of chronic anemia and ineffective erythropoiesis. Thus, the conditioning regimen before HSCT for the hemoglobin disorders typically requires a combination of ablative and immunosuppressive activities. In addition, there is a marked variability of clinical phenotype in sickle cell disease, which affects the decision making about when and in whom to consider this aggressive therapy.

Together, these broad examples of nonmalignant conditions illustrate the variety of clinical and genetic parameters one must consider in selecting appropriate transplantation candidates and regimens. These considerations are highlighted in the sections that follow.

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCY DISORDERS

PIDs classically are associated with significant morbidity and early mortality caused by life-threatening infections in the first months and years of life. Before the availability of HSCT, these infections invariably caused death in the vast majority of affected children. SCIDS is the most widely recognized manifestation of a PID. SCIDS is a genetically heterogeneous group of over 20 mutations in 13 genes identified to date that result in the common phenotype of impaired T-cell production and/or function (Table 103.1). These mutations in varied target genes lead to impaired immunity as a consequence of absent T-cell function, but often defects in B-cell and natural killer (NK) cell number or function occur in parallel, as many of the genes affect all three lineages. However, the level of B- and NK-cell activity is highly variable. In rare cases, autoimmune phenomena are observed in these patients.[13] This is particularly noteworthy in children with Omenn syndrome, which is caused by mutations in genes that participate in rearrangements of T-cell receptors and VDJ regions of immunoglobulins. Mutations in these genes elicit a phenotype that mimics graft-versus-host-disease as a consequence of the expansion of T-cell clones that are reactive to self-antigens. There is also reduced peripheral and central tolerance in these patients, which contributes to the observed phenotype.

Preparative Regimen

The first transplant for SCIDS using an HLA-matched sibling bone marrow donor was performed in 1968.[14] In this case, no preparative regimen was administered to prevent graft rejection due to the absence of an immunologic barrier to engraftment. Thus, donor hematopoietic stem cells simply were infused and successful immune reconstitution followed. However, fatal graft-versus-host disease (GVHD) often occurred in donor/recipient settings in which there was a major HLA disparity. By testing transplantation in animal models of SCIDS, it was determined that by using the technique of donor T-cell depletion, it was possible to eliminate GVHD after HLA-mismatched HSCT, if thorough T-cell depletion was accomplished.[15,16] In addition,

TABLE 103.1

MOLECULAR CAUSES OF SEVERE COMBINED IMMUNODEFICIENCY

Gene Defect	Defective Protein, Function, Features	Percentage of SCID[a] Cases	Lymphocyte Profile		
			T[b]	B	NK
IL2RG (X-linked)	Common γ-chain (γc) of receptors for IL-2, -4, -7, -9, -15, and -21	45–50 (only males)	−	+	−
ADA	Adenosine deaminase enzyme	16	−	+	−
IL7R	α-Chain of IL-7 receptor	9	−	+	+
JAK3	Janus kinase 3, activated by γc	6	−	+	−
RAG1, RAG2	Recombinase activating genes required for T- and B-cell antigen receptor gene rearrangement	5	−	−	+
DCLRE1C (Artemis)	Part of T- and B-cell antigen receptor gene rearrangement complex, also required for DNA repair	<5	−	−	+
TCRD, TCRE, TCRZ	CD3 δ, ε, and ζ chains of the T-cell receptor complex, required for T-cell development	Rare	−/low	+	+
CD45	Protein tyrosine phosphatase receptor (PTPRC), required for T-and B-cell activation by antigen	Rare	−/low	+	+/low
LCK	Lymphocyte tyrosine kinase p56lck, required for T-cell development and activation	Rare	−/low	+	+
PNP	Purine nucleoside phosphorylase enzyme; deficiency also causes neurologic impairment	Rare	Low	Low	+/low
LIG4	DNA ligase IV required for antigen receptor gene rejoining	Rare	−	+	+
DNAPKCS	DNA protein kinase catalytic subunit, required for T- and B-cell antigen receptor rearrangement, and DNA repair	Rare	−	−	+
NHEJ1 (Cernunnos)	Nonhomologous end joining of DNA; deficiency also causes microcephaly and radiation sensitivity	Rare	−	−	+
AK2	Adenylate kinase 2; deficiency causes reticular dysgenesis with granulocytopenia, lymphocytopenia, and deafness	Rare	−	−	−
FOXN1	Forkhead box N1, required for thymus and hair follicle development (ortholog of nude mouse)	Rare	−/low	+	+
STAT5a	Signal transducer and activator of transcription 5, phosphorylated after cytokine receptor engagement; deficiency also causes growth-hormone–resistant growth failure	Rare	−/low	+	−
CORO1A	Coronin-1A, protein mediating lymphocyte migration and T-cell emigration from the thymus	Rare	−/low	+	+
Currently unknown	Unknown defects, including SCID and congenital anomalies; SCID with multiple bowel atresias	~10	−/low	+/−	+/−

[a]Based on Buckley,[18] Puck[25] and Lindegren et al.[12]
[b]Some patients have substantial numbers of maternally derived T-cells at time of diagnosis; autologous T-cells are shown.

after successful HSCT in the mouse, there was durable engraftment of the donor cells with restored host immunity. However, even in the earliest clinical reports of HSCT after T-cell depleted HLA-haploidentical HSCT for SCIDS, B-cell engraftment was quite poor, as most patients required long-term immunoglobulin replacement after HSCT.

In a cohort of 161 patients treated by HSCT at a single U.S. institution, Railey et al. reported the results in individuals with SCIDS who received no pre-transplant chemotherapy or GVHD prophylaxis.[17] Notably, only 16 (10%) of these patients had HLA-identical sibling donors, and thus most received T-cell depleted HLA-haploidentical marrow. In this clinical series, it

was observed that survival was highest among those patients who were transplanted before 3.5 months of age (94% compared to 70%, $P = 0.002$). Of those who died, the majority (76%) experienced progressive viral infections that pre-dated HSCT. There were very few deaths related to GVHD or infections that were acquired after HSCT. Thus, this series suggested that no chemotherapeutic preparation is necessary in patients with SCIDS who are treated by HSCT shortly after birth. However, many patients require regular immunoglobulin (IVIG) infusions after successful HSCT for SCIDS due to absent engraftment of donor B-cells, particularly in the absence of a conditioning regimen before HLA-haploidentical related donor HSCT in recipients with B-cell positive SCIDS.[18,19]

Long-term follow-up of patients showed mixed results regarding the stability of long-term donor T-cell engraftment after HLA-haploidentical HSCT in the absence of a conditioning regimen before HSCT. With up to 25 years follow-up in a report by Buckley, 11 of 19 patients had no evidence of decreased T-cell function or diminished T-cell repertoire diversity. However, as noted above, most patients lacked donor B-cell engraftment and thus received long-term replacement immunoglobulin therapy.[8] In another series that included survivors with up to 16 years follow-up, 35% of the patients had low T-cell antigen receptor excision circle (TREC) levels and a limited T-cell repertoire as evidenced by oligoclonality that was demonstrated in 27.5% of patients.[20] Based upon these observations, it has been suggested that the use of an ablative conditioning regimen before HSCT may be required to ensure long-term T-cell engraftment in the setting of HLA-haploidentical donors.

Whether improved T-cell engraftment translates into improved survival remains in question, however. Patel et al. retrospectively reviewed a series of 22 patients with SCIDS who were treated by HSCT at a single institution.[21] In this series, no statistical difference in overall survival was with respect to whether a preparative regimen was administered regardless of donor type. In addition, experience from a large European cohort treated between 1968 and 2005 showed that chemotherapeutic preparation did not improve overall survival in patients with SCIDS.[22] These authors argued that a conventional ablative chemotherapeutic preparation does not improve survival in patients with SCIDS, particularly in those who undergo HSCT in the first 3½ months of life. Unfortunately, proceeding directly to HSCT early in life is not always feasible, as affected individuals often are not identified in the first several months of life or before they have developed serious infections. Thus, the decision of whether to use a conditioning regimen should hinge on several salient clinical features, including the patient's age, the donor, and the baseline immunologic function with regard to resistance to donor engraftment. Also, recipients with SCIDS who have a T–/B+ lymphocyte profile appear to have better outcomes than recipients who lack B-cells.[23] The advent of pilot newborn screening programs by TREC screening from blood spots has the potential to mitigate the limitation of patient age.[24–26]

Reduced Intensity Conditioning

To date, optimization of a conditioning regimen that might be safely applied in all patients with SCIDS has been elusive. In an attempt to reduce transplant-related morbidity and mortality, reduced intensity conditioning regimens that are not ablative and contain a diverse array of immunosuppressive agents such as fludarabine, busulfan (BU), etoposide, cyclophosphamide (CY), and low-dose radiation have been tested.[27,28,29] Current data suggest that reduced intensity regimens are most appropriate in recipients with T-cell deficiency syndromes and in unrelated donor HSCT.[30,31] However, graft rejection associated with inadequate suppression of residual host immune function remains a concern, particularly in patients with T- and NK-cell function at baseline. Ultimately, the selection of a preparative regimen and its intensity will vary according to the level of retained immunity in the recipient, and with the degree of HLA matching in donor hematopoietic cells.

Donor Source

HLA-identical marrow HSCT has yielded very good results in SCIDS, with approximately 70% to 80% of patients surviving long-term[32] (Fig. 103.1). Because most patients lack a HLA-ID sibling donor, alternative donor sources have been explored in clinical trials. Roifman et al. reviewed transplant outcomes after HLA-mismatched related donor HSCT compared to HLA-matched unrelated donor HSCT for SCIDS.[33] They reported that survival was superior in those receiving HLA-matched unrelated marrow. Specifically, patients who received a HLA-matched unrelated HSCT had better engraftment and immune reconstitution. They concluded that HLA-matched unrelated marrow transplantation is superior to HLA-mismatched related donor HSCT and should be considered as the first choice when a related HLA-identical donor is unavailable. In other patient series noted above, excellent results were observed after T-cell depleted HLA-haploidentical HSCT. Thus, the optimal donor source for HSCT remains a point of controversy.

More recently, the application of umbilical cord blood transplantation (UCBT) has been explored in SCIDS. Fernandes et al. recently compared results after HLA-mismatched related donor and unrelated donor UCBT in patients with SCIDS.[34] There were 175 HLA-mismatched donor HSCT recipients and 74 UCBT recipients in this retrospective cohort of patients with SCIDS or Omenn syndrome. The median follow-up was 58 and 83 months in each group, respectively. Most UCBT recipients received a myeloablative preparative regimen, whereas a larger fraction of the related donor recipients did not. UCBT recipients were more likely to have complete donor chimerism and faster lymphocyte recovery independent of the preparative regimen. T-cell engraftment was equivalent in the two groups, and immunoglobulin replacement was discontinued earlier after transplantation in the UCBT group. There was a statistically insignificant higher incidence of grade II–IV acute GVHD and statistically significant rate of chronic GVHD after UCBT. However, the 5-year overall survival rates were equivalent. Other data suggest that B-cell engraftment may be better after UCBT.[35] Although a randomized, prospective trial has not been performed, these data indicate that UCB appears to represent a suitable alternative donor source.

Late Effects and Future Directions

There are limited series of long-term follow-up after HSCT for SCIDS in which the follow-up period exceeds 10 years.[20,21,36] In several of these series, loss of T-cell diversity and autoimmune disorders was observed late after HSCT, although follow-up through 25 years after HSCT suggests improvement in the T-cell repertoire.[37] In addition, patients with adenosine deaminase deficiency in particular have experienced a high incidence of central nervous system abnormalities that include motor dysfunction, sensorineural hearing loss, and cognitive deficits that contribute to emotional and behavioral difficulties.[20] In addition, chronic infection by human papilloma virus also has been reported.[20] It is unclear which, if any of these, is related to pre-transplant conditioning and GVHD prophylaxis or to the underlying genetic defect. Finally, for those who lack a transplant donor, gene therapy is an alternative therapy for some patients, although development of this technology is ongoing.[38] A consensus group has discussed plans for future multicenter studies in North America, both retrospective and prospective, focused on collecting data from newborn screening and natural history sources.[39] The importance of collaboration in developing new protocols for these rare disorders

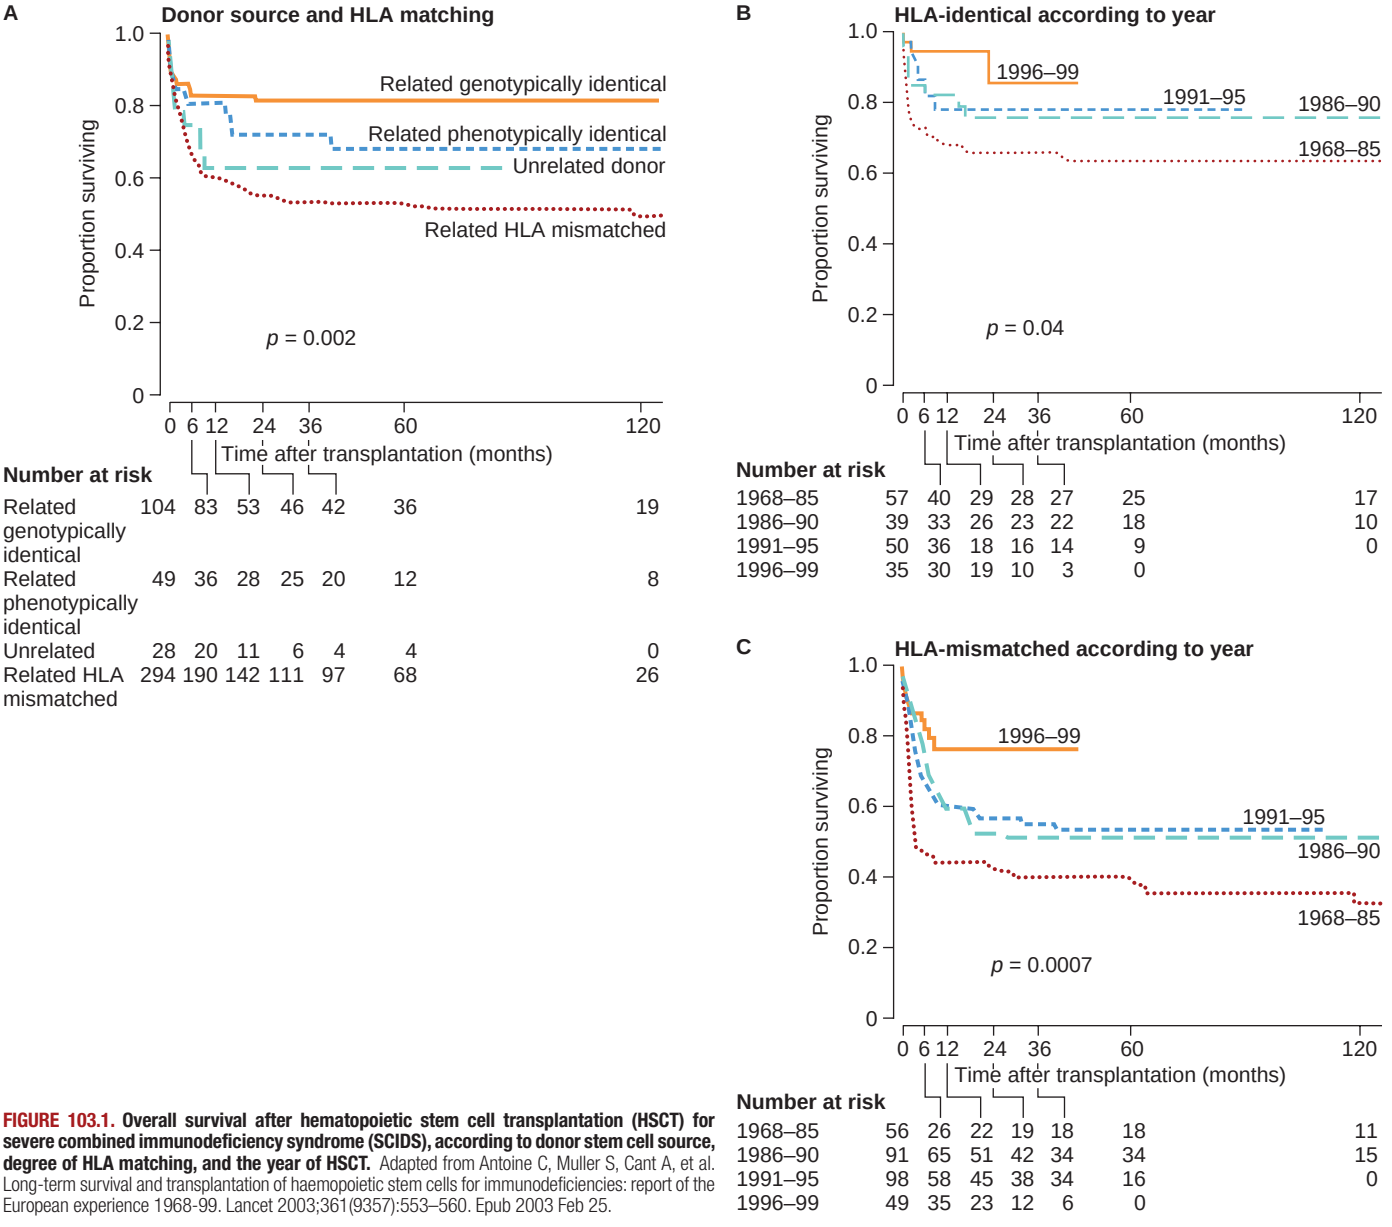

FIGURE 103.1. Overall survival after hematopoietic stem cell transplantation (HSCT) for severe combined immunodeficiency syndrome (SCIDS), according to donor stem cell source, degree of HLA matching, and the year of HSCT. Adapted from Antoine C, Muller S, Cant A, et al. Long-term survival and transplantation of haemopoietic stem cells for immunodeficiencies: report of the European experience 1968-99. Lancet 2003;361(9357):553–560. Epub 2003 Feb 25.

was illustrated best by recent data showing that long-term mortality rates for both SCIDS and non-SCIDS patients with a PID are higher than their age- and gender-matched controls in the general population.[40]

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR FANCONI ANEMIA

Fanconi anemia is the most common hereditary cause of bone marrow failure. The genetic defect responsible for these findings has been characterized in 15 complementation groups, termed *FANC* genes, most of which are autosomal and recessive (Table 103.2).[41,42] The most common mutations occur in *FANCA, FANCC, FANCG*, and *FANCD2* genes. These gene products participate in a signal transduction pathway involved in DNA repair, called the FA/BRCA pathway (Fig. 103.2).[43] Thus, its diagnosis is confirmed by a chromosome fragility test that when positive, should be followed by an attempt to define the complementation group by DNA testing.

The most common hematologic manifestation is progressive marrow aplasia that causes cytopenias in the blood, which typically occur in the first or second decade of life.[44] Erythrocyte macrocytosis and elevated fetal hemoglobin often are present. In some cases, the diagnosis of FA will not be established until after the patient has developed myelodysplastic syndrome or AML. Some patients never develop pancytopenia but do experience an increased risk of malignancy. Based upon studies of a cohort of FA patients at the NCI, the risks of developing MDS and AML by age 50 are estimated to be 40% and 10%, respectively.[45,46] The overall survival and cancer-free survival in this cohort is shown in Figure 103.3 with a median overall survival of 33 years in those with FA.

Because of poor survival, HSCT was developed as a therapeutic measure to restore normal hematopoiesis and reduce or eliminate the risk of hematologic malignancy. There were several important

observations generated in the early clinical trials. The first was that high-dose alkylating chemotherapeutic drugs at doses administered for severe aplastic anemia and gamma irradiation caused severe toxicity including mucositis and hemorrhagic cystitis as a consequence of the sensitivity to DNA damage in all tissues.[47,48] Second, the risk of acute GVHD was increased in comparison to other indications for HSCT, presumably also as a consequence of impaired DNA repair and an extended duration of tissue injury eliciting an allogeneic reaction by donor T-cells.[49] The initial reports by Gluckman and her colleagues in 1984 showed that a reduced-dose regimen of CY (20 to 40 mg/kg) and a single fraction of total body irradiation or thoracoabdominal irradiation (400 to 450 cGy) effectively modulated the toxicity and was sufficient to ensure engraftment after HLA-ID sibling bone marrow transplantation with a long-term survival rate of 58.5%, although the rates of acute (55%) and chronic (70%) GVHD were quite elevated.[50] However, an updated experience of this regimen in 35 patients was reported in 2007, and included antithymocyte globulin (ATG) in the conditioning regimen.[51] These results showed a probability of survival of 89% at 10 years, with the incidence of acute and chronic GVHD at 23% and 12%, respectively.

Several other notable improvements have occurred in the 25 years since these initial results after HSCT for Fanconi anemia were reported. The elimination of irradiation from the conditioning regimen has been associated with better results. In a series from Saudi Arabia, the replacement of thoracoabdominal irradiation by a combination of CY with ATG generated better results after HLA-ID sibling bone marrow transplantation (overall

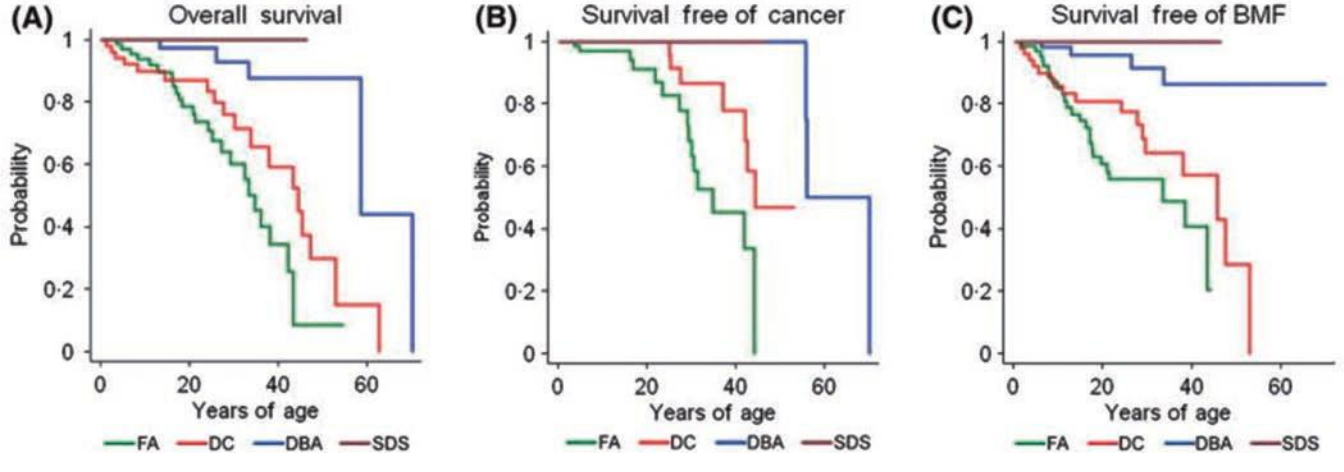

FIGURE 103.3. Survival, cancer-free survival, and survival free of marrow failure in a cohort of patients with bone marrow failure syndromes from the National Cancer Institute. The probabilities of overall survival (A), survival free of cancer (B) and survival free of bone marrow failure (C) are depicted in the 3 panels among patients with Fanconi Anemia, Dyskeratosis Congenita, Diamond-Blackfan Anemia, and Schwachman-Diamond Syndrome. From Alter BP, Giri N, Savage SA, et al. Malignancies and survival patterns in the National Cancer Institute inherited bone marrow failure syndromes cohort study. Br J Haematol 2010;150(2):179–188. Epub 2010 May 29.

survival 96.9% versus 72.5%, $P = 0.013$).[52] Alternatively, the use of CY alone at a reduced dose of 60 mg/kg by investigators in Brazil generated an overall survival and event-free survival 93% and 88%, respectively, with acute and chronic GVHD occurring in 71% and 28.5% of recipients after HLA-ID sibling transplantation.[53] Thus, in patients who have a HLA-ID sibling donor and who have not yet progressed to MDS or AML, the results of the reduced intensity conditioning regimens are excellent. In addition, by eliminating radiation from the conditioning regimen, the risk of developing a malignancy after transplantation also should be lowered.

Another important discovery was the benefit of fludarabine in the conditioning regimen, which effectively reduces the rate of graft rejection, in particular after alternate donor HSCT, without contributing significantly to toxicity.[54,55] The application of unrelated donor HSCT to Fanconi anemia is vital to expanding this treatment modality, as most individuals with FA lack a sibling donor. Initial trials of unrelated donor HSCT in which the same regimen of low-dose CY and irradiation was used were plagued by high rates of graft rejection, organ toxicity, and GVHD, with overall survival in the 30% to 40% range.[56,57] The escalation of the dose of radiation to 600cGy and the addition of ATG did little to improve overall survival.[58] However, in a retrospective analysis of the effect of fludarabine in the conditioning regimen, a significant impact was noted.[59] The probability of neutrophil and platelet recovery after HSCT improved from 69% to 89% and from 23% to 74%, respectively, and this translated in a lower transplant-related mortality (47% compared to 81%). The 3-year overall survival was 52% in those who received a fludarabine-containing regimen compared to 13% in those who did not (Fig. 103.4).

Another contributor to the positive effect of fludarabine on transplant outcome might be related to a condition of T-cell mosaicism that develops in some patients with FA. This condition is characterized by having two populations of host T-cells, one of which is sensitive to clastogenic/mutagenic agents and another that is resistant as a consequence of a reversion of the FA mutation.[60] McMillan et al. showed that T-cell mosaicism was a risk factor for graft rejection, presumably as a consequence of the reduced conditioning intensity used in FA not being sufficiently intensive to eradicate all the host T-cells.[58] Of interest, fludarabine mitigates this risk, as the incidence of graft rejection was not increased among those who had T-cell mosaicism and who received fludarabine.[59]

There is growing consensus that marrow from an unrelated donor should undergo T-cell depletion to reduce the risk of GVHD. A benefit after T-cell depletion of donor marrow has been observed after HLA-ID sibling and after unrelated HSCT.[55,60,61] In the retrospective analysis noted above, the incidence of acute GVHD decreased from 71% to 21% in the T-cell depleted group and was decreased further to 16% if fludarabine and T-cell depletion were utilized together. In parallel, umbilical cord blood also has been tested in FA as a source of HSC because it naturally contains fewer T-cells and is associated with a lower risk of GVHD after HSCT. Of note, the first successful report of UCB transplantation in 1989 was conducted in a patient with FA and who survives free of disease more than 20 years later.[62] A retrospective review of 93 cases of FA treated by unrelated donor UCB transplantation showed acute and chronic GVHD rates of 32.5% and 16%, respectively, confirming a benefit.[63] Unfortunately, this benefit was balanced by high rate of graft rejection, with an overall survival rate of 40%. For this reason, the selection of UCB as a source for HSCT is generally assigned a lower priority in patients with FA.

Late Effects in Fanconi Anemia Patients

The most important late complication after HSCT for FA is the development of cancer.[64] The most common forms include squamous cell carcinomas of the head and neck, carcinoma of the esophagus, and gynecologic squamous cell carcinoma. Exposure to radiation increases this risk, thus its elimination from conditioning regimens is an important advance. Survivors of successful transplantation still experience an increased risk of developing a malignancy. The risk is increased fourfold in those who receive transplantation compared to those who do not, and the cumulative incidence of a secondary cancer is 40% during the 15 to 20 years after HSCT.[65] In addition, the time to developing a secondary cancer is shortened on average by 16 years, for which the development of GVHD is a key risk factor.[56,66] Together, these factors must be considered carefully when making a decision about when to proceed to an alternate donor transplantation, particularly because some patients with marrow aplasia can be managed for extended periods of time by the administration of androgens and judicious use of transfusions without significant risk of progressing to MDS/AML.

Hematopoietic Stem Cell Transplantation for Hemoglobin Disorders

Together, thalassemia and sickle cell disease account for the most common hereditary disorders worldwide with broad distribution in regions of the world where malaria is endemic. However, the majority of transplantations performed for these disorders have been conducted in developed nations, which means that very few of those affected globally are ever considered for transplantation.

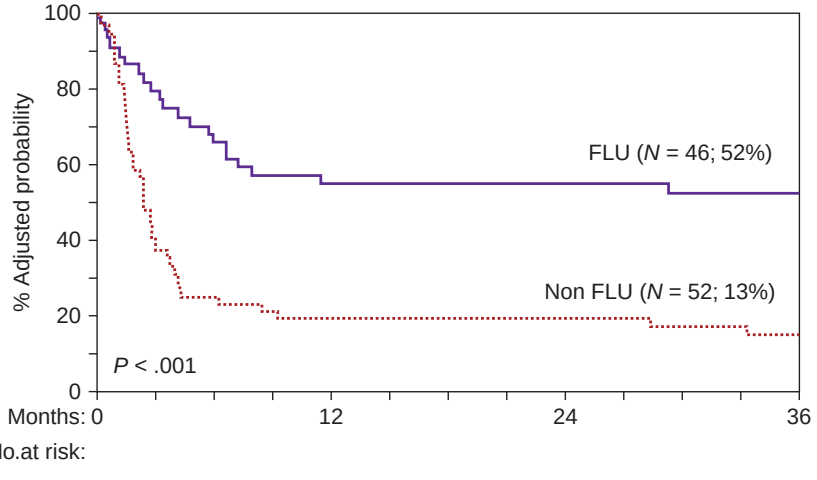

FIGURE 103.4. Effect of fludarabine administered before hematopoietic stem cell transplantation (HSCT) in patients with Fanconi anemia. From Wagner JE, Eapen M, MacMillan ML, et al. Unrelated donor bone marrow transplantation for the treatment of Fanconi anemia. Blood 2007;109(5):2256–2262. Epub 2006 Oct 14.

The first case report of successful transplantation for thalassemia occurred 30 years ago and has been followed by several thousand children with thalassemia who have been treated successfully.[67,68] The first reports of successful transplantation for sickle cell disease occurred somewhat later, and because of the variable clinical course many children experience, far fewer individuals with sickle cell disease have been treated by HSCT.[69,70] Nonetheless, outcomes after HLA-ID sibling donor bone marrow transplantation for the hemoglobin disorders are excellent. The broader application of HSCT is limited by the risks of HSCT, which must be balanced by complications inherent to the underlying disease, for which significant progress in supportive care has occurred.

With the institution of universal newborn screening programs in the United States and elsewhere, now it is possible to identify patients with hemoglobin disorders shortly after birth and to institute comprehensive preventive care.[71] As a consequence, the majority of children with SCD survive to adolescence and nearly all children with thalassemia major survive into the third decade of life.[72,73] Still, the most severely affected patients with sickle cell disease experience significant morbidity and life-limiting complications that include stroke, acute chest syndrome, painful episodes, and with regular RBC transfusions, the development of iron overload.[74] However, in most children with sickle cell disease, supportive care measures are safe and mitigate the risk of life-threatening events. For these reasons, very few children with sickle cell anemia are treated by HSCT.[75] Unfortunately, the outlook for adults with sickle cell anemia has not changed substantially since the 1980s, when a median survival in males of 42 years, and in females, of 48 years was observed in the Cooperative Study of Sickle Cell Disease (CSSCD).[76] As a consequence, although most children with sickle cell disease survive to age 20, the outlook for young adults remains unsatisfactory.[77,78] Thus, decisions about HSCT for sickle cell anemia are often driven by an individual's outlook in the long term and by donor availability. In the child with thalassemia major where the genotype more reliably predicts the phenotype of the disease, families today are more likely to pursue HSCT in childhood if there is a suitable donor.

Hematopoietic Stem Cell Transplantation for Thalassemia

Pioneering studies that span several decades were performed by the transplant team in Pesaro led by Lucarelli.[68] Using a backbone combination of BU and CY before transplantation and a standard combination of methotrexate (MTX) and cyclosporine (CSP) to prevent GVHD, the majority of children were cured after a HLA-ID sibling bone marrow transplantation. However, the likelihood of cure was highest in those recipients who had good-risk features, defined as having no hepatomegaly, no evidence of portal fibrosis by liver biopsy, and by having adhered to a regular program of iron chelation therapy. Alternatively, children who had one (risk class 2) and two or more prognostic features (risk class 3) fared worse. Class 3 patients experienced a thalassemia-free survival probability of 50% and 30% had graft rejection with thalassemia recurrence (Fig. 103.5).[79] The improved outcomes that followed this initial report occurred by targeting good-risk young patients for transplantation promptly when there was an HLA-ID sibling donor, and by modulating the conditioning regimen in high-risk recipients to improve the safety profile. The latter also served to deliver sufficient pre-grafting immunosuppression necessary for ensuring the stable engraftment of donor cells.

Initially, attempts to reduce the toxicity of transplantation in high-risk features focused on modifications to the BU/CY backbone. In particular, it was possible to reduce the incidence of regimen-related toxicity by reducing the dose of CY. Unfortunately, this was accompanied by a higher incidence of graft rejection, so that the overall thalassemia-free survival rate did not improve after modifying the CY dose.[80] In response, a greater emphasis was placed on the role of immunosuppressive therapy before transplantation as a strategy for reducing graft rejection. Thus, Protocol 26 was established, which employed a combination of HU, azathioprine, and hypertransfusion with intensive iron chelation therapy that was administered 6 weeks before transplantation to modulate the proliferative erythron and induce an immunosuppressive effect.[81] This was followed by a backbone of BU/CY with CY dosing that ranged from 120 to 160 mg/kg. This combination of changes resulted in a substantially improved outcome with an event-free probability of 85% and rejection incidence of 8% in class 3 recipients (Fig. 103.6). Thus, it was possible to modify the transplantation regimen in such a way as to generate outcomes that appeared indistinguishable from those in children with good-risk features. The importance of this modification was illustrated in a different fashion by results from a separate patient series from the Center for International Blood and Marrow Transplant Research (CIBMTR) registry. This retrospective analysis reported outcomes after HLA-ID sibling bone marrow transplantation from non-Italian centers. Using a modified risk categorization based upon patient age and liver size, outcomes were outstanding among recipients who had good-risk features.[82] However, the use

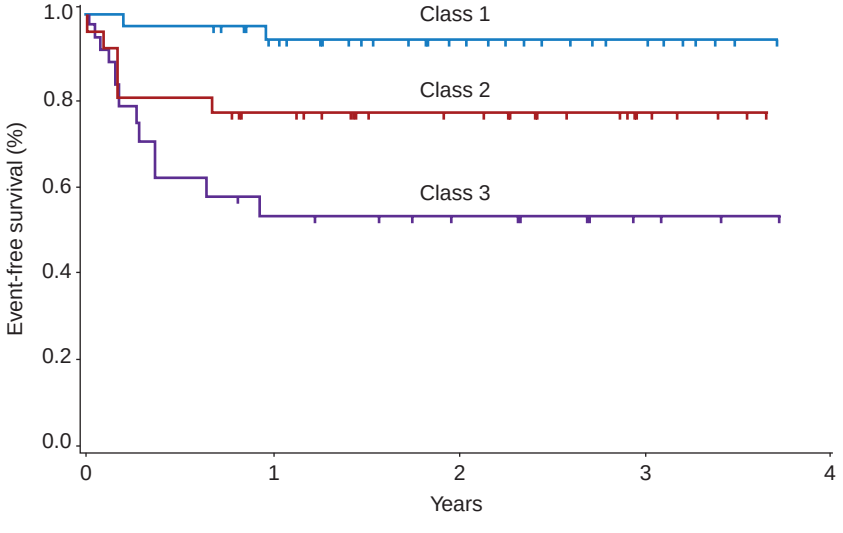

FIGURE 103.5. Probabilities of event-free survival after HLA-ID sibling BMT for thalassemia according to risk category. From Lucarelli G, Galimberti M, Polchi P, et al. Bone marrow transplantation in patients with thalassemia. N Engl J Med 1990;322(7):417–421.

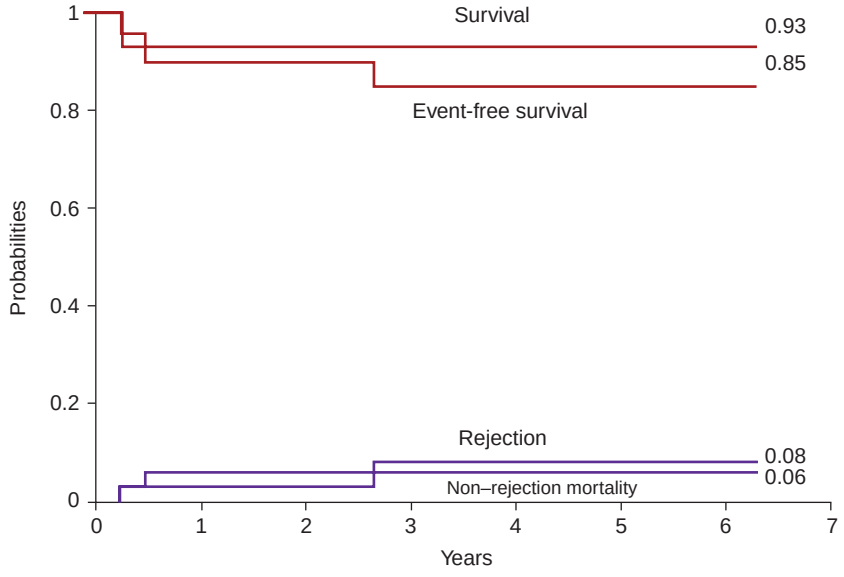

FIGURE 103.6. Outcomes after HLA-ID sibling BMT for thalassemia in Class 3 patients. From Sodani P, Gaziev D, Polchi P, et al. New approach for bone marrow transplantation in patients with class 3 thalassemia aged younger than 17 years. Blood 2004;104(4):1201–1203. Epub 2004 Mar 25.

of the BU/CY conditioning backbone was associated with a far inferior outcome in this high-risk category of patients older than 7 years who had hepatomegaly, where the thalassemia-free survival probability was 50% (Fig. 103.7). This observation strengthened the conclusion that high-risk patients require a modified conditioning regimen for reasons of safety and efficacy.

As most individuals with thalassemia major lack a sibling donor, the development of unrelated donor transplantation and alternative sources of hematopoietic stem cells has been pursued to broaden the availability of HSCT. An early report from the Pesaro team showed that the use of HLA-mismatched related donors was associated with an inferior outcome, and in particular, a high rate of graft rejection.[83] Thus, it became apparent that additional modification of the conditioning regimen would be needed to ensure engraftment across a MHC barrier and that selecting donors with optimal HLA matching also was necessary. In one series, the BU/CY backbone was augmented by thiotepa to intensify the pre-grafting immunoablation. Among 32 patients, most of whom had class 2 or 3 risk features, the thalassemia-free probability was 66% and graft rejection occurred in 13% of the cases.[84]

Of interest, 22 of 32 recipients shared at least one extended HLA haplotype with the donor. Of these, 19 survived and 17 survived free of thalassemia after transplantation. Thus, the importance of donor selection was suggested by these data. The unrelated donor HSCT outcomes were updated 5 years later and included the replacement of fludarabine for CY which accompanied thiotepa and BU in the conditioning regimen.[85] This combination was associated with reduced toxicity and lower transplant-related mortality (reduced from 25% to 13.3%) and a thalassemia-free survival rate of 71%. Most recently, the team from Pavia, Italy reported its experience with the use of treosulfan, a myeloablative drug that has a reduced toxicity profile when compared to BU. Using a combination of treosulfan, fludarabine, thiotepa, and ATG, 60 patients treated between 2005 and 2009 experienced 93% survival and 84% event-free survival probabilities after HLA-ID sibling (N = 20) or unrelated donor bone marrow transplantation (N = 40).[86] Twenty-one of the patients had Lucarelli class 2 or 3 features and 12 were adults. Thus, incremental progress in unrelated donor transplantation shows the potential for outcomes that appear indistinguishable from those after HLA-ID sibling HSCT.

Hematopoietic Stem Cell Transplantation for Sickle Cell Disease

The application of HSCT for sickle cell disease has developed more slowly than in thalassemia, in part due to the heterogeneous phenotype of sickling syndromes and also from a lack of suitable donors. However, several patient series were conducted in the mid- to late-1990s in the United States and Europe and demonstrated very similar outcomes.[87–89] The aim of these clinical trials was to identify children who were at risk for early mortality or extensive morbidity, but to treat by HSCT before organ damage had occurred that might increase the risk of transplant-related complications. Thus, patients were deemed eligible if they had a stroke and were receiving regular RBC transfusion therapy to prevent another stroke, if they had recurrent painful episodes, or if there were recurrent episodes of acute chest syndrome. The current eligibility criteria are shown in Table 103.3.

Following these eligibility requirements, myeloablative conditioning regimens with a backbone of BU 14 to 16 mg/kg and CY 200 mg/kg were used, with or without ATG. Post-transplantation immunosuppression consisted of CSP and MTX in most cases. The results of transplantation showed a disease-free survival of approximately 80% to 85%. A total of 5% to 10% of patients died of complications related to transplantation, with GVHD and its treatment as the leading cause of death.

In the Belgian series, many patients with symptomatic sickle cell disease were children of parents from Africa who were studying abroad in Europe.[70] It was reasoned that because supportive care was limited in their country of origin, the possibility of cure by HSCT was a reasonable justification for pursuing this therapy. The initial small series of patients reported in 1988 was later expanded to include 50 patients, and this was the earliest clinical trial to suggest that having the diagnosis of sickle cell anemia in and of itself was sufficient justification for bone marrow transplantation.[88] Of the 50 patients reported, 5 (10%) had graft rejection accompanied by recurrent sickle cell anemia and 86% survive free of sickle cell anemia. Of interest, some of the patients with graft rejection had persistent elevation of fetal hemoglobin levels despite having no evidence of donor cells in the marrow. This phenomenon of persistent fetal hemoglobin expression was associated with resolution of sickle-related complications.[90] Although in these cases, the fetal hemoglobin elevation was not durable and eventually levels declined, a long-lived elevation of fetal hemoglobin of host origin in thalassemia was observed in a more recent report.[91]

TABLE 103.3

INDICATIONS FOR HCT FOR SICKLE CELL DISEASE

Patients with sickle cell disease (HbSS or HbSβ^0-thalassemia)
One or more of the following complications:
Stroke or CNS event lasting longer than 24 hours
Recurrent acute chest syndrome
Recurrent vaso-occlusive painful episodes or recurrent priapism
Impaired neuropsychological function with abnormal cerebral MRI and angiography
Other indications under consideration:
Elevated cerebral arterial velocity by transcranial doppler
Pulmonary hypertension
Silent cerebral infarction

CNS, central nervous system; HCT, hematopoietic cell transplantation; MRI, magnetic resonance imaging.

An international study of BMT for sickle cell disease led by investigators in the United States was conducted between 1991 and 2000 and enrolled 59 patients from the United States, South America, and Europe.[87,92] Early in the course of the study, a high rate of neurologic complications was observed, including intracranial hemorrhage.[93,94] These events occurred in the setting of CSP administration, hypertension, and in some cases, thrombocytopenia or elevated hemoglobin levels as a consequence of hypertransfusion. These events also were observed in the European patient series. In response to observing these events, a standard approach for preventing neurologic complications was instituted and it included the strict control of hypertension, administration of anticonvulsant prophylaxis during CSP use, RBC transfusion support to maintain the hemoglobin between 9 and 11 gm/l to avoid hyperviscosity, and to keep the platelet level >50,000/mm^3. After the institution of these preventive measures, there were no further episodes of intracranial hemorrhage in the international study, although seizures still occurred in approximately 20% of recipients.[95]

The largest single patient series of HSCT for sickle cell disease was reported in France and included 87 patients who received HLA-ID bone marrow or in 12 cases, umbilical cord blood grafts between 1988 and 2004.[89] Initially, patients were prepared for transplantation with a BU/CY backbone alone, but after the initial 12 patients were treated, rabbit ATG was added to the conditioning regimen. The overall cumulative incidence of graft rejection was 7%; however, the rejection rate was significantly lower after the addition of rabbit ATG to the conditioning regimen (Fig. 103.8). In addition, the level of mixed donor–host hematopoietic chimerism was analyzed with regard to the effect of ATG, and it was measured in 77 of the patients. A higher level of persistent host hematopoiesis was observed in those who received ATG. A larger fraction transplant recipients had full chimerism noted at 12 and 24 months after transplantation after receiving BU/CY alone. However, the development of mixed chimerism was not associated with sickle-related events after HSCT, although 2 patients with only 20% donor cells had moderate anemia (8.5 to 9 gm/dl) and did not require RBC transfusions.

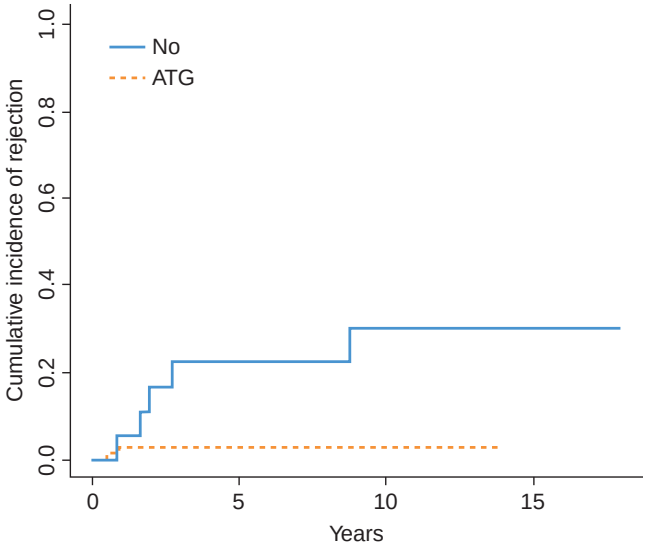

FIGURE 103.8. The effect of rabbit antithymocyte globulin (ATG) on the cumulative incidence of graft rejection after sibling hematopoietic stem cell transplantation (HSCT) for sickle cell anemia. From Bernaudin F, Socie G, Kuentz M, et al. Long-term results of related myeloablative stem-cell transplantation to cure sickle cell disease. Blood 2007;110(7):2749–2756. Epub 2007 Jul 4.

The development of stable donor chimerism has been observed after transplantation for thalassemia and sickle cell disease, and has been studied most extensively in the thalassemia cohort from Pesaro.[96,97,98] The cause of the phenomenon is uncertain, and it is associated with oligoclonal skewing of the T-cell repertoire, which is not associated with impaired immune function.[99] In the RBC lineage, there is a natural enrichment of donor cells in the blood, as a consequence of ineffective erythropoiesis and longer RBC survival in donor erythrocytes. Most important, even when there is a minority of donor cells, the patients who develop stable mixed chimerism do not experience symptoms of the underlying hemoglobinopathy and thus survive disease-free.

These observations in part became the basis for exploring if a reduced intensity or nonmyeloablative conditioning regimen might be sufficient to establish mixed chimerism and thereby generate an alternative safer means of transplantation for these disorders. Initial clinical trials tested a minimal toxicity regimen of fludarabine with a single fraction of total body irradiation (TBI, 200 cGy) in patients with hemoglobinopathies.[100] The results showed that only transient donor chimerism was achieved in most patients, and that donor chimerism was lost when the intensity of the post-grafting immune suppression was tapered and discontinued. The addition of rabbit ATG to a backbone of fludarabine and TBI did not improve the outcome.[101] There has been better success with the application of reduced intensity regimens that require hospitalization and cause cytopenias, but still retain a favorable toxicity profile. The use of alemtuzumab, an anti-CD52 antibody, in combination with melphalan and fludarabine in the conditioning regimen has generated better results and most patients achieve full donor chimerism after HSCT. In one series, 12 of 16 patients with nonmalignant disorders survived with donor engraftment after receiving this conditioning regimen.[102] In a more recent trial at the National Institutes of Health, adult recipients with severe sickle anemia who were judged too ill to receive a standard myeloablative preparative regimen received a nonmyeloablative combination of fludarabine, campath, and 300cGy of TBI before HLA-ID sibling mobilized peripheral blood stem cell transplantation. Sirolimus as a single agent was administered for post-grafting immunosuppression.[103] To date, 23 patients have been treated in the trial, and all 23 survive, and 20 survive with mixed chimerism sufficient to eliminate sickle-related clinical features including an improved reticulocyte count, LDH, and serum bilirubin after HSCT (Fig. 103.9). Although many of the recipients appear to require long-term immunosuppression with sirolimus to stabilize engraftment, this is a promising approach in older patients.

As in Fanconi anemia, umbilical cord blood might also have benefits in HSCT for hemoglobin disorders due to the lower risk of GVHD. In addition, finding suitably HLA-matched donors in underrepresented ethnic groups in the unrelated marrow donor registry still presents challenges.[104] Unlike marrow-derived hematopoietic stem cells, UCB units are immediately available upon request and are not affected by donor scheduling or health for procurement. Because of the lower GVHD risk, a greater degree of HLA disparity is acceptable when selecting a UCB unit, which effectively expands the pool of possible donors for patients.[105] Unfortunately, there are several limitations of cord blood units, including small volume, relatively low stem cell number, variable collection methods, and viability after cryopreservation. The nucleated and CD34+ cell dose are the major factors that affect outcome.[106] Thus the role of UCB transplantation for hemoglobin disorders is still evolving.

Locatelli et al. reported the outcome after HLA-ID sibling cord blood transplantation for patients with SCD and thalassemia.[107] A total of 44 patients was included in the series (median age 5 years, range 1 to 20) and the patients had thalassemia (n = 33) or SCD (n = 11). The majority of children (n = 40) received CSP alone or CSP / MTX as GVHD prophylaxis and their median total nucleated cell dose was 4.0×10^7/kg (range 1.2 to 10×10^7/kg). Eighty-two percent of patients were alive and disease-free with a median follow-up of 2 years (range 4 to 76 months), and only 4 (9%) had grade II acute GVHD. The two-year event-free survival probabilities were 79% and 90% for patients with thalassemia and SCD, respectively. Results were best in patients who did not receive MTX to prevent GVHD and also in those patients who received an additional immunosuppressive drug such as thiotepa or fludarabine with the BU/CY backbone.

In an attempt to extend these encouraging results observed after sibling donor UCB transplantation, the applicability of unrelated donor UCB transplantation was explored. Recently, a prospective investigation of unrelated donor HSCT for severe sickle cell disease reported the results after UCB transplantation.[108] In this phase II trial, eight children who met study criteria for severe SCD underwent unrelated-donor cord blood transplantation. They received alemtuzumab, fludarabine, and melphalan as their preparative regimen and either CSP or tacrolimus in addition to mycophenolate mofetil as GVHD prophylaxis. All patients had either 6 of 6 (n = 1) or 5 of 6 HLA matching based on low-/intermediate-resolution typing of HLA-A, -B, and -DRB1. Because of excessive graft rejection rates in the cord blood cohort, that arm of the trial was closed. Similarly, results after unrelated donor UCB transplantation in patients with thalassemia major are inferior to those with related marrow donors. Ruggeri et al. reported results of the CIBMTR data registry that included a cohort of 35 thalassemia patients who underwent either matched or mismatched UCB transplantation.[109] Despite acceptable HLA matching, disease-free survival and overall survival for patients in this report were 21% and 62%, respectively. Of these patients, 20 had graft failure that was fatal in 5. A larger cell dose (>5×10^7/kg) was associated with lower risk of graft failure, indicating that perhaps survival could be improved through the use of multiple cord blood units or ex vivo expansion.

LATE EFFECTS

Assessment of Disease-free Survival

Disease-free survival after HSCT for hemoglobin disorders is defined as freedom from transfusions and iron loading in thalassemia, and in addition among those with sickle cell disease, freedom from sickle-related complications. However, the iron that accumulates as a consequence of RBC transfusions before and after HSCT is not eliminated after successful HSCT to any appreciable extent. Left untreated, iron overload causes significant morbidity and mortality with progressive liver disease and even cirrhosis after transplantation.[110] A prospective analysis of annual liver biopsies in thalassemics not treated by iron chelation and in whom thalassemia was cured by HSCT demonstrated that iron overload and hepatitis C virus infection were independent risk factors for progressive liver fibrosis. Patients who had an active hepatitis C infection and also had very high levels of hepatic iron had an 80% risk of developing progressive hepatic fibrosis 10 to 12 years after successful transplantation.[111] Conversely, patients with a liver iron level less than 16 mg iron/gm liver dry weight and who were also free of evidence of active hepatitis C virus infection, showed no signs of progressive hepatic fibrosis.

Phlebotomy is safe, inexpensive, and highly efficient, and therefore it is the treatment of choice of transfusion iron overload after HSCT. With this approach, excess iron can be completely mobilized from the body without any significant side effects. Following completion of the phlebotomy program, significant improvement in liver function was observed, particularly in patients infected with hepatitis C virus.[111] It is possible to reverse severe hepatic fibrosis and even early cirrhosis.[112] Patients with early cardiac involvement characterized by left ventricular diastolic dysfunction

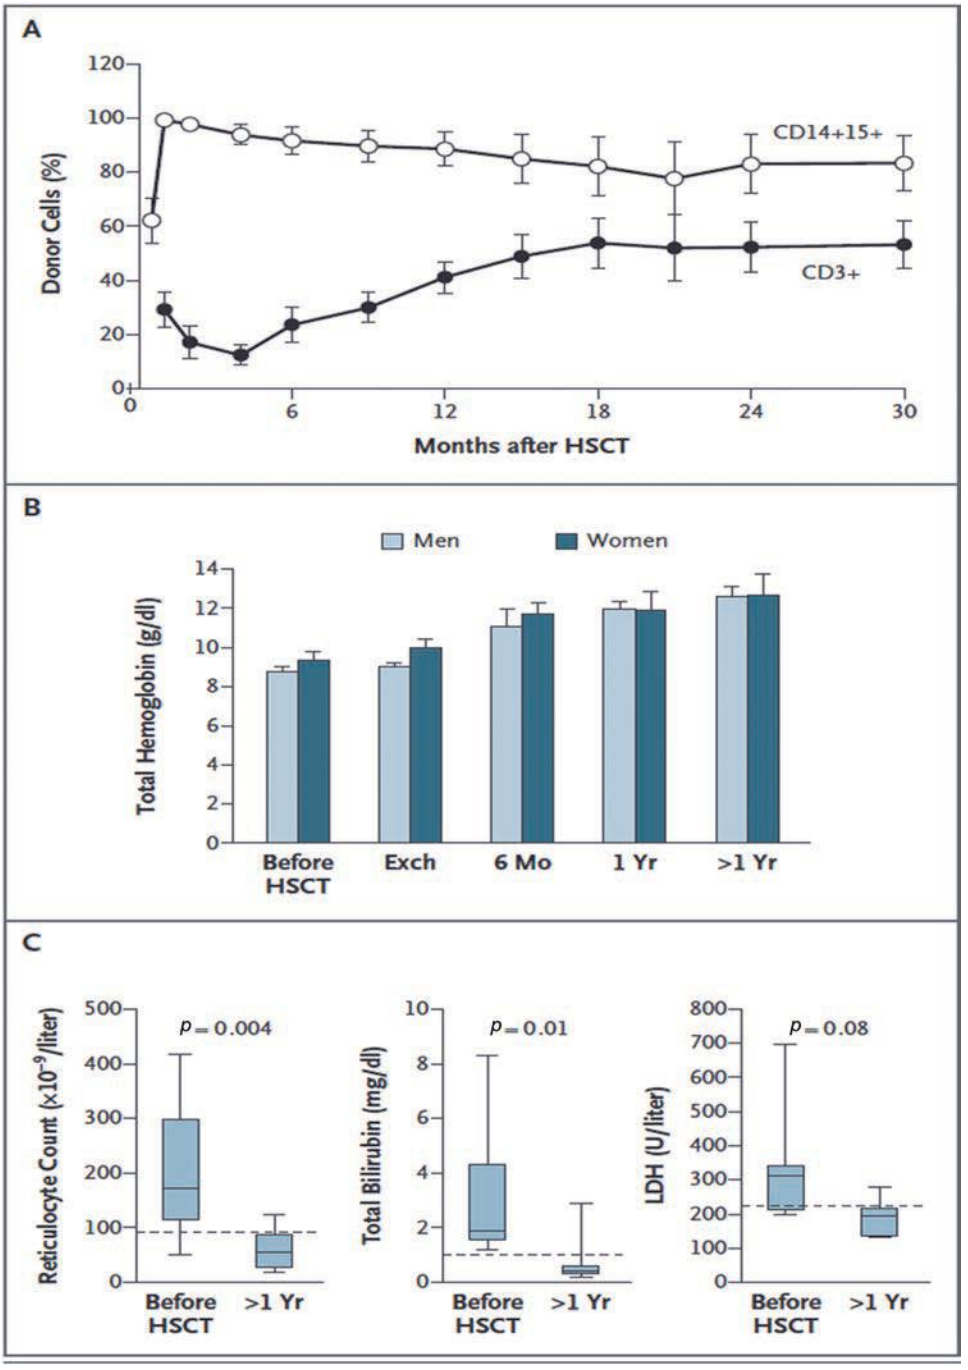

FIGURE 103.9. Effect of donor chimerismw on sickle cell disease expression after nonmyeloablative hematopoietic stem cell transplantation (HSCT) from HLA-ID siblings in adult recipients with severe sickle cell disease. In panel A, the percentage of donor myeloid and T-cells in the blood over time is shown. In Panel B, the change in the hemoglobin level over time in males and female transplant recipients is shown. In panel C, the reticulocyte count, total serum bilirubin and LDH levels before and after transplantation are shown. From Hsieh MM, Kang EM, Fitzhugh CD, et al. Allogeneic hematopoietic stem-cell transplantation for sickle cell disease. N Engl J Med 2009;361(24):2309–2317. Epub 2009 Dec 17.

and impaired left ventricular contractility demonstrated regression of subclinical cardiac disease after phlebotomy.[113]

After successful HSCT for sickle cell disease, patients with stable engraftment of donor cells do not experience sickle-related clinical complications, even if there is stable mixed donor–host hematopoietic chimerism.[89,97] In addition, investigators have reported improvements in splenic function and osteonecrosis.[114,115] Patients treated by HSCT also had stabilization of the underlying cerebrovascular disease.[95] Of 55 patients who were enrolled in the multicenter study, 46 underwent cerebral MRI performed a median of 25.4 months after transplantation. Of 59 patients, 29 had stroke or other significant central nervous system disease as an indication for transplantation and 28 survived after BMT. Surviving patients with stroke who also had stable engraftment of donor cells (n = 25) experienced no subsequent stroke events after BMT. However, patients who had graft rejection after BMT were not protected from stroke. One patient with graft rejection experienced a second stroke when the Hb S fraction reached 60% after BMT and another patient with graft rejection had a subarachnoid hemorrhage after BMT. In total, 28 of 29 (97%) of patients with stroke survived after transplantation, and 26 of 29 (90%) survived stroke-free after HSCT. Evidence of silent cerebral infarction before transplantation was found in 10 patients, and of these, all 8 who had MRI studies performed after HSCT had stable or improved appearance. There were no clinical strokes after HSCT in this group. No documented central nervous system disease before transplantation was found in 16 patients. MRI appearance was normal in all 10 patients in this group and

none had stroke. Together, these observations suggest that there is stabilization of cerebral vasculopathy after hematopoietic cell transplantation. These data also suggest that in those with silent cerebral infarction who are at risk of developing stroke, there is protection from disease progression and a first stroke. The French group reported a similar experience.[89] Among the 36 patients with a history of stroke before hematopoietic cell transplantation, 2 had a recurrent stroke. With a median follow-up of 6 years, the risk of recurrent stroke was 5.6%, which is a significantly lower rate of second stroke observed in sickle cell disease patients who are treated by regular transfusion therapy after a first stroke.

LONG-TERM TOXICITIES OF CONDITIONING

The incidence of secondary solid tumors in thalassemia and sickle cell disease after transplantation is less than 10/100,000 patient-years, a rate that does not appear different compared to patients who receive supportive care treatment for β thalassemia.[116] These findings also are consistent with data reported by the CIBMTR; patients with nonmalignant disorders treated by HSCT had an incidence of secondary malignancies that was not significantly increased compared to the normal population.[117]

Gonadotropin and sex hormone levels confirm the toxic effect of BU on gonadal function after HSCT. In addition, hypogonadism is the most common endocrine disorder in medically treated patients with thalassemia major, affecting approximately half the patients.[118,119] In a study involving 68 children with thalassemia after HSCT, 32% reached an advanced or complete puberty spontaneously (34% of girls and 63% of boys), despite clinical and hormonal evidence of gonadal impairment in most cases.[110] In this group, iron overload and the conditioning regimen were the major factors influencing endocrine function. In the cooperative study of HSCT for SCD follow-up gonadal function studies were performed in patients who were 21.6 (range, 16.1 to 28.5 years) and 21.7 (range, 14.1 to 27.8 years) years of age in males and females, respectively.[95] Among those evaluated, the luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels were normal in 9 males and less than normal in 4 after transplantation. However, only 3 of 13 had normal testosterone levels, consistent with hypogonadotrophic hypogonadism in most of the pubertal males. In contrast, 8 of 14 females had increased gonadotropin levels and/or below normal estradiol levels, a finding consistent with primary ovarian failure in the majority of post-pubertal females. Only 4 of 14 females had normal estradiol levels. However, one female had a successful pregnancy 13 years after BMT and another female with graft rejection gave birth to a healthy baby following preimplantation genetic diagnosis 14 years after BMT, although she had experienced 2 previous spontaneous abortions several years earlier. Among 6 evaluable pre-pubertal girls in the Belgian cohort, 5 had primary amenorrhea with elevated serum LH and FSH.[88] Two post-pubertal females developed secondary amenorrhea. Testicular function was also adversely affected in 4 of 6 evaluable boys who demonstrated decreased testosterone and elevated FSH levels. In the French series, 7 post-pubertal females, aged 13 to 22 years, developed amenorrhea after hematopoietic cell transplantation with decreased serum estradiol and elevated LH and FSH levels and received hormone replacement therapy.[89] It is anticipated that many, if not most, of the females will require hormonal replacement therapy after HSCT. The development of reduced intensity conditioning regimens is anticipated to reduce the late effect of gonadal toxicity.

Eggelston et al. reported growth outcomes in children who were enrolled in a multicenter investigation of HSCT for SCD.[121] The baseline height and weight and growth velocities after HSCT were compared to children who were treated by HU and who were enrolled in the CSSCD, previous investigations of SCD during which prospective height and weight measurements were documented.[122,123] It was determined that growth after HSCT was not impaired, except in older males, where data from the CSSCD showed a more rapid height and weight velocity after age 11.6 and 12.1 years, respectively. However, males grew 0.67 cm/year faster after HSCT compared to males in the HU group before treatment with HU was initiated. Thus, the data showed that conventional myeloablative HCT generally had no adverse effect on height or weight gain in young children. However, diminished growth may occur in patients who undergo HSCT at or near the growth spurt. This study emphasized the importance of treating children early in the course of their disease to minimize toxicity.

CONCLUSION

HSCT for nonmalignant disorders can be life-saving when applied early in life of children who inherit a fatal condition such as SCIDS. In other disorders, early mortality caused by marrow failure or a predisposition to acute leukemia, as occurs in Fanconi anemia, similarly can be life-saving, but as applied over a longer time period. In the setting of hemoglobin disorders, the decision making about HSCT is more nuanced, and often families and their physicians must make decisions based upon long-term projections of mortality and the quality of life. Common to all these disorders, however, is a strict requirement for optimizing donor selection to avoid GVHD, a complication that offers no benefit in these disorders, and an understanding of conditioning regimens that are best tailored to minimize short- and long-term toxicities but still ensure engraftment of donor cells. It is these considerations and the development of improved methods of HSCT that remain the focus of ongoing clinical investigation and which are very likely to improve future outcomes for these disorders.

CHAPTER 104

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION (HCT) FOR HEMATOLOGIC MALIGNANCIES

Bipin N. Savani, Nishitha M. Reddy, Madan Jagasia, Haydar Frangoul

INTRODUCTION

The curative potential of allogeneic hematopoietic stem cell transplantation (HCT) in hematologic malignancies is well established,[1] and currently acute myelogenous leukemia (AML) is the most common indication for HCT, accounting for approximately more than one-third of adult HCT.[2] As the donor pool expands to include more unrelated and HLA-mismatched donors and umbilical cord blood (CB), and as treatment-associated morbidity and mortality rates decline with improvements in HLA matching, antimicrobial therapy, and management of graft-versus-host disease (GVHD), it has become increasingly feasible to offer this modality of treatment.[3]

HCT is offered either to increase the chance of cure in a disease that may have a low chance of cure with nontransplant approach (AML in first complete remission [CR1] with high-risk cytogenetics) or to cure an otherwise incurable disease (myelodysplastic syndrome [MDS], AML beyond CR1). Given the inherent risks of HCT, the risk–benefit ratio depends on the natural history of the disease versus the non-relapse mortality or transplant-related mortality due to the procedure itself. Although randomized control trials have been done, an ideal study of "intent to transplant analyses" is lacking in most disease types. With the advances in human leukocyte antigen (HLA) typing and supportive care, the non-relapse mortality after transplant continues to improve. The emergence of reduced-intensity conditioning (RIC) in deference to myeloablative conditioning (MST) broadens the applicability of this modality to patients who formerly would have been excluded from HCT because of advanced age or co-morbid conditions.[4,5,6,7] Here we discuss the indications, benefits, and risks of HCT in patients with hematologic malignancies.

Chronic myelogenous (or myeloid) leukemia (CML) was a model disease to cure with HCT in the pre-tyrosine-kinase inhibitors (TKI) era. The introduction of TKIs led to a paradigm shift. Current indications of HCT are outlined in the National Cancer Center Network (NCCN) guidelines and addressed in Chapter 81. Consideration of HCT is recommended at 3 months post-TKI therapy if there is a >10% increase in BCR-ABL transcript as measured by quantitative PCR (QPCR) using the International Scale, or if conventional cytogenetics shows less than a partial cytogenetic response. Loss of cytogenetic response, molecular progression, or evolution of new mutations associated with TKI resistance should prompt a transplant evaluation. HCT consideration is often delayed based on response to second generation TKIs. Patients presenting in accelerated phase (AP) or blast crisis (BC)should be considered for earlier HCT.

Acute Myeloid Leukemia

In the United States, approximately 25% of AML patients younger than 70 years undergo an HCT. Median age at transplantation is 45 years; 75% of HCT recipients are younger than 55 years.[2,8,9,10,11] The increasing need for HCT in adults with AML requires that all patients and their siblings undergo HLA typing early after diagnosis to determine if a matched related donor (MRD) is available and to allow for the possibility of unrelated donor (URD), haploidentical donor or umbilical cord blood (CB) searches.

Rationale of Hematopoietic Stem Cell Transplantation in First Complete Remission

Transplants should preferentially be performed on time and not reserved for relapsed disease or complete remission 2 (CR2) in high-risk patients. Although several reports of successful HCT in CR2 with a curative potential of 25% to 30% have been reported, such data are highly selective and should not influence a decision against earlier HCT, especially at experienced transplant centers. Moreover, the risk of relapse after URD HCT is higher for patients with unfavorable cytogenetics, irrespective of whether the transplant is performed in CR1 or CR2. Since the probability of achieving CR2 after chemotherapy in this group of patients is low, early HCT provides the optimal approach.[9,10,12,13]

Indications of Hematopoietic Stem Cell Transplantation in Acute Myeloid Leukemia First Complete Remission

Several clinical features at presentation are associated with particularly poor outcome for AML patients. Age over 60 years, hyperleukocytosis, secondary AML (after antecedent myelodysplasia), or treatment-related myeloid neoplasm and, in some series, two induction cycles rather than one to attain CR1 are clinical factors that portend a worse outcome. As a result, many investigators proceed to offer HCT to such individuals.[9,12,13]

Cytogenetics, however, remains the most robust prognostic marker for risk stratification of AML at the time of diagnosis as well as in selection of post-remission treatments. On the basis of specific structural and numerical cytogenetic abnormalities, AML patients are divided into favorable, intermediate, and adverse risk groups (Chapter 75). A notable exception is the favorable cytogenetic risk group, in which HCT did not further improve outcome.

In recent years, a variety of novel molecular markers including mutations in the *FLT3* (FMS-like tyrosine kinase) gene, the *NPM1* (nucleophosmin) gene, and the CCAAT/enhancer binding protein alpha (*CEBPA*) gene have refined the risk stratification of intermediate-risk AML. Several investigators have used combinations of molecular markers to improve the patient's risk assessment in cytogenetically normal AML.[8]

The most challenging group of patients with de novo AML falls within the intermediate-risk category.[8,12] Intermediate-risk patients who achieve CR1 after chemotherapy have a 50% probability of disease recurrence without HCT, and the probability that CR2 can be attained is low. With advances in the molecular classification of AML such as *NPM1*, *FLT3-internal tandem duplication (ITD)*, *CEBPA*, and *KIT*, the indications for HCT can now be extended to approximately 40% of patients with AML with no chromosomal abnormalities.[9,10–13] In a recent meta-analysis by Koreth et al.[14] for the transplant period 1982 to 2006, a significant overall survival benefit was reported for patients with poor-risk and intermediate-risk AML who received HCT in CR1. NPM1 positivity has been considered a good-risk feature. More recently, it has been shown that only the subgroup with wild type isocitrate dehydrogenase 1 and 2 (IDH1/IDH2) along with NPM1 mutations are expected to do well.[15] Thus, the prognostic impact

of known well validated mutations continues to evolve as new mutations are identified and the interactions of these mutations are understood.

Donor Source and Outcome in Acute Myeloid Leukemia First Complete Remission

Importantly, the outcome of transplantation appears to be comparable for recipients of URD vs. MRD transplant. With improvements in transplant procedures including better donor selection (with high-resolution HLA- typing), excellent supportive care, and pre-emptive therapy in high-risk patients, we anticipate that outcomes will continue to improve.[3,16–21]

The results of 4 comparative studies together with meta-analyses of cord blood transplant (CBT) vs. URD transplant, the results of CBT appear to be as promising as those of matched URD transplant in adults with hematologic malignances.[10,12,20,22] In the absence of an HLA-matched donor, both CBT and haploidentical-stem cell transplantation (SCT) strategies (center dependent) are suitable options to treat high-risk patients. An upcoming blood and marrow transplant (BMT)-clinical trials network (CTN) study (BMT-CTN 1101; clinicaltrials.gov NCT01597778) will compare haploidentical-SCT with CBT.

Effect of Consolidation Therapy Pre-stem Cell Transplantation in Acute Myeloid Leukemia First Complete Remission

Relapse is the major cause of treatment failure after HCT in patients with AML[10,23]; new approaches to prevent disease recurrence are being explored. A question of practical importance is whether patients undergoing transplantation in CR1 will benefit from post-remission chemotherapy prior to transplantation. There are no prospective studies demonstrating that any form of post-remission chemotherapy further reduces the risk of post-transplant relapse. However, results from two retrospective registry analyses suggest no benefit from adding further consolidation chemotherapy prior to HCT; in both studies (transplant period 1980 to mid-1990s), most patients were young and received full-intensity conditioning MRD HCT.[9,12,14,24] The role of post-remission consolidation chemotherapy prior to RIC HCT in HR AML has not been adequately addressed.[13,25] In a recently published CIBMTR study, relapse occurred in 37% to 40%, and was higher in patients receiving RIC regimens. These findings highlight the importance of the depth of remission pre-SCT, especially in recipients in the RIC group.[18] The efficacy of current chemotherapeutic regimens to achieve minimal residual disease negativity needs to be balanced against the risk of increasing co-morbidities prior to HCT.

Given the expanding use of RIC conditioning and the argument that treatment intensity may be important for cytoreduction prior to SCT, assessing the impact of pre-transplant consolidation therapy in AML CR1 on outcomes post RIC HCT is an important clinical question that remains unanswered. There is an ongoing CIBMTR analysis to determine if consolidation chemotherapy prior to RIC regimen for AML CR1 improves survival and relapse risk after RIC HCT.

Allo- vs. Auto-Stem Cell Transplantation vs. Chemotherapy in First Complete Remission

A recent summary of several clinical trials comparing HCT with alternative therapies for patients with AML CR1 showed benefits of HCT over alternative therapies.[8,9,13,26] Studies showed lower relapse rates for allograft recipients compared with those who received auto-SCT or further chemotherapy. None of the studies demonstrated an advantage for any of the alternative modalities (auto-SCT or further chemotherapy) as compared with HCT.

Full Myeloablative vs. Reduced-intensity Conditioning Regimen for Acute Myeloid Leukemia First Complete Remission

Conditioning regimens prior to HCT serve two purposes. One is the suppression of host immunity to allow for donor cell engraftment, and the other is the ablation of underlying malignancy. Ideally both these tasks need to be accomplished with minimal extramedullary toxicity. Conditioning regimens can be broadly classified as myeloablative (MST), RIC, and non myeloablative (NMA), based on the intensity of conditioning. MST regimens cause irreversible cytopenia and hence stem cell support is necessary. RIC regimens cause profound cytopenia and should be given with stem cells but cytopenia may not be irreversible. NMA regimens can theoretically be given without stem cell support.

MST HCTs are associated with decreased relapse but with increased transplant-related mortality (TRM). We now know that myeloablation is not as critical for engraftment as is immunosuppression. Reduced-intensity immunosuppressive approaches such as antithymocyte globulin (ATG), alemtuzumab, rituximab, and others can be used for transplant conditioning. There is a balance between reducing TRM by reducing intensity, and risking more relapse as the regimen is weakened.[6,27]

No study to date has shown superiority of RIC to MST in AML[4,27–29,30]; we recommend reserving RIC (but not truly NMA) for patients thought to be ineligible for the more intense MST regimen. The importance of disease control at the time of transplant, especially for those patients undergoing the RIC condition, appears to have paramount importance when evaluating outcomes. In Martino's large-scale retrospective analysis of AML patients undergoing SCT, those patients transplanted in CR1 had similar rates of relapse (MST: 27% vs. RIC: 32%).[31] A prospective study randomizing patients to MST or RIC HCT regimens based solely on age of $<$ or $>$50 years for AML patients in CR1 revealed similar non relapse mortality of 19% for MST and 20% for RIC with equivalent relapse and survival.[32] These data suggest that MST conditioning may not be needed for those AML patients in CR1 at the time of HCT. Ongoing prospective randomized clinical trials (BMT-CTN 0901; clinicaltrials.gov NCT01339910) will answer this question more definitively.

Hematopoietic Stem Cell Transplantation for Patients Not in Remission and Beyond First Complete Remission

HCT for AML was first tested in patients with recurrent or relapsed refractory disease three decades ago. The transplant outcome for patients with induction failure or resistant relapse AML or for those with extramedullary disease treated with standard-dose chemotherapy remains quite poor. Although the results are less than satisfactory, there is still a role for HCT for patients with advanced AML.

Difficulties in Achieving Complete Remission 2 Pre-stem Cell Transplantation

More recently, the investigators from City of Hope National Medical Center (COHNMC) reported their extended experience with 71 patients with refractory AML who were treated with HCT during a period of 22 years with 82% receiving grafts from MRD. The median age of these patients was 37 years (range 2 to 62 years) and the median follow-up was 1 year. Three-year disease-free survival (DFS) was 29% with a relapse rate of 54%. Cytogenetic data were available on 51 of the patients treated at COHNMC. Three patients had favorable, 27 intermediate, and 21 unfavorable cytogenetics. Those patients with favorable or

intermediate cytogenetics had DFS of 44% vs. only 18% in those with unfavorable cytogenetic features.[33]

A score to predict transplantation success was developed in a retrospective survey of 1,673 patients who underwent a MST HCT for AML in relapse. In patients with low score the 3-year overall survival (OS) was 42% and those with a very high score had a dismal prognosis with only 6% alive at 3 years. The high score refers to the same group of patients in whom attempts to reinduce second remission are likely to fail. Patients with a short CR1, poor cytogenetics, and/or circulating blasts present a major clinical challenge.[34,35]

Sequential Chemotherapy Followed by Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation

An interesting strategy of sequential cytoreductive chemotherapy, immediately followed by RIC and prophylactic donor lymphocyte infusion (DLI) in refractory and early relapse patients, was evaluated.[36] This German protocol known as the FLAMSA (fludarabine, Ara-C, amsacrine)–RIC approach was reported in a prospective multicenter study involving 103 patients. The median survival of 16.4 months and the 4-year estimated OS of 32% were promising.[36] This approach requires an HLA-matched donor available just when relapse is diagnosed. Therefore, for AML patients in CR1 even if HCT is not scheduled, a search for a donor should be initiated to enable sequential transplantation in case of early relapse.

Persistent Cytogenetic Abnormalities Pre-stem Cell Transplantation

Risk stratification is important to identify patients with AML who might benefit from HCT in CR1. An MD Anderson Cancer Center (MDACC) study analyzed 150 patients with AML and diagnostic cytogenetic abnormalities who underwent MST HCT while in CR1 to evaluate the prognostic impact of persistent cytogenetic abnormalities at HCT.[37] Three risk groups were identified. Patients with favorable/intermediate cytogenetics at diagnosis (n = 49) and patients with unfavorable cytogenetics at diagnosis but without a persistent abnormal clone at HCT (n = 83) had a similar 3-year leukemia-free survival of 58% to 60% despite the higher 3-year relapse incidence in the latter group (32.3%, versus 16.8% in the former group). A third group of patients with unfavorable cytogenetics at diagnosis and a persistent abnormal clone at HCT (n = 15) had the worst prognosis, with a 3-year relapse rate of 57.5% and 3-year leukemia-free survival of only 29.2%. These data suggest that patients with AML and unfavorable cytogenetics at diagnosis and a persistent abnormal clone at HCT are at very high risk for relapse after HCT.[37,38] These patients should be considered for clinical trials designed to optimize conditioning regimens (e.g., clofarabine-based regimen, see below) and/or to use preemptive strategies (e.g., chemotherapy [azacitidine], DLI, early withdrawal of immunosuppression if no GVHD, etc.) in the post-transplant setting, aimed at decreasing relapses.

Acute Myeloid Leukemia Complete Remission 2 and Beyond

Although the results of HCT in CR1 indicate an overall improved outcome compared with chemotherapy, many patients do not undergo transplantation while in CR1 based on either non-severe disease symptoms and/or on the patient desire, or mainly due to physician/patient preferences.

The currently available data suggest that patients with AML with untreated first relapse can expect an outcome following MST HCT similar to that of those patients proceeding to transplantation during CR2.[10] Studies evaluating patients who receive an HCT in second or subsequent relapse, or third or later remissions following standard therapy, have demonstrated very few long-term survivors.

Relapse Prevention and Management of Relapses after Hematopoietic Stem Cell Transplantation

Monitoring of Relapse

Although HCT can be curative, even in advanced disease, treatment failure is commonly manifested by relapse of disease, for which treatment is successful in only a minority of patients.[23] Detection of minimal residual disease in post-transplant surveillance is felt to be a necessary component of any strategy.[39,40] Past strategies for relapse prevention have focused on the use of DLI with variable success. Peritransplantation intervention and maintenance therapies (e.g., azacitidine) are under current investigation.[41,42]

Traditionally, the detection of impending relapse in the post-transplant period had been based on donor chimerism analysis (e.g., poor donor chimerism has been associated with increased risk of relapse), but the lack of specificity remains a problem. In AML, the development of post-transplant minimal residual disease strategies is more complex because of the genetic heterogeneity of these disorders. Nevertheless, for some genetic subtypes, for example, reciprocal translocations or *NPM1*-mutated AML, minimal residual disease monitoring in the post-transplant period has already been realized.[39,43–45]

Walter et al.[24] investigated 99 AML patients receiving MST HCT CR1 by 10-color flow cytometry before transplantation. minimal residual disease-positive patients had lower 2-year estimates of survival (30.2% versus 76.6%) and higher 2-year estimates of relapse (64.9% versus 17.6%), compared with minimal residual disease-negative patients. After adjustment for other prognostically relevant parameters, a positive minimal residual disease status pre-HCT was significantly associated with increased overall mortality and relapse relative to minimal residual disease-negative HCT. Kebriaei et al.[46] found a trend toward improved outcomes in 68 patients in cytogenetic remission compared with those with residual cytogenetic abnormalities at the time of HCT.

In the conservative treatment setting of AML, many minimal residual disease studies confirmed the potential of real-time PCR to predict the relapse risk in patients with reciprocal rearrangements. Some studies investigated the potential of molecular minimal residual disease monitoring for patients with reciprocal rearrangements also in the post-transplant period.[39,43,47]

Novel Conditioning Regimen

Incorporating novel agents in the conditioning regimen with potent antileukemic activity is a strategy that is currently under investigation.[48] Clofarabine is a novel nucleoside analog that has potent antileukemic activity. It has shown efficacy in refractory disease as well as upfront scenarios. Geyer et al.[49] combined total-body irradiation (TBI) with clofarabine and cytarabine for HCT in pediatric patients with refractory or multiply relapsed leukemia in a phase I/II study. The early results show the probability of a 1-year progression-free survival of 57.4%. Andersson et al.[50] reported on a clofarabine/fludarabine/busulfan–based RIC regimen for advanced MDS and AML in 42 patients, which included children. In this high-risk patient population, 20 patients are alive at median survival of 23 months, which is an encouraging early result and warrants further studies.

Targeted immunotherapy post-SCT: One of the strategies for the prevention of relapse of AML/MDS post-SCT is to use targeted immunotherapy as part of the conditioning regimen such as the employment of vaccines, and DLI. Additionally, natural killer cells

could be transferred for the treatment of leukemia relapse both during and after SCT.[23,51,52]

Post-transplant Therapy

The posttransplant therapeutic approach has been limited to TKI in patients with *BCR-ABL1*–positive leukemia. However, other strategies, including the use of interleukins, monoclonal antibodies, immunomodulatory agents (bortezomib), DNA methyltransferase inhibitors, and histone deacetylase inhibitors, are currently being explored in AML.[39] The goal of these approaches is to treat minimal residual disease while minimizing adverse side effects and avoiding the impediment of donor cell engraftment. The use of hypomethylating agents (e.g., azacitidine) in patients with AML/MDS has drawn increased interest because of their demonstrated efficacy and relatively acceptable toxicity profile.[41,42,53]

As our ability to monitor minimal residual disease post-HCT improves, along with identification of actionable molecular mutations, it will allow for the development of clinical trials aimed at prevention of relapse in a targeted fashion. Therapeutic interventions will be needed not only to prevent relapse but allow for simultaneous favorable modulation of the GVHD-graft versus tumor (GVT) balance.

Relapse after HCT for AML carries a very poor prognosis. Second HCT, although curative, is not an appropriate treatment option for a large number of relapsing patients (only 2% to 20% patients receive a second HCT), and efforts to increase the number of patients who may benefit from a second HCT are ongoing.[23]

Incorporating Novel Agents

The development of novel agents is expected to gather momentum as new actionable mutations are identified. A mutation in *FLT3* is well known to be a poor prognostic marker in newly diagnosed and relapsed AML. Specific inhibitors of FLT3 such as sorafenib, lestaurtinib (CEP-701), and quizartinib (AC220) have been studied in relapsed or refractory AML.[10,39,54] FLT3 inhibitors need to be investigated post-SCT in patients with *FLT3* + AML to prevent relapse, a most common cause of transplant failure.[55]

Hypomethylating agents are active in high-risk MDS, and to a lesser degree in highly proliferative AML. 5-Azacitidine was shown in one study to prolong survival in elderly AML patients with low proliferative disease (expected disease course after HCT), and hence has drawn attention as an agent that may control low proliferative relapses after HCT.[53]

Summary

The initial approach for patients should be determined by cytogenetic risk factors, molecular markers, availability of a donor/ stem cell source, and response to induction chemotherapy. Patients with cytogenetic features associated with a good prognosis who achieve a CR with induction followed by consolidation chemotherapy should be observed without immediate transplantation, although HLA typing of these patients and their siblings is warranted at diagnosis. Patients with intermediate or poor markers who achieve a CR with induction/consolidation chemotherapy should undergo an HCT procedure early during CR1 if a histocompatible donor is available or any other stem cell source is available with low risk for transplant procedure. For those patients who do not enter a CR or who relapse after standard therapy, an HCT should be performed sooner rather than later. The transplant approach should be individualized for all patients based on remission status, performance status, and coexisting medical problems, i.e., MST vs. RIC regimens.

The treatment outcome of patients who have suffered a relapse of AML following HCT remains poor. Additional chemotherapy and second transplants are associated with exceptionally high morbidity and mortality and have generally resulted in short remissions. Chemotherapy followed by second non-myeloablative stem cell transplant (NST) HCT or DLI is a reasonable option for patients with late relapse after HCT. Relapse remains a major cause of transplant failure. We believe that the outcome of AML will be further improved by an innovative approach to reducing relapse risk, and that enrollment in clinical trials is the way to go and should be encouraged for all HCT recipients.

Myelodysplastic Syndrome

MDS is primarily a disease of older patients, with a median age at diagnosis in the eighth decade of life. Despite new therapeutic interventions, HCT remains the only curative option for this disease, with long-term survival probabilities ranging from 25% to 70%.[56–59] There is a significant selection bias for HCT as illustrated by the age difference between the average MDS patients and those who ultimately receive a transplant.

Rationale of Hematopoietic Stem Cell Transplantation in Myelodysplastic Syndrome

MDS originates in hematopoietic stem or precursor cells, and a logical approach is, therefore, to replace the clonal MDS cells by healthy donor cells via HCT procedure. Successful HCT requires that the infused cells from the healthy donor establish themselves (engraft), and that the malignant cells of the patient's disease are eliminated by graft-versus-tumor (GVT) effects.

Over the past decade the approach to treating MDS has undergone major changes, at least in part related to the Food and Drug Administration (FDA) approval of several drugs for MDS and the development of new concepts for HCT. The drug therapy has improved the prognosis of patients with MDS, with 35% to 65% of patients achieving clinically relevant hematologic responses which may last from a few months (for high-risk MDS) to several years (predominantly for low-risk diseases). Concurrently, the emphasis with HCT has shifted from high-dose therapy, aimed at maximum tumor cell kill, to low- or reduced-intensity conditioning, relying heavily on donor cell-mediated immune effects to eradicate the disease (GVT effect). This GVT effect eliminates residual cells of the patient's disease via recognition of minor histocompatibility antigens.

Patient Selection for Hematopoietic Stem Cell Transplantation

Since age is a major factor determining the decision about HCT, many patients younger than 60 years of age are likely to be considered for transplantation sooner and more often than older patients.[60] Kuendgen et al. recently presented registry data that included 232 patients less than 50 years of age and 2,496 patients more than 50 years of age, where approximately 42% of the younger patients underwent transplantation compared to only 8% of the older patients.[61]

The International Prognostic Scoring System (IPSS) and World Health Organization prognostic score (WPSS) (discussed in the MDS chapter) are generally thought to identify patients in whom HCT should be considered sooner rather than later.[62] In a retrospective registry-based analysis, Cutler and collaborators showed that upfront transplantation was associated with a greater number of added life years for intermediate-2 and high-risk IPSS patients.[63] Delaying HCT offered the longest life expectancy in patients in IPSS categories low and intermediate-1. In the MDACC experience in 89 MDS patients who underwent HCT from 2002 to 2008, the 3-year OS rates were 79%, 49%, and 27%, respectively, for patients with WPSS low-intermediate-, high-, and very-high-risk categories, respectively.[56]

The European Group for Blood and Marrow Transplantation (EBMT) analyzed the post-transplant outcome of 692 patients with MDS according to their cytogenetic status. The overall survival and relapse rates were 47% and 34% for good-risk, 40% and 35% for intermediate-risk, and 31% and 57% for high-risk cytogenetics.[64] A recent analysis showed that patients with secondary MDS had a post-transplant prognosis comparable to patients with de novo MDS once the data were adjusted for cytogenetic risk. In a small series of 47 patients with high-risk MDS, the 3-year OS was better in patients who received HCT than in those who did not (71% v 31%).[65]

Novel genetic factors are being studied to determine possible predictors of transplant outcomes.[56] A significant correlation between HLA-DR15 and tumor necrosis factor (TNF) polymorphisms at position 308 among patients with MDS has been observed. The TNF-308 AG genotype conferred an increased risk of TRM compared to the GG genotype. Conversely, the TNF-863 AA genotype was correlated with decreased overall mortality and TRM compared with the CC genotype.[66]

Timing of Hematopoietic Stem Cell Transplantation

Determining the optimal timing of HCT for MDS has proven difficult, although all available data indicate that patients transplanted at an early stage of their disease have superior outcomes. Al-Ali et al.[67] observed that HCT outcome was best if SCT was performed between 6 and 12 months after diagnosis, the negative effect of later HCT being possibly related to frequent blood transfusion, longer duration of pancytopenia, and disease progression while waiting for HCT. If SCT is delayed, for example because of a lengthy search for an unrelated donor, bridging treatment with hypomethylating agents may delay progression to AML.[68]

It is expected that incorporation of newer prognostic tools such as flow cytometry or molecular markers will improve our ability to select patients for transplantation at an earlier time period.[69,70] Newer risk models and individual risk factors (such as co-morbidities) will hopefully identify covariates that are likely to affect outcomes across non-transplant and HCT therapies.[59,71–74]

Pre-transplant Disease Status

In an attempt to improve chances for post-SCT success, patients with a high marrow myeloblast count, (e.g., >5–10%), typically will receive pre-SCT therapy with a hypomethylating agent or with more classical induction-type chemotherapy.[56,58,68] The clinical impression is that pre-SCT therapy may select chemosensitive patients since it appears that patients who do respond to such therapy have a superior outcome, and patients who fail to respond have a poorer outcome than do untreated patients.[75]

The CR status at the time of transplant may impact relapse and TRM rates favorably; however, CR in chemotherapy-treated patients with MDS is infrequent. Warlick et al.[76] studied 84 patients undergoing HCT, and observed a 1-year cumulative incidence of relapse of 18% in patients in CR compared to 35% for those transplanted with active disease. In a retrospective analysis of 49 MDS/AML patients treated with T cell–depleted grafts, the 2-year cumulative incidences of TRM were 23%, 38%, and 40%, respectively, dependent upon response status prior to HCT (responsive disease, untreated, and refractory).[77] Oran et al. also documented the benefit of minimal tumor burden at HCT in patients with high-risk MDS/AML undergoing RIC HCT. CR at SCT was associated with day-100 and 2-year TRM rates of 0% and 20%, respectively. Estimates of 2-year OS were 66% for those in CR, 40% for patients with active disease without circulating blasts, and 23% for patients with circulating blasts.[78]

Nakai et al.[79] compared the outcomes of 283 adult patients with MDS (n = 215) or secondary AML (n = 68) who received (n = 188) or did not receive (n = 95) induction chemotherapy prior to HLA-identical sibling donor HCT, and showed no difference in survival rates between the two groups, with 5-year OS rates of 54% and 57%, respectively. Similarly, Scott and collaborators in Seattle failed to demonstrate a clear survival advantage for a cohort of patients studied retrospectively that received induction chemotherapy pre-transplant, although the risk of relapse was somewhat reduced.[80]

In the absence of controlled data, the decision to use pre-SCT induction therapy should be made on an individual basis. The treatment strategy should also take into account the fact that promising novel drugs are becoming available, although it is unclear if this approach will change long-term outcomes.

CURRENT OUTCOME DATA

An analysis by Warlick et al.[76] showed a 1-year OS of 48%, a cumulative relapse incidence of 23%, and a DFS of 38%. The EBMT registry analyzed results in a cohort of 374 patients with <5% myeloblasts who received HCT from HLA-matched donors after various conditioning regimens.[81] At 4 years, DFS was 48%, the relapse incidence 15%, and deaths not related to relapse 37%. The risk of relapse was increased after RIC compared to MST conditioning (HR 2.8), but overall survival did not differ significantly. Patients transplanted from URD had a lower relapse risk (HR 0.6), but a higher risk of non-relapse mortality (NRM) (HR 1.4), and OS did not differ significantly between related and unrelated HCT. T cell depletion of the transplanted cells resulted in higher NRM. Younger patients and patients transplanted within 12 months of diagnosis had superior outcomes.

The Fred Hutchinson Cancer Research Center (FHCRC) published results in 257 patients transplanted for secondary MDS. At 5 years, 19% of patients with tAML were surviving in remission, compared with 25% of patients with refractory anemia with excess blasts (RAEB), and 41% of patients with refractory anemia/refractory anemia with ringed sideroblasts (RA/RARS). Two-thirds of patients developed acute GVHD grades II–IV and 57% developed chronic GVHD. After adjusting for karyotype, there were no significant differences in outcome between the cohort with secondary MDS and the cohort of 339 patients with de novo MDS. The probability of relapse and DFS correlated significantly with disease stage ($P < 0.001$) and cytogenetics ($P < 0.001$). As in many other studies, patients transplanted from unrelated donors (n = 122) had a lower risk of relapse ($P = 0.003$) and superior DFS ($P = 0.02$) compared to patients transplanted from related donors.[58] These results were confirmed in principle in a more recent analysis of CIBMTR data.[82] These studies emphasize the importance of cytogenetics on HCT outcome.

Martino et al.[83] analyzed HCT results in an EBMT cohort of 215 patients with MDS conditioned with RIC and 621 patients who received MST conditioning and were transplanted from HLA-matched related donors. For the MST and RIC cohorts, NRM at 3 years was 32 versus 22%, OS was 45% versus 41%, and DFS 41% versus 33%. Lack of remission before HCT ($P = 0.001$), poor-risk cytogenetics ($P = 0.03$), transformation to AML, and older age were risk factors for inferior DFS.

A British trial[84] evaluated the results in 75 patients conditioned with an alemtuzumab-based RIC regimen and transplanted from unrelated donors. After 3 years transplant-related mortality (TRM), DFS, and OS for patients with refractory cytopenia with multilineage dysplasia (RCMD) were 24%, 55%, and 59%, respectively; the corresponding numbers for patients with RAEB (1 and 2) were 44%, 18%, and 18%, respectively. HLA-mismatch negatively affected all endpoints, as did disease status at HCT and patient co-morbidities.

Strategies to Improve Transplant Outcome after Hematopoietic Stem Cell Transplantation

Pre-transplant Use of Hypomethylating Agents

Field et al.[85] presented data in 54 consecutive patients with MDS or chronic myelomonocytic leukemia (CMML) who underwent HCT from HLA-matched donors. Thirty patients had received azacitidine for one to seven (median 4) cycles, and 24 patients had not received azacitidine. At 1 year after HCT with conditioning involving high-dose busulfan and fludarabine, 47% of azacitidine-treated patients were alive, compared with 60% of patients not given azacitidine, but relapses were 20% and 32%, respectively. The authors concluded that outcome was consistent with a trend toward a lower incidence of relapse in azacitidine-treated patients.

In a study by De Padua Silva et al.[86] 17 patients with MDS underwent HCT after having received decitabine. At 1 year, 11 patients were alive, whereas six had died: four from disease progression, one from GVHD, and one with septicemia. Lubbert et al.[87] presented data on 15 similarly treated patients who then underwent HCT following RIC regimen. At the time of reporting, 6 patients were alive in remission, whereas four had died from progressive disease and five from transplant-related complications while in remission.

FHCRC recently reviewed results in 68 patients who underwent HCT for MDS or AML transformed from MDS (tAML). Thirty-five patients had received cytoreduction with azacitidine prior to SCT followed by either an MST (40%) or RIC (60%) regimen, and 33 patients had undergone induction-type chemotherapy followed by SCT with MST conditioning. The 1-year overall survival was 57% in the azacitidine group, and 36% in the group given induction chemotherapy. Although the risk of post-SCT relapse and NRM was lower in the azacitidine group, none of the differences were statistically significant.[88]

Hypomethylating Agents Post-transplantation

Post-SCT relapse has remained a major cause of failure, particularly in high-risk MDS. Earlier studies had shown that intensification of the transplant conditioning regimen reduced the relapse frequency, though the associated increase in NRM may prohibit such use. It may be advantageous to allow for recovery from the conditioning-related effects, and then administer additional agents. As most of the post-transplant relapses occur within the first 1 to 2 years, addition of hypomethylating agents may have immunomodulatory effects that could potentially increase the GVT response.[68]

In a phase I dose-finding study, de Lima et al.[53] at the MDACC started azacitidine at 6 to 7 weeks after HCT and determined that a dose of 32 mg/m^2 given for 5 consecutive days was well tolerated. Forty-five patients with high-risk MDS/AML were treated and 1-year RFS was 58%. In addition, the authors noted that the incidence of chronic GVHD was lower in 5-azacitadine-treated patients than in historical controls. This observation was confirmed in a study at Washington University, which emphasized, in addition, that the beneficial effect on GVHD did not compromise the GVT effect.[89]

Similarly, Platzbecker et al.[41] reported a prospective study of patients receiving HCT for MDS and AML. If the donor chimerism fell below 80%, patients were offered treatment with 5-azacitidine. This event occurred in 25 of 59 screened patients at a median of 169 days, and azacitidine was initiated at 75 mg/m^2/day for 7 days. Sixteen patients responded with an increase in donor chimerism or stabilization at 80%. Eleven patients were given additional 1 to 11 (median 4) cycles of azacitidine. Hematologic relapse eventually occurred in 13 patients (65%), but was delayed to days 56 to 558 (median 231). Therefore, preemptive azacitidine treatment may be effective in delaying hematologic relapse.

Other Post-stem Cell Transplantation Interventions

DLI may improve transplant outcomes in high-risk MDS by decreasing relapse rates. Kolb et al.[90] investigated escalating doses of DLI to treat a subset of patients with high-risk MDS (n = 67) or patients with secondary AML (n = 90) after RIC HCT. Relapse appeared less likely in patients given DLI.

Another approach under investigation by several groups is the use of vaccines against leukemia-specific antigens such as Wilms tumor gene 1 (WT1) and proteinase-3-derived PR1 peptide (or the use of antigen-specific cytotoxic T-lymphocytes). Peptide-based vaccination has been shown to elicit immunologic T cell and clinical responses in myeloid leukemia.[51,52]

Relapse after Hematopoietic Stem Cell Transplantation

Post-SCT relapse remains a challenging problem, particularly in patients prepared for HCT with RIC regimens.[23,57,60] Multiparameter flow cytometry has been used effectively to show that aberrancy of marrow blasts pre-SCT can influence outcome after SCT.[69] However, the definition of minimal residual disease in patients with MDS has not been clarified.[39]

The infusion of donor lymphocytes in patients with relapse has shown only limited efficacy, as has withdrawal of immunosuppressive therapy (IST).[23,58] Early administration of hypomethylating agents may be more effective.[23,41,53,89] The prophylactic use of drugs such as hypomethylating agents or small molecule inhibitors that are coming into use in patients with high-risk disease may be even more effective. Intensive chemotherapy has generally been disappointing, and second allo-SCT in adults has yielded low-success rates.[23,91]

Summary

HCT continues to be the only curative option for MDS. Since the majority of patients with this disease are often older and frail, treatment-related mortality and morbidity remain major obstacles to be overcome. The development of reduced toxicity regimens has allowed HCT to be offered to older patients and those with clinically relevant co-morbid conditions.

Post-transplant relapse and GVHD remain problems requiring further research in this area. Ongoing studies are exploring the incorporation of novel agents (used in non-transplant therapy) during the peri-transplant period.

Acute Lymphoblastic Leukemia

HCT is a potentially curative therapeutic modality for acute lymphocytic leukemia (ALL). Unlike the dramatic advances made in the treatment of childhood ALL with 5-year survival at more than 80%, therapeutic progress for adult ALL has been relatively slow, with long-term survival being achieved in only about 30% to 40% of patients.[92,93]

As modern induction regimens can obtain CR rates in up to 80% to 90% of patients, the major barrier to improved results in the treatment of ALL in adults remains the high relapse rates in patients with CR1. Among the various post-remission therapies, HCT remains the single most effective modality for consolidation and prevention of relapse.

Among 3,113 patients ≥ 20 years of age receiving HLA-matched sibling HCT for ALL between 2000 to 2009, the 3-year survival probabilities were 51%, 34%, and 21% for patients with early, intermediate, and advanced disease, respectively. Corresponding probabilities among the 3,086 recipients of unrelated donor HCT

were 45%, 33%, and 16% (Center for International Blood and Marrow Transplant Research, CIBMTR, 2011).[2]

Major predictors of HCT outcome in ALL are remission state at time of transplantation and age.[94] Defining prognostic markers to help determine the optimal use and timing of HCT in the treatment algorithm of patients with ALL is critical. This part of the chapter describes the recent studies and current practice patterns concerning the who, when, and how of HCT in the management of adult ALL.

Indications of Hematopoietic Stem Cell Transplantation

Generally accepted prognostic indicators including age, WBC count, immunophenotype, certain high-risk cytogenetics, and treatment response during induction therapy remain classic prognostic features. OS ranges from 34% to 57% for patients less than 30 years compared with only 15% to 17% for patients greater than 50 years. Generally, a WBC count greater than 30,000/ul or 50,000/ul for B-lineage ALL and greater than 100,000/ul for T-lineage ALL predict for poor prognosis. T-lineage ALL also appears to have better outcomes than B-lineage ALL, while among T-lineage ALL, patients with cortical T ALL appeared to have the best outcomes.[93]

The achievement of CR and time to CR after induction therapy also carries significant prognostic implications, with patients who require more than 4 weeks achieving a CR having a lower likelihood of being cured. Specific cytogenetic abnormalities also have a major impact on prognosis. The presence of the Philadelphia (Ph) chromosome and t (4;11) (q21;q23) have been associated with inferior survival in multiple large series. Additionally, the presence of the t(8;14)(q24.1;q32) complex karyotype defined as ≥ 5 chromosomal abnormalities, or low hypodiploidy/near triploidy, were noted to have poor survival in the analysis of patients treated in the UKALL XII/ECOG 2993 trial.[95,96]

Despite documented improvements in the long-term survival of adult patients with certain phenotypes of ALL, the results have not been as good as those achieved in children. Several large studies have shown that CR can now be achieved in 80% to 90% of newly diagnosed adult patients under the age of 60 years. With modern intensive chemotherapy, approximately 30% of adult patients can achieve a cure of the disease. For patients with poor-risk features (discussed above), HCT is the therapy most likely to lead to long-term DFS. For those patients who relapse, HCT offers the only chance for long-term disease control.

For patients with high-risk features, there is general agreement that allo-HCT in CR1 is a potentially curative option; however, there is no consensus on early transplant for standard-risk patients.[92,97] Minimal residual disease evaluation and monitoring is developing as an important prognostic factor and could guide physicians in determining which patients, especially those with standard risk, might require transplant.[98] On the basis of the Medical research Council and Eastern Cooperative Oncology Group (MRC/ECOG) data, it is worth considering HCT for standard-risk patients in CR1, as the relapse rate is high and the prospects of achieving CR2 are uncertain. [99,100]

Philadelphia Chromosome-Positive (Ph+) Acute Lymphoblastic Leukemia

Historically, patients with Ph+ ALL have had a poor prognosis with long-term DFS rates of 10% to 20%.[101] In the pre-imatinib era, HCT from a related or unrelated donor was widely used for consolidation, with 30% to 65% long-term survival for patients receiving HCT in CR1. Beyond first remission, HCT was curative in only a small fraction of patients with DFS ranging from 5% to 17%.[92,93,100]

In the post-TKI era, the incorporation of imatinib into standard ALL therapy has resulted in significantly improved remission induction rates, as well as improved depth of remissions, enabling more HCT performed in CR1. Indeed, in a report from the MRC/ECOG group, the rate of HCT was found to be improved with the addition of imatinib (28% in the pre-imatinib era, compared with 44% for patients receiving any imatinib on protocol).[102] With the use of an imatinib induction combined with a MST HCT, 3-year OS rates of between 50% and 65% have been reported.[103] In recent years, there has been increasing use of second-generation tyrosine kinase inhibitors together with chemotherapy in the frontline therapy for patients with Ph+ ALL. Results have been encouraging with high CR rates (more HCT eligible patients) and encouraging DFS, albeit with relatively short follow-up. The data on HCT in patients treated with second-line agents, however, remains very limited.[103]

Reduced-intensity vs. Myeloablative Regimen in Tyrosine-Kinase Inhibitor era

The key challenges in the treatment of Ph+ ALL are the selection of appropriate pre-transplantation therapy, the minimization of transplantation toxicity, the use of TKIs after transplantation, and the appropriate use of and response to BCR-ABL monitoring.

Where imatinib-based induction was combined with MST HCT, the 3-year OS rate in the UKALL12/E2993 protocol was 59%.[99] Successive German Multi-Centre ALL (GMALL) studies in Ph+ ALL also revealed that excellent outcomes can be achieved with MST HCT when an imatinib-based induction is used; OS at 3 years was 72%.[104] A recent Japanese Adult Leukemia Study Group also reports a 3-year OS probability of 65% after imatinib-based induction and MST HCT.[105]

In recent data from the Seattle group, the subgroup of Ph+ patients receiving an HCT following a Fludarabin (Flu)/TBI non-myeloablative allogeneic stem cell transplantation (NST) regimen had an impressive 3-year OS of 62%, up to 73% in the group without minimal residual disease at transplant, and a relapse rate of 32% when done in CR1, thus demonstrating that GVT contributes to the excellent outcomes in this patient population.[106] Importantly, it may be feasible to achieve CR following a milder induction regimen consisting of TKI combined with steroid therapy only, followed by RIC or NST HCT consolidation in the older patient population who are ineligible for intensive induction.

In summary, HCT approaches appear promising, offering DFS rates in Ph+ ALL that appear higher than could be obtained with chemotherapy and imatinib alone. A comparative study of EBMT registry reports of the outcome of MST versus RIC HCT in patients with ALL confirms this impression.[107] In a multivariate analysis, the type of conditioning regimen was not significantly associated with outcome.

Patients with Poor Donor Options

TKIs such as imatinib, dasatinib, and nilotinib are now standard therapy for Ph+ patients and the resultant increase in initial remission rates has allowed greater eligibility for HCT.

It is hard to be exactly sure if the risk of TRM balances against the increased risk of relapse. Haploidentical HCT often results in a very high TRM. However, recently the group at Johns Hopkins developed a novel approach of haploidentical transplantation using unmodified haploidentical marrow followed by the use of post-transplantation cyclophosphamide to eliminate alloreactive T-cells, with encouraging preliminary results in patients with hematologic malignancies.[108] CBT in adults has a higher TRM than matched-unrelated donor (MUD) HCT. However, where the donor is not fully matched, CB is arguably a better option. A recent report from Japan documented 8 adults with Ph+ ALL who, after a median of 26 months of follow-up, had an estimated 3-year OS

of 100% and a leukemia-free survival of 85%.[109] In a recent report from the University College London group of 50 patients receiving mismatched-URD grafts after RIC for a variety of disorders, including acute leukemias, there was no difference in 3-year OS (53% vs 49%, $P = 0.44$) between fully matched and mismatched-URD, even though the mismatch occurred at the antigenic level in 40 cases.[110]

The advent of these new alternative sources of stem cell transplants have allowed increased accessibility of HCT to patients without matched adult donors. The results from the limited studies discussed above have demonstrated the feasibility of such transplants. However, more studies will be necessary in order to determine the optimal timing and use of these novel approaches, and until then these should be performed in experienced centers and ideally in the context of a well-designed clinical trial, if available.

Post-transplant Tyrosine-Kinase Inhibitor

A very important and as yet unanswered question concerns whether TKIs should be administered after HCT and under what circumstances.

A Programa para el Estudio de la Terape´utica en Hemopatı´a Maligna (PETHEMA) study reported that imatinib was poorly tolerated after MST HCT; only 62% of patients were able to start at a median of 3.9 months after HCT, and many patients required discontinuation or a significant dose reduction.[111] In an ongoing GMALL study for which preliminary results have been reported, patients were randomized after HCT to either upfront imatinib beginning at 3 months after HCT wherever possible, or imatinib started only upon any BCR-ABL reappearance.[103] This study also reported poor tolerance of imatinib when given early after HCT. In contrast, most patients who started imatinib after the detection of BCR-ABL had a prompt suppression of BCR-ABL in response to the drug, and no difference in outcome between the groups. A small, nonrandomized, single-center study from the University of Minnesota showed a trend toward improved outcome in patients who could be treated with imatinib in the pre- and post-transplantation period after TBI-based MST regimen.[112] Similarly, Ram et al.[106] reported that imatinib given for a median duration of 11.5 months after RIC with fludarabine and 2 Gy of TBI (which was relatively well tolerated after transplantation, with only 3 of 18 patients needing to stop the drug) was associated with significantly reduced mortality on univariate analysis, although the effect on relapse was not statistically significant.

There is insufficient evidence to conclude that TKI should be given to all patients after HCT. However, outside of a clinical trial, careful consideration should be given on a patient-by-patient basis as to whether and when to start TKI.

Philadelphia-Negative (Ph-) Acute Lymphoblastic Leukemia

Stem Cell Transplantation in First Complete Remission for HR Patients

HCT in CR1 from related or unrelated donors is generally accepted as the most effective available therapy for patients with Ph- ALL.[92,93,94]

For standard-risk patients, earlier studies did not show a benefit for HCT. In the LALA87 trial, for example, standard-risk patients had no significant benefit from being assigned to the HCT arm, with a 10-year OS of 49% as compared to 43% in the chemotherapy arm.[113] Two recent studies have, however, suggested that HCT may benefit standard-risk patients. Standard-risk patients in the MRC/ECOG trial with a donor had a statistically significant benefit in OS to having a sibling donor and receiving an HCT, with a 5-year overall OS in the donor group of 62% compared to 52% for patients with no donors ($P = 0.02$).[99] A recent study from the HOVON Cooperative Group allocated standard- and high-risk patients with a matched sibling donor to HCT and those without to auto-SCT. Interestingly, in this study, the differences in OS were again more pronounced in the standard-risk group (5-year OS 69% vs. 49%) than in the high-risk group.[114]

In the more recent meta-analyses by Ram et al.[115] and Pidala et al.,[116] the survival benefits for HCT were more pronounced in the standard-risk arms.

Relapse and Refractory Diseases

Transplantation in Complete Remission 2

Patients with ALL refractory to primary chemotherapy or who relapse have extremely poor prognoses; HCT is the only curative option if they can achieve remission pre-transplantation.

In patients with refractory disease or who relapse following initial chemotherapy, the CR rates to salvage therapy range from 40% to 45% and the OS is usually less than 10%.[92,93,94] The 609 adults with relapsed ALL who were previously treated on the MRC UKALL12/ECOG2993 had a 5-year survival rate of 7%. Importantly, in the subgroup analysis based on treatment strategy, 5-year survival following HCT ranged from 15% to 23% depending on donor type (15% for autograft, 16% for URD, 23% for MRD), and was significantly better than chemotherapy (4%) ($P < 0.05$).[99]

Oriol et al.[117] reported on the outcome of 263 adults with relapsed ALL, all of whom were previously treated on four consecutive PETHEMA trials with similar induction therapies. Forty-five percent of patients achieved a second remission, with better outcome noted in the group who then proceeded to HCT. The best outcome was noted for patients younger than 30 years with a long first remission duration transplanted in CR2, with OS 38% at 5 years. In an analysis of 421 patients previously treated with the LALA-94 trial who had disease relapse, 44% of patients achieved a CR2, but the 5-year OS was again significantly better in the subset able to receive HCT (25% vs. 7% for the whole group).[118]

The results from these trials demonstrate that in patients in CR2, HCT offers a better chance for long-term survival as compared to chemotherapy alone.

Marks et al.[119] recently demonstrated that the relative risk of relapse is significantly higher for patients with Ph- ALL in CR2 compared to CR1, particularly for those patients whose duration of CR1 was less than 1 year. Outcomes for patients with active disease are dismal and this contributes to the argument that perhaps all patients should be transplanted in CR1, as CR2 is frequently not achievable.

Active Disease Pre-stem Cell Transplantation

Given the high risks associated with salvage chemotherapy, some argue that for patients with an available donor, low to moderate tumor burden, and disease features suggestive of a highly aggressive course, reinduction chemotherapy may be omitted in preference for immediate HCT. In one of the largest retrospective reviews specifically addressing this issue, Terwey et al.[120] were able to show a 5-year OS rate of 47% in 19 patients with relapsed or refractory disease who received an HCT without prior reinduction chemotherapy, a result that was superior to the group that had received prior reinduction chemotherapy (5-year OS = 18%). Further prospective data are necessary before any recommendations can be made, and currently, management decisions regarding reinduction chemotherapy versus upfront transplant in early relapse will have to be individualized depending on the patient, their disease behavior, and the availability of donors.

Importance of Minimal Residual Disease

In addition to age and cytogenetics at diagnosis, the most important prognostic factor, and a direct reflection of sensitivity to chemotherapy, is the achievement of CR (minimal residual disease negativity).

The developments of molecular techniques both to diagnose and monitor small amounts of ALL cells have been utilized to determine the risk of relapse in patients undergoing either standard therapy or HCT.[98]

The role of minimal residual disease quantitation to evaluate treatment response and predict relapse is evolving in adult populations with exploration of flow cytometry and RT-PCR techniques. Several studies have indicated that testing for minimal residual disease both pre- and post-transplant for patients with ALL may also be useful. In general, these studies show that relapse was higher in patients who showed a positive assay before SCT or within the first year after HCT, compared to those who showed no PCR positivity.[98]

Presence of minimal residual disease is associated with adverse outcomes even in patients otherwise considered at standard risk, and these patients may benefit from early allo-HCT in CR1. Data support an minimal residual disease level of (0.01%) or greater as the current determinant of high risk for disease relapse.[98]

Management of Relapse after Hematopoietic Stem Cell Transplantation

Once patients with ALL relapse after HCT, the prognosis is extremely poor. Similarly to the approach in patients with AML and CML, manipulation of the antitumor effect mediated by the donor graft is often employed as a treatment strategy.[23,121] Unfortunately, in patients with ALL, this therapy has not been as effective as it has been for patients with CML.[122]

Overall, few patients who relapse after HCT are long-term survivors. In a series of 130 patients who relapsed after HCT for treatment of ALL, 94 patients underwent salvage therapy. Relapse more than a year after SCT and isolated extra-medullary relapses were associated with a higher probability of subsequent remission. However, of the 52 patients who achieved a remission, only three became long-term survivors.[123] DLIs and second HCT are also considered in patients who relapse late after SCT.[19,124,125] In a series of 15 patients who relapsed after SCT, a second HCT was associated with TRM of 36% at day 100, and only 8% had long-term DFS.[125]

DLIs rarely produce long-term DFS in ALL. In a report from Europe, 40 patients with ALL received DLI as treatment for relapse and of 29 evaluable patients, only one achieved CR. Therefore, DLI as a sole therapy appears to have low potential for contributing to a remission and long-term control of disease in patients with relapsed ALL, and, if considered, should be a component of a chemotherapy-based treatment program (e.g., chemo-DLI or chemo-second SCT options).[120] Studies focused on developing antigen-specific T cell immunotherapy for ALL may help augment the GVL activity of donor T cells.

Summary

HCT is an effective post-remission therapy in patients with ALL, and HCT adult CR1 from related or unrelated donors is generally accepted as the most effective available therapy for patients with ALL. Increased advances in RIC preparative regimens and alternative donors have increased the accessibility of HCT. A risk-adapted paradigm, using minimal residual disease analysis, may help in the selection of patients at highest risk for relapse, who may benefit most from HCT.

A recently published American Society for Blood and Marrow Transplantation (ASBMT) evidence-based review reports: (1) MST HCT is an appropriate treatment for adult (<35 years) ALL in CR1 for all disease risk groups; and (2) RIC may produce similar outcomes to MST. Treatment recommendations unchanged or strengthened by new evidence include: (1) HCT is recommended over chemotherapy for ALL in CR2 or greater; (2) HCT is superior to auto-SCT; and (3) there are similar survival outcomes after related and unrelated HCT. New treatment recommendations based on new evidence include: (1) in the absence of a suitable allogeneic donor, auto-SCT may be an appropriate therapy, but results in a high relapse rate; (2) it is appropriate to consider CBT for patients with no HLA well-matched donor; and (3) imatinib therapy before and/or after SCT (for Ph+ ALL) yields significantly superior survival outcomes.[122]

Lymphoid Malignancies

Over the past decade, the number of HCTs performed for lymphoma continues to rise and lymphoma is a common indication for consideration of HCT. HCT in lymphoma is often indicated in patients with recurrent disease relapse, failure after auto-SCT, or massive bone marrow involvement on presentation. Primary refractory disease or disease relapse following immune-chemotherapy are usually incurable with chemotherapy alone. Despite recent advancements in immune-chemotherapy, a significant proportion of patients succumb to disease relapse. The curative potential of graft-versus-lymphoma (GVL) effect has been demonstrated in several lymphoma histologies. The response to DLI further strengthens the argument that the GVL effect exists in both Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). The timing of transplantation needs to be redefined in this modern era of maintenance and targeted therapies. There is a great interest in considering HCT earlier under certain circumstances. RIC or NST HCT is gaining popularity among lymphoma patients needing HCT and is being increasingly performed as it can be offered to older patients with less toxicity and yet with the benefits of the GVL effect. In this part of the chapter we will discuss the role of HCT in patients with various lymphomas.[126,126–128,129]

Follicular Lymphoma

The optimal timing of HCT in FL is yet unclear.[130] A prospective study comparing auto-SCT and HCT was closed early due to poor accrual.[131] Retrospective analyses of large registry data support the use of HCT which is associated with lower relapse rate and longer DFS.

The GELTAMO group has reported the outcome in 37 FL patients who underwent an MRD using melphalan and fludarabine conditioning. The majority of patients had chemosensitive disease and 40% were in CR at the time of HCT. After median follow-up of 52 months, the 4-year DFS for patients with PD, PR, or CR at transplantation were 29%, 48%, and 64%, respectively; whereas the 4-year cumulative incidences of NRM were 71%, 33%, and 26%, respectively.[132] A B cell lymphoma–specific NST regimen—fludarabine, cyclophosphamide, and rituximab (FCR)—is reportedly safe and effective and this regimen resulted in a TRM of 10%, with 85% patients alive without disease at 8 years. In the updated 12-year follow-up analysis, the OS and progression-free survival (PFS) were 78% and 72%, respectively.[133,134]

Favorable outcomes were also reported by the Cancer and Leukemia Group B 109901 trial in 16 patients with relapsed chemosensitive FL using an NST regimen consisting of fludarabine and cyclophosphamide (FC). This study reported a 3-year EFS and OS of 75% and 81%, respectively. Compared with studies employing NST regimens (such as FC or FCR), there is no evidence that the more substantial RIC regimens (fludarabine and melphalan or busulfan) provide any advantage in disease control in patients with chemosensitive disease.[135]

A tandem auto- followed by allo-HCT approach for aggressive disease in 27 patients demonstrated an OS and PFS of 96% at

3 years. These results are encouraging, albeit in a highly selected group of patients, but this approach is worth considering in patients with advanced disease.[136] Non-ablative or RIC HCT is feasible and safe to perform after prior auto-HCT failure.[137]

T cell depletion allografts among 82 patients were evaluated recently. The NRM was 15% with a very favorable 4-year PFS of 76%.[138] In the United Kingdom (UK), alemtuzumab was incorporated in the conditioning regimen with fludarabine and melphalan. The NRM with this regimen was only 11% with a 3-year OS of 73%.[139]

The experience of HCT for patients with FL is summarized in Table 104.1.

There are no randomized controlled data available to support allografting in chemosensitive FL patients in first remission. Limited single institution data are available for HCT in a small subset of high-risk FL patients with primary refractory disease. Such high-risk FL patients with primary refractory disease could be considered for an HCT within the context of a clinical trial.

Auto-Stem Cell Transplantation vs. Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation for Relapsed Follicular Lymphoma

A commonly encountered question is whether to offer auto- or RIC HCT to patients with FL relapsing after multiple lines of prior therapies. An adequately powered prospective trial comparing these two options is lacking. Unfortunately, the very important BMT-CTN trial comparing auto-SCT to RIC HCT in FL was closed early because of poor accrual. While acknowledging the scarcity of good quality clinical trial data, it appears that the TRM rate with FCR RIC allo-HCT is relatively low, with much lower risk of disease relapse and no risk of sMDS/ AML, when compared against auto-SCT. Considering these facts, it is appropriate to offer RIC allo-HCT for selected FL patients when curative intent is pursued. While the timing remains controversial, we consider this option mainly in patients who have progressed after 2–3 lines of prior therapies (including at least one with anthracyclines and/or fludarabine), provided that the disease remains chemosensitive and patients are not candidates for clinical trials. Auto-SCT could be considered for patients who are medically unfit for RIC HCT or those without an adult or alternative donor, with the understanding that a cure may not be achievable.[133,140]

Summary

It is important to obtain a good remission status prior to HCT. Intensified therapies to improve disease control prior to SCT are needed to make HCT an eligible option. Various strategies are being investigated to improve outcome in patients with refractory disease and to prevent relapses after SCT, including incorporating novel agents into the conditioning regimen to increase effectiveness without increasing toxicity, and enhancing GVL effects through tumor-specific immunization or post-transplantation immunomodulation (e.g., DLI with or without rituximab).[141,142]

Chronic Lymphocytic Leukemia

Poor-risk patients, defined as resistant to purine analog therapy, 17p deletion, *TP53* mutations, responding to salvage therapy, are considered for early HCT.

HCT in CLL dates back to 1992; initial data reported the outcome on 26 patients who underwent MST HCT for refractory CLL. The high NRM (50%) with this regimen was disappointing. Long-term PFS can be achieved in 30% to 60% of transplanted patients by RIC HCT.[143] In the CLL3X trial of the German CLL Study Group (GCLLSG), 90 patients underwent HCT with an FC-based regimen. In this study, patients with purine analog resistance had similar PFS as patients without purine analog refractoriness. Patients with uncontrolled disease at the time of transplant affected outcome adversely. The negative impact of del 17p was overcome by HCT.[139,144] In an analysis of 46 patients receiving RIC HCT for advanced CLL as reported by Brown et al., the 2 year OS and PFS were 54% and 34%, respectively. The number of prior regimens was inversely proportional to patient outcome.[139,145]

As with FL, the FCR RIC regimen was applied to patients with CLL. Following HCT, about half of the patients required immune manipulation including therapy with DLI, again suggesting a GVT effect.[139,146] The potential curative role of HCT in patients with 17p deletion was noted in 44 patients with this chromosomal abnormality. In this study, the 3-year PFS and OS were 37% and 44%, respectively. The vast majority (89%) of the patients in this study had received RIC.[139,147] In the study by the Seattle Consortium, a 5-year PFS of 39% was reported with very few late events despite a high proportion (87%) of patients with fludarabine refractoriness.[139] The vast majority (89%) of the patients in this study had received RIC. In older registry data the NRM rates were up to 44% following MST HCT for CLL; whereas more recent data obtained with RIC uniformly show a NRM between 15% and 25% and the latest studies using FCR RIC HCT show around 10%.[139,148,149]

The experience of all-SCT for patients with CLL is summarized in Table 104.2.

The EBMT consensus on indications for HCT in CLL includes eligible patients with previously treated, poor-risk CLL, that is, purine analog refractoriness, early relapse after purine analog combination therapy, and CLL with p53 lesion requiring

treatment. These consensus guidelines were based on evidence of grade II or less. As mentioned earlier, evidence is increasing that RIC HCT can mitigate the adverse prognostic impact of purine analog refractoriness and del 17p- as long as CLL has not become generally resistant to salvage treatment.[150]

The addition of novel treatment modalities and emerging clinical data, though they may not result in cures, should be incorporated into HCT. To date, HCT is the only treatment with the potential of providing long-term disease control in this condition. In addition to the disease risk, patient-related risk factors, such as age and co-morbidity, have to be considered when the decision about HCT is made. Prospective data is available on RIC HCT patients rather than MST regimens, which are mainly derived from registry data. Given the safety, efficacy, and age at which this disease manifests, RIC is possibly superior despite the lack of randomized data.[151]

Transformed Lymphoma

There is a paucity of literature on the treatment of TL, and therefore deciding on the optimal evidence-based treatment is a challenge. The most specific publications report on auto-SCT showed encouraging results. However, these series are highly selected groups of patients, and unfortunately, the majority of patients with transformed lymphoma (TL) are likely to be too old, with poor performance status, or to have had an insufficient response to reinduction chemotherapy, making them ineligible for SCT. Non-HCT treatment options are limited by a high relapse rate and short DFS. HCT is safer than ever before and it is possible that novel immunomodulatory RIC might provide a high cure rate in this otherwise fatal lymphoid malignancy.

Consideration of Early Allogeneic Stem Cell Transplantation in Transformed Lymphoma

With increasing use of RIC regimens, many older patients are able to receive HCT as curative intent. The hypothesis that RIC transplants could be used to deliver an effective GVL effect is true. Indeed, the typical delayed regression of malignant disease, long after any effect from the preparative regimen has passed, is proof of principle that RIC HCT exerts strong and curative alloresponses against the recipient's malignancy.

Given the high relapse rate seen even after auto-SCT, and the potential benefit of a GVL after HCT, many more eligible patients with NHL including TL are receiving upfront HCT.[152,153] Historically, the limitation of HCT has been TRM. In order to offer the curative HCT treatment option to most patients, safer regimens with acceptable GVHD associated morbidity and TRM are preferred (discussed above in FL).

Novel Hematopoietic Stem Cell Transplantation Approaches for Transformed Lymphoma

For patients in whom a nonablative transplant is preferred, radioimmunotherapy can be employed to provide cytoreduction to safely induce disease control while minimizing nonhematologic toxicity. The HCT could maintain the remissions via the GVL effect, and reconstitute hematopoiesis. Using this approach, 16 patients with relapsed CD20+ lymphoma, of which 15 patients were chemotherapy resistant, underwent therapy with 0.4 mCi/kg Y-90 ibritumomab tiuxetan followed by fludarabine and 2 Gy TBI conditioning regimen and matched HCT. At day 28, seven of 16 patients demonstrated responses.[154] Khouri et al. reported a feasibility study using escalated doses of 90Y-ibritumomab tiuxetan prior to FCR HCT in 7 patients with relapsed B cell NHL. Though longer follow-up on outcome and toxicities are needed, it is clear that such approaches need to be urgently considered for TL to make many more TL patients eligible for a curative HCT option.

Summary

There is an almost universal consensus that chemosensitivity and disease control before HCT is important to prevent early relapse, which is a major cause of treatment failure in TL. Incorporating novel radio-immunotherapy as part of the RIC regimen might be a very attractive option to prevent early relapse before GVL takes over disease control.[155] Tandem auto followed by HCT needs to be explored in selected patients with early good results in a small series.

In this era, a stem cell source can be found for virtually all patients who have an indication to receive HCT. RIC haploidentical-related donor or CBT have emerged as alternatives to fill the gap for those patients who do not have MRD or URD, and the outcome of these types of transplantations are expected to be better than chemotherapy alone or even better than auto-SCT for selected high-risk, heavily pretreated TL. The individual transplant center experience choosing URD, CBT, and haploidentical transplantation should also be taken into consideration.

Diffuse Large B cell Lymphoma

Allo-SCT has been used as treatment of high-risk first relapse, refractory disease, and in patients who have relapsed after auto-HCT.[156] In high-risk large cell lymphoma patients (double-hit,

triple-hit, failure after auto) HCT should be offered early with a potential survival benefit. For relapsed disease, Lazarus et al. retrospectively analyzed the outcomes of diffuse large B-cell lymphoma (DLBCL) patients undergoing first autologous (n = 837) or HLA-identical sibling allo-HCT using MST conditioning (n = 79) reported to the CIBMTR between 1995 and 2003. The allo-HCT group had more patients with an intermediate-high or high IPI score, extranodal involvement, B symptoms, more prior chemotherapy regimens, and more resistant disease. Allo-HCT was associated with a higher TRM and treatment failure. Auto-HCT was associated with superior OS. Despite having several adverse risk features, patients in the allo-HCT group had a similar risk of relapse. The high TRM rate of MST allo-HCT (45% at 5 years) greatly limited the potential benefit of this approach.[157]

Given the high TRM associated with MST conditioning, the use of RIC regimens has increased for HCT in DLBCL. RIC regimens rely more on the GVT effect and less on the intensity of the chemotherapy to eradicate lymphoma. They are in general better tolerated and can be used for older patients or for patients with co-morbidities. The French Society of Bone Marrow Transplant reported the collective experience on 68 patients undergoing RIC HCT for DLBCL. Prior to transplant, 47% of the patients were in remission and 79% had received a prior auto-SCT. The donor was an HLA-identical sibling in 82% of the cases. With a median follow-up of 49 months, the estimated 2-year OS rate was 49%, the PFS rate was 44%, and cumulative incidence of relapse was 41%. The 1-year cumulative incidence of NRM was 23%.[158]

Bacher et al. analyzed the outcomes (registry data) of 396 adults who received HCT for DLBCL following MST conditioning (n = 165), RIC (n = 143), or non-MST conditioning (n = 88) regimens between 2000 and 2009.[159] Significant baseline differences between the cohorts included the following: RIC and NST recipients were older (54% and 58% >50 years vs. 39% for MST conditioning), and they were more likely to have received prior auto-SCT (36% and 51% vs 18%), prior radiation, and more prior chemotherapy regimens (55% and 70% vs. 44% with >3 regimens) than those recipients with MST conditioning. The TRM rate at 5 years was significantly higher in MST conditioning recipients (56%) than in the RIC (47%) and NST conditioning (36%) recipients. Lymphoma relapse/progression at 5 years was significantly lower in the MST conditioning group (26%) than in the RIC (38%) and NST conditioning (40%) groups, but the respective 5-year PFS rates (18%, 15%, and 25%) and OS rates (18%, 20%, and 26%) did not differ significantly. Others have shown similar survival rates with TBI and fludarabine conditioning regimens.[128,160]

The experience of all-SCT for patients with DLBCL is summarized in Table 104.3. HCT can induce long-term PFS regardless of the intensity of conditioning, with a lower incidence of TRM with the RIC and NST conditioning regimens. The risk of relapse or progression is concordantly higher in the RIC and NST conditioning recipients so that survival does not differ significantly among conditioning regimens. However, the use of RIC or NST conditioning allowed older and sicker patients to proceed to transplant with a lower TRM. HCT has also been used as a salvage strategy with encouraging results for patients who failed a previous auto-HCT. In a retrospective analysis by the EBMT registry that included 101 patients, approximately two-thirds received a RIC regimen and 70% had an identical sibling donor. Outcomes at 3 years were encouraging, with a NRM of 28%, a relapse rate of 30%, a PFS rate of 41%, and an OS rate of 54%. With a NRM that can be considered acceptable in this heavily-pretreated population, HCT led to a long-term survival in this poor-risk group.[161] Patients with a long remission after auto-SCT and with sensitive disease at allo-HCT appear to be the best candidates for this approach.

Summary

At this time it is not clear which conditioning intensity to use in HCT for DLBCL. MST conditioning carries a higher mortality with a lower risk of relapse and may still be the preferred option for younger patients without co-morbidities and for those considered to be at high risk for relapse (not in CR at transplant). RIC and NST conditioning regimens may be preferred for older patients or for those with multiple comorbid conditions and with a lower risk of relapse. HCT is effective salvage strategy in patients who have failed a previous auto-SCT for DLBCL.

Mantle Cell Lymphoma

Despite improvements in outcome with chemotherapy, mantle cell lymphoma (MCL) is not considered curable with this approach. Strategies including more intense multiagent chemotherapy as induction followed by consolidation with auto-HCT have demonstrated higher response rates (RR), improved PFS, and the possibility of improved OS. However, even with this aggressive approach, relapse frequently occurs, with the worst outcomes in those with the highest mantle cell international prognostic index (MIPI) scores. Once relapse occurs after auto-HCT, survival can be limited, especially for those transplanted beyond first complete or partial remission or with relapses within 1 year of transplant. HCT is felt to be the only therapeutic strategy with curative potential. Most MCL patients are older and are typically excluded from this approach. The advent of RIC regimens has allowed this treatment to be administered safely to older patients, allowing its use in a greater number of patients.

TABLE 104.3

OVERALL SURVIVAL OF PATIENTS FOLLOWING HCT FOR DIFFUSE LARGE B CELL LYMPHOMA

Author/Year	N	Conditioning Regimen	Type	PFS	OS	NRM

			MST = 37	3 y 42%	3 y 54%	28%

Flu, fludarabine; Mel, melphalan; MST, myeloablative; TBI, total-body irradiation; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality.

Improved Outcome after HCT in Heavily Pretreated Patients

The emerging role of RIC regimens has created a paradigm shift by reducing TRM, and therefore offering more individuals the option of HCT in MCL. We reported a 5-year survival rate of 70% with an NRM of 12.5%, albeit in a highly selected group receiving HCT.[162] In the era of improved supportive care and decreasing TRM, RIC HCT should be offered for otherwise fit patients who have relapsed following high-dose chemotherapy. The group at MDACC published the most encouraging long-term results of NST in 35 patients with relapsed MCL. Six-year OS was 53%; DFS was 46%. No patients had grade 3 to 4 acute GVHD. This study suggests RIC HCT could be offered up front to a selected group of patients.[163]

Maris et al. published the results on 33 patients with relapsed MCL undergoing NST (related or unrelated donor) HCT. At 2 years, the OS was 65% and PFS was 60%.[164]

The British Society for Blood and Marrow Transplantation (BSBMT) published the results of a retrospective analysis of 70 heavily-pretreated patients with relapsed/refractory MCL who received RIC allo-HCT with or without alemtuzumab.[164,165] In this heterogeneous group, the 1-year NRM was 18%, the cumulative risk of relapse at 5 years was 65%, the 5-year OS rate was 37%, and the 5-year PFS rate was 14%. Twenty-seven patients received DLI; all but 1 had received alemtuzumab as part of the conditioning regimen. The 3-year OS rate for patients who received DLI for relapse was 79%, indicating a powerful GVL effect.

Le Gouill et al. reported a multicenter retrospective analysis of 70 heavily-pretreated patients with MCL who received RIC allo-HCT in 12 centers in France and Germany.[166] A previous auto-HCT had failed in 47 patients. The 2-year EFS and OS rates were 50% and 53%, respectively, and the 2-year TRM was 32%. This study showed that RIC allo-HCT is effective not only in patients with chemosensitive disease regardless of the number of prior lines of therapy, but also as salvage therapy for those patients in whom auto-HCT had failed.

The experience of all-HCT for patients with MCL is summarized in Table 104.4. Based on the presented data, HCT appears to be effective for relapsed and refractory MCL and the only approach associated with long-term survival.[167] However, toxicity is a limiting factor, and some patients may be unable to tolerate this therapy. Early referral for HCT is certainly warranted, especially in patients with elevated Ki-67 levels who do poorly with conventional chemotherapy and auto-HCT.

Early discussion of transplantation is warranted since the safety and tolerability of RIC HCT has allowed older and heavily pre-treated patients to benefit from this promising therapy.

Management of Relapses after HCT

One interesting approach to this disease state is DLI (with or without prior chemotherapy). Some of the earliest reports of HCT for MCL included patients who relapsed and were shown to respond to DLI. Since that time, additional studies have paid specific attention to this phenomenon and reported responses to DLI in their relapsed patients, particularly the studies which included alemtuzumab as part of the pre-transplant conditioning. The report by Cook et al. included 36 relapses after RIC HCT, 32 of whom were further evaluable. The 3-year OS among patients who received DLI for treatment of relapse was 60% (with no deaths reported after approximately 15 months) compared to 0% for those who did not receive DLI for relapse.[165]

The data for post-HCT relapse show that the disease is potentially salvageable with a re-challenge with antilymphoma chemotherapy with or without immunomodulation (e.g., DLI). Since the data available for HCT are relatively limited, it should come as no surprise that the data for management of relapsed MCL after HCT are even less robust. Since it remains a relatively unknown issue, such patients are probably best treated in the context of a clinical trial.

Summary

Most studies highlight that HCT is often not used in first remission, instead implementing it for relapsed or refractory disease. Reserving HCT until later in the natural history of MCL means patients receiving this therapy often have a disease biology that is more refractory to conventional therapy. The majority of the published literature on HCT for MCL in the past 10 years has focused on RIC HCT. The success with RIC HCT seems to improve when this approach is used for patients with disease that is still chemosensitive. It should still be noted that data also do show that heavilypretreated patients or patients with active disease can still potentially benefit from RIC HCT. Another facet of these studies that raises some additional questions is the use of further adoptive immunotherapeutic strategies (administration of rituximab with the conditioning regimen) to augment the response to RIC HCT, and these studies did have some of the highest rates of OS and PFS.[168]

Peripheral and Cutaneous T-cell Lymphoma

HCT Concept and Indications in peripheral T-cell lymphoma (PTCL)

PTCL are a rare heterogeneous group of lymphomas with a worse prognosis compared with B cell lymphoma. Auto-SCT is offered for patients whether in CR1 or at the time of relapsed disease with chemosensitivity. Auto-SCT has been to shown to achieve a promising early response, but median PFS ranged from less than 100 days to about a few months. HCT is an option for patients who relapse after auto-SCT but who are chemosensitive. HCT provides a GVT effect with potential survival benefit despite the high NRM associated with HCT. All published cases

TABLE 104.4

CONDITIONING REGIMEN AND SURVIVAL OF PATIENTS UNDERGOING HCT FOR MANTLE CELL LYMPHOMA

Author/Year	*N*	Conditioning Regimen	Type	PFS	OS	NRM

Tam (2009)	35	FC/FCR	RIC	6 y 46%	6 y 53%	9%
Cook (2010)	70	Flu/Mel, Flu/Bu, BEAM ± anti-CD52	RIC	5 y 14%	5 y 37%	21%

A, Cytarabine; anti CD52, alemtuzumab; B, BCNU; Bu, Busulfan; C(y), Cyclophosphamide; E, Etoposide; Flu, fludarabine; Mel, Melphalan; RIC, reduced-intensity conditioning; TBI, Total-body Irradiation ; PFS, progression-free survival; OS, overall survival; NRM, non-relapse mortality; FC, fludarabine, cyclophosphamide; FCR, fludarabine, cyclophosphamide, and rituximab.

after HCT following MST or RIC regimens showed a decreased relapse rate and increased overall- and PFS when compared to published data of conventional therapies. Patients who relapsed after HCT have been shown to achieve remissions again after DLI (with or without prior chemotherapy), which strongly supports the existence of a GVL effect. RIC regimens may lead to decreased TRM rates and improved results. Therefore, RIC-based HCT seems to represent a promising treatment approach, especially when combined with post-transplant therapies with DLI. As GVHD frequently occurs in the skin, the major manifestation site of mycosis fungoides/cutaneous T-cell lymphoma (MF/CTCL), this phenomenon may also contribute to the efficacy of HCT in this disease entity.[169]

Outcome Data after HCT

In a retrospective study of 77 patients, at a median follow-up of 43 months, the 5-year OS and PFS were 57% and 53%, respectively, and NRM was 34% at 5 years.[170] RIC regimen was used in 17 patients as reported by Corradini et al.; 8 patients had previous auto-SCT and 16 patients underwent related donor transplant. The estimated 3-year survival was 81% with a NRM of 6% at 2 years.[171]

Shustov et al.[172] published data using the Seattle NST regimen with fludarabine and 2 Gy TBI on 17 patients. Of these, 6 patients relapsed after prior auto-SCT. At a median follow-up of 3.3 years, the 3-year OS and PFS were 59% and 53%, respectively, with 19% 3-year probability of NRM.

In a retrospective review on 34 patients receiving HCT for PTCL, the 2-year OS was 61%, 2 of the 3 patients receiving DLI demonstrated response supporting a GVL effect.[173] A recently published retrospective study from EBMT centers, which is the first large multicenter analysis of HCT in CTCL patients, showed a PFS of 42% at 1 year and 34% at 3 years. The current PFS at the last published follow-up was 52% in patients who received NST and 29% in patients who received MST HCT. Estimated OS rate was 66% at 1 year and 53% at 3 years.[174] These noncontrolled results are promising and challenge the outcomes known so far after conventional treatment options. Nevertheless, a controlled study to confirm the role of HCT in CTCL patients is needed.

The long-term outcome on 52 patients undergoing HCT was reported by Dodero et al. Patients received related or alternative donor transplants including haplo-transplants. At a median follow-up of 67 months, 52% were alive. The cumulative incidence of NRM at 5 years was 12%. Refractory disease and age over 45 years were negative prognostic features.[175] An HCT is particularly successful in patients with nodal disease and less so in those with extranodal disease. The experience of all-SCT for patients with PTCL is summarized in Table 104.5.

Auto vs. Hematopoietic Stem Cell Transplantation

In a recent meta-analysis comparing auto- vs. HCT in patients with MF/SS, 20 patients received HCT and 19 underwent auto-HCT. OS rates at 1 and 5 years were 68% and 23% in the auto-HCT, and 85% and 80%, respectively, in the HCT group. The most common cause of death in the HCT group was GVHD.[176]

Currently, ongoing Italian and German trials are comparing auto-HCT vs. HCT after first line induction therapy.

Summary

Despite the lack of randomized studies in recommending HCT for this disease, our experience has been that responses with conventional therapies are short-lived, and long-term remissions in carefully chosen patients can be achieved with HCT. HCT has been demonstrated to achieve long-term remissions in many cases; and conditioning regimens with reduced intensity and therefore with less toxicity might be superior to MST conditioning, and represent an option for the elderly, who represent the majority of patients.

Hodgkin Lymphoma

Auto-HCT is offered for patients who relapse after initial chemotherapy. This approach has a 40% to 50% 5-year survival rate.[177] For patients who relapse after auto-HCT, prompt consideration of RIC HCT is important. Referral to a transplant center for coordination of donor search and discussions of salvage regimens may improve outcomes.

The earlier CIBMTR results reported a 3-year OS of 21% in patients undergoing HCT for relapse after auto-HCT.[178]

The EBMT group compared various conditioning regimens and reported on outcomes of patients undergoing MST or RIC HCT.[179] Of the 168 patients who underwent HCT, 89 patients received RIC allo-HCT. The NRM was significantly lower in the RIC group: at 1 year 23% vs. 46% in the MST arm. In this patient population, 61% had prior auto-HCT. Robinson et al. reported the results on 285 patients who underwent RIC HCT in HL. At 12 months, the NRM was 20% and 3-year OS was 56%.[180]

In a retrospective study by Sarina et al., based on donor availability status, 185 patients were analyzed, among whom 66% had an available donor and 85% underwent HCT using a RIC approach.[181] In patients who had an available donor, the 2-year OS was 66% compared with 42% without a donor.

In a study of 90 patients with relapsed HL, related, unrelated, or haploidentical donors were used with a non-MST conditioning regimen. The 2-year OS was 53% for matched donors and 58% for unrelated and haploidentical donors.[182] Interestingly, in this study, the NRM was lower in the haplo-transplants as

TABLE 104.5

SURVIVAL OF PATIENTS FOLLOWING HCT PERIPHERAL T-CELL LYMPHOMA

compared with HLA-matched recipients. Reducing the number of donor T-cells may decrease the risk and severity of GVHD. Alemtuzumab (anti-CD52) with fludarabine and melphalan was used as a conditioning regimen for relapsed HL. In a series of 67 patients as reported by Peggs et al.[183] were treated with or without alemtuzumab. The 3-year PFS was higher in patients with T cell depletion, at 43% compared with 25%. This was, however, counteracted by increased DLI use. The experience of all-HCT for patients with HL is summarized in Table 104.6.

Responses after the use of DLI in relapsed HL patients have been reported. This suggests the role of graft versus HL activity. In a similar patient population as reported earlier, in patients undergoing T-cell depletion more frequent use of DLI was noted. Of the 16 patients that underwent DLI, 56% of patients experienced a response that led to a 4-year survival of 56%.[184]

Newer treatments are being considered in a maintenance setting following auto-HCT. Until we have further data from these clinical trials, HCT is considered for patients who relapse after auto-HCT. Current data does not favor a particular donor pool. Depending on various studies, in patients with chemosensitive disease RIC HCT results in OS of 40–66% with NRM rates between 20% and 30%. More importantly, outcomes with related vs. alternative donors do not appear to be different.[126,185]

Relapse after Reduced-intensity Conditioning Hematopoietic Stem Cell Transplantation

As shown above, there are proportions of patients with relapsed/refractory HL who achieve a lasting cure with RIC allo-HCT, although many patients unfortunately suffer relapses. To better counsel patients in this situation and to evaluate specific management strategies in this setting, Ram et al. described 101 patients with lymphoma who had relapses after RIC and HCT.[186] This group included 26 patients with relapsed/refractory HL, 50% (13 patients with HL) of whom had prior auto-HCT. HL patients tended to relapse later than those with other lymphoma histologies (6.3 months vs. 3.4 months for indolent NHL and 1.3 months for aggressive NHL). Relapse occurred much sooner in the HL group with prior auto-HCT (median 4.6 months) compared with patients who did not have prior auto-HCT (median 12 months). The estimated 3-year OS after relapse in HL patients was 47%. Patients with HL, despite a longer time to initial relapse relative to indolent NHL, were shown to have the greatest risk of PD even after response to initial therapy for post RIC allo-HCT relapse.

Thus, further strategies to achieve lasting remission following RIC HCT are needed. One potential option that has been evaluated includes brentuximab vedotin, which was shown by Gopal et al., in a multicenter series of 25 patients with HL recurring following allo-HCT, to yield a 50% response rate in evaluable patients.[187] This if followed by DLI at response would be the best available strategy for responding patients. Nevertheless, despite interest in this area, improved strategies are still needed for management of post-HCT relapse.

Myelofibrosis

Myelofibrosis is a heterogeneous disease for which long-term, effective medical therapeutic options are currently limited. There is only one curative treatment in myelofibrosis patients using HCT. As myelofibrosis is primarily a disease of the elderly, this has historically been a rare indication of HCT. However, with the advent of RIC regimens, the applicability of this approach has been broadened to include a larger proportion of myelofibrosis patients.[188–190,191–193,194]

Janus kinase (JAK)2-inhibitor therapies have been developed for patients with myelofibrosis. Clinical trials have shown that these agents have considerable therapeutic potential in myelofibrosis patients, thus offering an additional treatment option as a potential alternative or integration of JAK inhibitors during the HCT process.

Allo-Outcome and Hematopoietic Stem Cell Transplantation Indications

In a recent study from the United Kingdom, 51 patients with primary myelofibrosis (24%, 33%, and 43% with Dupriez low-, intermediate-, and high-risk disease) received mostly related MST or RIC HCT. The 3-year OS was 44% for MST and 31% for RIC HCT; the corresponding relapse rates were 15% and 46%, nonrelapse mortality rates were 41% and 32%, and extensive chronic GVHD rates were 30% and 35%.[195]

A higher 5-year DFS (51%) was reported from another RIC allo-HCT study in which relapse was predicted by high-risk disease and prior splenectomy.[196] A history of splenectomy did not affect outcomes in the recent study from the Center for International Blood and Marrow Transplant Research (CIBMTR).[197]

More recent results from FHCRC in more than 100 patients with myelofibrosis, aged 18 to 70 years, show a 7-year actuarial survival of 61% for HLA-matched related and unrelated transplants. NRM at 5 years was 34%, but, as we all know, NRM does not equate with treatment-related mortality. Many patients who underwent HCT had life expectancies of <5 years, based on disease severity, and a 5-year mortality of that magnitude would have been expected even without HCT.[192]

European Leukemia Net suggests that patients with transfusion dependence or unfavorable cytogenetics should be considered for HCT, reflecting the inclusion of these factors in the dynamic international prognostic scoring system (DIPSS).[198]

TABLE 104.6

SURVIVAL OF PATIENTS FOLLOWING HCT FOR HODGKIN LYMPHOMA

Author/Year	*N*	Conditioning Regimen	Type	PFS	OS	NRM

Robinson (2009)	285	Flu/TBI ± T-cell depletion	RIC	3 y 25%	3 y 29%	21%
Sarina (2010)	122	Variable	RIC	2 y 39%	2 y 66%	9%

BEAM BCNU, etoposide, cytarabine, melphalan; Cy, cyclophosphamide; HCT, hematopoietic stem cell transplantation; Mel, melphalan; MST, myeloablative; RIC, reduced-intensity conditioning; TBI, total-body irradiation; PFS, progression-free survival; OS, overall survival; NRM, nonrelapse mortality.

A number of important non–disease-related factors, such as age, donor type, and comorbidities, also have a major influence on the outcome following HCT, and these have to be carefully integrated into the decision to proceed to HCT.[199–203]

In summary, on the basis of the available data the risk of HCT is currently not justified in patients with myelofibrosis with low- or intermediate 1–risk disease patients. There are no convincing data that transplant-related mortality and morbidity in myelofibrosis have been favorably altered by the use of RIC transplantation when TRM, relapse, and cGVHD rates remain high. Therefore, if HCT is indicated because of high- or intermediate 2–risk disease, the use of MST HCT is preferred in all eligible patients, considering its association with a lower risk of relapse compared with RIC transplantation. It is reasonable to offer RIC transplantation for older patients (ineligible for MST regimen)[204] with high- or intermediate 2–risk disease, especially if a matched donor is available.[205] Utilization of umbilical cord blood units or a haploidentical source must still be considered as experimental for myelofibrosis and an experimental option for myelofibrosis transplant candidates lacking a suitable MRD or URD.

In the event of blastic transformation of Myelofibrosis, where the median survival is only 2 to 7 months, HCT, if eligible, may offer a chance of long-term survival, with some encouraging results in a small series.

Role for Splenectomy and JAK-2 Inhibitor Therapy Pre-hematopoietic Stem Cell Transplantation

The splenomegaly itself may lead to sequestration of donor cells after HCT, and may cause delayed engraftment or graft failure. Indeed, some reports have shown faster engraftment in splenectomized patients, which may allow hematopoietic recovery without increased rate of the GVHD, characterized by significantly faster recovery of neutrophil and platelet counts.[188]

A vast majority of myelofibrosis patients referred for consideration of HCT have bulky splenomegaly. Its attraction as a tumor debulking strategy is often upheld in clinical practice and the question still remains if there is a subgroup of patients who will benefit from splenectomy pre-HCT. Data reports decreased transfusion requirements and enhanced neutrophil recovery in patients undergoing HCT, favoring pre-transplant splenectomy.[206]

In contrast, a recent study reported a higher rate of relapse at 3 years in those who underwent splenectomy, 51% versus no splenectomy 20%; $P = 0.005$.[196] A retrospective CIBMTR study did not suggest an effect of prior splenectomy on either graft failure rates or DFS.[197] It is important to note that successful engraftment can still occur despite the presence of even massive splenomegaly. Ciurea et al.[207] recently described a cohort of patients ($n = 10$) with splenomegaly, five of whom were defined as extensive with a longitudinal spleen diameter >30 cm, undergoing RIC HCT. All patients engrafted and had a progressive reduction in spleen size, occurring as marrow fibrosis resolved.

There is currently limited data to support the need for splenectomy before transplantation. An alternative to surgical splenectomy is the use of cytoreductive therapy or JAK inhibitors (that produce rapid spleen shrinkage, improvement of constitutional symptoms in the immediate pre-transplantation setting, and decreasing inflammatory cytokine with additional theoretical benefits, discussed below).[208] JAK2 inhibitors lead to a marked reduction in levels of inflammatory cytokines in patients with myelofibrosis and might play a role in reducing the rates of GVHD post-HCT.

Monitoring Post-transplantation and Treatment of Relapse

Several studies have assessed whether the presence of JAK2 V617F can be used as a marker of minimal residual disease after HCT in order to institute preemptive immunotherapy prior to overt relapse.[209–213] One study used a sensitive reverse transcription (RT)-PCR detection method to monitor and quantify JAK2 V617F levels following 22 RIC HCT procedures for 21 JAK2 V617F positive myelofibrosis patients. Patients became JAK2 V617F negative in 17 of 22 cases (78%) after a median of 89 days following HCT. Of the 5 patients who remained PCR-positive, 4 fulfilled the criteria for CR, demonstrating the utility of this technique as a marker for minimal residual disease and hence depth of remission achieved. In one of these cases, residual JAK2 positivity was eliminated following DLI.[209] A subsequent study demonstrated that achievement of JAK2 V617F negativity after HCT for myelofibrosis was significantly associated with decreased incidence of relapse. Patients who achieved PCR negativity 6 months following HCT had a relapse risk of 5% compared with 35% in those who remained PCR-positive.[210]

The timing of DLI, whether as a preemptive or salvage approach, post-HCT is less clear in myelofibrosis than other diseases. Kroger et al.[214] initially reported the use of both salvage and preemptive DLI (triggered by JAK2 V617F persistence on sequential monitoring) in 17 patients, with a median time from transplant to relapse of 269 days (127 to 1,570). DLI was used preemptively in 8 patients and as salvage in 9. Grade II–IV GVHD occurred in 3 patients (18%) in the salvage cohort. Encouragingly, the overall complete molecular response rate was 68% (100% in the preemptive group versus 44% in the salvage group), confirming the efficacy of this approach.

Little evidence is available to help delineate the role of post-HCT chemotherapy or second HCT in relapsed-myelofibrosis. A recent retrospective study reported on the use of DLI +/− second HCT for relapsed patients (morphologic relapse [$n = 24$] and molecular relapse [$n = 6$]). A total of 17 patients underwent a second RIC HCT at a median time of 17 months (11 to 77) post-initial transplant. Outcome data was encouraging; a total of 16 engrafted and responses identified in 12 evaluable patients, demonstrating the feasibility of a second HCT in this group.[215] However, the toxicity of a second HCT should not be underestimated, particularly given the median age of this patient population.

Hematopoietic Stem Cell Transplantation in HIV patients

Before the highly active antiretroviral therapy (HAART) was available, initial attempts to treat HIV-infected patients with allo-HCT led to extremely poor outcomes.[216] After HAART became widely available, several case reports suggested a potential benefit of HCT in this patient population. HCT in patients with malignancy and HIV infection has particular challenges, including the risk of opportunistic infection before and after transplantation, the high frequency of other concomitant viral infections, the potential impact of HIV in bone marrow environment and immune reconstitution post-transplant, and the potential for complex interactions between HAART, high-dose therapy, and immunosuppressive agents.

The CIBMTR retrospectively evaluated the results of allo-HCT in 23 HIV-infected patients undergoing transplant between 1987 and 2003, including patients receiving transplantation prior to the advent of HAART.[217] The indications for transplant included primarily malignant conditions, with lymphoma being the most common, followed by acute leukemia. With a median follow-up of 6 months, 30% of the patients were alive at 2 years; the primary causes of death were organ toxicity and infection. Despite initial mortality due to organ damage and infection, several patients achieved long-lasting remission. The BMT-CTN is conducting a prospective multicenter trial (BMT-CTN 0903; clinicaltrials.gov NCT01410344), enrolling patients with HIV infection and malignancy or bone marrow failure to assess the day-100 mortality after allo-HHCT. This trial will also study OS, PFS, and the impact of HCT on HIV reservoirs.

Summary

The challenge to the transplant community is to make transplantation safer and to decrease the incidence and morbidity of GVHD without compromising the GVT effect. This dream will be realized as our understanding of transplant immunology increases. The role of HCT in the diseases discussed in this chapter will continue to evolve as transplantation becomes safer. On the other hand, advances in non-transplant genomic-driven targeted therapy, and advances in response assessment using minimal residual disease will continue to shape the future of HCT in hematologic malignancies. The use of targeted therapy post-HCT is inevitable. The impact of these agents on immunologic parameters will need to be assessed. Both transplant and non-transplant specialists will need to collaborate in an integrated team approach to advance this field and improve patient outcomes.

CHAPTER 105

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-TUMOR RESPONSE

Joseph Pidala, Frederick L. Locke, Claudio Anasetti

INTRODUCTION

Graft-versus-host disease (GVHD) is the most common treatment complication following hematopoietic stem cell transplantation (HSCT) from an allogeneic donor, and it is a major cause of recipient morbidity and mortality. GVHD results from the recognition of recipient tissue antigens by immune competent T cells transplanted with the graft. There is an acute form of GVHD with a rapid onset, usually early after transplantation, and a chronic form of GVHD with late onset. These two GVHD syndromes are largely distinct in pathogenesis, clinical manifestations, prevention, and treatment, and therefore are presented separately in this chapter. Donor cells in the graft also produce an immune response against targets in the recipient malignant cells, through a reaction that contributes substantially to the antitumor activity of allogeneic HSCT. Such a graft-versus-tumor (GVT) response is presented in the third section of this chapter.

ACUTE GRAFT-VERSUS-HOST DISEASE

Pathophysiology

The requisites for the development of GVHD were recognized over 50 years ago by Billingham: (1) the inclusion of immune competent cells in the graft, (2) the inability of the recipient to reject the graft, and (3) the presence of recipient tissue antigens foreign to the donor. Animal model studies, primarily in rodents, led to a three-step model of GVHD pathophysiology that simplifies the complex immune interactions by placing emphasis on cellular interactions and cytokines: (1) host antigen-presenting cell (APC) activation, (2) donor T-cell activation, and (3) pathogenic effector cells and inflammatory mediators produce the disease.[1,2] GVHD biology is extremely complex involving intracellular signaling, soluble mediators, and cellular interactions. Positive and negative signals exist at multiple levels including the cell surface, signaling protein networks, transcription promoters, mRNA, and posttranslational modification. In addition to histocompatibility antigen disparities between donor and recipients, genetic polymorphisms at any of these immune checkpoints may promote or prevent GVHD. The interaction of immune cells, visceral organ tissue, cytokine, and chemokine signals, cellular trafficking into and out of lymphoid and visceral organs is similarly complex. Recent attempts to rein in these numerous, continuous, and interrelated processes led Paczesny and Reddy to create a comprehensive model of GVHD pathophysiology based on the framework of normal immune system interactions. It is the expected behavior of donor immune cells to cause pathophysiology within the host that harbors unrecognized antigens which are treated as foreign by the donor cells. Put more simply, acute GVHD arises when donor T cells react in a physiologically appropriate way against recipient proteins recognized as foreign. However, the signaling events, intracellular pathways, and immune cell trafficking are extremely complex and remain to a large degree incompletely understood. This proposed nonlinear model consists of four interrelated elements to describe the role of immune system recognition and activation at the genetic, cellular, and cytokine level: triggers, sensors, mediators, and effectors of GVHD (Table 105.1).[3]

Critical to acute GVHD onset is the degree of genetic variability between donor and host, the level and site of tissue damage set forth by the conditioning regimen, the ability of host or donor cells to present antigen, the cellular and cytokine mediators of response, and the nature and degree of the immune effector activity.

Triggers

Human leukocyte antigens (HLAs) are encoded by the major histocompatibility gene complex (MHC) on chromosome 6p and function as major histocompatibility antigens in transplantation. The natural function of HLA is to present antigenic peptides to specific T cells. Exogenous and endogenous proteins present within human cells are continually broken down into peptides. HLA molecules on professional APCs bind those peptides within their groove and present them from the cell surface to the T-cell receptors on T lymphocytes. Inasmuch as the human genome includes greater than 10^7 polymorphic sequences, there is great likelihood that donor and recipient differ for one or more of the proteins that are presented as HLA:peptide complexes to T cells. These polymorphic proteins function as minor histocompatibility antigens (mHAs) in transplantation. Autoreactive T-cell recognition of "self" peptides in the thymus leads to negative selection (death), so that the probability of an individual developing autoimmunity is minimized. After transplantation, this delicate balance of self and nonself is perturbed. Donor and recipient may differ for HLA molecules or mHA. Each peripheral T cell harbors a unique T-cell antigen receptor; therefore, the human repertoire for recognition of foreign antigens is enormous. Donor and recipient *HLA* mismatching plays a critical role in the development of GVHD, because each type of HLA presents a unique repertoire of antigenic peptides. When recipient cells are mismatched at an *HLA* locus, the donor T cells have not undergone thymic deletion to avoid recognizing those HLA:peptide complexes. Therefore, the degree of *HLA* disparity directly increases the probability and severity of acute GVHD following transplantation.[4,5] For umbilical cord blood donors a greater degree of *HLA* mismatch is tolerated presumably due to the small number of T cells within the cord blood ($\sim 10^4$ per kg recipient weight) as compared to adult donor blood ($\sim 10^8$) or marrow ($\sim 10^7$).

mHA are polymorphic proteins genetically encoded anywhere outside *HLA*. Host mHA proteins are presented as HLA:peptide complexes to donor T cells and elicit an immune response even when presented via a matched HLA molecule. mHA mismatches are only partially characterized for the ability to affect acute GVHD. Some mHA have broad tissue expression such as the male-associated H–Y antigen.[6] Alternatively, HA-1 and HA-2, for example, have their expression restricted to hematopoietic cells, including leukemia, and immune cells.[7] It is this variability of tissue mHA expression that may allow for tailoring therapy toward hematopoietic-restricted mHA to promote GVT response without GVHD. Efforts to prevent GVHD would have to target immune responses against the ubiquitously expressed mHA.[6,8,9]

Other triggers of GVHD include molecules that activate the innate immune system. Pre-transplant radiation or chemotherapy damages host cells and enteric microbes that contain damage-associated molecular patterns (DAMPs) or pathogen-associated molecular patterns (PAMPs), respectively. DAMPs such as proteases

TABLE 105.1

ACUTE GRAFT-VERSUS-HOST DISEASE PATHOPHYSIOLOGY: TRIGGERS, SENSORS, MEDIATORS, AND EFFECTORS

Key Elements	Physiologic Role	Aberrant Process in Graft-versus-Host Disease
Triggers		
HLA molecules	Present antigen to T cells	Mismatches in HLA molecules from donor to host lead to recognition of the cell as foreign by T cells.
mHA	Normal variability of protein within genome	mHA are recognized as foreign by MHC:T-cell interactions.
DAMPs and PAMPs	Common organic patterns originating from damaged cells or pathogens triggering innate immunity	DAMP release after cell death due to conditioning therapy or PAMP presence via pathogens triggers innate immunity and cytokine cascade.
Sensors		
Antigen presenting cells	Present antigens to effectors	Present exogenous and endogenous protein sequences to T cells via direct, indirect, or cross presentation.
Mediators		
CD4 T helper subsets	Skew effector responses to the appropriate degree	Effects of T-cell subsets on graft-versus-host disease incompletely understood.
Regulatory T cells	T-cell subset which acts to prevent untoward autoimmunity	Donor regulatory T cells play a role in reducing graft-versus-host disease.
Inhibitory signals	Signals provided in concert with antigen presentation to decrease the immune response	
Co-stimulatory signals	Signals provided by professional antigen presenting cells to initiate immune response	
Effectors		
Activated CD4 and CD8 T cells	Lead to killing or neutralization of foreign cells or debris via IFNγ, perforin, or granzyme secretion	Donor cells act to damage host cells and organs leading to manifestations of graft-versus-host disease.

HLA, human leukocyte antigen; DAMPs, damage-associated molecular patterns; mHA, minor histocompatibility antigen; MHC, major histocompatibility complex; PAMPs, pathogen-associated molecular patterns.
Adapted from Paczesny S, Hanauer D, Sun Y, Reddy P. New perspectives on the biology of acute GVHD. Bone Marrow Transplant 2010;45:1–11.

or ions released from damaged epithelial cells and PAMPs such as lipopolysaccharide within common bacteria, can activate Toll-like receptors setting off a cascade of immune events characterized by proinflammatory cytokine secretion.[10] To a large degree these processes are responsible for initiation of the "cytokine storm" described as critical in earlier models of acute GVHD.[11]

Sensors

Sensors of GVHD refer to the cells and processes that recognize the mHA or HLA mismatches as foreign, thereby setting the immune response in motion. Antigens are presented by host professional APC such as dendritic cells, macrophages, or Langerhans cells. Host dendritic cells may be primed for antigen presentation via the cytokine storm accompanying the conditioning therapy. The nature of antigen presentation interactions includes *direct presentation*, which mimics physiologic APC–T-cell interactions. Specifically, direct presentation consists of host APC presenting endogenous (cytosolic) host peptide to donor CD8 T cells, and exogenous (extracellular, endocytosed peptide, processed in lysosomes) antigens are presented to donor CD4 T-cells. *Indirect presentation* specifies exogenous antigen presented from donor APC to donor CD4 cells. Cross-presentation refers to exogenous antigen (derived from host cells) presented to donor T cells from donor APC. Over time APC change from primarily host origin to donor origin. It is likely that direct presentation by host APC is predominant during early stages of acute GVHD, whereas indirect or cross-presentation by donor APC is predominant in chronic GVHD. APC-T–cell interaction involves not only interaction between HLA plus cognate antigen with T cell receptor (TCR), but co-stimulatory and inhibitory signals at the immune synapse, secondary signals from cell subsets, and paracrine or autocrine mediators. APC provide necessary co-stimulatory signals directly when activating T cells, such as CD28, CD40, and ICOS as well as inhibitory signals such as CTLA-4 and PD-1. Manipulation of these signals via antibody interference or small molecule blockade of downstream signaling events remains a field ripe for modulation of GVHD. Exogenous cell types critical to inhibition of APC include regulatory T cells, gamma–delta T cells in the GI tract, natural killer (NK) cells, and host NKT cells. T-cell response is an adaptive immune response which is often triggered by the innate immune response. As described, Toll-like receptors are sensors of the DAMP and PAMP release precipitated by the condition regimen. These Toll-like receptor interactions lead to release of proinflammatory cytokines such as tumor necrosis factor alpha (TNFα) and interleukin (IL)-6 which contribute to the inflammatory milieu surrounding T-cell–mediated GVHD damage.

Mediators

GVHD is primarily mediated by donor T cells, and differing subsets that have normal physiologic activities outside the framework of transplant, act at different capacities to induce or inhibit GVHD development. Most animal models point to the relevance of naive T cells, rather than memory T cells, in the induction of GVHD. The process of homeostatic proliferation in the lymphoablated host causes brisk clonal expansion of the transferred donor T cells and plays an important role for the initiation of acute GVHD. Donor regulatory T cells (Treg) repress the GVHD responses. Treg are CD4 T cells that express the FOXP3 transcription factor, high levels of the alpha chain of the IL-2 receptor, but no IL-7 receptor and function as a natural suppressor to maintain peripheral tolerance. These donor-derived regulatory T cells inhibit the activation and proliferation of donor T cells implicated in the pathogenesis of acute GVHD and may spare the GVT effect.[12] Recent data show that low-dose IL-2 expands regulatory T cells in vivo and may be effective therapy for established GVHD,[13] whereas anti-IL-2 receptor antibodies, tested before Treg importance and biology were recognized, appear to accelerate GVHD.[14]

Additional CD4 T-cell subsets are critical. It is Th1 cells, characterized by IL-2 and interferon gamma (IFNγ) secretion, which

are the likely main T-cell mediators of acute GVHD. Th2 T cells have been linked to protection against acute GVHD. Th17 CD4 cells secrete IL-17 and function distinctly from Th1 cells in a manner that is not yet fully characterized in the context of human GVHD. Murine transplant models provide evidence that Th17 can cause GVHD.[15,16] T-cell trafficking is another important step in GVHD pathogenesis. Differential expression of chemokines on GVHD target organs and draining lymph nodes mediate differential trafficking of T-cell subsets expressing different chemokine receptors. An initial report indicated that a CCR5 inhibitor can prevent GVHD in gut and liver.[17]

Effectors

The effectors of acute GVHD are the cytolytic cellular elements and inflammatory cytokines. Activated CD4 and CD8 cytotoxic T lymphocytes are the primary effectors of GVHD. Upon interaction with their cognate HLA:peptide they act to lyse or cause apoptosis of target cells via secretion of perforin and granzyme or binding of FAS, respectively. IFNγ and TNFα are both critical to the inflammatory process of GVHD. Inflammatory cytokines induce and amplify cellular damage.

EPIDEMIOLOGY

The major source of treatment-related morbidity and mortality is GVHD. The incidence of clinically relevant (grade II to IV) acute GVHD ranges from 35% to 80%, with a higher incidence reported for recipients of unrelated donors compared to matched related donors.[18,19] The day 100 incidence of severe acute GVHD (grades III–IV) occurs in approximately 15%, but may be as high as 35% depending upon risk factors such as *HLA* disparity.[5]

RISK FACTORS

Risk factors for the development of acute GVHD include T-replete transplant, recipient and donor *HLA* disparity, female donor for a male recipient, donor and recipient age, hematopoietic stem cell source (peripheral blood progenitor cells [PBPCs] > marrow > cord blood), graft cellular composition (worse with higher T-cell and CD34 cell numbers), higher conditioning intensity, diagnosis (worse with chronic myeloid leukemia), and immune response gene polymorphisms.[20,21] Predictive factors are of great interest to stratify patients prior to development of serious morbidity or mortality and to focus prevention upon the proper biological parameters.

HLA matching is critical to prevent acute GVHD. A single allele mismatch at *HLA-A*, *HLA-B*, *HLA-C*, or *HLA-DRB1* increases the likelihood of acute GVHD development, and mismatch for multiple alleles compound the risk.[5,22]

Female donor for a male recipient and donor parity are risk factors for the development of acute GVHD. The increased risk for male recipients of female as opposed to male donors is attributed to the recognition of H–Y mHAs by female donor T cells.[23,24] During pregnancy, female donors develop an immune response to the paternal mHAs of the fetus and mount a secondary, augmented T-cell alloimmune response against the same mHAs if expressed in the recipient.[25]

Increasing donor age is associated with increased risk for the development of severe acute and chronic GVHD, and worse mortality.[26] Age of the recipient is also important with higher rates of acute GVHD in older compared to younger cohorts.[20,27]

The rate of chronic GVHD in patients receiving PBPC grafts is higher compared to bone marrow; however, the association of PBPC with acute GVHD is not clearly established.[28,32] Unrelated cord blood transplant is associated with a low rate of acute GVHD when compared to transplant with similarly *HLA* mismatched adult donors.[33,34] Multiple factors may contribute to this effect; however, the low number of T cells in the graft and T-cell naive likely play a protective role.

The conditioning regimen used affects the incidence of acute GVHD. With high-dose intensity conditioning the incidence of acute GVHD is higher. For example, increasing doses of radiation can double the incidence of acute GVHD.[35] Several large retrospective studies showed that reduced intensity regimens lead to reduced rates of grade II–IV acute GVHD when compared to higher intensity regimens.[36,37] Animal models suggest the correlation of the incidence of GVHD with intensity may be due to increased damage to host tissue and amplified release of cytokines followed by activation of APC.[38] In addition, higher intensity regimens decrease the fraction of recipient T cells that persist after the regimen, leading to a lower barrier to donor engraftment and greater homeostatic re-population by donor T cells, which is associated with worse acute GVHD.[39,40]

The cellular composition of the graft is linked to the incidence of GVHD. Despite the link between chronic GVHD and CD34 cell dose, conflicting studies outline the importance of CD34 cell dose on acute GVHD.[41,42] The preponderance of evidence suggests that there is no correlation between CD34 cell dose and the incidence of acute GVHD, whether the progenitor source is marrow or PBPC,[43–45] although one study, looking at patients given cyclosporine as a prophylactic agent, revealed a positive association of CD34 dose with acute GVHD.[46]

Genetic polymorphisms of immune response genes are associated with an increased incidence of acute GVHD. Single nucleotide polymorphisms (SNPs) can alter cytokine binding domains, thereby altering affinity in a functional or nonfunctional way. Particular SNPs in genes coding IL-10, IL-6, IL-2, HPSE, CTLA-4, and MTHFR have all been identified as increasing the risk of clinically relevant or severe acute GVHD, likely via increased level or activity of these cytokines or receptors.[47]

Cytokine biomarkers correlate with the presence of acute GVHD and provide prognostic information independent of the severity of GVHD. Although not widely in diagnostic use, the panel which includes IL-2-receptor-alpha, TNF-receptor-1, IL-8, and hepatocyte growth factor, can confirm the diagnosis at the onset of clinical symptoms.[48] An expanded 6 biomarker panel which also includes elafin, a skin-specific marker, and regenerating islet-derived 3-α, a gastrointestinal (GI) tract-specific marker was shown to predict response rate at day 28 after onset and survival at day 180 after onset, for patients with acute GVHD. This panel was predictive at 3 time points; onset, 2 weeks, and 4 weeks into therapy. Future clinical trials will determine if such stratification into high and low risks groups will lead to improved outcomes by capitalizing on the opportunity for early intervention.[49]

PROGNOSIS

Acute GVHD response rates to high-dose steroid therapy are in the range of 50%, and achievement of response to steroids is the most important predictor of outcomes. Durable responses of a month or longer can be expected in about 30% and partial responses (PRs) in 20%. Lower intestinal acute GVHD has been linked to worse response rates compared to patients without lower intestinal manifestations.

CLINICAL MANIFESTATIONS OF ACUTE GRAFT-VERSUS-HOST DISEASE

The most common sites of involvement are skin, GI tract, and liver. Additional organ sites may be involved and clinicians should maintain a high degree of suspicion for acute GVHD as a

cause for any unexplained abnormalities in eyes, buccal mucosa, and lung. A biopsy of the presumptive site should be attempted whenever possible to confirm diagnosis, although histological manifestations can overlap with many inflammatory conditions confounding histological results. A pathologist familiar with acute GVHD is preferable, and appropriate immunohistochemical stains should be employed to rule out viral infection, particularly of the GI tract.

The onset and natural history of acute GVHD is variable depending on organ site, nature, and severity of disease. A hyperacute form, occurring in the first 14 days after transplant,[50] is characterized by early onset of typical signs and symptoms, with a preponderance of patients, 90%, exhibiting skin involvement. In addition a higher percentage of patients are likely to experience stage III–IV disease (88% vs. 66%).[51,52]

Most cases of acute GVHD manifest within the first 100 days following transplant. With the use of modern prophylaxis regimens including cyclosporine or tacrolimus, the onset is typically 20 to 25 days after cell infusion. With T-cell depletion, average onset is typically at 30 days, although it can be delayed several months as T cells reconstitute.[53] NIH consensus criteria for chronic GVHD includes classification of acute GVHD occurring after day 100 (late-onset acute GVHD) and for patients manifesting signs and symptoms of both acute GVHD and chronic GVHD (overlap subtype of chronic GVHD).[54] The severity of acute GVHD can easily be quantified using Keystone consensus grading criteria (Table 105.2).

Skin

Skin is the most commonly involved site of acute GVHD, being present 80% of the time at onset. A maculopapular rash is characteristic and may be described as a painful or pruritic sunburn. Characteristically involved sites include the back of the neck, palms, soles, dorsal surfaces of the extremities, and ears, although the rash can spread quickly to include the entire body. Although many cases are mild, severe manifestations can include bullous lesions and a clinical picture consistent with toxic epidermal necrolysis. Careful full-body examination allows for staging of acute GVHD by the Keystone consensus criteria. This scale is based upon percentage of body surface area (BSA) involvement. For example, when acute GVHD is confined to the skin and involves <50% of BSA, it is classified as grade I acute GVHD. Such a degree of involvement may require no more than topical steroids and frequent monitoring of symptoms (see "Primary and Secondary Therapy of Acute Graft-versus-host Disease" below). A biopsy of the skin can help to solidify the diagnosis, however, treatment is usually based on the clinical diagnosis.[55]

Hepatic

Liver acute GVHD is typically characterized by involvement of the bile duct epithelium, resulting in cholestasis. Bilirubin and alkaline phosphatase elevation, accompanied by cholestatic jaundice are the typical manifestations. Direct hepatocyte damage is rare, absent a more chronic fibrosis, although transaminitis often occurs. Hyperbilirubinemia must be distinguished from other common post-transplant complications such as toxicity from preparative chemotherapeutics, sinusoidal obstructive syndrome (also called hepatic veno-occlusive disease), and occasionally fulminant viral hepatitis. Sinusoidal obstructive syndrome is characterized by hyperbilirubinemia, portal hypertension, and weight gain due to third spacing of fluids. Portal hypertension is part of the clinical picture of sinusoidal obstructive syndrome, and not a manifestation of acute GVHD in patients without underlying liver disease. Doppler assessment of portal hypertension, measurement of the hepatic vein occlusive pressure, and if necessary histological examination, are critical in resolving the differential diagnosis. A transjugular liver biopsy is preferable to transcutaneous biopsy, as portal pressures can be measured. Acute GVHD produces cholestatic hepatitis, with histology showing frequent acidophilic bodies evolving to bile duct exocytosis and disruption. As the disease progresses beyond day 100 post-transplant, portal fibrosis is seen with increasing bile duct dropout.[56] This is in contrast to sinusoidal obstructive syndrome, which is characterized by occluded hepatic venules, sinusoidal fibrosis, and hepatocyte necrosis.[57]

TABLE 105.2

KEYSTONE CONSENSUS CRITERIA STAGING AND GRADING OF ACUTE GRAFT-VERSUS-HOST DISEASE

	Skin	Liver	Gut
Stage			
1	Rash on <25% of skin	Bilirubin 2-3 mg/dl	Diarrhea >500 ml/d or persistent nausea
2	Rash on 25–50% of skin	Bilirubin 3–6 mg/dl	Diarrhea >1000 ml/d
3	Rash on >50% of skin	Bilirubin 6–15 mg/dl	Diarrhea >1500 ml/d
4	Generalized erythroderma with bullous formation	Bilirubin >15 mg/dl	Severe abdominal pain with or without ileus
Grade			
I	Stage 1–2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III		Stage 2–3 or	Stage 2–4
IV	Stage 4 or	Stage 4	
Functional Grading			
	Skin	**Liver**	**Gut**
I	Rash on <50% of skin		
II	Rash on <50% of skin or	Bilirubin 2-3 mg/dl or	Diarrhea >500 ml/d or persistent nausea
III–IV	Generalized erythroderma with bullous formation or	Bilirubin >3 mg/dl	Diarrhea >1000 ml/d

Criteria for grading given as minimum degree of organ involvement required to confer that grade.
Grade IV may also involve lesser organ involvement but with extreme decrease in performance status. From Przepiorka D, Weisdorf D, Martin P, et al. 1994 consensus conference on acute GVHD grading. Bone Marrow Transplant 1995;15:825–828.

Gastrointestinal Tract

Anorexia, nausea, and vomiting are the most common symptoms of GI acute GVHD, but diarrhea, abdominal pain, and hemorrhage are symptoms of serious lower-tract disease. Almost any site along the tract can be involved. Unexplained GI symptoms such as mouth ulcers or ileus can be caused by acute GVHD. Endoscopy with biopsies of the upper and/or lower tract should be obtained for persistent symptoms, inasmuch as histology provides critical information. The differential diagnosis of upper-tract GVHD includes herpes simplex, cytomegalovirus, or candida esophagitis, stomach ulcer, and peptic gastritis or duodenitis. The differential diagnosis of lower tract disease includes enteritis from *C. difficile*, cytomegalovirus, Norfolk viruses, cryptosporidium, giardia, or enteric pathogens such as *Salmonella*, and side effects of irradiation or medications including cytotoxic chemotherapy, tacrolimus, and mycophenolate mofetil among others. Radiologic findings by computed tomography (CT) scan can include thickening of the esophageal, small, or large bowel wall; adjacent vasa recta engorgement; mesenteric fat stranding; or mucosal enhancement.[58] Radiologic modalities should not be relied upon for confirmation of diagnosis. Upper or lower endoscopy affords both a visual examination of the mucosa which may exhibit edema, erythema, ulceration, and mucosal sloughing, as well as the opportunity to obtain tissue for histology. Classic microscopic findings include epithelial crypt apoptotic bodies and lymphocytic infiltration. Involved mucosa can be noncontinuous and a lack of findings or a low degree of severity at one level does not rule out other areas or degrees of involvement.[59]

Lung

Lung complications following allogeneic transplant can be of cardiac, infectious, vascular, or immune nature. Infections and pulmonary embolism should always be entertained in the differential diagnosis of a transplant patient with shortness of breath, hypoxia, or new infiltrate. Volume overload and cardiogenic pulmonary edema is another mechanism of respiratory distress. Immune-mediated processes should be entertained when infectious work-up is negative, or CT scanning is not consistent with infectious processes. Diffuse alveolar hemorrhage has long been recognized as a post-transplant complication and occurs in approximately 10% of patients, with myeloablative regimens associated with a higher incidence. Patients manifest with dyspnea (92%) accompanied with mild to severe bleeding into the alveoli, although hemoptysis is seen in a minority (15%) of cases. Fever can be a presenting symptom (67%) and diagnosis is typically made following bronchoscopy. Patients often require ventilatory support and mortality rates can reach 70%.[60,61] Lung wedge resection or video-assisted thoracoscopic biopsy should be entertained for patients where an organism is not identified and diagnostic uncertainty remains. Bronchiolitis obliterans with organizing pneumonia (BOOP) is seen in up to 2% of patients during the post-transplant period. Although not considered a manifestation of GVHD,[62] biopsy-proven BOOP occurs at a median of 108 days after transplant and can display a wide range of severity and reversibility. It is typically a restrictive lung disease with radiographic findings showing peripheral patchy consolidation, ground glass infiltrates, and nodular opacities. BOOP after transplant is associated with GVHD and steroid therapy affords a chance for improvement.[63,64]

PREVENTION

A half century ago, Storb and collaborators determined that the immunosuppressive agent methotrexate could mitigate or prevent the onset of acute GVHD, when applied shortly after transplantation. Although oral and liver toxicity can be severe and preclude up to 40% of patients from receiving a full course of therapy, methotrexate remains widely in use, now typically in combination with a calcineurin inhibitor.[27] Calcineurin inhibitors act to inhibit IL-2 mediated T-cell expansion. Cyclosporine, the first calcineurin inhibitor, was found to be synergistic with methotrexate, leading to a reduction in severe (grade III/IV) acute GVHD when utilized in *HLA*-matched sibling allografts and to a lesser degree with unrelated donor allografts.[65,66] Subsequent development of the calcineurin inhibitor, tacrolimus, included two phase III head-to-head comparisons of methotrexate/cyclosporine and methotrexate/tacrolimus.[67,68] The combination of methotrexate/tacrolimus reduced the incidence of grade II–IV acute GVHD for both matched sibling donors (31.9% vs. 44.4%; $P = 0.01$) and unrelated donor transplants (56% vs. 76%, $P = 0.0002$), but it did not prevent chronic GVHD or improve survival. This lack of survival advantage propagated the use of both combination regimens at the discretion of individual transplant centers.

Attempts at further decreasing the incidence of acute GVHD have included the addition of agents to a calcineurin inhibitor with or without methotrexate. Mycophenolate mofetil is a prodrug of mycophenolic acid, an inhibitor of de novo synthesis of purines in lymphocytes required for lymphocyte proliferation. Mycophenolate mofetil has been examined in combination with cyclosporine or tacrolimus. Single-center randomized studies of mycophenolate mofetil suggest greater safety but not greater efficacy over methotrexate. One study was stopped early as cyclosporine/mycophenolate mofetil showed a clear advantage over cyclosporine/methotrexate in regard to decreased mucositis (21% vs. 65%, $P = 0.008$) and faster neutrophil engraftment (11 days vs. 18 days, $P < 0.001$) but without a difference in the incidence of acute GVHD.[69] A second single-center study revealed that mycophenolate mofetil decreased severe mucositis, use of parenteral nutrition, and promoted early hospital discharge, however, mycophenolate mofetil was associated with higher rates of severe (grade III–IV) acute GVHD (19% vs. 4%, $p = 0.03$), which was predominantly seen with unrelated donors.[70]

Sirolimus is an mTOR inhibitor that has complex immunomodulatory properties affecting T cells and APC. The drug requires therapeutic monitoring and is affected by inhibitors or inducers of *CYP3A4*. Sirolimus is associated with the risk of endothelial damage such as in sinusoidal obstructive syndrome.[71-73] Initially shown to be safe in combination with tacrolimus and methotrexate,[74] sirolimus has now been tested in several phase II studies in combination with tacrolimus and the two agents likely synergize to reduce acute GVHD rates.[75,76] In particular, sirolimus supports regulatory T-cell reconstitution post-transplant, which are protective against acute GVHD after transplantation.[77]

Bortezomib is a proteasome inhibitor that has activity against multiple myeloma via nuclear factor kappa B inhibition and other mechanisms. A phase I/II trial showed that bortezomib could be added to tacrolimus and methotrexate as acute GVHD prophylaxis. This regimen is promising as the 180 cumulative incidence of grade II–IV acute GVHD was 13%.[78]

The chemokine receptor CCR5 plays a role in alloreactivity via effects on lymphocyte migration, and has shown promise in an early phase study. Blockade using the CCR5 antagonist, maraviroc, in combination with tacrolimus and methotrexate as acute GVHD prophylaxis led to inhibition of lymphocyte trafficking, without attenuating T-cell function or impairing stem cell function in vitro.[17]

Special circumstances surrounding the selection of acute GVHD prophylaxis include *HLA*-incompatible related donors, unrelated donors, or cord blood. For cord blood transplants, cyclosporine has been the drug primarily utilized as a prophylaxis backbone.[79] For *HLA* mismatched donor transplants, a calcineurin inhibitor/methotrexate-based regimen is generally

inadequate for GVHD prophylaxis. Triple combination regimens, ATG, and other methods of T-cell depletion have been shown effective in prevention of acute GVHD for mismatched donor transplants.[71,80]

As T cells are the primary effectors of acute GVHD, methods of depleting T cells from the graft or in vivo, following transplant have succeeded in reducing rates and the severity of acute GVHD. An ex vivo method of soybean agglutination and E-rosetting was performed[81] to achieve T-cell depletion from allografts, resulting in high rejection rates, presumably due to rejection by residual recipient T cells.[82,83] When combined with more immunosuppressive conditioning regimens this complication is ameliorated, yet even so T-cell depletion has not proven to increase overall survival following transplant, considering increased likelihood for relapse and higher infection rates.[84] Similarly, the anti-CD52 monoclonal antibody, alemtuzumab, has been utilized ex vivo to deplete T cells, resulting in low incidence of grade II/IV GVHD (12%), but a concerning rate of graft failure (15%).[85] CD34+ cell isolation has been studied and shown to result in extremely low rates of severe acute GVHD in high-risk patients.[86]

In vivo alemtuzumab has been utilized in combination with several different regimens, both with and without a calcineurin inhibitor, with acceptable rejection rates and low incidence of GVHD.[87] The use of alemtuzumab is associated with increased infectious complications.[88]

Antithymocyte globulin (ATG) refers to polyclonal antibodies against thymus tissue. When used for as prophylaxis or treatment for patients with acute GVHD it leads to depletion of T lymphocytes. It may cause an acute cytokine release syndrome that may include fever, hypotension, and may progress to shock, and delayed "serum sickness." Infectious complications include Epstein-Barr virus re-activation and associated post-transplant lymphoproliferative disorder, and human herpes virus-6 re-activation and associated encephalitis.[89,90]

Another agent used to reduce T-cell numbers following transplant is cyclophosphamide, which is a potent immunosuppressive agent, yet spares stem cells. This strategy can result in low rates of severe acute GVHD, even when used as a single prophylactic agent.[91]

PRIMARY AND SECONDARY THERAPY OF ACUTE GRAFT-VERSUS-HOST DISEASE

Primary therapy for acute GVHD consists of high-dose steroids (the equivalent of 1 to 2 mg/kg/day of prednisone, with a taper initiated as soon as patients have a major decrease in GVHD signs or symptoms). This standard is based upon historical empirical evidence and randomized controlled data which suggest no advantage to prednisone-equivalent steroid doses of >2.5 mg/kg/day and no disadvantage for 1 mg/kg/day for grade II acute GVHD.[92]

Standardized consensus response criteria for acute GVHD clinical trials are defined as a complete response, with resolution of all signs and symptoms of disease and normalization of laboratory values, and a very good partial response (VGPR), which allows for residual nonbullous erythematous rash on <25% of BSA, occasional nausea or vomiting, and a reduction of bilirubin to <25% of baseline at enrollment.[93] The definition of VGPR (Table 105.3) allows for confounding variables that clinicians must recognize while monitoring for resolution of acute GVHD such as residual GI and hepatic toxicities from conditioning or prophylactic medicines and the recognition of erythema or darkening skin as resolving skin lesions. Prolonged high-dose steroid use leads to a significant degree of morbidity and mortality, and the tapering of these drugs must take precedence once symptomatology and abnormal laboratory data recede.

TABLE105.3

CONSENSUS TERMINOLOGY DESCRIBING VERY GOOD PARTIAL RESPONSE FOR ACUTE GRAFT-VERSUS-HOST DISEASE

Skin	No rash, or residual erythematous rash involving <25% of the body surface, without bullae (residual faint erythema and hyperpigementation do not count)
Liver	Total serum bilirubin concentration <2 mg/dl or <25% of baseline at enrollment
Gut	Tolerating food or enteral feeding
	Predominantly formed stools
	No overt gastrointestinal bleeding or abdominal cramping
	No more than occasional nausea and vomiting

From Endpoints for Clinical Trials Testing Treatment of Acute Graft-Versus-Host Disease: A Consensus Document. from Martin PJ, Bachier CR, Klingemann HG, et al. Endpoints for clinical trials testing treatment of acute graft-versus-host disease: a joint statement. Biol Blood Marrow Transplant 2009;15:777–784.

The largest studies to date have not been consistent in identifying predictors of response. Risk factors to steroid therapy are not uniform,[94,96] although lack of response to primary therapy is clearly a predictor of decreased survival. Unfortunately complete response (CR) rates to high-dose steroid monotherapy are as low as 20% to 50% of patients, although patients may tolerate steroid taper following a PR. Few data exist to inform the rate of steroid taper. Continuation of the taper must be conducted with frequent monitoring of GVHD parameters to prevent a flareup of symptoms.

Several agents have been added to steroids in comparative studies; at this time no evidence supports the use of these in combination, beyond a well-designed clinical trial for primary acute GVHD therapy. A recent randomized, phase II multicenter trial evaluated four agents, each in combination with glucocorticoids, as initial therapy for acute GVHD. Of the four agents (etanercept, mycophenolate mofetil, denileukin diftitox, and pentostatin) used individually in combination with steroids, the mycophenolate mofetil and steroid combination provided the most encouraging 28-day CR rate,[97] however, this was not confirmed in a subsequent phase III trial.

For patients unresponsive and unable to tolerate a steroid taper, consideration of second-line therapy in addition to steroids should be made at an interval appropriate to the severity of symptoms. For patients without a significant decrease in symptoms or laboratory parameters, within 3 to 5 days an additional agent is typically added. No particular agent has been shown to be superior to another as therapy for steroid-refractory patients as data on comparative effectiveness of salvage agents is sparse, thereby limiting conclusions and application to clinical practice. Combination therapy has not been systematically studied to date, and it remains uncertain if combinations of drugs will be of benefit for steroid-refractory GVHD patients. Some practitioners utilize differential subset response rates from differing agents to inform selection of agents.

ATG has been studied as second-line therapy with variable overall response rates (ORR) in the range of 30% to 56%. CR was more likely for manifestations in the skin than in other sites.[98] Other antibodies that have been studied but have yet to prove of benefit over alternatives for use as second-line therapy for steroid-refractory acute GVHD include anti-CD147, expressed on activated T and B lymphocytes as well as APC, anti-CD3 antibodies (OKT3, visilizumab), anti-CD5-ricin conjugated antibodies, and anti-CD52 (alemtuzumab), expressed on most hematopoietic cells.

Anti-CD25 antibodies (daclizumab, enlimomab, basiliximab) against the IL-2 alpha receptor subunit act to block T-cell proliferation and signaling, but also may block or deplete regulatory T cells. These agents have led to ORRs of 40% to 67%[99] and response rates are greater in skin compared to other organs, whereas infectious complications due to concomitant glucocorticoids remain a prominent cause of mortality.[100] Denileukin diftitox (Ontak) is recombinant IL-2 fused to diphtheria toxin and has demonstrated some activity in acute GVHD in phase I trials.[101,102]

Antibodies against TNFα (infliximab and etanercept) have shown promise in retrospective single institution series with an ORR of 50% to 67%. At least one series showed intestinal involvement predicted for response, although this was not supported in the other series.[103–105]

Mycophenolate mofetil has been studied for glucocorticoid refractory GVHD in several reports.[106,107] ORRs with mycophenolate mofetil are in the range of 31% to 67%, and dose-limiting cytopenias must be taken into account. Sirolimus has been studied as an agent for refractory acute GVHD in several retrospective series and one safety study. Adverse effects have included hyperlipidemia and cytopenias. Thrombotic microangiopathy has been observed in up to 35% of patients when used in combination with calcineurin inhibitors. Pentostatin, a nucleoside analogue, has shown activity in refractory GVHD.

Extracorporeal photochemotherapy utilizes 8-methoxypsoralen and exposes peripheral blood cells to UV-A light extracorporeally. It is believed this alters APC activation and promotes Th2 polarization. This therapy is relatively well tolerated and has been associated with an ORR of 67% to 75%. Best response is typically seen after 2 months of therapy; lesser responses seen in patients with GI involvement and patients with higher-grade disease.

SUPPORTIVE CARE

For prophylaxis, there should be appropriate minimization of exposure to precipitating agents such as the sun. Patients with active acute GVHD, there should be special attention paid to the immunocompromised state of the patient. Understanding of the hospital and community bacterial resistance patterns is essential to select appropriate prophylactic antibiotics. Patients on high-dose steroids are at high risk for contraction of fungal pneumonia and appropriate coverage with antifungal medication is warranted. It was recently shown in a large randomized trial that the antifungal agent posaconazole was superior to fluconazole at preventing invasive aspergillus when used as prophylaxis in patients with GVHD requiring high-dose steroid, combination immunosuppresive therapy, or ATG.[108] A comparison of transplant outcomes between the time period of 1993 to 1997 and 2003 to 2007 at a large single center, revealed significant reduction in mortality. Although this change is due to many factors including the advent of reduced intensity regimens, decreased infection related deaths, and decreased severe GVHD, improved supportive care plays a key role.[109]

CONCLUSION

Acute GVHD remains a significant source of morbidity and mortality after allogeneic transplant. The advent of improved prophylactic regimens has led to decreases in the rates and severity, although the most effective primary therapy remains steroids. Future directions should focus on genetic risk factors for the development of disease, ways to predict which patients will not respond to steroids as primary therapy, and agents or cellular therapies that will prevent the development or stop the progression of acute GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE

Introduction

Major efforts in basic, translational, and clinical research in chronic GVHD are underway, and promise to improve outcomes of affected patients. The following sections review major progress in our understanding of the pathobiology, clinical advances in the management of the syndrome, and remaining challenges for future research.

Biology

Although there is uncertainty in the mechanisms at work in human chronic GVHD pathogenesis, pre-clinical models have suggested several areas for ongoing investigation and potential avenues for novel therapeutic approaches.

CD4 T-cell Subsets

Allied clinical observations suggest the role of alloreactive donor T cells: peripheral blood mobilized stem cell products, which contain greater donor T cells compared to bone marrow harvested stem cells, impose a greater risk for chronic GVHD and prolonged duration of immune suppression.[110] Ex vivo T-cell depletion strategies,[111,112] as well as in vivo strategies such as antithymocyte globulin,[113] ATG-Fresenius,[113] or alemtuzumab, are associated with decreased risk of chronic GVHD.[114,115] Ongoing investigation aims to discern the relationship between regulatory T cells and chronic GVHD. Early clinical evidence suggests an inverse relationship between regulatory T-cell numbers and the risk of chronic GVHD.[116] In a randomized trial comparing sirolimus/tacrolimus versus methotrexate/tacrolimus, sirolimus-treated patients had selective recovery of functional regulatory T cells, and significant reduction in NIH moderate–severe chronic GVHD.[77] Taken together, current evidence suggests that selective immune modulation may favorably affect chronic GVHD pathogenesis.

Loss of Central Tolerance

Negative selection of autoreactive T cells naturally constitutes a major mechanism of immune tolerance. Immature T cells are positively selected first in the thymic cortex through recognition of class I or class II MHC. In the thymic medulla, T cells engage marrow-derived APCs bearing self-antigens. Strongly self-reactive T cells suffer negative selection through apoptosis. Thus, in normal immunity, naive T cells are educated in the thymus, and autoreactive cells are deleted. Dysregulation of central tolerance due to thymic epithelial damage, which may result from transplantation conditioning therapy or prior GVHD, constitutes a major hypothesis for development of chronic GVHD after allogeneic HSCT. A murine model of thymic dysfunction largely recapitulates a chronic GVHD phenotype. Here, lethally irradiated C3H/HeN recipients receive T-cell–depleted bone marrow from MHN-mismatched B6 mice deficient in MHC class II antigens (*B6 H2-Ab1*$^{-/-}$).[117] Thus, thymic negative selection is compromised by lack of MHC class II in thymic dendritic cells. The resulting phenotype includes sclerodermatous (Scl) skin changes, weight loss, bile duct loss, mononuclear cell infiltration of the salivary glands, and mortality. Evidence of impaired thymic negative selection has not been observed in other murine models. The clinical relevance of these findings has also been challenged, as thymic function declines with age and may not be relevant to development of GVHD in adult recipients of HSCT. Experimental models have suggested benefit of keratinocyte growth factor to prevent thymic injury, however, this strategy was not successful in human clinical investigation.[118]

Altered B-cell Homeostasis

Several major basic and clinical observations support the role of loss of B-cell tolerance and altered B-cell homeostasis following transplantation in chronic GVHD pathogenesis. B cells have multiple functions, including antibody production, immune regulation, antigen presentation, and cytokine production, which all may have relevance to chronic GVHD pathogenesis.[119] A major murine chronic GVHD model, the systemic lupus erythematosis (SLE)-chronic GVHD model, supports the coordination of CD4 T and B cells for antigen presentation and antibody production responsible for the chronic GVHD phenotype. In this model, involving parent-into-F1 combinations, both class I and class II MHC mismatched immune cells are adoptively transferred into nonirradiated mice, resulting in autoantibody production and immune-complex glomerulonephritis. In this model, B cells present antigen to CD4 T cells, leading to activation and production of Th2 cytokines including IL-4 and IL-10. These cytokines activate B cells, which produce autoantibodies. Further antigen reprocessing and presentation leads to activation of other CD4 T cells, and epitope spreading. Despite differences between this model and human chronic GVHD, it supports the role of B cells in chronic GVHD pathogenesis. B-cell stimulatory signals, including B-cell–activating factor (BAFF), have a key role in B-cell reconstitution and homeostasis after transplant. In such models, B-cell survival is dependent on B-cell receptor and BAFF signaling, and B-cell homeostasis is dependent on soluble BAFF concentration. BAFF levels, as well as the balance of autoreactive B cells and competing naive B cells determine the fate of autoreactive B cells.[120,121]

Beyond these basic findings, multiple lines of human clinical evidence support this hypothesis: first, autoantibodies have been detected in patients with chronic GVHD. After sex mismatched HSCT, alloantibodies directed against the Y chromosome-associated mHAs, or H–Y antibodies, have been detected and correlate with the occurrence of chronic GVHD.[122,123] In the setting of cutaneous sclerosis of chronic GVHD, activating anti-platelet-derived growth factor receptor (PDGFR) antibodies have been detected. As well, reduced levels of immature B cells in patients with chronic GVHD support altered B-cell homeostasis.[124] It is important to note that investigators have demonstrated aberrant B-cell homeostasis and elevated BAFF levels in human HSCT recipients with chronic GVHD. A consolidative model suggests that, in patients who develop chronic GVHD, high BAFF levels and decreased numbers of naive B cells (high BAFF/B-cell ratio) support alloreactive pre- and post-germinal center CD27+ B cells that contribute to chronic GVHD development.[125] Additionally, recipient BAFF SNP has association with chronic GVHD phenotypic presentation.[126] This mounting basic and clinical evidence has informed allied clinical investigation: multiple clinical trials have demonstrated activity of the anti-CD20 monoclonal antibody, rituximab, in the treatment of chronic GVHD which has failed standard glucocorticoid therapy,[127,129] and there is interest in the incorporation of B-cell–depleting agents in both prevention and primary therapy of chronic GVHD.

Profibrotic Pathways

Clinical and basic evidence suggest that profibrotic pathways play a role in chronic GVHD development. In particular the coordination of Th2 CD4 cells, TGF-β and IL-13, and potentially stimulatory anti-PDGFR antibodies, effect fibroblast production of collagen and lead to fibrosis. One major murine model, the Scl-chronic GVHD model, has provided mechanistic insight into fibrotic chronic GVHD phenotypes. In this model, B10.D2 ($H\text{-}2^d$) into BALB/c ($H\text{-}2^d$), donor immune cells (bone marrow and splenocytes) are adoptively transferred into sublethally irradiated mice that are matched at MHC, but mismatched for mHAs. With full donor lymphoid chimerism, chronic GVHD is mediated by donor immune cells. The resulting phenotype includes fibrosis in multiple organs (skin, GI tract, liver, lung, and parotid salivary gland), mononuclear cell infiltration and collagen deposition, and mortality. In this model, inflammatory signals lead to activation of donor and host APC, recruiting CD4 T cells, which in turn produce TGF-β and IL-13. These signals drive fibroblast collagen synthesis and resultant fibrosis. The specific role of TGF-beta has been supported by amelioration of chronic GVHD manifestations after neutralization of this cytokine in murine models, and the clinical observation of an inverse relationship between TGF-beta signaling in CD4 and CD8 cells and the risk of chronic GVHD.[130] In the setting of cutaneous sclerosis of chronic GVHD, activating anti-PDGFR antibodies have been detected, and agents with activity against this receptor kinase such as imatinib have demonstrated activity in this condition.[131]

Diagnosis of Chronic Graft-versus-Host Disease

Chronic GVHD occurs in the majority of patients at risk, up to 60% to 80% of those who survive more than 100 days after transplantation.[132,133] The reported incidence of chronic GVHD in the published literature is dependent upon classification of the syndrome, patient and transplantation characteristics, pharmacologic GVHD prophylaxis utilized, and the use of further in vivo or ex vivo T-cell–depleting agents. Accurate recognition and management of the syndrome is important, as it is a major source of late HSCT-related morbidity and mortality,[134,135] an important determinant of overall health, functional ability, and quality of life,[132,133,136,138] as well as prolonged immune suppressive therapy after HSCT.[139]

The syndrome is characterized by diverse manifestations, and has several parallels to human autoimmune and inflammatory disorders, such as systemic lupus erythematosis, Sjogren's disease, systemic sclerosis, and inflammatory bowel disorders, among others. The most commonly occurring manifestations arise in the skin, eyes, mouth, and liver. Common skin manifestations include pigmentation changes, lichen planuslike changes, poikiloderma, as well as more advanced cutaneous and subcutaneous sclerosis. Note that cutaneous erythema is a manifestation shared by acute GVHD and overlap subtype of chronic GVHD (when present together with other diagnostic findings of chronic GVHD). Oral findings include lichen planuslike changes, hyperkeratotic plaques, or decreased oral range of motion. Patients can suffer from oral and ocular sicca symptoms, including dry mouth and dry or gritty eyes. Hepatic involvement with chronic GVHD results in a cholestatic pattern of elevated alkaline phosphatase and bilirubin. In the GI tract, diagnostic chronic GVHD features include esophageal web, stricture, or concentric rings on endoscopic or radiographic study. Other manifestations such as anorexia, nausea/vomiting, and diarrhea are shared between acute and overlap subtype of chronic GVHD. Bronchiolitis obliterans is a less common manifestation of chronic GVHD. Bronchiolitis obliterans represents a diagnostic manifestation of chronic GVHD, and is characterized by clinical symptoms (e.g., cough, dyspnea) and respiratory physiologic abnormalities (forced expiratory volume in 1 second [FEV1]/forced vital capacity ratio <0.7, FEV1 $<75\%$ predicted value, evidence of air trapping or bronchiectasis on CT scan, residual volume of $>120\%$, presence of another chronic GVHD manifestation, and absence of infectious etiology). Tissue biopsy is not required for diagnosis.

Given the importance of the syndrome, a major challenge for clinicians remains to recognize chronic GVHD accurately, and distinguish it from competing syndromes, such as acute GVHD (i.e., sole presence of acute GVHD manifestations), other medical conditions, infectious etiology, or adverse effects from medications (e.g., hepatic function abnormalities due to medications such

as azole antifungals). Once the syndrome is recognized, it should be classified appropriately, and severity assessed; these data together provide both prognostic information, as well as indications for topical or systemic therapy.

CLASSIFICATION AND SEVERITY GRADING

Major changes in the classification and severity grading of the syndrome have been suggested by the NIH Chronic GVHD Consensus Conference. Among these proposed changes, the previously accepted division between acute and chronic GVHD according to the landmark of 100 days post-HSCT was eliminated. The guidelines propose definition of chronic GVHD according to diagnostic manifestations of the syndrome, rather than the time of onset following HSCT.

Accordingly, manifestations of acute GVHD occurring before day 100 are defined as acute GVHD, and sole acute GVHD manifestations occurring after day 100 are considered persistent, recurrent, or late acute GVHD based on the prior occurrence of acute GVHD. Classic chronic GVHD is defined based on the definitive manifestations of the syndrome in the absence of concurrent acute GVHD manifestations. Diagnosis of chronic GVHD requires the presence of at least one diagnostic clinical sign of chronic GVHD or the presence of at least one distinctive manifestation confirmed by biopsy or allied diagnostic test. The concurrent presentation of both chronic GVHD and acute GVHD manifestations defines the overlap subtype of chronic GVHD. Readers are directed to Filipovich et al. for comprehensive coverage of chronic GVHD diagnosis and severity grading criteria.[54] Although prior retrospective studies reported after the NIH Consensus failed to support the importance of the overlap subtype of chronic GVHD consistently, prospective data from the Chronic GVHD Consortium demonstrates that patients with overlap have greater symptom burden, worse quality of life, impaired function, and significantly inferior survival compared to classic chronic GVHD cases.[140]

In addition, consensus guidelines for chronic GVHD severity grading were proposed to replace the previously accepted scheme based on limited versus extensive involvement. In the prior severity grading scheme, limited involvement included only localized skin involvement or hepatic dysfunction, whereas extensive chronic GVHD was defined by the presence of generalized skin involvement or the presence of aggressive chronic hepatitis, bridging necrosis or cirrhosis in liver biopsy, or involvement of other target organs such as the eye, mouth, or lung. Rather, chronic GVHD severity according to the NIH Chronic GVHD Consensus is scored according to objective criteria for each organ involved, with attention to the functional implications of the degree of involvement, such as degree of weight loss in GI scoring, or frequency of artificial tear use or more aggressive interventions needed for therapy of ocular sicca manifestations.

The individual organ scores are then summarized for an overall global severity score of mild, moderate, or severe. A global severity score of mild encompasses no more than 2 organs, with severity of 1 each; moderate global severity indicates any organ site with a score of 2 (or lung score of 1), or involvement of 3 or more organ sites; finally, the severe category results from either any individual organ site score of 3, or a lung score of 2.[54] Data from the Chronic GVHD Consortium validates the importance of the proposed NIH Consensus severity criteria: global severity scores at cohort study enrollment were associated with nonrelapse mortality ($P < .0001$) and survival ($P < 0.0001$); 2-year overall survival was 62% (severe), 86% (moderate), and 97% (mild) (Fig 105.1).[141]

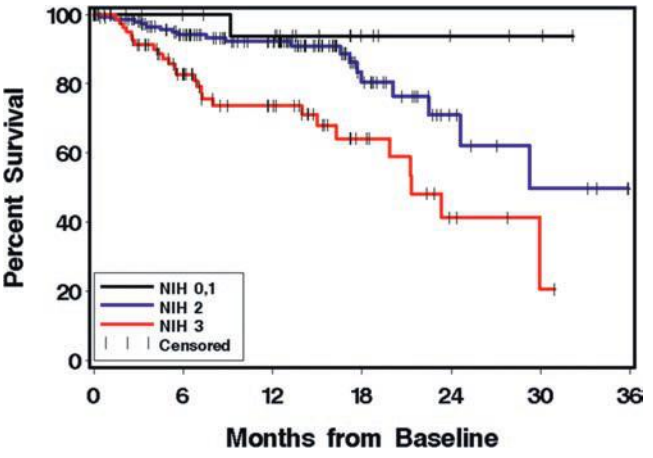

FIGURE 105.1. Survival outcomes per NIH chronic GVHD overall severity. From Arai S, Jagasia M, Storer B, et al. Global and organ-specific chronic graft-versus-host disease severity according to the 2005 NIH consensus criteria. Blood 2011;118(15):4242–4249.

Clinical Predictors of Chronic Graft-versus-Host Disease Development

Clinical predictors for the development of chronic GVHD may facilitate identification of patients at risk, and could potentially provide a rationale for risk-adapted strategies for prevention of the syndrome. The most consistently reported risk factors for development of chronic GVHD have included increasing age of the donor or recipient, donor/recipient *HLA* disparity and donor relation, male recipients of allografts from alloimmunized female donors, prior occurrence of acute GVHD, and the use of peripheral blood mobilized stem cells versus bone marrow.[110,142–144] However, it should be noted that these analyses have utilized the historical definition for chronic GVHD, rather than the proposed NIH Consensus criteria for diagnosis and classification of chronic GVHD. These potential limitations are highlighted by the fact that a recent analysis did not demonstrate that these traditional risk factors for chronic GVHD development had association with severity of chronic GVHD.[141]

PROGNOSTIC VARIABLES

Previously reported prognostic variables include extensive involvement versus limited progressive onset of chronic GVHD from acute GVHD, platelet count less than 100,000/μl at chronic GVHD diagnosis, impaired performance status, and failure to respond to therapy.[134,145–147] In a recent large Center for International Blood and Marrow Transplant Research analysis, investigators examined prognostic factors to develop a chronic GVHD risk score in a sample of 5,343 chronic GVHD-affected patients. In this analysis, 10 variables were significantly associated in multivariate analysis with overall survival and nonrelapse mortality: age, prior acute GVHD, time from transplantation to chronic GVHD, donor type, disease status at transplantation, GVHD prophylaxis, gender mismatch, serum bilirubin, Karnofsky performance status, and platelet count. From these data, six risk groups were identified based on the number of risk factors present. Nonrelapse mortality at 5 years ranged from 5% in the lowest risk group to 72% in those with greatest risk. Similarly, 5-year overall survival ranged from 91% in the lowest risk group down to 4% in the greatest risk group ($P < 0.01$).[148] Moving forward, predictive variables for long-term outcome need to be examined based on current transplantation practices and in the setting of the revised diagnostic and severity grading criteria. Analyses performed to date from the Chronic

GVHD Consortium support both the NIH overall severity,[141] and the overlap subtype of chronic GVHD[140] as significant determinants of overall survival and nonrelapse mortality.

PREVENTION OF CHRONIC GRAFT-VERSUS-HOST DISEASE

Successive advances in pharmacologic prophylaxis strategies for acute GVHD prevention have led to more effective reduction in grade II–IV and grade III/IV acute GVHD. Inasmuch as severe acute GVHD, especially that refractory to standard first-line steroid therapy, results in significant mortality, these approaches represent major breakthroughs in reduction of early transplant-associated complications and mortality. However, these benefits in acute GVHD prevention have largely not resulted in reduction in chronic GVHD. Randomized phase III trials in matched sibling and unrelated donor HSCT supported the superiority of tacrolimus/methotrexate over cyclosporine (cyclosporine)/methotrexate for prevention of acute GVHD, but did not result in reduction of the incidence of chronic GVHD.[67,68] Similarly, single-center phase II trials examining the combination of sirolimus/tacrolimus,[149] as well as a comparative trial of mycophenolate mofetil/tacrolimus versus methotrexate/tacrolimus[70] have not shown major benefit in chronic GVHD prevention when methotrexate is replaced with alternative agents.

The optimal duration of immune suppression administration is not known, however, and chronic GVHD can often arise during or after discontinuation of immune suppression. Thus, several investigators have explored whether prolonged administration of immune suppression may reduce the risk for chronic GVHD. Some reports indicated decreased risk with prolonged administration of cyclosporine,[150,151] however, prospective trials have not consistently demonstrated a benefit. In a randomized trial of allogeneic related or unrelated marrow transplant recipients, the hazard for chronic GVHD did not significantly differ between 6 and 24 months of cyclosporine administration after transplantation.[152] Others have demonstrated in peripheral blood stem cell grafts from matched related donors reduced incidence of chronic GVHD in those treated with 12 versus 6 months of cyclosporine after transplantation.[153] In the setting of nonmyeloablative conditioning, retrospective analysis did not demonstrate significant differences in extensive chronic GVHD between three tapering schedules.[154] Emerging data from a randomized trial comparing sirolimus/tacrolimus and methotrexate/tacrolimus suggests that prolonged administration of sirolimus through 1 year after transplantation may be associated with reduction in NIH moderate–severe chronic GVHD, however, further follow-up is needed.[77] Based on the rationale that alloreactive T cells are responsible for chronic GVHD development, investigators have pursued both in vivo and ex vivo strategies for T-cell depletion. Memorial Sloan Kettering Cancer Center published a phase II trial of ex vivo T-cell depletion employing CD34 enrichment by the Miltenyi device in 35 unrelated donor transplants.[112] The median CD3+ cell dose was 1.52×10^3/kg. With no pharmacologic prophylaxis, the incidence of chronic GVHD was only 29%. Epstein-Barr virus-associated post-transplant lymphoproliferative disease occurred in 9% of the cases. With intense conditioning, the relapse incidence was low, 6% at 4 years, despite a largely advanced disease cohort. In addition, the BMT CTN 0303 trial confirmed the efficacy of this protocol in *HLA*-matched sibling donor transplantation ($n = 44$) for acute myeloid leukemia in first or second complete remission.[111] T-cell–depleted allografts contained a median CD3+ dose of 6.6×10^3/kg. Without pharmacologic prophylaxis, extensive chronic GVHD was 6.8% (0% to 14.4%) at 24 months. With median follow-up of 34 months, the 36-month leukemia-free survival was 58%. These results demonstrate that subtotal depletion of donor T cells provides protection against chronic GVHD.

Investigators from Johns Hopkins have pioneered GVHD prophylaxis with post-transplant high-dose cyclophosphamide (50 mg/kg/d on days +3 and +4) based on its selective activity against alloactivated donor T cells.[91] In a recent phase I/II Bayesian design trial ($n = 117$) including *HLA*-matched related or unrelated donors, T replete marrow was transplanted following myeloablative doses of busulfan and cyclophosphamide. With sole post-transplant cyclophosphamide prophylaxis, chronic GVHD incidence was only 10% with median follow-up of 26 months. These data suggest that targeting alloreactive donor T cells may reduce chronic GVHD risk and facilitate transplantation tolerance. Investigators from MD Anderson Cancer Center reported a higher risk for chronic GVHD using post-transplant cyclophosphamide prophylaxis after peripheral blood stem cell transplantation rather than bone marrow, however. In vivo strategies for T-cell depletion, including antilymphocyte antibodies such as ATG or alemtuzumab, have promise to reduce risk for chronic GVHD as well. Long-term follow-up from a randomized phase III trial comparing ATG-Fresenius versus placebo alongside cyclosporine/methotrexate standard prophylaxis demonstrated cumulative incidence of extensive chronic GVHD after 3 years of 12% in the ATG-Fresenius group versus 45% in the control group ($P < 0.0001$), with comparable incidence of primary disease relapse and nonrelapse mortality. The hazard ratio for receiving immunosuppressive therapy was 0.31 after ATG-Fresenius ($P < 0.0001$), and the 3-year probability of survival free of immune suppression was 53% and 17% in the ATG-Fresenius versus control.[113]

Finally, based on preclinical insights supporting the role of B cells in chronic GVHD pathogenesis, as well as activity of anti-CD20 therapy in steroid-refractory chronic GVHD, investigators have presented results of a single-center phase II trial of rituximab for chronic GVHD prevention.[155] There is also great interest in disruption of B-cell stimulatory signals (e.g., BAFF) after HSCT for prevention of chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE TREATMENT

Systemic immune suppressive therapy is generally required to control extensive chronic GVHD, or rather moderate to severe manifestations per the NIH Consensus severity grading. Those who have limited or mild chronic GVHD can often be treated with topical agents, such as artificial tears for ocular sicca; steroid mouth rinses for troublesome mouth symptoms such as dryness, sensitivity, or pain; topical steroid creams for mild cutaneous manifestations; or vaginal estrogen for vaginal dryness and atrophy. In total, the diverse manifestations of the syndrome require a tailored and multidisciplinary approach.

For those requiring systemic therapy, accepted standard primary therapy for chronic GVHD includes 1 mg/kg/day or greater of prednisone or equivalent with or without a calcineurin inhibitor.[132,156] A randomized trial comparing prednisone versus prednisone plus cyclosporine for primary therapy of extensive chronic GVHD did not detect significant differences in chronic GVHD control, transplant-related mortality, or overall survival, but showed less prednisone side effects in the combination arm.[156] Based on the limited durable response rates observed with standard primary therapy, several studies have been performed to determine whether combined therapy (i.e., steroids + additional systemic immune suppressive agent) improves response. The addition of other systemic immune suppressive agents has not provided benefit, as evidenced by trials employing azathioprine, thalidomide, hydroxychloroquine, or mycophenolate mofetil.[157–160]

Based on major published primary chronic GVHD therapy trials,[156–161] the following summarizes current evidence. Complete response rate assessed at 6 to 9 months following steroid-based therapy (either 1 mg/kg of prednisone alone or this in combination with additional agents such as azathioprine, thalidomide,

hydroxychloroquine, or mycophenolate mofetil) includes a range of reported values from 16% to 37%. In the study by Sullivan et al., 9-month complete response rate to prednisone was 33%, prednisone + azathioprine 37%, and prednisone alone among high-risk cases 16%.[157] Arora et al. reported 6-month complete response rate of 17% in prednisone + thalidomide and cyclosporine, and 28% for prednisone and cyclosporine alone.[158] In a more recent trial comparing activity of prednisone versus prednisone and mycophenolate mofetil, Martin et al. reported a 6-month complete response rate of only 23%.[160] Finally, Gilman et al. reported CR rates at 9 months of 38% and 33%, respectively, for hydroxychloroquine + prednisone versus prednisone alone. Thus, available randomized trials suggest an average complete response rate at 6 to 9 months of 27%.

ORR (total of CR + PR) has been reported as the following. Sullivan et al., reported ORR of 62% among prednisone-treated patients, 64% for prednisone with azathioprine, and only 32% for prednisone-treated patients with thrombocytopenia.[157] Arora et al. reported ORR of 84% at 6 months for prednisone-treated patients and 88% for those treated with prednisone and thalidomide.[158] Martin et al. reported an ORR of 62% at 6 months for patients treated with prednisone + mycophenolate mofetil or prednisone + placebo.[160,162] Gilman et al. reported ORR at 9 months of 39% and 46% for hydroxychloroquine + prednisone versus prednisone alone.[159] Thus, published randomized trials support an average ORR at 6 to 9 months of 60%. Note that Martin et al. demonstrated that ORR at 6 months of therapy was significantly associated with the ultimate risk for treatment failure, defined as initiation of secondary systemic GVHD treatment, nonrelapse death, or development of bronchiolitis obliterans. The cumulative incidence of treatment failure was 37% versus 63% in those with overall response versus not, $P = 0.01$.[162] Ongoing clinical trials aim to study targeted therapeutic approaches for specific chronic GVHD phenotypes [e.g., imatinib or rituximab for treatment of cutaneous sclerosis (NCT01309997)and fluticasone, azithromycin, and montelukast for treatment of bronchiolitis obliterans (NCT01307462)].

Based on limited response to primary therapy, many will go on to require additional immune-suppressive agents for chronic GVHD control. Steroid-refractory chronic GVHD has most commonly been defined as either progressive manifestations despite 1 month, or rather incomplete response despite 2 months of 1 to 2 mg/kg of prednisone or equivalent.[132] Multiple immune-suppressive agents, including pharmacologic agents such as mycophenolate mofetil, sirolimus, pentostatin, tacrolimus, and thalidomide, monoclonal antibodies including rituximab, and strategies such as extracorporeal photopheresis have demonstrated moderate activity in this setting, both ameliorating objective chronic GVHD manifestations, as well as facilitating decrease in systemic steroids.[132] Their activity is incomplete, however, and many with steroid-refractory chronic GVHD will require multiple agents to achieve disease control.

Note that chronic GVHD is associated with prolonged immune suppressive therapy after HSCT. In an analysis of 751 patients with chronic GVHD, the cumulative incidence of discontinuation of immune suppression at 7 years following chronic GVHD diagnosis was 50%; nonrelapse mortality was 24%, and relapse was 19%. On multivariable analysis, several factors were associated with decreased likelihood of discontinuation of immune suppression: peripheral blood stem cells, female donor:male recipient, number of chronic GVHD sites involved, bilirubin > 2 mg/dl at diagnosis, *HLA* mismatch, and year of transplantation.[139]

ASSESSMENT OF THERAPEUTIC RESPONSE

The established method for response determination in the majority of chronic GVHD therapy trials has been that of clinician-determined response. This method relies on the clinician's integration of dynamic chronic GVHD manifestations for a summary response categorization. CR indicates complete resolution of all chronic GVHD manifestations; PR signifies reduction in disease activity at response assessment compared to pre-treatment levels, but without complete resolution; stable disease indicates no response and no progression; and progressive disease indicates progressive chronic GVHD manifestations from baseline to response assessment.

Following the NIH Consensus Conference for Chronic GVHD, several additional means of response assessment in chronic GVHD therapeutic trials have been proposed. These include change in overall NIH severity categories, proposed NIH response criteria, 0–4 and 0–10 ordinal scales that rely on clinician assessment, organ-specific tools such as the Vienna skin scale, as well as patient-determined change in chronic GVHD activity, chronic GVHD-associated symptom burden, functional limitations, and change in quality of life. A national Chronic GVHD Consortium is currently assessing these competing measures of disease activity and their relationship to longer-reaching outcomes indicating clinical benefit, such as survival, discontinuation of immune suppression, and patient-reported benefit. One analysis recently reported demonstrates limited agreement between clinician-determined response and that calculated by the proposed NIH Consensus response criteria (Fig. 105.2)[163]; thus, response rates reported in the literature need to be interpreted with attention to the response metric utilized.

SUPPORTIVE CARE

Patients with chronic GVHD require careful supportive care and infectious prophylaxis. Given the immune dysfunction associated both with chronic GVHD as well as the immune-suppressive agents used to treat it, they are at increased risk for morbidity and mortality from infectious complications. Prophylactic antimicrobials should be utilized to prevent *Pneumocystis jiroveci*, encapsulated bacterial infections such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitides*, and *Varicella zoster*.[164] Systematic monitoring and pre-emptive therapy for *cytomegalovirus* reactivation is also important. The routine use of antifungal agents as prophylaxis beyond 75 days after transplantation has not been proven to be effective in preventing invasive fungal infections; however, many administer these agents for prophylaxis, particularly in those patients on prolonged courses of glucocorticoids. The use of intravenous immunoglobulin following HSCT has not been proven to be of benefit.[165] Other important components of supportive care include vaccination once appropriate after transplantation, skin care, oral cavity health and symptom control, management of ocular sicca symptoms, supportive care for vulvovaginal manifestations of GVHD, physical therapy for musculoskeletal impairment, prevention and management of osteopenia and osteoporosis, management of fatigue, and psychosocial support. A comprehensive review of appropriate, evidence-based ancillary care has been published.[164]

CONCLUSION

In summary, investigation into chronic GVHD pathogenesis, diagnosis and classification, and therapy offers promise for improved patient outcomes. Insights into chronic GVHD biology will provide novel strategies for prevention and therapy. Validation of the proposed NIH Consensus diagnostic and severity classification criteria, as well as determination of best-response criteria will move the state of chronic GVHD clinical trials forward. Novel preventive and therapeutic strategies based on detailed understanding of chronic GVHD pathogenesis will advance the field.

GRAFT-VERSUS-TUMOR RESPONSE

Evidence for Graft versus Tumor in Animals and Humans

Multiple lines of evidence point to a powerful immune response of donor immune cells against tumor cells after allogeneic HSCT. Initial proof of principle for an allogenic GVT effect was established in rodents.[166,167] Single-center and registry studies found an inverse correlation between acute and chronic GVHD and relapse of malignancy after human marrow transplantation (Fig. 105.3).[168,169] The probability of relapse was higher after twin compared to *HLA*-identical sibling transplants, pointing to disparate mHA as the target of the GVT effect. Similarly high was the probability of relapse after a T-depleted allogeneic transplant, pointing to mature donor T cells as GVT effectors. There was protection from relapse after a T-replete allogeneic HSCT in patients without history of GVHD, indicating that GVHD is not required for the GVT effect. Lower relapse rates, however, were in patients who had experienced acute GVHD, and the lowest in those with chronic GVHD. As shown in Figure 105.3, the GVT effect in allogeneic recipients with GVHD did account for about half of the total antitumor activity of the transplant procedure, thus GVT was as effective as the high-dose chemoradiotherapy administered before the transplant. Allogeneic HSCT after safer, low-intensity conditioning regimens, are also associated with durable responses in some malignancies.[170] As immune-suppressive therapy to prevent or treat GVHD also affects GVT responses, spontaneous remissions have been observed after stopping immune suppression in a variety of hematologic malignancies that had relapsed after allogeneic HSCT.[171] Direct evidence for a GVT effect was provided by infusion of donor lymphocytes for sole treatment of relapse after allogeneic HSCT (Table 105.4).[172] Response to donor lymphocyte infusions occurs after allogeneic transplants but not twin transplants, as disparate histocompatibility antigens are the GVT targets, and require stable donor engraftment, although it does not help

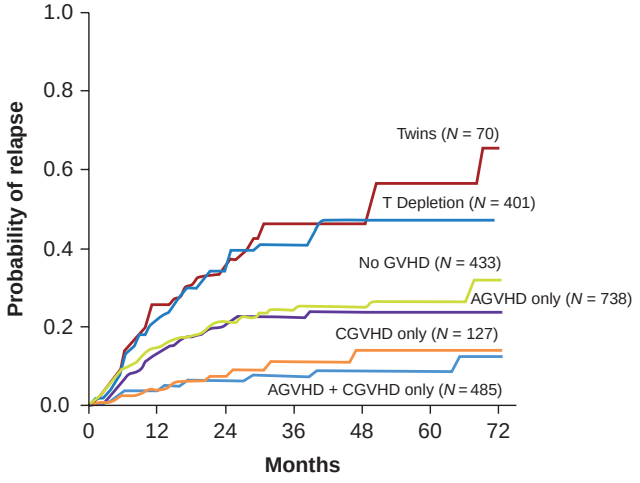

FIGURE 105.3. Actuarial probability of relapse after bone marrow transplantation for early leukemia according to type of graft and development of graft-versus-host disease (GVHD). AGVHD, acute GVHD; CGVHD, chronic GVHD. From Horowitz MM, Gale RP, Sondel PM, et al. Graft-versus-leukemia reactions after bone marrow transplantation. Blood 1990;75:555–562.

TABLE105.4

EVIDENCE FOR A GRAFT-VERSUS-TUMOR RESPONSE

1.	Allogeneic but not syngeneic marrow transplants can cure mice with leukemia.
2.	Allogeneic marrow transplants are more effective than twin transplants in preventing leukemia relapse in humans.
3.	Patients with graft-versus-host disease are more likely to be cured from leukemia than those without graft-versus-host disease.
4.	Spontaneous remissions occur after stopping immune suppression in patient with relapsed malignancy after allogeneic marrow transplantation.
5.	Donor lymphocyte infusions induce remission in patient with relapsed malignancy after allogeneic marrow transplantation.

patients who have rejected the graft. Donor lymphocytes are most effective in patients who have received a T–depleted graft, in those who have not already experienced GVHD, in chronic more than acute leukemia, and in patients with minimal tumor burden.[173]

T-cell–mediated Graft versus Tumor

Infusions of isolated CD4 or CD8 donor T cells for treatment of relapse have demonstrated that each of these cell types can mediate GVT.[174,175] The predominant GVT targets are mHA expressed in the recipient's malignant cells. As discussed under the "ACUTE GRAFT-VERSUS-HOST DISEASE" section, mHAs can be expressed ubiquitously (including, e.g., skin and leukemia) and are therefore targets for both GVHD and GVT (i.e., the H–Y associated male antigens), or their expression can be restricted to one or more hematopoietic lineages so they are targets for GVT but not GVHD (e.g., HA-1 and HA-2 antigens). Little is known about most mHAs, because diversity assessment of the human genome predicts over 10^7 polymorphisms that can function as mHAs in transplantation. A variety of genetic techniques have sped up the discovery of functional mHAs, and investigators hope to find a relatively small number of dominant mHAs that can be targeted for prevention of GVHD and exploitation of GVT.[176] Weaker immune targets are a variety of tumor-associated antigens that by themselves are not sufficiently immunogenic to elicit a protecting immune response, but in conjunction with the adjuvant effect of an allogeneic transplant can contribute to the GVT effect. These include the following: (1) tumor-specific antigens that result from the oncogenic mutations such as the Bcr/Abl tyrosine kinase in chronic myeloid leukemia, and the promyelocytic leukemia/retinoic acid receptor-α transcription factor in promyelocytic leukemia; (2) viral proteins, such as those from human papilloma virus in cervical cancer; (3) tissue-specific proteins, such as prostate-specific antigen in prostate cancer and proteinase-3 in myeloid leukemias; (4) germ-cell antigens, such as the melanoma-associated antigen (MAGE) family; (5) tumor-selective overexpressed self-proteins, such as WT1 in Wilms tumor or acute myeloid leukemia. Proteinase-3-derived PR1 peptide and WT1 are the best characterized tumor-associated antigens in patients after allogeneic HSCT.[177,178] Initial attempts have been made to amplify tumor immunity after allogeneic HSCT by vaccines.[179]

Natural Killer-cell–mediated Graft versus Tumor

As disparate HLA molecules are strong GVHD targets, one may expect that they would also be GVT targets for T cells. In contrast, most studies have failed to detect a GVT effect of *HLA* mismatch in T-replete transplants.[180,181] One hypothesis is that GVHD is so forceful after T-replete transplants from *HLA*-incompatible donors, that the required immune suppression may dissipate any possible appearance of GVT. Most *HLA*-incompatible transplants are performed nowadays with ex vivo or in vivo T-cell depletion. Early recovery of functional NK cells after T-depleted transplants from *HLA*-incompatible related donors has unveiled a powerful effect against myeloid leukemia without GVHD. NK-cell alloreactivity has been related to a reduced risk of leukemia relapse, no GVHD, and markedly improved survival in *HLA* disparate transplants.[182,183] For patients with acute myeloid leukemia in remission, the cumulative incidence of relapse was significantly lower after transplantation from NK alloreactive donors (3% vs. 47%; $P < 0.003$), and this translated into an improved event-free survival (67% vs. 18%; $P = 0.02$). For patients in relapse at the time of HSCT, donor NK-cell alloreactivity was not protective. Based on these data, donor NK alloreactivity against recipient cells has become a selection criterion for *HLA*-disparate donors when a T-depleted protocol is employed. To this purpose, high-resolution *HLA-C* typing is a good predictor of NK-cell alloreactivity, because the basis for NK allorecognition resides primarily in a bi-allelic system of inhibitory killer-cell Ig-like receptors (*KIR*) that silence NK effector function after recognition of their cognate ligands encoded by *HLA-C* alleles.[184] KIR2DL1 recognizes HLA-C molecules characterized by a Lys80 residue (i.e., HLA-Cw4), and KIR2DL2 and KIR2DL3 recognize HLA-C with an Asn80 residue (i.e., HLA-Cw3). Also, KIR3DL1 is the receptor for HLA-B alleles that include a Bw4 domain and the CD94/NKG2A heterodimer (encoded by the *KLRD1/KLRC1* genes) is an inhibitory receptor for HLA-E. During development, HLA class I molecules select for a self-tolerant *KIR* repertoire so that every mature NK-cell expresses at least one inhibitory receptor for self-HLA. NK cells that express a KIR for the class I group absent on allogeneic targets, sense the missing expression of self-class I HLA and kill the allogenic target ("missing self" model). The alternative "missing ligand" model has also been proposed to predict protection from relapse after HLA-matched sibling transplants.[185] When KIR ligand-matched donors possess anergic NK cells with an "extra" KIR for which neither donor nor recipient has an HLA ligand, upon transfer into the recipient, those NK-cells may regain competency and produce a GVT effect.[186] Activating *KIR*s regulate both NK- and T-cell functions. Unlike inhibitory *KIR*s, activating *KIR*s exhibit extensive population variation in gene number and content. Transplantation from donors carrying activating *KIR* genes is associated with improved control of leukemia relapse after unrelated donor transplantation.[187] Several biological models suggest that alloreactive NK-cells are responsible for favorable transplantation outcomes. Transfer of human alloreactive NK-cells into immune-deficient mice eradicated human myeloid leukemia.[183] KIR ligand mismatches correlate with the ability of donor NK-cell clones to kill recipient leukemic cells.[183] Alloreactive NK clones are detected in the recipients long after transplant.[188]

Conclusions

HSCT from allogeneic donors provide powerful GVT effects, via innate and adaptive immunity. The most recent effects of these findings have been: (1) decreased reliance on the use of toxic and sometimes lethal conditioning regimens to control leukemia; (2) use of donor lymphocyte infusion for prevention or treatment of relapse; (3) development of tumor vaccines to amplify the immune response after T-replete transplants; (4) selection of NK alloreactive, *HLA*-incompatible donors to decrease relapse of myeloid leukemias after T-depleted transplants.[189,190] We anticipate that further understanding of the factors that regulate GVT will continue to shape the protocols for allogeneic HSCT.[191]

CHAPTER 106

LATE EFFECTS AFTER TRANSPLANTATION

Bipin N. Savani, Minoo Battiwalla

INTRODUCTION

Allogeneic hematopoietic cell transplantation (HCT) provides curative therapy for a variety of diseases. Over the past several decades, significant advances have been made in the field of HCT, and now HCT has become an integral part of treatment modality for a variety of hematologic malignancies and nonmalignant diseases. Historically, the limitation of HCT has been transplant-related mortality (TRM). In order to offer the curative HCT treatment option to most patients, safer regimens with acceptable graft-versus-host-disease (GVHD)–associated morbidity and TRM are preferred. The development of less toxic pretransplant conditioning regimens, more effective prophylaxis of GVHD, improved infection control, and other advances in transplant technology have resulted in a rapidly growing number of transplant recipients surviving long-term free of the disease for which they were transplanted.[1,2]

Since its introduction in the early 1970s the number of patients who undergo HCT for a variety of malignant and nonmalignant disorders has increased steadily and, today, nearly 60,000 allogeneic HCT are performed worldwide annually,[1,3,4,5] a number that has been increasing yearly. With broadening indications, more options for HCT, and improvement in survival, by 2020 there may be up to half a million long-term survivors after allogeneic HCT worldwide.[6] In this era, a stem cell source can be found for virtually all patients who have an indication to receive HCT. Since 2007, more allo-HCT procedures have been performed using alternative donor stem cell sources, such as volunteer unrelated donors (URD) or cord blood, than related donors.[5,7] Haploidentical-related donor or cord blood transplantations (CBT) have emerged as alternatives to fill the gap for those patients who do not have matched related donors or URD, and the outcome of these types of transplantations are expected to be better than chemotherapy alone or even better than autologous-SCT for selected indications. All these result in a steady increase in numbers of long-term survivors after HCT, creating an enlarging pool of children, youth, and mature adults at risk for long-term complications of HCT.

Many patients who recover from immediate posttransplant problems eventually regain health and return to normal activities of life. For those who survive 2 or more years post-HCT, the prospect for long-term survival is excellent (85% at 10 years after HCT). Yet, among long-term survivors, mortality rates are 4- to 9-fold higher than observed in an age-adjusted general population for at least 30 years after HCT, yielding an estimated 30% lower life expectancy compared with someone who has not been transplanted.[8] The most common causes of excess death other than recurrent malignancy are chronic GVHD (cGVHD), infections, second malignancies, respiratory diseases, and cardiovascular diseases (CVDs).[3,6,8,9,10]

cGVHD is a multisystem chronic alloimmune and autoimmune disorder that occurs later after HCT. It is characterized by immune dysregulation, decreased organ function, significant morbidity, and impaired survival. Approximately 10% to 30% of patients require continued immunosuppressive treatment because of cGVHD beyond 5 years after HCT.[8,11] Therefore, it is not surprising that cGVHD, corticosteroid, and other immunosuppressive therapies are major contributors to late complications after HCT.

With survivorship, a shift in survivorship care occurs from large transplant centers to community health care providers. As a result, many hematologists/oncologists and primary care physicians are assuming the post-HCT care of late effects. Preventive measures as well as early detection and treatment are important aspects to reducing morbidity and mortality. This chapter focuses on the essentials of diagnosis, screening, treatment, and long-term surveillance of survivors after HCT.

CARDIOVASCULAR EVENTS AND METABOLIC SYNDROME

CV causes are not only the leading contributor to mortality in the general population but also impact the health of long-term transplant survivors.[12] CV morbidity and mortality is typically latent in the early survivorship period because of the younger age and superior performance of transplant candidates. Nevertheless, there is growing data suggesting that traditional CV risk factors are elevated in long-term survivors, and that risk factor elevation is persistent and eventually results in premature CV events. CVD manifests as coronary artery disease/events, cerebrovascular disease/events, or peripheral vascular disease/events. Susceptible patients need to be identified early, and screened for modifiable risk factors with early intervention where possible.

Cardiovascular Events

Tichelli et al. were the first to show that CV events occurred prematurely in transplant survivors (median age 49 years), albeit at a long interval after transplantation, with the cumulative incidence of late CVD being 22% at 25 years (Fig. 106.1).[13] Interestingly, allogeneic HCT recipients were significantly more likely to have arterial events than autologous transplant recipients. The Late Effects Working Group of the European Group for Blood and Marrow Transplantation (EBMT) found a cumulative CV event incidence of 6% at 15 years.[9] In a matched cohort study of 1,491

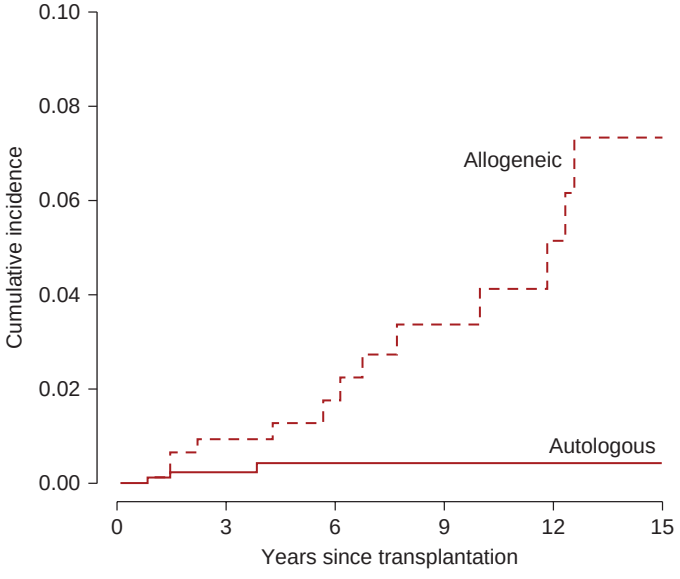

FIGURE 106.1. The cumulative incidence of cardiovascular events at 15 years, adjusted for age. (From Tichelli A, Bucher C, Rovo A, et al. Premature cardiovascular disease after allogeneic hematopoietic stem cell transplantation. Blood 2007;110:3463–3471.)

long-term survivors, transplant recipients experienced increased CV mortality (adjusted incidence rate difference, 3.6 per 1,000 person-years; 95% CI, 1.7 to 5.5) with increased cumulative incidence of ischemic heart disease, cardiomyopathy or heart failure, stroke, vascular diseases, and rhythm disorders.[14]

Disease Spectrum

Coronary artery disease and/or CV accidents are much more common than isolated peripheral artery disease. In a case control study of 63 patients with late CV disease, 44 subjects had coronary artery disease, and 19 had cerebrovascular diseases. Thirty-four of these 63 patients with CVD died, 31% of them from a CV event.[15] Furthermore, CVD may contribute to chronic ill health seen in long-term survivors. The magnitude of chronic illness in a study of 1,022 HCT survivors was 59% at 10 years after HCT and increased in comparison to their sibling controls.[16]

Cardiovascular Risk Factors

Traditional CV risk factors include male gender, family history, dyslipidemia, diabetes mellitus, obesity, hypertension, chronic kidney disease (CKD), and smoking. In addition, transplant survivors have unique risk factors such as exposure to ionizing radiation, immunosuppressant use (including steroids), and endocrinopathies.

CV risk factors generally increase with age and it is difficult to attribute the emergence of new CV risk factors to the transplant process itself without a good control population. A clear increase in the incidence of diabetes and hypertension was seen in a study of 1,022 HCT survivors, with the incidence of CVD being 3-fold that of their sibling controls.[16] In a cross-sectional study, HCT survivors had a 2.2-fold increase in the prevalence of metabolic syndrome, a clustering of CV risk factors characterized by abdominal obesity, dyslipidemia, hypertension, and elevated fasting glucose, compared to age- and gender-matched controls.[17] In a long-term study (17.5 years median) of 44 pairs of recipients and their respective donors after HCT, recipients were more likely to have hypertension ($P = 0.015$), dyslipidemia ($P = 0.002$), lower glomerular filtration rates (GFRs) ($P < 0.0001$) and reduced thyroid function ($P = 0.002$).[18] The occurrence of dyslipidemia is a function of age and immunosuppressive treatment. Dyslipidemia appears to play a central role in the elevated CVD risk after HCT.[19] De novo dyslipidemias may even impact a pediatric population.[20]

Pathobiology

The factors leading to persistent elevation of CV risk in HCT survivors long after cessation of immunosuppression remain unclear. Residual effects from radiation, endocrine dysfunction (including steroid exposure, hypogonadism, hypothyroidism, and growth hormone deficiency), and endothelial damage have been implicated.

Chest irradiation is a validated cause of CV mortality. Extrapolating from the CV impact of chest irradiation in nontransplant populations with malignancy, it is reasonable to suspect that the use of total body irradiation (TBI) in transplant conditioning contributes to increased CVD risk, but this remains to be proven in a well-controlled study. Pretransplant chest radiation exposure was associated with a 9.5-fold higher risk of CVD.[15]

Hypothyroidism is a frequent late effect in transplant survivors and is related to conditioning with TBI and prolonged cGVHD.[21] Hypothyroidism may affect ~30% to 40% of survivors, is often subclinical in presentation, and is strongly linked to dyslipidemias. Gonadal dysfunction will occur in the majority of transplant survivors and is linked to conditioning intensity and recipient age. Endocrinopathy and metabolic syndrome are strongly associated with gonadal dysfunction.[22] In males, metabolic syndrome and low androgen levels are strongly correlated,[23] and in females, estrogens are necessary for maintenance of CV health.[24,25] In a series of 109 long-term allogeneic HCT survivors, CV risk factors were significantly elevated in males but not in females who were all recipients of hormonal supplementation.[26] Relative growth hormone deficiency may be a factor in adult and pediatric transplant survivors. Growth hormone deficiency in adults leads to insulin resistance and is characterized by dyslipidemias and hypertension.[27] Pediatric survivors of cancer treatment and HCT are particularly sensitive to the metabolic consequences of impaired growth hormone secretion.[22,28]

Leptin is an adipokine responsible for regulating food intake and energy metabolism. Hyperleptinemia has been implicated as the pathobiologic link between transplant and metabolic syndrome.[29,30] Vascular endothelium may be the target of damage by radiation exposure and by alloreactivity (e.g., GVHD). Radiation has a dose-dependent impact on vasculature and endothelium in animal models. In a rodent model, TBI with 10 Gy injured coronary microvasculature, and altered endothelial physiology and myocardial mechanics.[31] Host endothelial cells are a target of alloreactive donor cytotoxic T lymphocytes, and chronic skin GVHD is characterized by the progressive loss of microvessels.[32] cGVHD is also characterized by elevations in von Willebrand factor,[18] which may be released by endothelial injury. Chronic hypomagnesemia is common early after transplantation[33] and is known to induce insulin resistance, diabetes, and metabolic syndrome. However, its precise impact on CV risk, if any, requires confirmation.

Management of Cardiovascular Risk

Since the burden of CV risk in transplant survivors has been poorly defined till now and CV events occur late, management of CV risk has often been a low priority. In a recent cross-sectional study of 86 adult survivors at a median of 3 years from HCT, 25% of cases with hypertension, 17% with abnormal glucose metabolism, and 60% with dyslipidemia were untreated.[17] Current guidelines suggest a central role for transplantation centers in counseling primary health providers on screening and prevention.[34]

The management focus should be on modifiable CV risk factors: lifestyle (diet, smoking, and activity), obesity, diabetes, dyslipidemias, hypertension, hypothyroidism, hypogonadism, and other endocrinopathy. Dyslipidemias may be the most important driver of CV risk and are susceptible to therapy.[26] The management of CV risk in transplant survivors is an evolving effort, but expert guidelines are now available.[6,12,19] Table 106.1 summarizes the approach to the hyperlipidemia in long-term survivors after HCT.

SECONDARY MALIGNANCIES

The risk of second malignancies as an important late effect after HCT was first recognized in the early 1990s. As the age and life expectancy of survivors continue to rise, second malignancies are expected to become an increasingly common complication.[3]

Secondary malignancies following HCT are commonly categorized into one of three histologic types: leukemia, lymphoma, and solid tumors.[35] However, these disorders have distinctive chronology. Secondary leukemia generally occurs at a median of 6.7 months after auto-SCT, lymphoma at a median of 2.5 months, while the median time to development of solid tumors lies between 5 and 6 years.[3]

Risk of Second Malignancies and Risk Factors

Based on large retrospective analyses, the cumulative incidence of solid tumors following HCT ranges between 1.2% and 1.6% at 5 years, 2.2% and 6.1% at 10 years, and from 3.8% to 14.9% at 15 years post-HCT.[36–38,39] The incidence rate does not plateau; rather, there is a steady increase over time.[39] Second cancers are

TABLE106.1

APPROACH TO LIPID MANAGEMENT IN HCT PATIENTS

Evaluation

Obtain fasting lipid profile prior to transplantation

Evaluate CVD Risk

1. If patient has CVD or CVD risk equivalent, then manage as high-risk with appropriate therapy to reach LDL goal
   a. Option to consider allogeneic HCT patients age 40 or older as high-risk
2. Otherwise, calculate 10-y risk with online risk assessment tool (www.nhlbi.nih.gov) and manage LDL per ATP-III Guidelines

Monitor lipid profiles after HCT

1. Check lipid profile within 4 wk after HCT then at least every 3 mo for patients on IST
2. For patients at treatment goal on stable therapy every 6–12 mo as indicated, or after significant change in IST regimen in patients with dyslipidemia
3. If patients develop significant dyslipidemia after HCT compared to baseline, consider secondary causes of dyslipidemia (IST, diabetes, hypothyroidism)
4. Even patients without dyslipidemia should have lipids monitored every 1–2 y after allogeneic HCT, given increased CV risk

Management

If patient has high CVD risk (>20% 10-y risk), treat dyslipidemia with appropriate agent(s) to meet LDL goal, but monitor clinically if on IST or renal dysfunction

In patients with low (<10%)or moderate CVD risk (10–20%), consider drug treatment based upon severity of dyslipidemia, estimated prognosis post-HCT, and risks of lipid drug therapy (if on long-term IST for GVHD)

1. Patients with low CVD risk that develop moderate secondary dyslipidemia on IST can be managed conservatively, if IST will be tapered off
2. Patients with low to moderate CVD risk that develop severe hypertriglyceridemia (>500 mg/dl) should be treated to prevent pancreatitis

Consider referral to a lipid specialist for the following:

1. Severe dyslipidemia (total cholesterol > 300 or LDL > 180, triglycerides > 500–1,000)
2. Patients with dyslipidemia refractory to treatment and not meeting goals
3. Patients with intolerance or contraindications to lipid lowering therapy
4. Patients requiring combination lipid therapy, particularly in setting of IST
5. Patients needing individualized CV risk assessment due to strong family history of premature CVD or other factors

a very important contributor to late nonrelapse mortality (NRM) in patients who survive more than 2 to 5 years posttransplantation, accounting for 5% to 10% of such deaths.[8,40,41] And, in a recent study of 28,874 HCT survivors, the incidence of new solid tumors was double that of an age- and gender-matched general population.[39] The risk increased over time, reaching 3-fold among patients followed for 15 years or more after transplantation.

Pathobiology

The process of malignant transformation of secondary solid tumors after HCT is not well understood but multiple factors have been implicated.[42] These include exposure to TBI, primary disease, male sex, and pretransplantation therapy. The risk of developing a nonsquamous cell cancer (SCC) is associated with younger age at transplantation and the use of radiation in the conditioning regimen. Radiation is also a known significant risk factor for the development of several other solid tumors, particularly cancers of the breast, thyroid, brain, central nervous system, bone and connective tissue, and melanoma; and screening is available for some of these tumors.[10,42] For the majority of these sites, risks are greater among those who survived 5 or more years after initial radiotherapy, in keeping with the latent period typical for radiation-related solid cancers.[8,10,40,43]

cGVHD and immunosuppressive therapy (IST) are associated with SCC of the skin and mucosa.[43–45] A particularly high-risk was observed in the 1 to 4 year interval after HCT, which remained elevated among long-term survivors. Duration of IST, and particularly prolonged exposure to azathioprine, has been associated with development of SCC.[46]

Several oncogenic types of human papillomavirus (HPV) have been implicated in the etiology of SCC of the female genital tract and head and neck, and may play a role in HCT-associated SCC.[46,47] Certainly, some inherited genetic polymorphisms have been reported to increase the risk of malignancies in patients who received alkylating agents either as pretransplant chemotherapy or as part of the conditioning regimen.[48]

Types of Secondary Solid Cancers

In a 2009 registry data study, 189 new cancers were found in 28,874 HCT recipients who underwent long-term follow-up.[39] The average age at HCT was 27 years, and 67% received TBI as part of their conditioning regimen. The findings demonstrated that the risk of developing a nonSCC was dependent on the age at exposure to conditioning radiation. The relative risk of nonSCC for patients irradiated at ages <30 years was 9-fold that of nonirradiated patients, while the comparable risk for older patients was 1.1. cGVHD and male gender were the main determinants for the risk of SCC. The oral cavity, salivary glands, liver (prior hepatitis C exposure), skin, brain, breast, thyroid, and bone/connective tissue were the sites with a significant increase in secondary malignancy. These data indicate that HCT survivors, particularly those irradiated at young ages, face increased risks of solid cancers, supporting strategies to promote lifelong surveillance among these patients.

The risks of secondary solid cancers in HCT survivors who have not received irradiation are not well understood and deserve further study, because radiation-free conditioning regimens are being more frequently utilized. When chemotherapy alone is used for conditioning, the rates of solid tumors are still increased, as evidenced by a report examining solid tumor incidence in survivors who underwent high-dose busulfan-cyclophosphamide conditioning. In this study of 4,318 patients who received HCT for AML and CML, the cumulative incidence of solid tumors at 5 and 10 years after HCT was 0.6% and 1.2% for AML, and 0.9% and 2.4% for CML patients. The recipients had invasive solid cancers at a rate that was 1.4 times higher than expected in the general population.[49] Sites with a significant increase in secondary malignancy included the oral cavity, esophagus, lung, soft tissue, and brain. cGVHD was found to be an independent risk factor for all solid cancers. Recipients of HCT using busulfan-cyclophosphamide conditioning are thus similar to TBI in the risk for developing solid cancers.

Diagnosis, Screening, and Prevention

Since there is no plateau in the incidence curve of new malignancies, consensus guidelines call for lifelong surveillance, and early diagnosis and treatment.[50] Recommendations include the following: A. Recognition that radiation exposure and photosensitization by transplant medications increases the risk of skin malignancy, suggesting that survivors should protect against UV skin exposure by appropriate clothing or high-SPF sunscreen. B. Survivors should be reminded of the risks of secondary malignancies annually. Routine self-screening by breast and skin examination is to be encouraged, as is avoidance of high-risk behaviors, particularly all forms of tobacco use and unprotected UV exposure. C. Annual health screening should include symptom review for secondary malignancies. Screening mammography is recommended *earlier than* age 40 years for women exposed to radiation. Mucocutaneous involvement by GVHD increases the

risk of malignant sequelae, and annual specialist examination (dermatologic, gynecologic, dental, or ENT) may be required.

Management

Successful management of second malignancies requires recognition of the special attributes of transplant survivors and close collaboration between the transplant center and the primary physician. Impaired hematopoietic reserve may be evident years after HCT and may manifest as prolonged myelosuppression after standard doses of cytotoxic agents or XRT. cGVHD management will often be a great challenge to treatment. Secondary SCC is biologically more aggressive, with frequent invasion beyond free surgical resection margins and metastasis to draining lymph nodes. Support should be provided for psychologic vulnerability in survivors facing a new diagnosis of malignancy.

LATE PULMONARY COMPLICATIONS

Lung injury is a frequent contributor to post-HCT morbidity and mortality.[11,51,52] Pulmonary injury can be delayed, and the cumulative incidence of chronic pulmonary dysfunction in long-term HCT survivors ranges from 30% to 60%, depending on donor source and elapsed time from transplantation.[11,51] Bronchiolitis obliterans syndrome (BOS) is the most frequent and potentially lethal noninfectious pulmonary complication. BOS is now considered one of the diagnostic criteria for defining cGVHD by the NIH consensus report.[52,53] It is characterized by an insidious onset, high morbidity and mortality, and is typically accompanied by other manifestations of cGVHD. Much knowledge of BOS has been borrowed from the field of lung transplantation, in which BOS impacts more than half of the long-term survivors and is the major contributor to morbidity and mortality.[54]

Pathophysiology

Airway narrowing in BOS is mostly in the small airways, the terminal and respiratory bronchioles, with an internal diameter <2 mm. These small airways can be considered parallel high-resistance conduits which account for the vast majority of the total airway volume and the cross-sectional area. Small airway damage must be extensive and 45% of the terminal bronchioles need to be lost before impacting the forced expiratory volume 1(FEV1) or FEV1/FVC ratio. Furthermore, small airway obstruction may have less effect on lung mechanics than on ventilation distribution.[55,56]

Prevalence, Clinical Presentation, and Diagnosis

Recent prevalence estimates suggest that BOS is often underdiagnosed and that 14% of all long-term survivors with cGVHD may develop BOS. BOS is difficult to diagnose, may already be severe by the time the patient complains of symptoms, and is not easy to reverse.

Clinically, patients present with dyspnea on exertion, decreased exercise tolerance, or nonproductive cough, with their degree of symptomatology paralleling their degree of obstruction on pulmonary function testing (PFT). BOS usually occurs within the first 2 years, but may develop as late as 5 years after allo-HCT. Reliance upon symptoms for diagnosis can be dangerous, because once symptoms are apparent the extent of airflow obstruction may not only be significant (FEV1 < 40% predicted), but the process may be irreversible. With routine screening spirometry, BOS is often diagnosed on the basis of new airflow obstruction even before the patient is symptomatic.

BOS is diagnosed by demonstration of a fixed airflow obstruction that is defined as: (1) decreased 1-second FEV1 <75% of predicted, and evidence of airway obstruction as demonstrated by FEV1/forced vital capacity ratio of <0.7 on PFT; (2) signs of air trapping by PFT as shown by residual volume >120% of predicted, or evidence of air trapping on computed tomography or lung biopsy; (3) absence of acute respiratory infection; and (4) another manifestation of cGVHD in an additional organ system if no histologic evidence of BOS can be demonstrated.[52,55]

Early identification strategies, borrowed from the field of lung transplantation, utilize serial testing of the extent of FEV1 decline from pretransplantation baseline. Early onset of BOS can have worse outcomes than late-onset BOS, suggesting that these are two distinct clinical entities that may warrant different treatment approaches.[52,55] There is growing awareness that patients with BOS have high mortality rates regardless of therapy, suggesting the need for early identification, preemptive treatment, and novel approaches.[57]

Prophylaxis of Chronic Graft-versus-host-disease and Bronchiolitis Obliterans Syndrome

cGVHD can be a significant complication of HCT impacting up to 80% of patients receiving alternative donor grafts. cGVHD is independently associated with late pulmonary complications and BOS is strongly associated with cGVHD.[11,57] It has been reported that the administration of antithymocyte globulin (ATG) during the conditioning regimen or early after transplant, in addition to the conventional GVHD prophylaxis, can reduce the incidence and the severity of subsequent cGVHD.[56,58] The magnitude of reduction is ~ 20% or greater for both aGVHD grade II–IV and cGVHD.[51] In comparison to those who did not receive ATG, the incidence of cGVHD was reduced from 60% to 37% ($P = 0.05$), and extensive cGVHD reduced from 41% to 15% ($P = 0.01$). Significantly, the cumulative incidence of chronic lung dysfunction was reduced from 51% to 19% ($P = 0.005$). Further incentive for using ATG has been found in the conclusions of prospective randomized trials with ATG, which suggest that prevention of cGVHD is possible without significantly interfering with the graft-versus-malignancy effect and may result in wider use of ATG.

Management of Bronchiolitis Obliterans Syndrome

Systemic Glucocorticoids

The mainstay of therapy has been systemic IST including high-dose corticosteroids, CSA, azathioprine, and ATG with the intent of general control of cGVHD. Sullivan et al.[59] first described in 1981 use of prednisone along with azathioprine in a series of 52 patients with cGVHD as effective therapy. Since then, systemic high-dose corticosteroids have been thought to be the most efficacious treatment in cGVHD. Ratjen et al.[60] showed improvement in FEV1 with 7 of 9 patients in the pediatric population after HCT with clinical stability following treatment with high-dose methylprednisolone for BOS. Despite the unfavorable side-effect profile and the absence of strong evidence, systemic glucocorticoids remain the recommended first-line therapy (dosage varies from 0.1 to 1 mg/kg/day—depending on severity) for patients diagnosed with BOS (Table106.2).

Inhaled Corticosteroids

Inhaled corticosteroids may optimize local delivery while abrogating the risks of systemic corticosteroids in the treatment of BOS. Bashoura et al.[61] used fluticasone-propionate in patients with BOS after HCT and reported stabilization or improvement in FEV1 after 3 to 6 months of treatment in 16 of 17 patients. Similarly, Bergeron et al.[62] reported improvement in symptoms as well as in FEV1 at 3 to 6 months posttherapy using a combination of budesonide and formoterol. This strategy has yet to be evaluated in a prospective

TABLE 106.2

AVAILABLE THERAPEUTIC OPTIONS FOR BOS AFTER ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION (HCT)

Agent	Mechanism of Action
Systemic corticosteroids	Systemic immunosuppression
Inhaled corticosteroids	Localized antiinflammatory
Calcineurin inhibitors	Systemic immunosuppression
Mycophenolate mofetil	Inhibits fibroblast proliferation
mTOR inhibitors (e.g., sirolimus)	Inhibits fibroblast proliferation
Azithromycin	Macrolide antibiotic
	Impairs neutrophilic inflammation
	? prokinetic GI properties leading to reduction of GERD
Montelukast	Leukotriene receptor antagonist Reduces bronchoconstriction, eosinophilic and neutrophilic recruitment
Extracorporeal photopheresis	Mechanism not understood Involvement of regulatory T cells
Imatinib	Antifibrinogenic
Rituximab	Inhibits B cell proliferation (Anti-CD20 antibody)
Inhaled cyclosporine	Local immunosuppressant therapy
Etanercept	TNF-α blockade
Bortezomib	Proteosome inhibitor Inhibits TGF-β1
Combination therapy

randomized controlled manner, but the potential to deliver high doses of steroid therapy in the inhaled modality is a promising method of improving treatment without the systemic risks.

Systemic Immunosuppression Therapy

Other immunosuppressive agents such as calcineurin inhibitors (cyclosporine and tacrolimus), mammalian target of rapamycin inhibitors (sirolimus and everolimus), as well as mycophenolate mofetil have also been shown to be efficacious in treatment of BOS in patients who undergo lung transplant.[55]

Azithromycin

Azithromycin, a macrolide antibiotic, has been shown to modulate cytokine production and impair neutrophil function. Several small studies in the lung transplant literature have shown that chronic therapy with azithromycin can improve FEV1 or slow progression of BOS.[63–65] The largest study reported to date has been by Vos et al.,[66] whose cohort of 107 lung transplant recipients with BOS were evaluated on long-term azithromycin therapy. Forty percent of patients were responsive to treatment, and these patients were reported to have improved OS compared with those who did not respond to macrolide therapy. The same authors have also published data that prophylactic azithromycin thrice weekly for 2 years after transplantation may prevent BOS by improving FEV1 as well as BOS-free survival in the same cohort.[67] Khalid et al.[68] reported significant clinical improvement in FEV1 and forced vital capacity in 7 of 8 patients with BOS after allo-HCT using azithromycin 500 mg daily for 3 days followed by 250 mg three times weekly for a minimum of 12 weeks.

Given its ease of administration and favorable side-effect profile, it is being increasingly used as upfront therapy for BOS and is recommended as adjunctive therapy in addition to corticosteroids and additional IST.

Novel Combination Therapy

Norman et al.[69] have reported a small case series (n = 8) of BOS after HCT using combination therapy with fluticasone, azithromycin, and montelukast (FAM). Their results suggest that combination therapy may spare some patients from systemic steroids and is being investigated in a prospective phase II trial.

A list of other therapeutic agents available in clinical practice is summarized in Table 106.2.

Lung Transplantation

Although data is limited, lung transplantation upon failure of medical therapy is also an option, with several cases reported in the literature after HCT for patients who are thought to have achieved a cure for their hematologic malignancy but have severe BOS.[70–72] Currently, there are no defined criteria for the appropriate timing for referral to a lung transplant, but those who have remained in remission for years without significant comorbidities or other long-term complications from HCT may be good candidates for consideration.

INFECTION AND IMMUNE RECONSTITUTION

Infection remains an immense challenge in long-term survivors, especially in patients requiring prolonged IST for cGVHD. Infection in survivors, even in the absence of cGVHD, is over 20 times greater than reported in the general population. About 20% of patients remain on IST beyond 3 years post-HCT, with a higher incidence in older patients receiving HCT.[8,11] There is an elevated risk of bacterial, fungal, and viral infections occurring even years after HCT, although this plateaus after 2 years.[73] Infections remain a significant contributor to morbidity, rehospitalization and NRM in 5-year survivors.[50,74,75,76,77]

Immune reconstitution of the B and T cell repertoire from the donor can be insufficient, and long-term survivors still have an increased risk of infectious diseases.[8,78,79] cGVHD and the use of systemic IST for cGVHD are the main risk factor of long-term poor immune reconstitution after HCT.[80] Immune status should be monitored periodically,[34] especially in those with recurrent severe infections.

Bacterial Infection

Bacterial infections such as pneumococcal infection can be lethal, especially in patients with cGVHD. Fortunately there are effective preventive options such as antibiotic prophylaxis and vaccinations.[34,76] Prolonged antibiotic prophylaxis is generally recommended for preventing infection by encapsulated organisms among patients with active cGVHD on systemic IST. Oral penicillin is generally preferred, but consideration of susceptibility patterns may warrant other options such as second-generation cephalosporins, macrolides, or fluoroquinolones. However, because of the risks of resistance, vaccinations should always be initiated if available. Several guidelines have been published[34,76,81]; our current vaccination schedule is summarized in Table 106.3.

The optimal timing of vaccination is also important[34]; the guidelines recommend not postponing vaccinations with nonlive vaccines in patients with ongoing active cGVHD.[82] Checking antibody titers is useful in monitoring the success of vaccination in such patients. Live vaccines are generally avoided in subjects

TABLE 106.3

ROUTINE VACCINATIONS RECOMMENDED FOR HCT RECIPIENTS

Vaccine	Recommendation after HCT	Time Post-HCT to Initiate Vaccine (mo)	Number of Doses	Improved by Donor Vaccination
Pneumococcal conjugate (PCV)	Yes	3–6[b]	3–4[b]	Yes, may be considered when recipient is at high-risk for GVHD
Tetanus, diphtheria, Acellular Pertussis[c]	Yes Tetanus-Diphtheria	6–12	3[d]	Tetanus: likely Diphtheria: likely Pertussis: Unknown
Haemophilus influenza conjugate	Yes	6–12	3	Yes
Meningococcal conjugate		6–12	1	Unknown
Inactivated polio		6–12	3	Unknown
Recombinant hepatitis B		6–12	3	Likele[e]
Inactivated influenza	Yearly	4–6	1–2[f]	Unknown
Measles, mumps and rubella[g]		24	1–2[h]	Unknown

GVHD, graft-versus-host disease; HCT, hematopoietic cell transplant.
[a]A uniform specific interval between doses cannot be recommended, because various intervals have been used in studies. As a general guideline, a minimum of 1 month between doses may be reasonable.
[b]If immunization is started early, consider evaluating for antibody levels and if they are low, revaccinate. Following the primary series of 3 PCV doses, a dose of the *23-valent polysaccharide pneumococcal vaccine* (PPSV23) to broaden the immune response might be given. For patients with chronic GVHD (cGVHD) who are likely to respond poorly to PPSV23, a fourth dose of the PCV should be considered instead of PPSV23.
[c]DTaP is preferred; however, if only Tdap is available (e.g., because DTaP is not licensed for adults), administer Tdap. Acellular pertussis vaccine is preferred, but the whole-cell pertussis vaccine should be used if it is the only pertussis vaccine available.
[d]See text for consideration of an additional dose(s) of Tdap for older children and adults.
[e]Significant improvement of recipient response to hepatitis B vaccine posttransplant can be expected only if the donor receives more than 1 hepatitis vaccine dose prior to donation.
[f]For children <9 years of age, 2 doses are recommended yearly between transplant and 9 years of age.
[g]Measles, mumps, and rubella vaccines are usually given together as a combination vaccine. In females with pregnancy potential, vaccination with rubella vaccine either as a single or a combination vaccine is indicated.
[h]In children, 2 doses are favored.

with ongoing IST. Another investigational approach to hasten the recovery of immunity is to boost donors prior to graft collection to enhance immune recovery in the eventual recipients.

Fungal Infection

Late fungal infection is associated with cGVHD and systemic IST with Aspergillus spp. being the most common pathogen.[76,83,84] There is very limited evidence to demonstrate clinical benefit of antifungals in the setting of cGVHD; however, antifungal prophylaxis especially against Aspergillus is usually recommended for patients with severe cGVHD.[85]

Iron overload, a frequent finding after HCT, has shown a possible association with fungal infections and this represents a potential therapeutic target.[86–89] Iron overload is an established risk factor for infections in patients with myelodysplastic syndromes.[90] Iron chelation or phlebotomy could not only reverse transfusional overload, but might mitigate the risk of fungal infection.

Viral Infection

Viral infections, including CMV, varicella zoster virus (VZV), and influenza are responsible for late hospitalization, morbidity, and mortality in HCT survivors and are frequently associated with cGVHD.[73,77] While most CMV reactivations occur early, recent developments in transplant techniques such as preemptive CMV treatment strategies, cord blood, mismatched-related or URD HCT, and reduced-intensity conditioning have led to the emergence of late CMV reactivation and infection. CMV seropositive recipients of CMV seronegative grafts are at particular risk for prolonged reactivation.

Acyclovir prophylaxis to prevent VZV reactivation is nontoxic, effective, and routinely recommended for at least the first year after HCT.[91,92] Longer duration acyclovir prophylaxis beyond 1 year should be considered in patients with cGVHD or systemic IST. Vaccination against VZV requires administration of an attenuated virus, and early reports are promising.[93,94] However, live vaccines should be administered no earlier than 24 months after HCT; there may be differences in the safety profiles of different vaccine brands and, as yet, no VZV vaccine has been approved for HCT recipients.

There is considerable high-level evidence that annual influenza vaccination is beneficial to HCT recipients.[34,76,81] After HCT, the first dose is often insufficient in producing satisfactory antibody titers, but a booster dose can improve the immune response.[95–98] However, even with two doses of vaccine the most vulnerable HCT recipients, i.e., those who have a shorter transplant-to-vaccination interval and active GVHD, might fail to be protected.[95] Consequently, attention must also be paid to other proven measures, such as exploiting herd immunity by vaccinating household members and avoiding symptomatic contacts.

BONE MINERAL DENSITY LOSS AND AVASCULAR OSTEONECROSIS

Bone Mineral Density Loss

Definitions

Bone mineral density (BMD) loss is usually determined by dual-energy x-ray absorptiometry (DEXA). Scores in adults are compared to the mean BMD of a gender-matched younger adult population at peak density to generate the T-score. A T-score between –1.5 and –2.5 defines reduced bone mass or "osteopenia," while a T-score less than –2.5 defines "osteoporosis." For pediatric populations an age-matched score, the Z-score, is used. BMD loss alone does not predict fracture, and osteoporosis may be diagnosed independently in the presence of fragility fractures.

Bone Loss Risk

Accelerated BMD loss is observed in the vast majority of HCT survivors. In a representative series of 78 long-term survivors, 73% had BMD loss, 42% with osteopenia.[99] In terms of clinical sequelae, the 3-year cumulative incidence of fractures was 8% in a series of 146 transplant recipients, predominantly in childhood recipients.[100] For unclear reasons, and in contrast to their lower vulnerability to other transplant complications, children experience greater BMD loss than adults.[100,101] However, this susceptibility does not extend into young adulthood and the incidence of osteoporotic fracture rates is not increased in younger adults, arguing against the routine use of bisphosphonates in this population.[99]

Trabecular bone is particularly vulnerable. The spine and hip contain 50% to 75% trabecular bone and are most at risk for fracture after HCT. The magnitude of BMD loss is greater in the femoral neck[102] compared with the spine, and tends to be more difficult to reverse.[103,104] BMD loss is extremely rapid in the first 4 months of transplant. The BMD loss between baseline and day 100 DEXA scans is equivalent to the aging of bones by 7 to 10 years for auto-SCT and 13 to 17 years for allo-HCT recipeints.[105] Recovery of BMD occurs first in the lumbar spine, followed by slower recovery in the femoral neck: BMD nadir at month 6 for the spine and at month 24 for total body and femoral neck.[104] Partial or complete recovery of BMD is possible with improvement of bone turnover, but with variable kinetics.[106]

BMD loss has also been noted after autologous HCT.[107] However, the risk factors are different: lymphoma was associated with greater bone loss after autologous HCT than myeloma, whereas higher steroid dose was the most significant risk factor after allogeneic HCT.[108]

Pathobiology

BMD loss results from reduced bone formation and accelerated resorption, with increased markers of bone turnover being a consistent feature.[109] Corticosteroid exposure plays a major role; 50% of nontransplant patients will develop osteoporosis after 6 months of steroid exposure.[110] Studies have shown that transplant recipients have abnormally low vitamin D.[111,112] In addition, HCT recipients have unique pathologic influences on BMD loss. The most important and reversible condition is hypogonadism, which is a prominent feature of myeloablative conditioning regimens and disproportionately impacts females. Immunosuppressive medications, particularly cumulative steroid exposure, are widely accepted as an important risk factor. cGVHD either directly (via inflammatory cytokine release) or indirectly (via steroid usage) is a notable risk factor.[99]

The role of inflammatory mediators is not well understood, but emerging information implicates osteoprotegerin (OPG):Rank-L interaction, arguably the most critical mediator of bone remodeling.[113] Serum levels of OPG, the antagonist of the osteoclast differentiation factor Rank-L, are increased in transplant recipients.[114] Increased insulin resistance may also be contributory.[112] Multivariable risk models explain only 11% to 30% of the variation in transplant-related BMD change, suggesting that poorly characterized risk factors, likely inflammatory cytokines, play a dominant role in the pathobiology.[105] Additionally, the rapidity of BMD loss sustained after HCT could potentially increase fracture risk independently by inducing microarchitectural changes even when BMD loss is reversed.

Management of Post-hematopoietic Cell Transplantation Bone Loss

It is recommended that HCT recipients undergo evaluation to include BMD by DEXA starting shortly before and after transplantation, calcium/vitamin D supplementation, and sex hormone levels with possible hormonal supplementation. There should be a low threshold to consider bisphosphonate therapy (e.g., annual Reclast) for patients at significant progressive risk, such as long-term steroids.[115] The Fracture Risk Assessment Tool (FRAX; www.shef.ac.uk/FRAX/) is an algorithm commonly used to predict the 10-year risk of fracture and guide therapeutic intervention, but is not yet validated in HCT recipients.

Standard prophylactic measures for osteoporosis prevention as applicable to aging are far less effective in the HCT population.[116] Calcium with or without calcitonin is ineffective in preventing a decline in BMD.[117] Nevertheless, simple calcium and vitamin D supplementation is necessary in transplant recipients because of impaired gastrointestinal (GI) absorption. A minimum of 400–600 IU vitamin D per day appears to be required to achieve optimal serum 25-hydroxy D concentrations following HCT.[112] Current guidelines call for adequate daily calcium intake (at least 1,200 mg daily) plus vitamin D (1,000 IU per day, and higher if serum 25-hydroxy vitamin D levels are <30 ng/ml), regular weight bearing activity, and avoidance of smoking or excess alcohol.[118,119]

Hormone replacement therapy (HRT) is now standard for all females who are at risk.[120] In a prospective study for children at particular risk, 28 girls with a median age of 10 years with sex hormone deficiency after HCT were followed longitudinally. At their first evaluation, performed at a median of 3.8 years after HCT, BMD increased significantly from -2.7 ± 1.1 (Z-score) to -2.3 ± 1.2 after HRT administration, with 24 of 28 patients showing a good response.[121]

Antiresorptive therapy should be an individualized decision based upon the clinical status, T-score, fracture risk (FRAX score), tolerability, and risks. Bisphosphonates, the primary option, have been shown to be beneficial in improving BMD in the specific setting of HCT; however, the benefits need to be balanced against the risks, particularly of osteonecrosis.[122] Bisphosphonates have been proven to be superior in a nonrandomized trial comparing zoledronate and risedronate to calcium + vitamin D ± HRT.[123] Benefits are lost after stopping therapy with bisphosphonates.[124] Most experts advocate a drug holiday after 3 to 5 years of continuous bisphosphonates with stable BMD.[122] Second line therapies include calcitonin, raloxifene and human recombinant parathyroid hormone, but experience is limited. PTH is contraindicated in children with open growth plates, recipients of TBI, and those with renal dysfunction. Denosumab, which sequesters RANK-L, is yet to be formally evaluated in HCT recipients.

Avascular Necrosis of Bones After Hematopoietic Cell Transplantation

Avascular osteonecrosis (AVN) is a painful and debilitating bone complication distinct from BMD loss, with a different pathobiology but an important risk factor in common (prolonged steroid exposure). AVN is caused by focal bone necrosis and seen in 4% to 19% of allogeneic HCT survivors.[122,125,126] Early osteonecrotic changes in hips and knees have been seen in the transplant population with a frequency up to 43% by magnetic resonance imaging (MRI) screening. In the same study, 15% of patients had coexistent loss of BMD.[127]

AVN may occur at a median of 2 years, but may be detected as early as 6 months and as late as 10 years after HCT. Pathogenetic factors are poorly understood, but involve local vascular damage leading to ischemia, ineffective repair due to metabolic factors, and mechanical stresses.[128] Risk factors for AVN include GVHD therapy with steroids[129] and calcineurin inhibitors, an underlying diagnosis of acute lymphoblastic leukemia (probably also steroid-related), older age, female gender, and the use of TBI in conditioning.

AVN most commonly destroys the femoral heads and presents with severe pain. Knees, shoulder and other joints may be

TABLE106.4

ASSOCIATION OF RESEARCH CIRCULATION OSSEUS (ARCO) STAGING SYSTEM FOR OSTEONECROSIS

Stage	Radiologic Findings	Subclassification
0	All diagnostic studies normal, diagnosis by histology only

CT, computed tomography; MRI, magnetic resonance imaging.

involved and multiple joint involvement is common. Diagnosis is made by MRI, which is not only more sensitive but allows estimation of the extent of involvement. The Association of Research Circulation Osseus (ARCO) classification is typically used for staging (Table 106.4).[130]

Management requires a multidisciplinary approach with early orthopedic surgeon involvement, physical and occupational therapy, plus attention to pain control. Treatment decisions are individualized based upon the joint location, staging, expected longevity, a continued need for immunosuppression, comorbidities, and age. Although sometimes prescribed, there is no evidence that statins or bisphosphonates are helpful for prevention or treatment of AVN in HCT. Conservative management aims to preserve native joint function for as long as possible with analgesics and by minimizing impact to the joint. Surgical options are joint preserving (such as core decompression, vascularized fibular grafts, osteotomy) versus joint replacement. Nonoperative management is limited in scope, with satisfactory clinical results reported in 63.5% of hips in 24 studies of core decompression versus 22.7% of hips in 21 studies of nonoperative management.[131] Typically, for early symptomatic AVN involving <15% or asymptomatic lesions involving >30% of the femoral head, conservative management and core decompression are appropriate. Larger lesions, even if asymptomatic, or ARCO stage > II lesions warrant more aggressive approaches.[122] A recent series of 122 total hip arthroplasty procedures for AVN in nontransplant recipients demonstrated durability, with 89% joint survival rate at 15 years.[132]

OCULAR COMPLICATIONS IN LONG-TERM SURVIVORS AFTER HEMATOPOIETIC CELL TRANSPLANTATION

In a series of 620 allogeneic HCT recipients, major ocular complications occurred in 13% of patients. The most frequent complications were cGVHD, xerophthalmia without cGVHD, corneal ulcers, cataract, glaucoma, cytomegalovirus retinitis, fungal endophthalmitis, and acquisition of allergic conjunctivitis from atopic donors.[133] Of these, cGVHD and cataracts are the most frequent late complications. Management should always include regular ophthalmologic evaluations, with prompt referral for symptoms.

Ocular Graft-versus-host-disease

Ocular cGVHD often affects the lacrimal glands, the conjunctiva, the lids (including meibomian glands), and the cornea, but can also involve other parts of the eye such as the sclera. The typical presentation is that of keratoconjunctivitis sicca. In a series of 248 evaluable patients from the EBMT, the actuarial probability of developing dry eyes was 21% ± 3% at 15 years, and is strongly associated with systemic cGVHD (RR 3.5; CI, 1.9 to 6.9), female patients (5.6; CI, 1.6 to 18.8), age older than 20 years (3.1; CI, 1.6 to 5.6), single-dose irradiation for preparation to HCT (3.8; CI, 1.3 to 11.3), and methotrexate for prevention of GVHD (3.6; CI, 1.05 to 12.8).[134] There are no pathognomonic diagnostic features of ocular GVHD and evidence levels for diagnosis and treatment are generally low.[135] Therapeutic goals are to reduce inflammation and dryness in order to relieve symptoms and maintain functional ocular integrity. Therapy is individualized based upon the patient's overall condition, systemic IST, symptoms, ocular surface integrity, and inflammatory activity. Artificial tears are the first line of treatment. Topical immunosuppression, for example, with steroid[136] or cyclosporine eye drops,[137–139] reduces inflammation and dryness in ocular GVHD and improves symptoms in the majority of cases. Autologous serum eye drops are also effective.[140,141] Gas-permeable *scleral lens* for management of severe keratoconjunctivitis sicca may be necessary for severe cases refractory to conventional treatment.[142,143] Plugs for occlusion of the lacrimal drainage system and punctal cauterization[144] are usually reserved for resistant cases. Further clinical trials are necessary to elucidate risk factors for eye manifestation, complications, and visual loss, and to evaluate staging criteria and diagnostic and therapeutic measures for ocular cGVHD.

Premature Cataract Development after Hematopoietic Cell Transplantation

The risk of premature cataract was as high as 23% in pediatric HCT recipients.[145] Risk factors include steroids[146] and radiation.[147] The impact of TBI on the risk of cataract formation can now be quantified[148] and may support studies of lens shielding in susceptible populations. Aggressive management of dry eyes is an important adjunct to cataract surgery.[149]

ENDOCRINE AND SEXUAL DYSFUNCTIONS IN LONG-TERM SURVIVORS

Diabetes Mellitus after Hematopoietic Cell Transplantation

Adjusting for age, sex, race, and body mass index, survivors of allogeneic HCT are 3.6 times more likely to report diabetes than their sibling controls.[150] The actual prevalence of diabetes depends on the age of the transplant population and ranges from 3.3% to 15%.[151] Risk factors include cGVHD,[20] TBI,[152] and a cumulative prednisone dose of >0.25 mg/kg/day.[153] There are no specific guidelines for screening; however, it is prudent to screen high-risk patients periodically because diabetes may be asymptomatic. Euglycemic survivors with a history of steroid-induced

diabetes remain at higher risk for the future development of diabetes and should undergo aggressive screening (every 3 to 6 months).[154] Screening for diabetes is similar to that in the non-transplant population, with the exception that HbA1c is an unreliable marker in anemic or transfused recipients. Beyond lifestyle changes, therapy is usually based on insulin because traditional oral hypoglycemic agents are often contraindicated (Table 106.5).

Male Hypogonadism and Sexual Dysfunction

Male hypogonadism is common in survivors of malignancies but susceptible to neglect. Manifestations are low testosterone, reduced libido, impaired spermatogenesis and erectile dysfunction. Testosterone-producing Leydig cells are less damaged than the sperm-producing Sertoli cells in transplant survivors, resulting in mild elevation of luteinizing hormone hormone compared to greater elevations in follicle-stimulating hormone.[155] Impaired spermatogenesis is common, with recovery seen in only 50% to 90% of nonirradiated and about 20% of irradiated survivors.[156] Younger men receiving reduced-intensity HCT are more likely to recover spermatogenesis.[157] Both organic[158] and psychological[159] factors are responsible for erectile dysfunction and reduced libido.

The goals of therapy are to restore fertility if desired, improve libido and sexual function, and reduce bone loss. Since azoospermia is common, often the only options to preserve male fertility are semen banking and/or testicular tissue cryopreservation prior to transplantation.[160] A low morning total testosterone level with reduced libido[161] or bone mass[162] may be indications for supplementation. Testosterone dose should be titrated to achieve a mid-normal range while monitoring prostate-specific-antigen and hematocrit.

Thyroid Disorders in Long-term Survivors

The thyroid gland is frequently damaged in transplant survivors. TSH elevations, initially subclinical, are found in up to 17% of survivors and are dependent upon the dose of TBI.[163] In a long-term study of pediatric transplant recipients, approximately 30% eventually developed thyroid abnormalities; hypothyroidism was much more frequent than hyperthyroidism or thyroiditis.[164] Risk factors for hypothyroidism include age less than 10 years at transplant, conditioning intensity (particularly TBI), and cGVHD.[21,164,165]

In a study of 791 pediatric transplant recipients, thyroid tumors occurred at a median of 9.9 (4.5–22.3) years after HCT and included 13 with papillary carcinoma and 5 with benign adenomas.[164] Radiation exposure underlies most cases,[164,165] but age less than 20 years, female sex, cGVHD, and family history are also factors.[166] Thyroid nodules need evaluation by ultrasound and biopsy. Excellent outcomes are observed with total thyroidectomy and iodine ablation. Patients with elevated TSH who are symptomatic should be considered for early replacement therapy to improve quality of life (QOL) (even in patients with subclinical hypothyroidism).

TABLE106.5

RECOMMENDATIONS FOR DIABETES MELLITUS MANAGEMENT AFTER HEMATOPOIETIC CELL TRANSPLANTATION (HCT)

Screening Guidelines	Diagnosis	Treatment
• Periodic fasting and random glucose monitoring, especially in the setting of steroid usage	• Glycosylated hemoglobin (HbA1c) ≥ 6.5 • Fasting blood glucose ≥ 126 mg/dl (100–125 is impaired fasting glucose) • Random blood glucose ≥ 200 with hyperglycemic symptoms	• Therapeutic lifestyle changes • Consider starting insulin therapy if this fails • Oral hypoglycemic can be considered in certain cases

HCT, hematopoietic cell transplantation.

Adrenal Insufficiency

Even short-term supraphysiologic doses (equivalent to prednisone of >7.5 mg/day) of steroids are known to suppress the hypothalamic-pituitary-adrenal (HPA) axis, and adrenal insufficiency may last for up to 9 months. Glucocorticoid-induced adrenal insufficiency is highly prevalent (and often overlooked) in HCT survivors. In one series, 19 of 20 allogeneic HCT long-term survivors had abnormalities on ACTH stimulation.[167] Adrenal insufficiency may be clinically overt or diagnosable by ACTH challenge. Alternate day or early morning steroid administration minimizes HPA axis suppression and early replacement in symptomatic patients is a key step in management.

Pituitary Dysfunction

Pituitary complications are predominantly pediatric and manifest as growth failure, central hypogonadism, and central hypothyroidism. Irradiation, male gender, and young age at BMT are the most important factors for growth impairment, and 40 out of 141 children failed to achieve normal adult height.[168,169] Regular screening for growth and replacement in needed patients is essential in pediatric HCT survivors.

CHRONIC KIDNEY DISEASES: MONITORING AND MANAGEMENT GUIDELINES

Epidemiology and Prevalence

Estimates of the cumulative incidence of CKD in HCT survivors vary from 13% to 66% for adults and 62% in children, with variation attributable at least in part to the lack of a uniform disease definition.[170,171] The initial insult may occur pretransplant or evolve from acute kidney injury early after HCT, but is often delayed as much as 10 years posttransplant. CKD is independently associated with an increased risk of NRM; and progression to end-stage renal disease (ESRD) that requires dialysis is associated with a near 90% mortality.[170,171]

There are 3 separate clinical entities that are distinguishable after HCT (Fig. 106.2): thrombotic microangiopathy (TMA), nephrotic syndrome, and idiopathic or GVHD-related CKD. Acute deteriorations in renal function will occur in the majority of patients in the first few months after HCT. This acute kidney injury may persist and eventually contribute to the later development of CKD. Careful monitoring of blood pressure, renal function, and proteinuria is mandatory, especially in older patients and those with preexisting renal impairment. Renal function should be evaluated before HCT and monitoring should occur at least every 3 to 6 months in these patients. Renal biopsies are indicated in patients with proteinuria and persistent or progressive rises in serum creatinine to determine etiology and prevent the progression to ESRD.

Definition of Chronic Kidney Disease

CKD is defined by an elevation in serum creatinine, or a decreased GFR (GFR < 60 ml/min/1.73 m^2), for 3 or more months. Kidney damage is further described in terms of structural or functional abnormalities in morphology, imaging, or composition of the blood or urine, such as proteinuria (a ratio of greater than 300 mg of albumin per gram of creatinine on spot urine testing).[170]

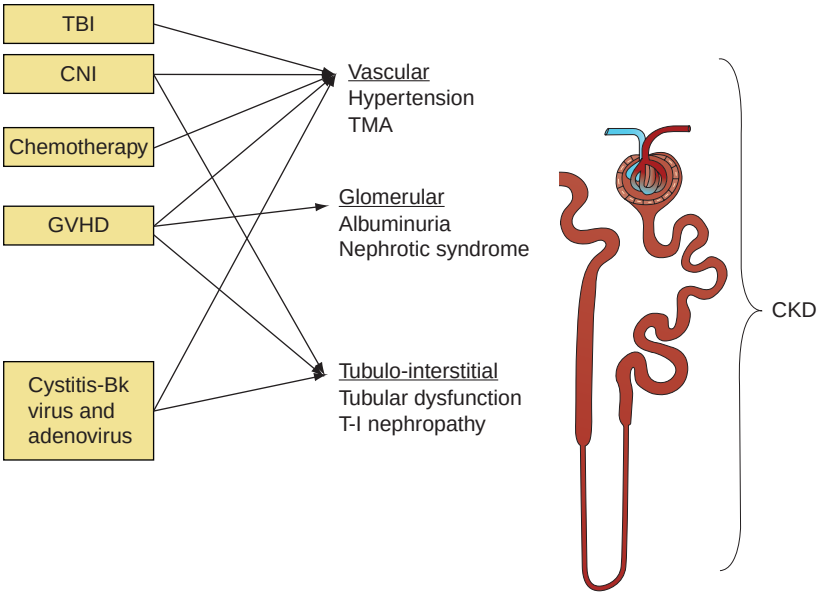

FIGURE 106.2. Types of CKD in long-term survivors of HCT: Sites of action of different renal insults with consequent clinicobiologic syndromes of kidney injury. CKD, chronic kidney disease; CNI, calcineurin inhibitor; GVHD, graft-versus-host-disease; HCT, hematopoietic cell transplant; TBI, total body irradiation; T-I nephropathy, tubulointerstitial nephropathy; TMA, thrombotic microangiopathy.

Spectrum of Kidney Disease

There are 3 major risk factors contributing to the pathogenesis of kidney injury after HCT: the underlying malignancy and previous therapies, transplant-related treatments, and complications and immunobiology of transplantation (GVHD). The spectrum of renal disease after HCT ranges from vascular (hypertension, TMA), to glomerular (albuminuria, nephrotic glomerulopathies), to tubulointerstitial abnormalities, which may all result in the reduction of GFR (Fig. 106.2). However, since it is not currently feasible to evaluate these components independently in clinical practice, it is common to group the disorders into three distinct clinical syndromes: TMA, nephrotic syndrome, and idiopathic or GVHD-related CKD.

Evaluation and Follow-up Guidelines of Patients with Chronic Kidney Diseases

Screening recommendations for patients beyond 6 months following HCT were developed by a consensus panel formed by CIBMTR, EBMT, and ASBMT[50] and are briefly summarized in Table106.6: 1. Hypertension should be investigated at every clinic visit and at least annually and managed aggressively. 2. Renal function should be evaluated at day 90 to 100 and then 6 and 12 months after transplantation for all patients, and yearly thereafter at a minimum for those with early renal insufficiency. Screening should include assessment of urine albumin and protein, serum BUN, and creatinine. Of note, serum creatinine is not an accurate measure of kidney function. Serum creatinine level and related estimating equations are dependent on muscle mass and are influenced by age, race, gender, and weight. 3. Ultrasonography should be used to exclude obstructive uropathy, especially in patients with acute or chronic kidney injury. 4. Renal biopsy is warranted to diagnose etiology of persistent AKI or CKD and nephrotic range proteinuria.

Long-term Implications, Surveillance, Prevention, and Management

The final consequences of CKD are independent of the underlying kidney disorder and include the possibility of progression to ESRD and complications from renal dysfunction such as metabolic, electrolyte, endocrine, bone and mineral abnormalities, hypertension, proteinuria, anemia, and contribution to CV risk.

Management guidelines include:

1. Avoidance of nephrotoxic drugs (NSAIDs, calcineurin inhibitors, contrast media, aminoglycosides, chemotherapy), renal

TABLE106.6

EVALUATION OF CHRONIC KIDNEY DISEASE (CKD) IN HEMATOPOIETIC CELL TRANSPLANTATION (HCT) SURVIVORS

Evaluation	Treatment
Specific diagnosis (type of kidney disease): – A thorough search for "reversible causes" of kidney disease should be conducted (pathology and non-invasive work-up) – Early referral to a nephrologist	Therapy based on the specific diagnosis: – GVHD – TMA – CNI – Viral infection – Other causes (GN, obstruction, etc.)
– **Disease severity** is assessed by the level of kidney function (stage of CKD) – Estimation of **disease progression** – Assessment of **complications** (related to the level of kidney function) – Assessment of **comorbid conditions** and risk factors for CKD (initiation/progression): Poor glycemic control in diabetes Uncontrolled hypertension Higher level of proteinuria Drug toxicity Urinary tract infections Other (urinary stones/obstruction, autoimmune diseases, systemic infections, smoking)	Measures to prevent and treat complications of decreased kidney function: Hypertension Water and electrolytes imbalance Anemia Mineral metabolism Malnutrition Medication dosage adjustments at each visit Detect drug interactions Management of comorbid conditions and measures to slow loss of kidney function Preparation for renal replacement therapy (dialysis or transplantation)
Evaluation of the risk for development of **cardiovascular disease**	Measures to prevent and treat cardiovascular disease

CKD, chronic kidney disease; CNI, calcineurin inhibitors; GVHD, graft-versus-host-disease; GN, glomerulonephritis; TMA, thrombotic microangiopathy.

dose adjustment, and drug level monitoring. While options are limited for substitution of calcineurin inhibitors, agents such as sirolimus are well tolerated.

2. *Nephrotic Syndrome*-Steroids, in addition to calcineurin inhibitors, can reverse minimal change or membranous nephropathy.[172] Rituximab has also shown benefits, by directly killing dysregulated B-lymphocytes which have been associated with membranous nephropathy.[173,174] Membranous nephropathy is a clinical entity that is more refractory to immunosuppression, with only 27% of patients achieving remission, compared to 90% for minimal change disease.[175]
3. *TMA management*-TMA is often confirmed by pathologic changes on kidney biopsy and may not produce clinically significant microangiopathic hemolysis. Deficiency in ADAMTS13 is uncommon, unlike nontransplant TTP, and plasma exchange produces inconsistent results.[176] Calcineurin inhibitors (cyclosporine and tacrolimus) and sirolimus often warrant discontinuation, but management may be complicated by the presence of GVHD. Sometimes, continued immunosuppressive treatment of GVHD while attempting to reduce endothelial injury by aggressive hypertensive therapy may be preferable.[177] A small case series showed that 4 of 5 patients with TMA after HCT responded to treatment directed against cGVHD with rituximab.[178] In another report of 12 patients with early TTP after transplant, 50% of patients responded to defibrotide.[179]
4. *Management of hypertension*-Treatment of hypertension is usually indicated unless the severity is mild or the condition is temporary, such as an elevation in tacrolimus levels. Consideration should be given to early referral to a nephrologist.

Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) are useful agents in CKD. In a rodent model of radiation-induced hemolytic-uremic syndrome (HUS) the use of these agents reduced azotemia, hypertension, and proteinuria, and led to long-term preservation of renal function.[180] In a randomized controlled trial, captopril demonstrated a trend toward improving the 1 year GFR and serum creatinine level.[181] ACEI and ARBs also produce indirect protective effects by reducing posttransplant inflammatory markers.[182]

5. *ESRD and renal transplantation*- It may be impossible to stall the progression to ESRD. Standard therapies include peritoneal and/or hemodialysis, but survival in HCT recipients is particularly poor.[171] Renal transplantation remains a therapeutic option for selected patients, with the additional advantage that those who received a kidney allograft from their original stem cell donor required minimal immunosuppression.[183,184]

GASTROINTESTINAL AND LIVER PROBLEMS

GI and hepatobiliary problems in HCT survivors are usually sequelae of GVHD, adverse medication effects, and infections.

Esophageal Symptoms (Heartburn, Dysphagia, and Painful Swallowing)

Gastroesophageal reflux disease is a common finding and may be exacerbated by GVHD and the dyspepsia associated with steroids. Involvement of the esophagus by cGVHD may lead to chronic dysmotility and reflux, necessitating prolonged proton pump inhibitor therapy. Rarely, esophagitis may be due to fungal or viral infection or to a retained pill. Therapy for strictures includes IST (for cGVHD) and careful endoscopic dilation to avoid progressive luminal narrowing.

Upper Gastrointestinal Symptoms (Anorexia, Nausea, Vomiting, and Satiety)

Causes include cGVHD, infections, and adverse drug effects. Upper GI GVHD can manifest in isolation, without other systemic manifestations of cGVHD.[53,185] GVHD must be distinguished from reactivation of herpesvirus (HSV, CMV, VZV) in susceptible individuals who have had antiviral prophylaxis and viral surveillance discontinued. Occasionally enteric viruses (e.g., rotavirus and norovirus) and parasites (*Giardia lamblia, cryptosporidia*) can present with anorexia and nausea with minimal diarrhea.[186,187]

Lower Gastrointestinal Symptoms (Diarrhea and Abdominal Pain)

cGVHD involving the lower GI tract is far less common than its acute counterpart. When this occurs, it may be a manifestation of delayed or recurrent acute GVHD, sequelae from gut injury in the early posttransplant period, infections, or common GI disorders. Subacute intestinal obstruction episodes may occur in those with a history of severe GVHD, with or without focal inflammation.[188] Treatment is either symptomatic with opioids or with topical or systemic IST or 5-aminosalicylic acid.

Chronic Liver Diseases in Long-term Survivors after Hematopoietic Cell Transplantation

Chronic liver dysfunction may be due to viral infection, GVHD, drug toxicity, biliary obstruction, iron overload, nodular regenerative hyperplasia, focal nodular hyperplasia, fatty liver (NASH, secondary to metabolic syndrome), cirrhosis, or recurrent malignancy.[88,89]

Cirrhosis may be related to chronic hepatitis C and is rising in frequency in patients transplanted before the 1990s. Viral replication and fibrosis may be accelerated by immunosuppression, injury by GVHD, and hemosiderosis.[89,189,190] Long-term HCT survivors have a significantly elevated risk of developing a new solid malignancy, and there is direct evidence for an increased incidence of hepatocellular carcinoma.[36,37] Survivors with a history of hepatitis B or C infection, obesity, and diabetes are particularly vulnerable and should be offered annual screening for hepatocellular carcinoma.[191]

Pancreatic and Biliary Disease

Exocrine pancreatic insufficiency is an uncommon finding in HCT survivors and presents with chronic diarrhea and malabsorption.[192–194] Potential causes include repeated episodes of pancreatitis, immunosuppressive agent toxicity, passage of a stone or sludge, damage by recurrent GVHD, viral infection, and hemosiderosis.[88,195] Screening involves measurement of serum trypsinogen, fecal elastase-1, and chymotrypsin levels, but imaging is required for evaluation of pancreatic atrophy.[89,194] Therapy is specific to the underlying cause and oral pancreatic enzyme supplementation may be of partial benefit.

HCT survivors have an increased risk of gallstones, and biliary sludge is found by ultrasound in approximately 70%[196] and at autopsy in 100% of HCT survivors.[197] This is thought to be related to immunosuppressive medications.

IRON OVERLOAD IN LONG-TERM SURVIVORS

Pathobiology

Transfusional iron overload is common in benign and malignant hematologic conditions and is often present prior to transplant. Iron overload can occur after as few as 20 units of PRBC

transfusions, impacts 30% to 60% of allotransplant recipients, and is liable to be overlooked.[88,198] Not only is nontransferrin bound iron deposited into the liver, heart, pancreas, cartilage, and endocrine tissues, but it may lead to the formation of reactive oxygen species.[199,200] While the liver is capable of accumulating a substantial amount of iron, the most significant sequelae are not hepatic, but cardiac and endocrine.[89]

Clinical Presentation and Diagnosis

Iron overload may masquerade as liver GVHD. Iron overload was the sole pathologic finding in one-third of cases with liver function test (LFT) abnormalities which underwent biopsy[201] and phlebotomy may normalize abnormal LFTs.[202]

Serum ferritin is the best screening test. Levels higher than 200 µg/L in women and 300 µg/L in men are generally considered elevated, but are not very reliable because of frequent confounding conditions in the transplant setting. It is important to distinguish iron overload from other causes of elevated ferritin such as systemic inflammation (GVH, infections), metabolic syndrome, hepatitis, and alcoholism.[88] Liver iron concentration is the gold standard for diagnosis, but biopsy has been supplanted by T2 quantitative MRI. Mutational analysis for hereditary forms of hemochromatosis is helpful in diagnosing selected cases where the transfusion burden is not great.

Prognostic Importance

There is growing data on the adverse impact of iron overload, particularly when severe, on transplant outcomes.[88,89,203–206] The impact of moderate degrees of iron overload on transplant outcomes remains debatable because excessive transfusions are a surrogate for a complicated clinical course.

Management

While more research is necessary to assess the role of iron overload in HCT survivors, clearly there is much to be gained from prevention even prior to transplant.[88,207–210] After the cessation of transfusions, the rate of spontaneous iron unloading is unsatisfactory.[206] Therapeutic options include phlebotomy and iron chelation; however, there are no randomized trials. Phlebotomy, sometimes supported by erythropoiesis stimulating agents and folic acid, is effective, relatively nontoxic, and inexpensive. Frequent phlebotomy is limited only by anemia, leading to considerations of iron chelation as an option. Iron chelation by deferoxamine, deferiprone, and deferasirox have all been shown to reduce iron overload in the transplant setting, and one retrospective study showed a significant reduction in relapse for iron-overloaded patients treated with deferoxamine.[211] With this exception, no study has shown significant clinical benefit for iron chelating agents and prospective trials are required to demonstrate their safety and optimize their administration in transplant survivors.

FEMALE LONG-TERM SURVIVORS AND RELATED ISSUES

Given the complexities involved with the evaluation and management of this patient population, it is important for close collaboration between the obstetrician/gynecologist and the hematologist/oncologist.[212] Preventive gynecologic care is critical to manage cGVHD of the genital tract, which can be a cause of significant morbidity. Other issues relevant to women of reproductive-age include HPV-related cervical dysplasia, contraception, infertility, pregnancy issues, sexual health, and hypogonadism.

Vulvovaginal Graft-versus-host disease

The incidence of female genital GVHD ranges between 25% and 49% of allo-HCT survivors.[213,214] Genital GVHD manifests in the vulva (68%), or the vulva and vagina concomitantly (26%).[212] Vulvovaginal cGVHD typically starts in the first year posttransplant but vaginal GVHD may present in a delayed fashion, after several years following HCT.[215,216] Late manifestations include vaginal synechiae, stenosis, and hematocolpos. Severe vaginal GVHD is strongly associated with sclerotic skin cGVHD,[216] but may be isolated in 27% of cases.[213] Genital cGVHD has been classified into grade I (mild), grade II (moderate), and grade III (severe).[213,214,216]

Management is complicated by symptom underreporting, empiric therapies directed at infectious or menopausal etiologies without gynecologic examination, or severe illness interfering with gynecology referral.[217] Treatment of only vulvar disease does not prevent development of vaginal GVHD. In one series, 63% of patients required surgery for vaginal GVHD despite aggressive treatment of vulvar cGVHD,[213] whereas others instituting regular monitoring avoided surgery.[214] The key to successful management is early recognition of genital GVHD and early implementation of topical immunosuppressive and estrogen therapy with concomitant use of dilators, if needed.[214,216,218] Surgery is necessary for severe resistant cases.

Human Papillomavirus–related Secondary Cancer and Other Diseases

The clinical manifestations of HPV infection include genital warts (condylomata acuminata), cervical, vaginal, vulvar, or anal intraepithelial neoplasia, and anogenital SCC. Cervical SCC in long-term allo-HCT survivors is reported to have a 13-fold increased risk compared to the general population,[36] and escalates to 18-fold higher if the patient is older than 34 years. Over 40% of female long-term survivors in another study had abnormal cervical cytology, with 20% having high-grade cervical dysplasia.[47] Lower genital tract dysplasia and anogenital condyloma, other manifestations of HPV infection, are also prevalent. These manifestations are strongly associated with prolonged systemic or local IST and likely represent reactivation of existing HPV infection, rather than acquisition of new infection. Loss of protective immunity explains why the resulting HPV-related disease is more prevalent and more rapidly progressive, as is observed in other immunocompromised populations.[219]

Current guidelines recommend annual screening after HCT.[218] Screening for cervical dysplasia is by cytology testing with reflex HPV testing. Colposcopy is reserved for cytology testing documenting atypical squamous cells of undetermined significance (ASC-US) coupled with concurrent positive testing for high-risk HPV types, atypical squamous cells suggestive of a high-grade lesion, low-grade squamous intraepithelial lesions, high-grade squamous intraepithelial lesions, or cancer. Women with ASC-US on cytology specimens a year apart are considered to have persistent abnormalities and should also undergo colposcopy.

Guidelines for vaccinating against HPV infections after allo-HCT have been proposed, although immune response may be suboptimal.[46,220] Vaccination in the year after transplantation could theoretically mitigate reactivation of HPV disease, if an immune response is generated.

Infertility and Sexual Health

Most women undergoing transplantation are in their reproductive years and are extremely susceptible to ovarian insufficiency or failure. Manifestations are amenorrhea, reduced libido, vaginal changes, and menopausal symptoms. Puberty may still occur spontaneously in up to 60% of prepubertal transplanted

females,[155] whereas postpubertal myeloablative transplants result in ovarian failure in >90% of women, with delayed recovery occurring in 29%.[221,222] For those whose menses return months or years after transplant, transient ovarian failure is common in the first year after treatment and liable to terminate in premature menopause.[25,223–225]

The likelihood of permanent ovarian failure and infertility is affected by age, pubertal status, conditioning intensity, radiation dose, and location.[222,226,227] The risk of premature ovarian insufficiency related to TBI increases with age.[228] Radiation doses of 6 Gy are sufficient to cause irreversible ovarian injury in most patients treated after age 40, while two to three times this dose is required to precipitate ovarian failure in irradiated children.[229] In contrast, the incidence of ovarian failure is greatly reduced (<40%) by utilizing reduced-intensity conditioning.[230] Apart from ovarian failure, fertility is also affected by uterine damage from radiation[228] and dyspareunia related to vulvo-vaginal GVHD.[216]

Successful pregnancies are uncommon. The largest series with 19,412 allogeneic and 17,950 autologous transplants documented only 312 pregnancies in 232 (0.6%) of patients or their partners.[231] Moreover, pregnancies in transplant survivors are complicated by an increased risk of low birth weight, preterm delivery, and cesarean section delivery. Additional concerns include intrauterine growth restriction, abnormal placentation, and uterine rupture.[232,233] Patients with decreased uterine volume after TBI are at increased risk for spontaneous abortion, even with the use of donor oocytes and in vitro fertilization.[228] The risk of spontaneous abortion is unclear, with conflicting data.[218,228,231,234] All conceptions in transplant survivors are high risk.

Sexual dysfunction is common in women and lags behind their male counterparts. 80% of female transplant survivors reported sexual dysfunction (in contrast to 46% of men). Female sexual dysfunction persists even when other measures of physical and emotional well-being return to normal.[235] Contributing factors include fatigue, medications, endocrinopathy, genital GVHD, and psychological causes. The goals of therapy are to restore fertility if desired, improve sexual function and libido, and reduce bone loss. Women should be advised to avoid pregnancy using a reliable method of birth control while they receive transplant-related medications, and should be assessed for engraftment disease status and ovarian function. Amenorrhea after menses have returned should prompt a pregnancy test, since fertility can recover in some patients.[236]

Options to preserve fertility after myeloablative HCT, when time permits, include preconditioning embryo, oocyte, or ovarian tissue cryopreservation for subsequent in vitro fertilization.[160,218,231] HRT is successful in treating menopausal symptoms[237] and in developing secondary sexual characteristics. However, HRT has little effect on sexual desire or dissatisfaction.[212] The optimum duration of HRT is undefined, but cessation at the normal age for menopause should be considered. For menopausal symptom control in those with contraindications to HRT, placebo-controlled trials suggest a benefit from SSRIs.[238]

QUALITY OF LIFE AND SOCIAL CHANGES IN LONG-TERM SURVIVORS

HCT survivors have undergone the most intense form of anticancer therapy. The prevalence of severe late complications in transplant survivors, even when a cure is achieved, emphasizes a necessity to also focus on QOL issues. HCT often reduces the overall health-related quality of life (HRQOL) of survivors, which is a result of decrements across all dimensions, including a significant symptom burden.[239] Discordance between the anticipated and the actual diminution of QOL after transplant may be a cause of significant dissatisfaction in survivors[240,241] and may be mitigated by careful pretransplant counseling. HRQOL includes physical, cognitive, emotional, and social functioning, as well as well-being components. Comparison of transplant QOL studies has been imprecise because of subjective designs, lack of standardized methodologies, differences in time points, overreliance on cross-sectional rather than prospective/longitudinal studies, lack of well-defined control groups, and population heterogeneity.[242]

Health-related Quality of Life Studies

A study of 2,800 pooled transplant survivors found that QOL declines immediately after transplantation,[243] with recovery over the next 1 year. More than half of transplant survivors return to work in 1 year.[244–246] Physical recovery precedes that of fatigue, dyspnea, or sleep patterns[247] and of psychological or work recovery.[248] 19% recovered on all outcomes at 1 year and 63% by 5 years. Among survivors without recurrent malignancy, 84% returned to full-time work by 5 years. Beyond 5 years, most survivors are disease free with an excellent performance status, preserved physical and psychological health, and excellent HRQOL.[249] Pretransplant factors impacting long-term QOL were studied in a registry cohort of 662 survivors at a median of 6.6 years posttransplant.[250] Surviving adversity can alter life-perceptions, and several transplant survivors report positive experiences related to psychological and interpersonal growth.[249–252] Posttraumatic growth is well documented in cancer medicine and studies are now beginning to also focus on the positive impact of transplant on QOL.[253]

Psychological and Cognitive Issues

Both autologous and allogeneic HCT survivors report a high prevalence of psychiatric symptoms[240] and 5% of survivors meet diagnostic criteria for posttraumatic stress disorder.[254] *Psychological stressors include the fear of relapse and the inability to return to pretransplant performance level.* Interestingly, the extent of psychological and cognitive decline appears to be similar for leukemia patients treated either with chemotherapy or HCT.[255,256]

Depression affects about one-third of posttransplant survivors. cGVHD, inferior social support, and female gender were significant factors for depression.[257] A significant generalized decline in neurocognitive performance has been observed as early as 80 days after HCT.[248] Although neurocognitive function improved from 1 to 5 years after HCT, deficits remained for more than 40% of survivors.[258] Impairments in attention, concentration, reaction time, reasoning, and problem solving were observed to last up to 8 years posttransplant and were directly correlated to the dose of TBI.[259] Inflammatory cytokines, such as TNF-α, have been implicated as putative factors for cognitive decline.[260]

Interventions to Improve Quality of Life

Psychosocial screening is routinely performed pretransplant but has not been adequately studied posttransplant. Consensus guidelines recommend additional periodic screening at 6 months and annually after transplant, by one of several simple screening instruments.[50] Screens are available for distress, depression, and posttraumatic stress disorder.[261,262] Fatigue that is not related to depression or underlying medical reasons may respond to an exercise program.[263] Behavioral intervention, pharmacologic therapy, and exercise may help depression.

CONCLUSION

A better understanding of the pathogenesis of late effects will allow for more effective screening to identify patients at risk prior to the allo-HCT procedure and allow more effective monitoring to

detect early evolution of the late effects after allo-HCT. This may, in turn, allow for improved therapeutic decision making while evaluating patients for HCT, and early institution of treatments directed at preventing and treating late effects in patients at risk after allo-HCT. We also recommend early referral or discussion with a transplant center for enrollment of patients in available late effect studies and for management guidelines.
